2. To each tube, one milliliter of the *undiluted or diluted* sample is added, thoroughly mixed, and the contents of the tube poured over a 9-cm bottom agar TYGA plate. The plates are incubated for 20 hours at 37 °C. The protocol recommends that each sample be tested at least in duplicate.

Samples with High Background Flora. For such samples, nalidixic acid is added to semisolid soft TYGB to a final concentration of 100 μg/mL. The conventional double agar layer method then is adopted.

Samples with Low Phage Counts. For samples in which the phage numbers are suspected to be low, the methodology calls for modifications as mentioned in the following text. Ten milliliters of semi solid TYGA is combined with one milliliter of host culture and 5 mL of sample dilutions (in duplicate) are poured over 50 mL of TYGA in a 14-cm petri dish. It is mentioned that this procedure is capable of detecting up to one phage particle per 50 or 100 mL if 10–20 plates are inoculated in parallel.

Confirmatory Test. Plates containing RNase (40 μg/mL) are prepared by mixing the appropriate volume of RNase solution to 2.5-mL semisolid TYGA in a tube and then pouring plates. Confirmatory tests are recommended when examining new sampling points, and when large circular clear plaques with smooth edges (probably somatic Salmonella phages) are routinely isolated.

Presence/Absence Test

Method

1. The host culture is prepared as described previously. Twenty-five milliliters (25 mL) of TYGB are added to a conical flask and prewarmed to room temperature.
2. The host culture (0.25 mL) is added along with the calcium-glucose solution (250 μL) to the TYGB-containing flask and incubated at 37 °C for three hours with shaking (100 rpm).
3. The water sample (1 mL) (prewarmed to room temperature) is added to the flask and incubated for 18 hours at 37 °C.
4. One milliliter (1 mL) of the culture is transferred to a centrifuge tube, and 0.4 mL of chloroform is added, thoroughly mixed, and centrifuged at 3,000 X g for five minutes.
5. The host culture is prepared as described previously.
6. Semisolid TYGA in bottles is melted and placed in a 45 °C water bath. Calcium-glucose solution then is aseptically added (500 μL/50 mL)
7. Aliquots (2.5 mL) of the TYGA media are placed into culture tubes with caps, placed in a 45 °C water bath.
8. To each tube, one milliliter of the host culture is added, mixed carefully to avoid bubble formation, and the contents are poured atop a TYGA plate in a 9-cm petri dish. Care is taken to make sure that the soft area is spread out evenly over the bottom agar plate and is allowed to solidify on a level surface.
9. The plates are dried in a laminar flow cabinet or in a 37 °C incubator for 30 minutes, while the plates are inverted and the lids are off.
10. A drop of the chloroform-treated culture is placed on the inoculated plate using a fine capillary pipette.
11. The spot is allowed to dry and the plates are incubated inverted (with the lids) at 37 °C for 18 hours.
12. The plates then are examined for clearance zones, which are indicative of F-specific phages.

The ISO (standard procedure) does mention that the protocol can be amended for use with larger samples (by using double-strength TYGB) and in a most probable number (MPN) format. Controls (both positive and negative controls, especially spiked positive controls) are strongly recommended. The results are expressed as plaque-forming particles per milliliter

$$(\text{pfp/mL}) = \frac{N - NRNase}{n} \times F$$

where pfp/mL is the confirmed concentration of F-specific RNA bacteriophages in milliliters, N is the total number of plaques counted on W49 plates, *NRNase* is the total number of plaques counted on WG49 plates with Rnase, n is the number of replicates, and F is the dilution factor.

ISO METHOD FOR THE ENUMERATION OF SOMATIC COLIPHAGES

The ISO method recommends the use of the *E. coli* strain c (ATCC 13706) for samples with low bacterial count such as drinking water and unpolluted natural waters. For samples containing large numbers of bacteria (e.g., wastewater and polluted source waters), the method recommends the use of the nalidixic acid–resistant *E. coli* strain CN (ATCC 70078) also known as WG5. (15).

Preparation of Host Culture. The host culture is grown in modified Scholtens' medium. The medium contains (per 1,000 mL) peptone 2 g, yeast extract 3 g, meat extract 12 g, NaCl 3 g, Na_2CO_3 solution (150 g/L) 5 mL, and $MgCl_2$ solution (100 g $MgCl_2 \cdot 6H_2O$ in 50 mL water) 0.3 mL. The pH of the medium after sterilization should be around 7.2.

Method

1. Molten semisolid modified Schölters' agar (MSA) medium is placed in a 45 °C water bath and 300 μL

of sterile calcium chloride solution (14.6 g/100 mL) is added to it.
2. Aliquots (2.5 mL) are placed into culture tubes with caps and placed in a 45 °C water bath.
3. To each of the culture tubes, one milliliter of the water sample or its dilutions (prewarmed to room temperature) is added.
4. The host culture (1 mL) is added to each of the culture tubes containing the media and the sample, and mixed well, taking care to prevent bubble formation. The contents of the tube are then poured over a bottom agar plate of MSA.
5. The plates are allowed to incubate for approximately 18 hours at 37 °C.

Samples with High Background Flora. For such samples, nalidixic acid at a final concentration of 250 μg/mL is added to the top agar (semisolid MSA).

Samples with Low Phage Counts. For such samples, the protocol suggests the use of 10 mL of semisolid media, 60 μL of calcium chloride solution, one milliliter of host culture, and 5 mL of sample in duplicate. The entire contents are poured over a 15-cm petri dish containing 50 mL of MSA.

Presence/Absence Test

Method

1. Modified Schölters broth (25 mL) is added to a sterile conical flask and prewarmed to room temperature.
2. Calcium chloride solution (1 M) (150 μL) is added aseptically to the flask.
3. Then, 0.25 mL of the host culture is added and followed by one milliliter of the sample (prewarmed to room temperature) and incubated for 18 hours.
4. An aliquot (1 mL) of the above culture is transferred to a centrifuge tube and 0.4 mL of chloroform is added, mixed well, and centrifuged at 3,000 x g for five minutes.
5. Bottles containing molten 50 mL of semisolid MSA are placed in a 45 °C water bath.
6. Prewarmed calcium chloride solution (300 μL) is added aseptically to the agar in the water bath and 2.5-mL aliquots are transferred to culture tubes with caps. The culture tubes are placed in a 45 °C water bath.
7. To each of these tubes, one milliliter of the host culture is added, mixed well, and the contents poured atop bottom agar plates containing MSA.
8. The plates are incubated for 30 minutes in a laminar flow hood or incubator at 37 °C and air-dried with the lids off.
9. One drop of the chloroform-treated sample culture is "spotted" on the above plates.
10. The plates are incubated at 37 °C for 18 hours.
11. The presence of phages is indicated by the appearance of clear zones near the spotted area.

The procedure can be used in an MPN approach to quantitatively estimate phage numbers. However, double-strength medium needs to be employed.

The number of pfp is computed as follows:

$$\text{pfp/mL} = \frac{N}{nvF}$$

where N is the number of plaques counted, n is the number of replicates counted, V is the volume employed, and F is the dilution factor

ISO METHOD FOR THE ENUMERATION OF BACTERIOPHAGES INFECTING *B. FRAGILIS*

The rationale for enumerating phages infecting *B. fragilis* is that the bacterium (*B. fragilis*) is an obligate anaerobe found only within the gastrointestinal tracts of warm-blooded animals. Thus, detecting such phages in source water or finished water is indicative that the sample has fecal contamination.

The primary difference between this bacterial host and the other hosts is obligatory anaerobic incubation requirements of the host bacteria. Although the bacterium is an obligate anaerobe, it does not require anaerobic handling conditions. Only the incubation has to be carried out under anaerobic conditions. Anaerobic cabinets, jars, or bags can be employed for this purpose. However, when using liquid media, it is critical that the containers are completely filled (to avoid oxygen-rich headspaces) and closed with a screw cap.

The specific host bacterial strain for the purposes of this methodology is *B. fragilis* RYC2056 (ATCC 700786) (16). The bacterium can be grown in (Bacteroides phage recovery medium broth) BPRMB. This medium contains (per liter) meat peptone 10 g, casein peptone 10 g, yeast extract 2 g, NaCl 5 g, monohydrated L-cysteine 0.5 g, glucose 1.8 g, $MgSO_4 \cdot 7H_20$ 0.12 g, and $CaCl_2$ solution (0.5g/mL) one milliliter.

Preparation of Host Bacterial Culture. A vial of the stock culture is allowed to equilibrate to room temperature. Using a cotton swab, the surface of the BPRM agar plate is streaked and incubated at 37 °C for at least 40 hours under anaerobic conditions. Using a cotton swab, portions of the colonies are transferred from the plate to a 10-mL tube containing 10 mL of BPRMB. This is incubated at 37 °C for at least 24 hours. The optimum cell density for plaque formation and visualization is between 1 to 4×10^8 CFU/mL. Appropriately designed side-arm flasks are used to obtain optical density readings.

Method

1. The host culture is prepared as described and allowed to equilibrate to room temperature.
2. Bottles containing molten 50 mL of semisolid BPRMA (top agar) is maintained at 45 °C in a water bath.
3. Ten milliliters (10 mL) of hemin solution (hemin 0.1 g, 1 N NaOH 0.5 mL, 99.5 mL H_2O), one milliliter of (0.05 g·mL) $CaCl_2$ solution, 25 mL of

1 M Na_2CO_3, one milliliter of 100 μg/mL kanamycin sulfate, and 4 m of nalidixic acid (100 μg/mL) are added to the medium already mentioned.
4. Aliquots (2.5 mL) are removed and placed into culture tubes with caps and placed in a 45 °C water bath.
5. To each of these tubes, 1 milliliter of water sample is added and mixed well, avoiding the formation of air bubbles.
6. The entire contents are poured on a bottom agar plate containing BPRMA in a 9-cm petri dish.
7. The plates are allowed to solidify, and incubated upside down under anaerobic conditions at 37 °C for 18 hours.
8. After incubation, the number of plaques is counted to estimate the phage concentration per unit volume of the sample.

Samples with High Background Flora. For such samples, it is recommended that kanamycin monosulfate at a final concentration of 300 μg/mL be added to the soft agar.

Presence/Absence Test. This test can be used to qualitatively determine the presence or absence of *B. fragilis*–specific phages in different samples volumes. The protocol given in the following text is for 100-mL sample volume.

Method

1. Double-strength BPRMB (100 mL) is added to a 250-mL screw cap glass bottle and prewarmed to room temperature.
2. The sample (100 mL) (also prewarmed to room temperature) is added to the bottle containing the medium.
3. The host culture in the exponential growth phase containing approximately 108 cells per milliliter is added to the bottle.
4. Additionally, medium is added to fill the bottle completely and the bottle is screwed tight. (To indicate anaerobiosis, resazurin can be added. Resazurin at a stock concentration of 0.025 g/100 mL is recommended. Anaerobiosis is indicated by a change of color from blue to straw color).
5. The bottles are incubated at 37 °C for 18 hours.
6. To 1 milliliter of this enrichment culture, 0.4 mL of chloroform is added, mixed, and centrifuged at 3,000 X g for five minutes.
7. Semisolid BPRMA (50 mL) is melted using a boiling water bath and incubated at 45 °C. Hemin, Na_2CO_3, and antibiotics are added as per the concentrations mentioned earlier.
8. Aliquots (2.5 mL) are placed in culture tubes with caps and the tubes are incubated at 45 °C.
9. Host culture (1 milliliter containing approximately 10^8 cells per milliliter) is added and mixed well with the media. Care is taken to make sure that no air bubbles form.
10. The contents of each tube are poured on to a 9-cm petri dish and allowed to solidify on an even surface.
11. One drop of chloroform-treated culture is placed on each plate and the plates incubated at 37 °C for at least 18 hours under anaerobic conditions.
12. The plates then are examined for characteristic clear zones or plaques.

QUALITATIVE DETECTION OF COLIPHAGES IN SOURCE WATER — U.S. EPA METHOD 1601

Method 1601, a two-step enrichment procedure, is a performance-based method for qualitatively detecting the presence or absence of male-specific and somatic coliphages in groundwater and source water (17). This protocol has been tested in a multilaboratory round robin testing protocol in the United States. Method 1601 specifies the host strains for isolating male-specific and somatic coliphages.

The attractive features of this protocol are that it can be used either with 100-mL or 1,000-mL sample volumes. The ability to use a large sample volume is advantageous because it increases the probability of detecting phages that may be present in the low concentrations. Somatic coliphages are screened using *E. coli* CN-13 as the host strain, whereas male-specific coliphages are screened using *E. coli* F_{amp} as the host strain. *E. coli* CN-13 is a nalidixic acid–resistant mutant of *E. coli* (ATCC 700609), whereas *E. coli* Famp is an ampicillin-streptomycin-resistant mutant of *E. coli*. *E. coli* CN-13 was originated at the University of Quebec in Canada, whereas *E. coli* Famp was originated by Victor Cabelli at the University of Rhode Island.

Method

1. Logarithmic phase host bacterial cultures are prepared in tryptic soy broth (TSB) amended with the appropriate antibiotics. *E. coli* CN-13 is grown in nalidixic acid–containing medium (10 mg/100 mL), whereas *E. coli* Famp is grown in streptomycin-ampicillin-containing medium (1.5 mg each antibiotic/100 mL).
2. The cultures are incubated at 37 °C on a shaker at 100–150 rpm for approximately four hours until the cultures are in log phase. The host cultures when ready can be placed at 4 °C for four hours until they are ready to be used in the protocol.
3. Spot Plate Preparation. Separate spot plates are prepared for the somatic and male-specific coliphages. Two flasks of tryptic soy agar (TSA) (100 mL) are autoclaved and cooled to 45 °C in a water bath. To one of the flasks, 2 mL of the host culture and one milliliter of 10 g/mL nalidixic acid solution are added. To the other flask, 2 mL of the host culture and one milliliter of 0.15-mg/mL ampicillin-streptomycin stock solution are added. Twenty-milliliter aliquots are poured into 100-mm petri plates. The plates are appropriately labeled as being either CN-13 or Famp plates depending on the type of antibiotic that was added. The plates

are allowed to solidify and could be used that day or stored at 4 °C for up to a week.

4. 100-mL Samples. Water samples (100 mL) are placed in sterile 125-mL bottles. To each of the bottles that contain the sample, 0.5 mL of the appropriate host bacterial culture, one milliliter of the appropriate antibiotic solution, 1.25 mL of a 4 M $MgCl_2 \cdot 6H_2O$ solution, and 5 mL of 10 X TSB medium are added. The bottles are tightly capped, mixed by inversion, and incubated for 24 hours at 37 °C with no further mixing.
5. 1,000-mL Samples. Water samples (1,000 mL) are placed in sterile 2-L bottles. To each of the bottles that contain the sample, 5 mL of the appropriate host bacterial culture, 5 mL of the appropriate antibiotic solution, 12.5 mL of a 4 M $MgCl_2 \cdot 6H_2O$, and 50 mL of a 10 X TSB are added. The bottles are tightly capped, mixed by inversion, and incubated for 24 hours at 37 °C with no further mixing.
6. Following incubation, 10 μL of the enriched sample is "spotted" on the appropriate spot plate that contains the appropriate host bacteria and antibiotic. For example, 10 μL of the sample bottle that contains the CN-13 host bacteria is spotted on the spot plate that has CN-13 and the nalidixic acid.
7. As many as 20 spots can be made on one 100-mm spot plate. The spots are allowed to absorb into the medium by incubating for approximately 30 minutes. Care must be taken to make sure that the spot inoculum is not allowed to "run" across the plate.
8. The plates are incubated at 37 °C for 16 to 24 hours.
9. Positive results are indicated when lysis zones (a circular zone of clearing) appear at the various spots. A positive result may also appear as one or more small plaques or clearings at the spots. If bacterial growth at the lysis zones interferes with an accurate determination of whether the spot is "positive" or "negative," aliquots of the enrichment sample can be centrifuged or filtered quickly and the supernatant can be spotted on a fresh spot plate.
10. Careful controls should be included in all experiments because the potential for phage cross-contamination is very high. The use of replicate spots on separate plates also is recommended.
11. Because this is a qualitative procedure the results can be expressed only as either positive or negative for each 100- or 1,000-mL sample.

QUANTITATIVE DETECTION OF COLIPHAGES IN SOURCE WATER — U.S. EPA METHOD 1602

Method 1602 is a quantitative method for the detection of coliphages in water samples (18). However, unlike the previously described Method 1601, this method allows the quantitation of the coliphage numbers that are detected and also employs *E. coli* CN-13 and *E. coli* Famp for somatic and male-specific coliphage detection, respectively. Method 1602 is only for 100-mL samples. The basic principle of the method is as follows: host bacteria, double-strength agar medium, and $MgCl_2$ are added to 100-mL water sample and the entire contents poured into 5 to 10 petri dishes. After overnight incubation, the total numbers of plaques are counted and tallied and the result reported as PFU(plaque-forming unit)/100 mL.

Method

1. The host bacteria and their respective antibiotic solutions are similar to the enrichment culture described under Method 1601.
2. The host bacterial cultures are prepared as described earlier. The cultures can be stored at 4 °C for no more than 48 hours.
3. Concentrated (2X) TSA (100 mL) is prepared and allowed to cool to 45 °C in a water bath. Separate flasks are prepared for the nalidixic acid amendment and for the ampicillin-streptomycin amendment.
4. Two 100-mL samples are placed in separate 500-mL flasks.
5. To each of these flasks, 0.5 mL of 4 M $MgCl_2 \cdot 6H_2O$ is added.
6. The flasks are placed into a 37 °C water bath for five minutes to prewarm the sample.
7. To each of the flasks, 10 mL of the appropriate host bacterium is added.
8. This sample/host bacterium mixture is then added to the 100 mL of the 2 X TSA that was cooled to 4 °C.
9. The contents of each of the flasks are poured into 100-mm petri dishes at 20 mL per plate. Care must be taken to make sure that the plates are labeled properly to designate whether they contain CN-13 or Famp host bacteria.
10. Positive and negative controls should be included with each assay.
11. The PFU/100 mL of either somatic or male-specific coliphages is calculated based on the total of the plaques obtained for all plates for that particular host bacterium.

OTHER METHODS

In addition to the protocols already mentioned, other methods have also been reported for the enumeration of coliphages. Armon and Kott (19) have reported on a simple, rapid, and sensitive presence/absence detection test for bacteriophages in 500 mL of drinking water. In this method, a probe filled with solidified soft agar and bacterial host cells was immersed in a glass jar containing the water sample and bacterial host cells (Fig. 1). The entire device was incubated in water bath at 36 °C. Following this incubation (which ranged from 90 minutes for *E. coli* CN13 to 8 hours for *B. fragilis*), the probes were removed and incubated further. Using this method, the authors report their ability to detect male-specific coliphages infecting *E. coli* Famp within six

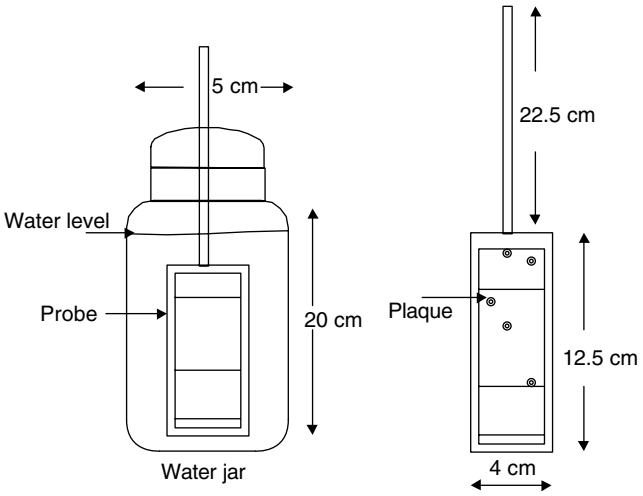

Figure 1. Presence/absence–based bacteriophage detection apparatus.

hours and phages infecting *B. fragilis* within eight hours. They successfully field-tested this approach on 45 different types of aquatic samples.

COLORIMETRIC DETECTION OF BACTERIOPHAGES

Ijzerman and coworkers (20) reported on liquid colorimetric presence/absence coliphage detection method. This methodology is based on the induction of β-galactosidase by *E. coli*. The release of this compound in the medium because of cell lysis as a result of coliphage infections permits the hydrolysis of a yellow chromogenic substrate that develops into a distinct red coliphage-positive sample. A coliphage-negative sample will remain yellow. The results can be obtained within 4.5 hours. The only apparent disadvantage of this method is the requirement that the water sample be concentrated to no more than 5 mL. Although the liquid colorimetric system was developed using *E. coli* strain C (ATCC 13706), the method has the potential to be adapted to any of the other bacterial host strains. According to the authors, in combination with adequate sample concentration methods, this protocol can detect 2 PFU/1,000 mL.

Colorimetric Method

1. *E. coli* (ATCC 13706) is inoculated into 25 mL of Luria broth supplemented with 5 mM of $CaCl_2$ and 1.25 mM of $MgSO_4 \cdot 7H_2O$.
2. The culture is incubated at 37 °C for one hour at 200 rpm on a rotary shaker (Lab-Line Orbit Environ-Shaker, Melrose Park, Illinois).
3. The culture is then aseptically inoculated with 25 μL of isopropyl-β-D-thiogalactoside (IPTG).
4. The culture is incubated for an additional 30 minutes at 37 °C.
5. Concentrated water sample (1.25 mL) (obtained through any virus concentration protocols) is added to the culture.
6. The culture is swirled and maintained at room temperature without shaking for 10–15 minutes and then returned to the shaker at 37 °C for an additional 105 minutes at 200 rpm.
7. The culture is placed in a sterile 50-mL centrifuge tube and centrifuged at 5,000 rpm (Beckman model TJ-6) at 6 °C for 15 minutes.
8. The supernatant is vacuum filtered through a 0.2-μm pore size low protein-binding filter into a sterile test tube.
9. In a clean tube, 9 mL of Z-buffer (20) was combined with one milliliter of the supernatant and 100 μL of chlorophenol red β-D-galactopyranoside and incubated at 37 °C for 30 minutes.
10. A positive coliphage test is observed by the immediate development of red color in an initially yellow solution that intensifies over a 15-minute period and reaches a maximum within 30 minutes. A negative test is indicated by an unchanged yellow color.

RECOVERY OF BACTERIOPHAGES FROM SOILS AND BIOSOLIDS

Mignotte and coworkers (22) tested eight virus extraction protocols for recovering phages and mammalian viruses from urban sludge. The three extraction techniques that resulted in the highest virus recoveries were as follows: beef extract (10%) solution at pH 9 combined with sonication, 0.3 M NaCl/7% beef extract solution at pH 7.5, and freon and 0.1 M borate buffer/3% beef extract solution (pH 9) combined with sonication. It is obvious that virus recoveries tend to be higher with organic buffers at elevated pH levels. Lasobras and coworkers (23) also have reported on high recoveries of somatic, male-specific, and *Bacteroides*-specific phages from different types of sludges encountered in water treatment plants. The protocol reported by Mignotte and coworkers (21) for optimum recovering phages from urban sludge is provided in the following text.

Method

Ten grams (10 g) of sludge is centrifuged initially at 1,500 g for 15 minutes.

The pellet is resuspended in 360 mL of 0.1 M borate solution containing 3% beef extract (pH 9.0).

The mixture then is stirred at 500 rpm (New Brunswick Scientific) for 15 minutes followed by sonication for one minute at a 100 W, 0.9s setting.

The sample is centrifuged at 10,000 x g for 45 minutes at 4 °C and the supernatant is neutralized to pH 7.2

Before bacteriophage analysis, the extract is decontaminated by adding one-third volume of chloroform and vigorously mixing for 30 minutes at 4 °C.

The sample is centrifuged at 1,500 x g for 10 minutes at 4 °C. The chloroform phase is removed and the remaining phase is used for the bacteriophage assay.

RECOVERY OF COLIPHAGES FROM SHELLFISH

Studies have shown that during depuration, FRNA phages are removed from the digestive tracts of a contaminated shellfish considerably more slowly than *E. coli* is removed. Because this relatively slow elimination has been shown to be similar to the elimination of enteric viruses (24), the presence of FRNA phages thus could be used as an indicator of enteric viruses. Dore and coworkers (25) recently reported on the isolation and use of male-specific RNA bacteriophages as candidate human enteric virus indicators for bivalve molluskan shellfish. They described a procedure for the detection of the FRNA phages using *S. typhimurium* WG49 as the host strain.

Method

1. Oysters are washed and scrubbed thoroughly under running potable water.
2. The oysters are opened aseptically with a flame-sterilized shucking knife and the meat and intravalvular fluid are removed, diluted in 0.1% (w/v) peptone water, and homogenized.
3. The diluted homogenates are centrifuged at 1,000 X g for five minutes at room temperature.
4. The supernatant is decanted into a sterile bottle and a 1 : 10 dilution with peptone water (pH 7.2) is made.
5. Ten milliliters of the undiluted supernatant and 4 mL of the 1 : 10 dilution are assayed for FRNA phages by using the standard double agar overlay method with 1 milliliter portions and 90-mm petri dishes. One milliliter of the sample is mixed with 2.5 mL of the molten soft agar and 1 milliliter of the host bacterium and poured over a prepared bottom agar plate.
6. The presence of RNA phages was confirmed using plates amended with RNase in parallel.
7. The reported sensitivity was 30 PFU of FRNA/100 g of shellfish.

RECOVERY OF BACTERIOPHAGES FROM AEROSOL SAMPLES

There have been a few studies reporting on the concentration of coliphages in bioaerosol samples. Most of these studies have centered on municipal waste handling operations such as biosolid land application sites and effluent spray irrigation sites. Although the survival of virus particles in bioaerosols is less than that of bacterial cells, detectable concentrations of both mammalian viruses and bacteriophages have been reported in the literature. There is no standard method for collecting and concentrating viruses in bioaerosols. A number of different samplers have been employed (26–28). Carducci and coworkers employed an impacting sampler (surface air system SAS, PBI, Milan, Italy) to collect the air samples. A Rodac plate made of a phage agar base was used as the impacting surface. A top layer of phage agar (7 mL) combined with 1 milliliter of host bacterial culture was poured over the Rodac plate to enumerate the phages. Pillai and coworkers (29) employed the impinger, AGI-30 samplers for 20 minutes at 12 L per minute using 0.1% peptone. The 20-mL sample was *concentrated* down to 7 mL using Centriprep-50 concentrators (Millipore, Bedford, Massachusetts). Aliquots of the concentrate were used in a conventional double agar layer format. It is extremely important to decide whether to employ impaction or impingement approaches because the method of sample collection will dictate the extent of sample processing and sample analysis.

MOLECULAR DETECTION AND CHARACTERIZATION OF BACTERIOPHAGES

The complete nucleotide sequences of a number of bacteriophages are currently available. The availability of this information has led to the development of oligonucletodie probe and primer sequences for the detection and characterization of bacteriophages. Molecular detection techniques are not being used primarily for the rapid detection of phages in environmental samples. These approaches are being employed to find relationships between the presence or absence of mammalian enteric viruses and phages.

Phylogenetically, F-specific RNA coliphages fall into four subgroups (30). Subgroups I and II are related and form the major group A. Subgroups III and IV are very similar and together make up major group B. Male-specific RNA coliphages are composed of serogroups I through IV. It has been shown (30,31) that strains isolated from human feces usually are group II and III, whereas groups I and IV usually are found in animal feces. Although serotyping of F + RNA coliphages can distinguish human fecal contamination from animal fecal contamination, antisera for F + RNA coliphages are not readily available and some isolates are difficult to stereotype (30,32). Given these reasons, the serotyping of phages is not being discussed in detail in this chapter.

Genotyping of male-specific coliphages with oligonucleotide probes is feasible (32,33). The oligoprobes were end-labeled with digoxigenin and used in DNA-RNA hybridizations and hybrids were observed by colorimetric, immunoenzymatic detection.

The nucleotide sequence of the oligoprobes used for genotyping is shown in Table 1.

The protocol for phage transfers and hybridization, which is provided in the following text, is based on the report by Hsu and coworkers (32).

Method

1. Two microliter volumes of the phage isolates and prototype strains that are representative of each group are spotted on a lawn of host bacteria and incubated at 37 °C overnight.
2. Plates are incubated at 4 °C for 30 minutes.
3. The bacterial lawn is covered with a nylon membrane for two minutes to adsorb phages from the plaques. Nylon membranes from Biodyne (Pall Biosupport, East Hills, New York.), Boehringer Manheim Corp, Indianapolis, Indiana, or Gene Screen (NEN Research Products, Boston, Massachusetts) show efficient transfer capabilities.

Table 1. Oligonucleotide Sequence Information for Group-Specific Probes (modified from F. -C. Hsu et al., *Appl. Environ. Microbiol.* 61, 3960–3966 (1995))

Probe	Sequence	Locus	Source Phage

4. Blotting buffer (7.5 X SSC buffer with 4.6 M formaldehyde) and heating at 65 °C for 15 minutes are used for the denaturation step.
5. The membranes are cross-linked using ultraviolet (UV) light treatment for five minutes and vacuum-baked at 80 °C for 15 minutes before hybridization.
6. Oligonucleotides are 5′ end labeled using dioxygenin by terminal transferase using the Genius labeling kit (Boeringer Manheim, Indianopolis, Indiana). Unincorporated nucleotides were removed using ethanol precipitation and probes are stored at −20 °C until use.
7. The membranes are prehybridized for two hours at 45 °C in prehybridization solution [6 X SSC buffer (0.9 M sodium chloride; 0.09 M sodium citrate), 5 X Denhardt's solution (100 x Denhardt's solution:for 500 mL: 10 g Ficoll 400; 10 g polyvinylpyrrolidone MW 360000; 10 g BSA fraction V), 16 mM tris-HCl (pH 8.0), 0.1% Sodium dodecyl sulfate solution (SDS), and 75 μg sheared salmon sperm DNA].
8. Hybridization is performed in the same solution using 5 pmol of DIG-UTP-labeled probe overnight at 45 °C.
9. The membranes are washed twice in 6 X SSC-0.01% SDS at 40 °C for 15 minutes.
10. The detection and color development is based on the labeling kit manufacturer's suggested protocol.

Using this approach, more than 80% of the phage isolates could be genotyped directly from plaques, providing evidence that genotyping is a much easier method of differentiating phages than sereotyping (which would have required extensive phage purifications). Hsu and coworkers (32) report that 17 isolates from piglet and porcine feces were classified as group-II phages (primarily human), suggesting that group classification will not always distinguish between human and porcine fecal contamination. Because the dietary and living conditions of pigs have historically involved exposure to human fecal wastes, this may account for the detection of group-II phages in pig feces (32).

GENE AMPLIFICATION–BASED METHODS

With the advent of gene amplification methods, the nucleotide sequence information that was available for the generation of oligonucleotide probes has been used to develop PCR primers. Primers have been developed against phages including MS2 and *B. fragilis* phages. Puig and coworkers (34) recently published a report describing the DNA amplification procedure for detecting *B. fragilis*phages in water. In this work, primers were designed from a 1.5-kb region that was specific to *B. fragilis* phages. The nested PCR assay was capable of detecting as few as 10–100 virus particles in seawater and sewage and 1–10 virus particles in river water.

CONCLUSION

A number of culture-based and molecular methods are available for the detection and characterization of coliphages. Many of these methods have been used successfully in multiple laboratories whereas some of them also have been rigorously evaluated as part of round robin multiple laboratory testing. Given the importance of male-specific coliphages to serve as indicators of fecal pollution, it is, however, necessary that these methods be tested, employed, and optimized using a variety of environmental samples under different environmental conditions. Molecular characterizations of male-specific RNA coliphages have demonstrated that it is possible to identify the sources of the male-specific coliphages once they are isolated. Thus, the ability to detect and characterize male-specific coliphages can assist in the detection of fecal contamination and in the identification of possible sources.

BACTERIOPHAGE OF ENTERIC BACTERIA: OCCURRENCE AND PERSISTANCE IN THE ENVIRONMENT

MARYLYNN V. YATES
University of California
Riverside, California

Bacteriophages, viruses that infect bacteria, are distributed ubiquitously in nature. Their potential use as indicators of fecal pollution and as models for the behavior of enteric pathogens has been studied for many years. This is due to the relative ease, cost, and speed of analysis for these organisms compared to that of pathogenic microorganisms. These uses of bacteriophages will be the focus of this article.

SURROGATES FOR HUMAN ENTEROVIRUSES

Human enteric pathogens include viruses, bacteria, and parasites that infect the gastrointestinal tract of warm-blooded animals. Exposure to these pathogens is through the oral route, and they are eliminated from the body in fecal material in the so-called "fecal-oral" route of transmission. The major source of pathogenic microorganisms in domestic wastewater is the fecal material of infected individuals; however, urine may also be a source of certain pathogenic viruses (1). There are hundreds of different types of microorganisms that may be present in domestic wastewater. The numbers and types of pathogens found in wastewater will vary both spatially and temporally, depending on the disease incidence in the population producing the wastewater, season, water use, economic status of the population, and quality of the potable water (2).

Between 1971 and 1998, there were more than 650 outbreaks of waterborne disease reported in the United States (3). These outbreaks resulted in more than 550,000 people becoming ill, and more than 125 deaths. The majority (90%) of these outbreaks were caused by microorganisms (see Fig. 1), most of them of enteric origin.

Indicators of Microbial Contamination

Because human pathogenic microorganisms have such an impact on public health, water microbiologists and regulators have searched for suitable compounds or microorganisms that can indicate microbial and fecal contamination of ground and surface water. Such a compound or organism is called an indicator.

Male-specific coliphages, such as MS-2, are often naturally present in sources of human wastes (e.g., septic tank effluent) and therefore their presence or absence in groundwater may be indicative of water quality. The suitability of a particular virus as an indicator is evaluated

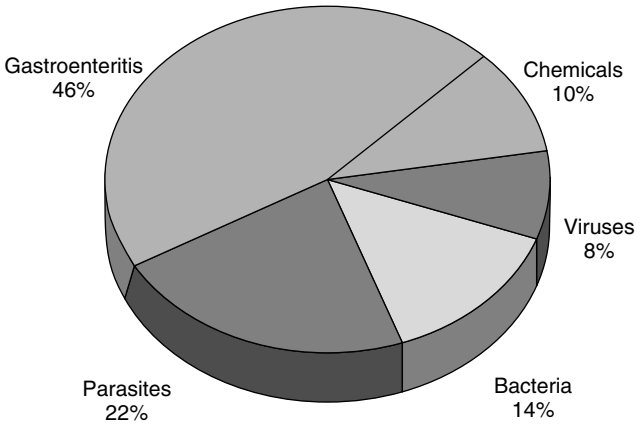

Figure 1. Causative agents on waterborne outbreaks (U.S.) 1971–1998.

on the basis of relative insensitivity to inactivation (4) and its ecological and morphological similarities to human viral pathogens (5).

There are numerous review articles on indicators available on this subject (6,7). Coliphages, particularly RNA phage, have been proposed as suitable indicators for human enteric viruses (6). Among the coliphages, MS2 appears to be the most suitable indicator (8,9).

Models for Pathogen Transport

When considering indicators to use as models for microbial survival and transport in the environment, a worst-case indicator for transport and fate should:

1. be unable to reproduce in the environment
2. show similar or less sorption and retention than pathogenic microorganisms in porous media under identical conditions
3. be at least as resistant to inactivation under natural conditions as pathogenic microorganisms
4. be nonpathogenic to humans (only if used as tracers in the field)

Several markers have been used as indicators for domestic wastewater contamination (10,11). Examples of such markers are coprostanol or surfactant related markers such as linear alkylbenzene. These markers have not been tested yet for their sorption and transport properties in porous media and no comparative studies with viruses are available at present.

Based on the mechanisms of virus sorption and retention and the experimental evidence of virus transport available, MS2 appears to be a reasonable candidate for a transport model at this time. MS2 was found to be a useful indicator for viruses because it showed similar or less sorption and retention than other viruses under identical conditions (12–14). However, this conclusion is based on the specific experimental conditions used in these studies, and there is no guarantee that MS2 behaves as a worst-case indicator under a variety of soil and water conditions. MS2 is not an ideal indicator in the sense that it can replace the exact behavior of a human enteric virus in the environment. However, because of the extremely complex sorption and transport mechanisms of viruses, recent studies have raised doubts regarding the applicability of any single indicator's ability to mimic the behavior of a specific virus. Jin and coworkers (15) have shown that MS-2 is relatively easily inactivated by the air-water interface in unsaturated systems and that it is sensitive to the presence of metal oxides (16). Penrod and coworkers (17) compared the deposition kinetics of bacteriophages MS-2 and λ and found that even subtle differences in viral surface structures could significantly influence the rate at which viruses were removed from the water phase by infiltration. Considering the complex sorption and retention mechanisms of viruses, it is unlikely that any single bacteriophage will adequately mimic the transport behavior of viral pathogens in the environment, particularly given that the surface structures of different waterborne human viruses are quite dissimilar.

ECOLOGY OF BACTERIOPHAGE

Coliphages, the viruses that infect coliform bacteria, are the most widely studied bacteriophages in terms of their use as surrogates. Coliphages are found in the feces of man and other warm-blooded animals, in domestic wastewater, and in wastewater-contaminated waters, thus suggesting the utility of these organisms as indicators of the presence of fecal material that may contain pathogenic microorganisms and thereby pose a threat to human health.

The distribution of coliphages in several hundred samples of feces from human and other warm-blooded animals is shown in Table 1. Reported concentrations of coliphages in various sources are shown in Table 2. Clearly, the concentrations and presence of coliphages in feces is extremely variable. In addition, these viruses are found more commonly in the feces of lower animals than in those of man.

However, in contrast to human feces, coliphages are consistently found in domestic raw wastewater. Raw sewage has been found to contain between 10^5 and 10^6 plaque-forming units (pfu)/L (Table 2). Septic tanks, which serve a smaller population than would be

Table 1. Distribution of Coliphage in Human and Animal Feces

Source	No. of Samples	No. Positive	% Positive
Birds (zoo)	25	23	92.0%
Fowl	30	9	30.0%
Mammals (zoo)	97	72	74.2%
Horses	30	3	10.0%
Cows	20	6	30.0%
Pigs	11	10	90.9%
Humans	597	140	23.5%

Table 2. Concentrations of Coliphages in Feces and Wastewater

Source	Typical Concentration	% Positive
Animal feces	$0–10^6$/g	12–75
Human feces	$0–10^7$/g	10–92
Gray water	$0–>10^{10}$L	12
Septic tanks	$10^3–10^6$/L	100
Raw sewage	$10^5–10^7$/L	100
Primary effluent	$0.2–10^6$/L	100
Secondary effluent (activated sludge)	$10^1–10^4$/L	100
Oxidation pond effluent	$10^3–10^7$/L	100

Source: Modified from (C. P. Gerba, Phage as Indicators of Fecal Pollution, Chap. 8, in S. M. Goyal, C. P. Gerba, and G. Bitton, eds., Phage Ecology, John Wiley & Sons, New York, 1987.)

served by a municipal system, have also been found to consistently contain coliphages. Concentrations in septic tank effluent have been reported to range between 10^3 and 10^6 pfu/L (Table 2). A recent report of coliphage analyses of septic tank effluent from a single septic tank revealed a mean concentration of 7×10^5 pfu/L (20). The ubiquitous presence of the coliphages in untreated domestic wastewater is the rationale behind the use of these organisms as indicators of fecal contamination of water.

Bacteriophages have been found in a variety of natural waters including lakes, streams, rivers, wetlands, and groundwater (19). In the majority of the studies that have been conducted, strains of *E. coli* have been used as the host organism. Thus most of the available data on phage occurrence in freshwater environments reflect coliphage occurrence. Table 3 lists concentrations of coliphages found at selected sites.

Phage that infect other enteric bacteria have also been isolated from freshwater. From rivers in the United Kingdom, bacteriophage that infect *Klebsiella pneumoniae* and *Salmonella typhi murium* have been isolated at concentrations ranging from approximately 1,000 to 1,000,000 per liter (21). Little work has been done on the occurrence of phage that infect indigenous freshwater bacteria. Phage that infect *Aeromonas hydrophila* have been recovered from river water by several investigators (21). Concentrations of these phage were on the order of a few thousand per liter of water. *Pseudomonas aeruginosa* phage have also been isolated from river water in the United Kingdom at a concentration of 3.5×10^3 per liter (23).

In addition to surface water, the occurrence of phages in groundwater systems has been studied. There has been a surge of interest in this area due to recent activity at the U.S. Environmental Protection Agency (EPA). In 2000, the EPA proposed the Ground Water Rule, the goal of which is to protect potable groundwater supplies from fecal contamination (23a). The difficulty associated with monitoring more than 150,000 water systems for enteric viruses spurred a great deal of interest in the identification of a suitable indicator for the presence of these microorganisms in groundwater. Due to the similarity to enteric viruses in terms of their size, shape, persistence in the environment, and transport behavior, bacteriophages are being considered as indicators for the purposes of this regulation.

One of the most extensive surveys of the occurrence of enteric microorganisms in groundwater involved the analysis of water samples from more than 400 groundwater wells in the United States. This survey revealed the presence of coliphages in 20% of the samples (24). In this study, three different hosts, *E. coli* C, *E. coli* C3000, and *S. typhi murium* WG49, were used to test for the presence of coliphages in concentrated groundwater samples. Of the 444 samples analyzed, 4.1%, 10.8%, and 9.5% were found to be positive using these three as the respective hosts. Only one sample was found to be positive for coliphages using all three hosts, while 92 of the samples (20.7%) were found to be positive using at least one host.

Coliphages have also been isolated from groundwater in an area influenced by recharge of the subsurface with reclaimed water (22). Coliphages were detected on at least one occasion in all twenty-six of the wells sampled. The shallowest of the wells had a perforated interval of 25.9 to 72.9 m; the deepest was perforated at 345.2 to 434.5 m. While some of the wells were located in close proximity

(20 to 40 m) to the recharge basins, others were located more than 100 m away; in one case the well was located more than 1,700 m from the recharge basins. Estimated travel times from the basins to these wells ranged from 24 to 5,852 days. Based on the data presented, it is clear that the presence of coliphages in some of the wells is not due to the presence of the recharge basins. The presence of other potential sources of coliphage, such as seepage from the domestic sewerage system, may be responsible for the presence of these viruses in the groundwater.

PERSISTENCE OF BACTERIOPHAGES IN THE ENVIRONMENT

There are a number of factors that affect the length of time that bacteriophages persist in the environment. The most important factors and the effects they have on persistence are summarized in Table 4. Some of these factors will be discussed in more detail in the following text. For a more complete description of the effects of these factors on the persistence of viruses in general, please see VIRUS SURVIVAL IN SOILS.

Temperature

Temperature is probably the most important factor influencing virus inactivation in the environment (25). In general, it has been found that the inactivation rate is significantly correlated with temperature, with faster inactivation rates occurring at the higher temperatures. Figure 2 presents a compilation of data (shown in Table 5) on the inactivation rate of MS2 coliphages as a function of temperature. This is the general trend, although there are clearly situations in which viruses are inactivated more rapidly at lower temperatures. Those exceptions can likely be explained by differences in other environmental characteristics, such as pH, microbial activity, etc.

The exact mechanism whereby temperature inactivates viruses in soils has not been determined, but several theories have been proposed. The inactivation may be due to denaturation of the viral capsid (25) as proteins are denatured at high temperatures. However, it has been shown that the RNA released during thermal denaturation remains infective as it is more resistant to heat inactivation than the protein capsid (26).

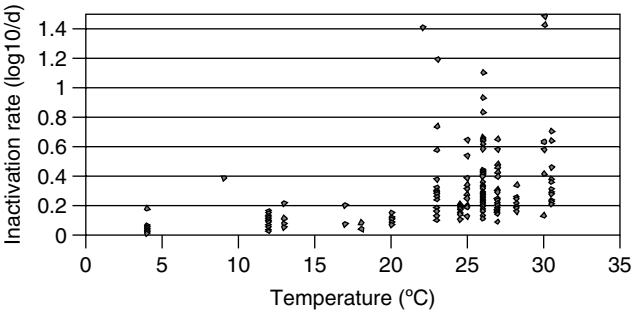

Figure 2. Survival of MS2 coliphage in groundwater as a function of temperature.

Microbial Activity

There are conflicting reports regarding the role of microorganisms in virus inactivation; many of these have been reviewed (27,28). The survival of MS2 viruses in groundwater that had been filtered to remove the indigenous bacteria compared to their survival in nonfiltered water is shown in Figure 3 (data shown in Table 5). There is no clear trend — in some cases the phage survived longer in the filtered water, in other cases survival was prolonged in the presence of the indigenous bacteria.

pH

The effect of pH on virus survival in soil has not been extensively studied. It has been suggested that pH indirectly influences virus survival by controlling adsorption onto soil particles, which, in turn, affects virus survival (29). The direct effects of pH on virus persistence have been studied by a few investigators. Hurst and coworkers (30) studied the survival of poliovirus 1 and

Table 4. Factors Affecting the Persistence of Viruses in the Environment

Factor	Effect on Persistence
Temperature	Viruses persist longer at lower temperatures
Microbial activity	Some viruses are inactivated more readily in the presence of certain microorganisms, and sorption to the surface of bacteria can be protective
Moisture content	Most viruses survive longer in moist soils and even longer under saturated conditions; unsaturated soil may inactivate viruses at the air-water interface
pH	Most enteric viruses are stable over a pH range of 3 to 9; however, survival may be prolonged at near-neutral pH values
Salt species and concentration	Certain cations may prolong survival depending on the type of virus
Virus association with soil	Viral association with soil generally increases survival, although attachment to certain mineral surfaces may cause inactivation
Soil properties	Effects on survival are probably related to the degree of virus sorption
Virus type	Different virus types vary in their susceptibility to inactivation by physical, chemical, and biological factors
Organic matter	Organic matter may prolong survival by competitively binding to air-water interfaces where inactivation can occur; organic matter may also retard viral infectivity

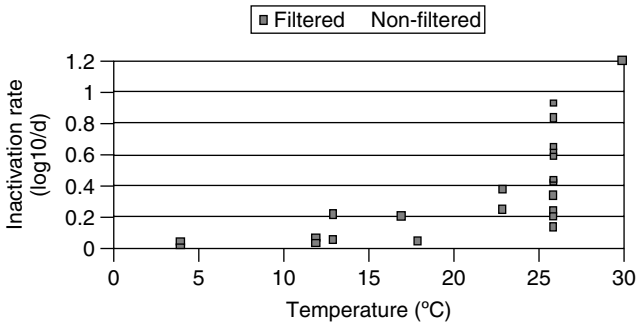

Figure 3. Survival of MS2 coliphage in groundwater in the presence and absence of indigenous bacteria.

two bacteriophages, MS2 and T2, in nine soils with pH values ranging from 4.5 to 8.2. They found that virus inactivation was significantly correlated ($p < 0.05$) with soil saturation pH, with longer survival at the lower pH values.

The exact mechanism whereby pH causes virus inactivation has not been fully elucidated, but results obtained by Salo and Cliver (31) suggested that virus inactivation involves alterations in the virus capsid. These investigators found that the RNA of the inactivated virus particles became sensitive to ribonuclease at all pH levels tested (pH 3 to 9), and at pH 5 and 7 the RNA was hydrolyzed in the absence of ribonuclease.

Loveland and coworkers (32) studied the effects of pH on the reversibility of virus attachment to mineral surfaces. Their experiments on the attachment of PRD1 to quartz and ferric oxyhydroxide-coated quartz indicated that attachment is controlled by the isoelectric point of the mineral surface. Attachment of PRD1 was observed at pH values 2.5 to 3.5 units above the isoelectric point of the mineral surface. Below this pH, the attachment of PRD1 was found to be complete and irreversible, whereas above this pH, the adsorption was minimal and reversible.

The mechanism(s) whereby pH affects virus adsorption to soil particles has been explained in terms of the electrochemical nature of the virus and soil surfaces (29,33,34). The outer surface of the enteric viruses is made of protein; therefore, the surface charge is influenced by the ionization of the carboxyl and amino groups in the capsid. The isoelectric point (pI) of many enteric viruses is below 7 (34); thus, at neutral pH, most viruses are negatively charged. Most soils are also negatively charged at neutral pH, and virus adsorption is not favored because of the mutual repulsion. If the pH of the environment is decreased, the surface charge of the virus will become positive (or less negative) due to increased ionization of the amino groups and decreased ionization of the carboxyl groups. While soils also become less negatively charged at lower pH values, soil pI values are generally lower than those of viruses, thus they may still have a net negative charge at acidic pH levels. This results in an electrostatic attraction between the virus particle and the soil, which leads to adsorption. In reality, the effect of pH on virus adsorption is not so clear-cut. There are many complicating factors that can interfere with the mechanism discussed earlier. One is that a given virus may have more than one pI: poliovirus 1 (Brunhilde strain) has pIs at pH 4.5 and 7.0 (34). The factors responsible for passage from one form to another are not known at this

Table 5. Survival of Coliphage in Groundwater

time. Other soil factors such as cations and humic and fulvic acids may also influence the net surface charge of viruses.

Salt Species and Concentration

The presence of certain chemicals may render a virus more or less susceptible to inactivation. Burnet and McKie (35) found that bacteriophage inactivation at 60 °C was partially prevented in the presence of 0.002 to 0.01 M $CaCl_2$, or $BaCl_2$. However, when the concentration was increased to 0.15 M or greater, thermal inactivation was increased.

Thurman and Gerba (36) studied the effects of modifying soil with several metals on the survival of MS2 and poliovirus. The addition of aluminum metal, magnesium oxide, and magnesium peroxide had a significant negative effect on the inactivation rate of MS2 when compared with unmodified control soils. The addition of unrefined substances such as zeolite, bauxite, limonite, and glauconite (which contain multivalent cations and oxides of iron and aluminum) did not have a significant negative effect on the inactivation rate of MS2. Rather, they seemed to have a protective effect, as indicated by the lower inactivation rate as compared with the unamended control soil. Further experiments by these investigators indicated that contact between the aluminum and virus was necessary for inactivation of the viruses. They postulated that a combination of electrodynamic van der Waals interactions and electrostatic double layer interactions promoted virus adsorption to the surface of the aluminum, where inactivation of the virus could then take place.

The role of soil cation exchange capacity (CEC) in virus adsorption has also been investigated. Burge and Enkiri (37) found that the CEC of four of five soils was correlated significantly ($p < 0.05$) with virus adsorption. In contrast, Goyal and Gerba (38) did not find a significant correlation between soil CEC and adsorption of 15 different viruses. Additionally, no correlation was found between virus adsorption and total phosphorus or between total and exchangeable iron, calcium, and magnesium.

Virus Adsorption to Soil

The adsorption of viruses to soils and other surfaces may prolong or reduce survival, depending on the properties of the sorbent. Murray and Laband (38a) found that poliovirus adsorption onto some inorganic substances, such as CuO, results in decreased infectivity of the virus. These investigators suggested that van der Waal's interactions between the virus and the particle surface induced spontaneous disassembly of the virus.

More commonly, however, adsorption to soils has been found to prolong virus survival. The mechanisms whereby adsorption to a solid surface prolongs or reduces virus survival have not been elucidated. However, Gerba and Schaiberger (39) have suggested several possibilities, including interference with the action of virucides, increased stability of the viral protein capsid, prevention of aggregate formation, and adsorption of enzymes and other inactivating substances.

Aggregation of Virus Particles

The formation of aggregates influences virus survival in natural waters. It has been suggested that this is because virus particles within the aggregates are highly resistant to destruction by environmental factors (25). It has been shown that aggregation renders virus particles more resistant to inactivation by chemical disinfectants such as bromine (40), free chlorine, and monochloramine (41). Although there are no definitive reports on the effects of aggregation on virus survival in soil, the results of studies in aqueous media would suggest that viruses in aggregates would survive longer in soils than would monodispersed viruses (33).

Soil Properties

The influence of soil properties on virus survival is probably related to the degree of adsorption. Hurst and coworkers (31) suggested that the correlation between pH and virus survival was probably mediated through its influence on virus adsorption. A positive correlation between virus survival and soil exchangeable aluminum and a negative correlation with resin-extractable phosphorus were also attributed to influencing virus adsorption onto the soil.

Virus Type

As is obvious from the previous discussions, different viruses vary in their susceptibility to inactivation in the subsurface environment. In a comparative study of the survival of poliovirus, echovirus, and coliphage MS2 in several different groundwater samples, no significant difference ($p < 0.01$) was found overall (6). There were, however, differences in the inactivation rates of the viruses in individual water samples.

The survival of poliovirus 1 and f2 coliphage in dry sand was compared by Lefler and Kott (42). Poliovirus survived for at least 77 days at room temperature. The f2 phage survived considerably longer, possibly for as long as one year under dry conditions. Based on the previous discussions, it is possible that the survival times of both viruses would be greatly increased if water were added to the soil.

Organic Matter

The influence of organic matter on virus survival has not been firmly defined. In some studies, it has been found that proteinaceous materials present in wastewater may have a protective effect on viruses; however, in others no effect has been observed (25).

The effects of natural humic material and wastewater sludge-derived organic matter on the transport of MS2 bacteriophages in unsaturated soil was studied by Powelson and coworkers (43). The transport of MS2 was found to be higher in a loamy fine sand column that had been treated with the organic material than in a parallel column that had not been treated. In a series of experiments, Bales and coworkers (13,44) studied the effects of hydrophobic organic material on the attachment of bacteriophages MS2 and PRD1 and

poliovirus 1 to silica beads. These investigators found that even very small amounts of hydrophobic organic material ($\geq$0.001%) can retard the transport of viruses in porous media.

Several investigators have found that organic material can act not only as a competitor for virus adsorption sites, but also as an eluting agent, that is, it can cause sorbed viruses to desorb from the soil (34). Pieper and coworkers (45) studied the effects of wastewater-derived organic matter on the transport of bacteriophage PRD1 in a sand and gravel aquifer on Cape Cod, MA. They found that the removal of the virus was greater in an uncontaminated area (83%) than in an area that had been contaminated by secondary wastewater effluent (42%). They concluded that the difference in removal was due to the higher content of organic matter in the contaminated zone (2.0 to 4.4 mg/L vs. 0.4 to 1.0 mg/L dissolved organic carbon), which blocked the adsorption of the PRD1. The attachment of the viruses to the soil surfaces was reversible, as demonstrated by the recovery of viruses upon addition of linear alkylbenzene sulfonates (LAS) to the system. In the contaminated zone, 87% of the attached PRD1 bacteriophages were remobilized. Jin and coworkers (14) also found that addition of a solution of 1.5% beef extract, which is high in organic matter, could remobilize ΦX174 bacteriophages from Ottawa sand.

Widespread use has been made of this property of organic matter in the area of removing viruses from filters to detect them in environmental samples. Mucks and other soils with high organic matter content are poor adsorbers of viruses (46) and may not be suitable for wastewater application sites (33).

In contrast to the other studies, Powelson and coworkers (46) found that the type of effluent (primary, secondary, and tertiary) had no significant effect on the transport of three viruses (poliovirus 1, MS2, and PRD1) through columns of an alluvial coarse sand.

CONCLUSION

Bacteriophages have been isolated from wastewater, surface water, and groundwater. There is a great deal of interest in the potential for the use of coliphages as indicators of the presence of human enteric pathogens, as well as of the potential for fecal contamination of groundwater. While bacteriophages show a great deal of promise as indicators, all scientific and regulatory communities have not yet accepted their use as such.

The interaction of factors affecting the survival of coliphage in the environment is a complex issue that has not yet been completely explained. The inactivation rates of two coliphages and the temperatures and pH values at which those inactivation rates occurred are shown in Table 5. Close examination of the data reveals that there are trends, as discussed earlier, but quantitation of these trends is not yet possible.

BIOAEROSOL SAMPLING AND ANALYSIS

MARK P. BUTTNER
University of Nevada, Las Vegas
Las Vegas, Nevada

Aerobiology is the study of airborne microorganisms and their effects on human health and the environment. Historically, aerobiology has been concerned with the airborne transmission of disease. However, in recent years, research in this field has expanded due to an increased awareness of the variety of health effects potentially arising from exposure to airborne microorganisms. Today the concentration and composition of airborne microorganisms is of interest in diverse areas, such as agricultural and industrial settings, medicine, home and office environments, and military research. Particular emphasis has been placed recently on the areas of indoor environmental quality and exposure assessment.

The term bioaerosol is used to describe living airborne particles or those that originate from living organisms (1). Microorganisms, including bacteria, fungi, viruses, parasites and algae, as well as microbial fragments, toxins and metabolites, may be present in bioaerosols. Bioaerosols can range in size from less than 0.01 μm to more than 100 μm in diameter. Bioaerosols in the respirable size range (≤10 μm) are of particular concern to human health.

Human exposure to bioaerosols can result in a variety of adverse health effects. Numerous microbial agents representing every class of microorganisms have been associated with adverse health effects resulting from bioaerosol exposure (2). Contamination and subsequent dispersal of biocontaminants in the workplace and living quarters may result in human exposure and adverse health effects, ranging from lost productivity to severe illness. Detection and measurement of biocontaminants in indoor environments are needed to assess contamination levels and estimate the resultant exposure of occupants. A wide variety of sampling and analysis methods have been used and new methods are being developed (3). However, several problems remain to be solved. For instance, no single sampling method is suitable for the collection and analysis of all types of bioaerosols and no standardized sampling protocols are currently available. Therefore data between studies are often difficult to compare because of differences in sampler design, collection time, airflow rate, and analysis method. In addition, there is currently no regulation limiting biocontamination or bioaerosol concentrations for home, office, and school environments. One reason for this is that human exposure limits have not been established for bioaerosols because of the lack of exposure, dose, and response data (1). This complicates the use of sampling results for risk assessment.

Conventional biocontaminant monitoring relies on the collection of airborne and surface microorganisms and analysis of samples by either culture on artificial growth media or microscopic assay. Although culture and microscopy methods are generally effective analytical tools, they are hampered by critical limitations. Culture analysis methods underestimate concentrations because only culturable cells are enumerated and identified, whereas nonculturable organisms go undetected (4). Microscopic assays are laborious and imprecise, and the level of identification is generally limited to the genus level at best. The inaccuracy of conventional methods and lengthy analytical time required to characterize bioaerosol concentrations emphasizes the need for developing new analytical techniques that can provide rapid and reliable data for bioaerosol exposure monitoring.

It is important for the investigator to consider carefully the objectives of sampling before any samples are taken. After determining what information is desired, an appropriate sampling and analysis method can be selected and incorporated into the monitoring design. The purpose of this chapter is to present various bioaerosol sampling and analysis methods to facilitate the selection of instrumentation and techniques. The collection methods used in bioaerosol sampling are presented with a description of sampling equipment currently available, including a discussion on sampling efficiency. Equipment calibration and sampling considerations such as collection times and the number of samples are also addressed. Analysis methods are presented in the second section of the chapter, beginning with traditional culture and total count methods and concluding with some recently developed biochemical and molecular techniques.

BIOAEROSOL SAMPLING

Bioaerosol sampling may be used to obtain useful data for a variety of applications, such as (*1*) measuring

the presence and concentration of airborne biocontaminants; (*2*) confirming dissemination from a biocontaminant source; (*3*) evaluation of bioaerosol exposure and health risks; (*4*) documentation of clearance to reoccupy a space, following remediation efforts; and (*5*) compliance monitoring in industrial environments. Regardless of the application, the objective of bioaerosol sampling is the efficient removal and collection of biological particles from the air in a manner that does not affect the integrity of the sample. This is dependent on the characteristics of the microorganisms and on the physical features of the sampling instrument (5,6). The selection of a sampler depends on a number of factors, such as sampler performance, expected bioaerosol concentration, and the analysis method. These factors are discussed later in the chapter.

Sampling Methods and Equipment

There is a wide variety of commercially available bioaerosol samplers (3,5,7). Bioaerosol samplers may be grouped according to their method of collection. The three main collection methods used in quantitative bioaerosol sampling are impaction, impingement, and filtration. Electrostatic precipitation has also been used for the collection of airborne microorganisms. Nonquantitative sampling by gravitational settling of particles will also be discussed. Several of the commercially available bioaerosol samplers are listed in Table 1.

Impaction. The majority of bioaerosol samplers utilize impaction as the collection principle. The impaction method uses the inertia of the particles to separate them from the air stream. The particles are deposited onto a collection surface that usually consists of an agar medium for culture-based analysis or an adhesive-coated surface for microscopic analysis. The impaction process depends on the inertial properties of the particle, such as size, density and velocity, and on the physical parameters of the impactor such as inlet nozzle dimensions and air flow pathway (7,8). The impactor sampler draws air through an inlet nozzle toward a collection surface, and particles with sufficient inertia impact while smaller particles remain in the air stream (Fig. 1a). Impactor samplers may be designed with multiple circular inlet nozzles; the sampler is then referred to as a multiple-hole or sieve sampler. If there are several stages with successively smaller nozzles, the sampler is referred to as a *cascade impactor*. For samplers in which air is drawn through a single nozzle, the shape of the nozzle is usually rectangular and the impactor is referred to as a *slit sampler*. Some impactors utilize centrifugal impaction, which also uses inertial forces to separate the particle from the air stream, but in a radial geometry (Fig. 1b).

Multiple-Hole Impactor Samplers. The Andersen impactor sampler (Fig. 2) has been widely used for culturable bioaerosol measurements (9). The sampler draws air at a flow rate of 28.3 lpm and is operated using an electric vacuum pump. The Andersen six-stage

Table 1. General Characteristics of Several Commercially Available Bioaerosol Samplers (see text for Manufacturer Information; Adapted from Buttner et al., 1997, with kind permission from ASM Press, Washington, DC)

Sampler	Collection Medium	Air Flow Rate (liters/minute)	Sample Analysis Method(s)	Comments
		Impaction		
Multiple-Hole Impactors				
Andersen viable impactors 1-, 2-, or 6-stage	Agar; 100-mm Petri dishes	28.3	C	Particle size discrimination (2 and 6-stage models); vacuum pump required; positive-hole correction
Burkard portable air sampler	Agar; l00-mm Petri dishes	10–20	C	Battery operated; positive-hole correction
MicroBio MB1 and MB2	55 mm contact plates	100	C	Battery operated; positive-hole correction
SAS Super 90, compact and high flow	Agar; 55-mm contact plates 85-mm contact plates	90 (compact, super 90) 180 (high flow)	C	Battery operated; programmable for multiple samples; positive-hole correction
Slit Impactors				
Air-O-Cell sampling cassette	Adhesive-coated surface	12–30	M	Determination of total fungal spores and pollen
Allergenco MK-3	Adhesive-coated glass slide	15	M	Determination of total fungal spores and pollen; programmable for multiple samples; electric or battery-operated
Burkard spore traps, 24-hour, 7-day, and personal samplers	Adhesive-coated surface, tape, or glass slide	10	M	Determination of total fungal spores and pollen; time discrimination (24-hour and 7-day models); battery operated (personal model)
Mattson/Garvin 220 and P-320	Agar; 150-mm Petri dishes	28.3	C	Time discrimination up to 1 hour
New Brunswick slit-to-agar, STA-101, -203, and -303	Agar; 150-mm Petri dishes	50	C	Time discrimination up to 1 hour; vacuum pump required for some models
Rotorod Models 20 and 40	Adhesive-coated polystyrene rods	48	M	Determination of total fungal spores and pollen; programmable for multiple samples; electric or battery-operated
Centrifugal Impactors				
Biotest RCS, RCS plus and RCS high flow	Agar; plastic strips	40 (RCS) 50(RCS Plus) 100(High Flow)	C	Battery operated; high volume sampling (High Flow); strips available unfilled or with agar medium
SASS 2000	Liquid	225	C,M,B,P,I	High volume sampling; High and low bioaerosol concentrations; electric or battery-operated
		Impingement		
All-glass impingers (AGI-30 and AGI-4)	Liquid	12.5	C,M,B,P,I	High and low bioaerosol concentrations; vacuum pump required

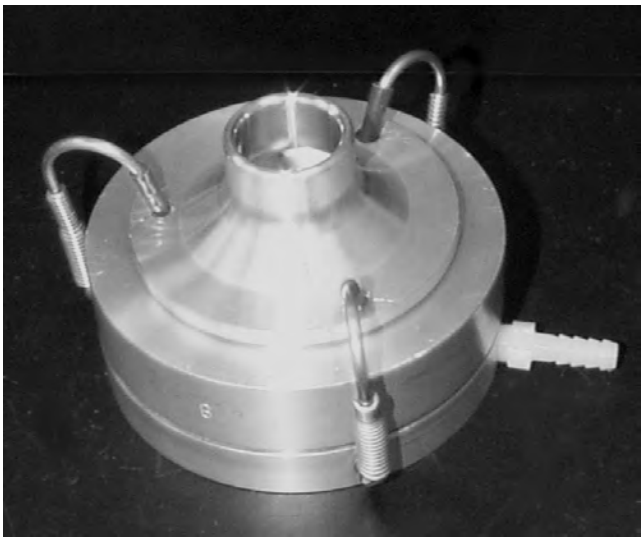

Figure 2. Andersen single-stage sampler (courtesy of Paula Jacoby-Garrett, UNLV).

impactor sampler (Andersen Instruments, Inc., Smyrna, Ga.) consists of six stages with decreasing nozzle diameter that collect progressively smaller particles onto agar plates. The number of colony-forming units (CFU) that form on the agar collection plates provides bioaerosol size distribution information (9). Single-stage and two-stage models of the sampler are also available. There are several portable, battery-powered single-stage impactor samplers designed for sampling culturable airborne microorganisms. These include the Surface Air System (SAS, International PBI, Milan, Italy, distributed by Bioscience International, Rockville, Md.); the Burkard portable air sampler (Burkard Manufacturing Co., Ltd., Rickmansworth, Hertfordshire, England); and the MicroBio MB1 and MB2 (Spiral Biotech, Inc., Bethesda, Md.) (Table 1).

Slit Impactors. Slit impactors are available for the measurement of either culturable or total airborne microorganisms. Many slit impactors have a moving collection surface that allows enumeration of bioaerosol concentration over time. Slit impactors that deposit the bioaerosol onto an agar surface for the estimation of culturable cells include the Mattson-Garvin air sampler (Barramundi Corp., Homosassa, Fla.) and the slit-to-agar sampler (New Brunswick Scientific Co., Inc., Edison, N.J.). Slit impactors that collect particles onto an adhesive-coated surface are generally used for the microscopic enumeration of fungal spores or pollen grains. These include the Burkard spore traps and the personal air sampler (Fig. 3) (Burkard Manufacturing Co., Ltd.; Spiral Biotech, Inc.), the Air-O-Cell sampling cassette, (Zefon International, Inc., St. Petersburg, Fla.), the Allergenco air sampler (Allergenco/Blewstone Press, San Antonio, TX) and the Rotorod (Sampling Technologies, Inc., St. Louis Park, MN) (Table 1).

Centrifugal Impactors. The Reuter centrifugal sampler (RCS) and RCS plus (Biotest Diagnostics Corp., Denville,

Figure 3. Burkard personal air sampler (courtesy of Paula Jacoby-Garrett, UNLV).

Figure 4. AGI-30 sampler (left) and SKC BioSampler (right) (courtesy of Paula Jacoby-Garrett, UNLV).

N.J.) are portable battery-powered samplers that centrifugally impact the microorganisms onto agar strips for culture analysis. The agar strips containing selected media formulations are available from the manufacturer. The Smart Air Sampler System (SASS) 2000 (Research International, Woodinville, WA) is a wetted-wall cyclone sampler that collects airborne particles in a thin liquid layer through centrifugal action.

Liquid Impingement. Liquid impingement samplers draw air through an inlet and particles are collected in a liquid (Fig. 1c). The particle is removed from the air by inertial force and impaction into a swirling or bubbling liquid. Aggregates of cells may be broken apart by the action of the collection fluid. The collection of bioaerosol particles in a liquid medium has several advantages, including the retrieval of bioaerosol particles over a wide range of airborne particle concentrations, the ability to divide the sample for multiple analyses, and the option of applying a variety of analysis methods as discussed in the following section. A liquid sample can be concentrated by filtration or diluted by liquid addition, depending on the concentration of collected microorganisms. In addition, several culture media can be inoculated with aliquots of the collection medium for the culture of groups of microorganisms with different nutrient requirements.

The AGI-30 all-glass impinger sampler (Fig. 4) (Ace Glass, Inc., Vineland, N.J.) is a widely used sampler that has a curved inlet tube designed to simulate the nasal passage, making this sampler useful for studying the respiratory infection potential of bioaerosols (10,11,12). For other applications the inlet tube is washed with a known volume of collection fluid to recover nonrespirable airborne particles. The AGI-30 has an impaction distance of 30 mm from the jet to the bottom of the sampler. The AGI-4 model features a shorter distance of 4 mm to improve particle collection efficiency over the AGI-30. However, added sampling stress may result from impaction against the glass bottom of the sampler, resulting in a loss of cell viability (3,7). The Burkard multi-stage liquid impinger (Burkard Manufacturing Co., Ltd.) is a stainless steel sampler that collects particles in three size fractions: $>10\ \mu m$, 4 to 10 μm, and $<4\ \mu m$. The BioSampler (Fig. 4) (SKC, Inc., Eighty Four, Penn.) combines impingement into a liquid with centrifugal motion (13). The BioSampler collects particles by drawing air through three nozzles that are directed at an angle toward the inner sampler wall and the liquid swirls upward on the inner wall of the sampler to remove collected particles. Although other impingers are designed for use with water-based collection fluids, the BioSampler can be used with viscous collection fluids (e.g., heavy white mineral oil) to minimize sampling stress and evaporation loss of the collection buffer.

Filtration. Filtration sampling is used to separate particles from the air stream by passing air through a

porous medium (Fig. 1d). Collection of particles depends on the aerodynamic diameter of the particle, the filter pore size, and the airflow rate (14). Inertial forces and other mechanisms such as interception, diffusion, and electrostatic attraction result in the collection of particles on the surface of the filter, including particles smaller than the pore size of the filter (12). Membrane filters housed in disposable plastic cassettes are typically used for filtration sampling (Table 1). The air sampling cassettes may contain 25-, 37-, or 47-mm diameter filter membranes and are available from a variety of manufacturers (e.g., Gelman Sciences, Ann Arbor, Mich.; Millipore Corp., Bedford, Mass.; Nuclepore, Corning Costar Corp., Cambridge, Mass.; Poretics Corp., Livermore, Calif.; SKC Inc., Eighty Four, Penn.). Filter material, including polycarbonate, cellulose mixed ester or polyvinyl chloride with a variety of pore sizes, may be used depending on the nature of the bioaerosol and the method of sample analysis (7,12,14).

The advantages of using filtration sampling for bioaerosol monitoring are its simplicity, low cost, and versatility. Filtration sampling is adaptable to a variety of assays but loss of viability of vegetative cells may occur, presumably due to desiccation stress during sampling (15,16,17). The MD8 air sampler (Sartorius AG, Göttingen, Germany) collects airborne microorganisms on a gelatin filter to reduce desiccation stress. The gelatin membrane is incubated on an agar medium of choice for culture analysis.

Electrostatic Precipitation. This method of collection uses electrical forces to separate particles from the air stream (18). The Space Charged Atomizing Electrostatic Precipitation (SCAEP) PM-1B sampler (Team Technologies, Newton Upper Falls, MA) operates by drawing air through a charged liquid spray that collects particles by electrical forces and concentrates them into a liquid.

Gravity Sampling. Gravity sampling, also referred to as *settling plate* or *depositional sampling*, is a semi-quantitative collection method in which airborne microorganisms are collected by gravitational settling onto an exposed agar plate. Although this method is simple and inexpensive, collection of airborne microorganisms using this method is affected by the size and shape of the particles and by the motion of the surrounding air (8). As a result, large particles are more likely to be deposited onto the collection surface (19). This can lead to misrepresentation of the prevalence of airborne microorganisms and the exclusion of smaller particles from collection (20). Furthermore, the number of colonies enumerated cannot be related to the bioaerosol concentration of the environment because the volume of air from which the particles originate is unknown. Gravity sampling has been compared with various volumetric culture sampling methods. The results show that the airborne concentrations derived from gravity sampling are not qualitatively or quantitatively accurate and do not compare favorably with those obtained by volumetric sampling methods (20–23).

Sampling Efficiency

No single sampler can be used for the collection and analysis of all types of bioaerosols. The selection of the appropriate sampler depends on a variety of factors including the sampling environment, the analysis methods used, and the monitoring objectives. Consideration of the theoretical aspects of air sampling efficiency and the experimental results of performance studies may assist in the selection of the appropriate sampling method for a particular monitoring situation. The performance of bioaerosol samplers can be divided into physical and biological components. The primary physical parameters that affect sampling efficiency are the inlet sampling efficiency and the particle collection efficiency. These criteria are presented briefly in the following section and have been discussed in detail in the literature (7). Biological sampling efficiency refers to the effects of sample collection on the culturabilty or integrity of the cells or cellular components for sample analysis.

Inlet Efficiency. The efficiency of the sampling inlet affects the ability of the sampler to extract airborne particles from the environment. Ideally the inlet should entrain particles from the air without bias due to their size, shape, or density. However, when sampling from a moving airstream, the air velocity and the orientation of the sampler may effect the inlet efficiency. The inlet characteristics of several bioaerosol samplers have been calculated for different types of bioaerosol particles sampled under various conditions (24). The results showed that certain sampling conditions could result in either overestimation or underestimation of the true bioaerosol concentration. Therefore it is important that while sampling in a moving airstream the samples be collected isokinetically, with the sampler inlet aligned with the airstream flow and with the velocity through the inlet equal to the airstream velocity (25).

Collection Efficiency. Collection efficiency, also termed *particle removal efficiency*, is the ability of the sampler to remove particles from the airstream and transfer them to the collection medium. Particle losses may occur between the sampler inlet and the collection device. The distance between the inlet and the collection device is therefore usually minimized to improve collection efficiency (7). For impactor samplers a useful parameter for evaluating collection efficiency is the "cut-off diameter" or d_{50}. The d_{50} refers literally to the particle diameter at which 50% of the particles are collected. However, because of the sharp cut-off characteristics of impactor samplers, the d_{50} is generally considered the particle diameter above which all particles are collected (26,27). The d_{50} values for several samplers have been calculated using the physical dimensions of the impaction nozzle(s) and the airflow rate (Table 2). For membrane filters, the collection efficiency is approximately 100% for particles larger than the pore size (28).

Biological Efficiency. Ideally a bioaerosol sampler should collect all airborne microorganisms without altering the culturability or the biological integrity required

Table 2. Calculated and Reported Cut Diameters (d_{50}) for Several Bioaerosol Samplers (Adapted from Buttner et al., 1997, with kind permission from ASM Press, Washington, DC)

for the detection and quantification of the microorganisms or their metabolites. However, the infectivity and allergenicity of bioaerosols may be affected by numerous chemical, physical, and biochemical factors (29). Airborne microorganisms are subjected to a variety of environmental stressors, such as UV radiation, chemical pollutants, desiccation, and temperature extremes (4). In addition, the stress of sampling may injure the collected microorganisms, depending on their physiological characteristics (30). As a result, microorganisms may be in a nonculturable state.

Many sampling methods rely on culturing the collected microorganisms. Minimizing sampling stress is therefore critical. For agar or liquid collection media, it has been observed that culturability of cells can be improved by using certain culture media (31–33) or by the addition of certain compounds to the collection medium such as osmoprotectants, which aid in the resuscitation of stressed or damaged cells (34). Filtration sampling, although highly efficient for the collection of airborne microorganisms, has the disadvantage of viability losses of vegetative cells, presumably as a result of desiccation (15–17). Therefore filtration sampling in combination with culture analysis is generally used when bioaerosol concentrations are very high and sampling times are short. Filtration sampling is also used to monitor desiccation-resistant forms, such as fungal spores or bacterial endospores, or in combination with a total count method of analysis (35). The length of collection time, discussed in the following section, also plays a major role in the efficacy of air sampling for the retrieval of culturable microorganisms.

Sampler Performance. Numerous sampler comparison studies have been published, evaluating overall sampler performance and this work has been reviewed (3). The Andersen 6-stage viable impactor and the AGI-30 liquid impinger sampler have been suggested as reference methods (5) due to their efficiency and wide spread use, and many sampler efficiency studies have included these samplers in side-by-side comparisons. Some of the factors that can negatively affect sampler performance are presented here and in the following sections.

Agar impactor samplers collect microorganisms directly onto the culture medium. One of the disadvantages of this sampling method is that the nonculturable component of the bioaerosol is not measured and can be a significant percentage of the total composition (35). Another disadvantage of agar impaction is overloading when bioaerosol concentrations are high, resulting in agar plates or strips that contain colonies that overlap and are numerous to count (36). In addition, aggregates or clumps of microorganisms may impact at the same place on the agar surface and be enumerated as a single colony, resulting in underestimation of the bioaerosol concentration. Other problems that may occur with impaction onto either agar or adhesive-coated collection surfaces and can lead to erroneous results are particle bounce, where particles rebound off the collection surface and reenter the airstream (8), and electrostatic forces that attract biological particles to the surfaces of the collection device (9).

Impingement of microorganisms by impaction onto a liquid-wetted surface may also result in culturability losses through sampling stress (9,37). Another difficulty is that the microorganisms collected into a liquid may become reaerosolized from the bubbling collection fluid during sampling. In addition, the collection efficiency of liquid impingers may decrease significantly due to liquid evaporation over time (38).

Sampling Considerations

In the development of a bioaerosol sampling design, the investigator should have an understanding of the objectives of sampling and the types of data that will be obtained. The selection of the sampling and analysis method(s) is a primary concern. Numerous other factors should also be considered before sampling is initiated, including the length of the sample collection time, the number of samples to be taken, and calibration of the sampling equipment.

Collection Time. The goal of sample collection is to obtain a representative sample of the bioaerosol of interest. If sampling times are too short, too few microorganisms are collected to reliably estimate the bioaerosol concentration and composition. If sampling times are too long, the sampler may be overloaded with particles too numerous to enumerate and sampling stress may cause losses. In the selection of sample collection times, parameters that must be considered are the expected bioaerosol concentration, the quantitation range of the sampler, and the effect of sampling stress on the overall collection efficiency (3).

Bioaerosol concentrations can vary over several orders of magnitude, from $<10^2$ to $>10^6$ colony-forming units (CFU) per cubic meter of air, depending on the environment. Concentrations of airborne microorganisms can also fluctuate over time within the same environment. Therefore a single air sample provides only a brief glimpse of the environment in a particular time and place. Although the ambient bioaerosol concentration is an unknown quantity, estimates of its concentration can be used to determine the sample collection time as shown below.

The quantitation range of a bioaerosol sampler can be determined for a specific collection time using the sampler airflow rate (39). The lower detection limit (LDL) of a sampler for a particular collection time may be calculated assuming the detection of a single microorganism. Air samples collected near the LDL of a sampler can contain an insufficient number of particles to accurately represent the true bioaerosol concentration. There is no definite upper detection limit (UDL) for filtration or impingement sampling methods because the liquid collection medium or the liquid used to elute microorganisms from a filter membrane may be serially diluted prior to analysis. For impactor samplers the UDL is determined by the number of sampling nozzles or the area of the collection surface. Overcrowding of the impaction surface may result in errors in enumeration for microscopic and culture analysis methods (see Sample Analysis in the following section). For multi-hole impaction samplers, the UDL is reached when a CFU develops under each of the sampling nozzles. Other problems at or near the UDL include difficulties in resolving distinct particles or colonies (36) and inhibition of the growth of microorganisms as a result of competition for space and nutrients.

One method for establishing the collection time for a particular sampler is to determine the ideal surface density of microorganisms on the collection area and to estimate the order of magnitude of the bioaerosol. Nevalainen and coworkers (27) calculated the optimal sampling time for five bioaerosol samplers by using the formula $t = (\delta)(A)/(C_a)(Q)$, where t is the sampling time, δ is the desired surface density, A is the area of the sampling surface, C_a is the average expected bioaerosol concentration, and Q is the sampler flow rate. In this way the investigator determines the optimal number of colonies or cells on the collection surface and predicts the bioaerosol concentration. The drawback of this method occurs when the actual bioaerosol concentration is substantially different from the estimate. For this reason, more than one collection time is often employed for sample collection to increase the likelihood of obtaining useful data.

Another factor that influences the selection of the sample collection time is sampling stress, which can result in the loss of culturability of airborne microorganisms or degradation of the sample. It has been observed that increased sampling time has resulted in decreased viability for aerosolized vegetative bacterial cells (10,39–41). Therefore a doubling of sampling time may not result in a doubling of CFU or other analytes, depending on the stress tolerance of the bioaerosol components. In many cases, taking several consecutive samples of short duration is preferable to fewer samples with a long collection time. For further information on the selection of collection times, guidelines for the use of various bioaerosol samplers have been published (1,8).

Number of Samples. As previously stated, air sample collection periods are of relatively short duration and a single sample is of limited monitoring value due to the heterogeneity and variability of bioaerosols. Multiple samples for each sampling method used should therefore be taken for bioaerosol assessment. Determining the number of samples required for a particular situation is dependent on several factors, including the objective of sampling, the statistical approach used to interpret the data, the variability of the bioaerosol, the length of the sample collection period, and the available resources for sampling and analysis. The number of samples required should therefore be determined before sampling during the experimental design phase.

A high degree of variability has been shown between paired samplers of the same type (21,42). Duplicate samples are therefore often recommended, and the sample measurement is reported as the average of the replicate data points. Guidelines indicating the number of samples required for monitoring in the occupational environment have been published (1). For example, to estimate average worker inhalation exposure, the ACGIH recommends sampling in duplicate at least three times a day per site for at least three consecutive days for each sample type collected. Statistical methods can also be applied to calculate the number of samples needed to estimate confidence intervals around a mean or to compare mean values from sampling locations.

Sampler Calibration. The concentration of a bioaerosol is calculated by dividing the number of microorganisms or other analyte in the sample by the air sample volume (e.g., CFU per cubic meter). Therefore the volumetric airflow

rate of a sampler must be known and should be calibrated regularly. For impactors, the sampler's d_{50} is a function of the airflow rate through the nozzle(s). A decrease in airflow increases the d_{50} and the sample collection is shifted toward larger particles (26). Conversely, an increase in airflow decreases the d_{50}, resulting in increased small particle collection and potentially increased stress on the microorganisms. Various calibration methods that measure the flow rate through a soap bubble meter or an electronic calibration instrument are available (7).

SAMPLE ANALYSIS

A wide variety of sample analysis methods can be applied to air samples to provide information on the concentration and composition of bioaerosol components. The selection of an analysis method should be determined before monitoring is conducted because sampling and analysis methods are not necessarily compatible. Many impaction-sampling methods rely on the traditional analysis methods of culture or microscopy. Filtration and impingement sampling methods are more flexible with respect to sample analysis options. Limitations in the traditional analysis approaches have led to the development of alternative techniques, such as biochemical, immunological, and molecular biological assays. New methods are continuously being developed for the enhanced detection of bioaerosols (see ENHANCED DETECTION OF AIRBORNE MICROBIAL CONTAMINANTS).

Culture

The majority of bioaerosol data reported has been generated using culture analysis, and many of the currently available samplers are designed for collection onto a nutrient agar surface. Airborne bacteria and fungi collected in this way can be cultured directly, whereas samples collected by impingement or filtration are processed and transferred to a culture medium. The major drawback of culture analysis is that only those cells that survive and reproduce to form visible colonies are enumerated. Microorganisms that have been subjected to aerosolization and sampling stress may not respond to the artificial nutrient conditions in the laboratory. In addition, microorganisms exhibit a wide range of nutritional and temperature requirements for growth, and no formulation is capable of culturing every type of microorganism. For example, different media are required for isolation of airborne bacteria and fungi. Therefore a common approach in bioaerosol monitoring is to choose general media that promote the growth of the greatest diversity of species. For the isolation of specific microorganisms or groups, conditions such as pH, temperature, water activity, nutrients, antibiotics, light and aeration, can be manipulated to select for the growth of the target microorganisms (43). Consequently, it may be necessary to perform replicate sampling using multiple types of nutrient media or to divide the samples prior to inoculation.

Culture Media and Incubation. Several broad-spectrum media have been evaluated for their utility in the retrieval of culturable airborne fungi (31–33,44). Although results and interpretations vary, a number of media have been recommended. Malt extract agar (MEA) is a widely used fungal isolation medium. Of the formulations available, unamended 2% MEA was found to promote sporulation better than MEA amended with glucose and peptone (45,46). Rose bengal–containing agars (e.g., rose bengal-streptomycin and dichloran-rose bengal-chloramphenicol) have been used to inhibit the spread of rapidly growing fungal genera (e.g., *Rhizopus* and *Mucor*), allowing the enumeration and identification of other fungi in the sample. However, rose bengal is photoactivated in direct sunlight, forming cytotoxic products that may inhibit fungal growth (47). Dichloran glycerol-18 is a low water activity medium ($a_w = 0.955$) developed for the isolation of xerophilic fungi (48) and it compares favorably with other media for culturing mesophilic airborne fungi (33). Other commonly used fungal media include potato dextrose agar and Sabouraud's agar (20,49). It should be emphasized that many bacterial species are capable of growth on general fungal media and the use of antibacterial agents, such as chloramphenicol as an amendment to the medium, is recommended. Incubation periods for fungi typically range from 3 to 10 days and most airborne fungi are mesophilic and grow well at temperatures of 20 °C to 25 °C.

For the culture of bacteria, several broad-spectrum media, including tryptic soy agar, nutrient agar, and casein soy peptone agar, are commonly used (12,43). These media should be amended with antifungal agents such as cycloheximide to restrict the growth of fungi. Incubation temperatures from 28 ° to 35 °C for 1–7 days are usually used for environmental and human source bacteria. Important exceptions are the thermophilic actinomycetes, which are cultured at 55 °C.

Enumeration. After the appropriate incubation period, culturable microorganisms are determined by enumerating the colony-forming units (CFU). The concentration of culturable airborne microorganisms (CFU per cubic meter) is calculated by dividing the number of CFU per sample by the volume of air sampled. When microorganisms are collected using multiple-hole impactor samplers (Table 1), positive-hole corrections are generally applied to the data before calculations to avoid underestimation of the culturable bioaerosol concentration (9,21,50). These corrections are based on the probability of multiple impactions of microorganisms through the same sampling hole. The magnitude and the standard deviation of the correction increase with the number of CFU (7).

When air samples are collected by impaction onto an agar plate and the bioaerosol concentration is unknown, too few or too many colonies may be cultured, leading to enumeration errors. Colony counts that are too low can be nonrepresentative of the population and exhibit high variability. High colony counts can lead to errors because of overlap of colonies and inhibitory effects of microorganisms on one another. When a limited amount of overlap occurs, the true bioaerosol concentration can be statistically calculated from the number of colonies on the agar (36,50). Enumeration errors for agar impaction

samplers can be reduced by selecting multiple sample collection times as previously discussed. For filtration or impingement sampling, the wash solution or collection buffer can be serially diluted to obtain counts within an acceptable range.

Identification. Identification of fungal isolates is based largely on microscopic determination of morphological characteristics and requires training and expertise in mycological techniques. Bacterial isolates may be identified by several methods. Often culturable bacteria are differentiated according to their Gram stain reaction. Identification to the genus or species level requires the use of classical biochemical methods or various commercially available identification systems.

Microscopy

Microscopy is another commonly used method for the enumeration of airborne microorganisms collected by impaction onto an adhesive-coated surface or by filtration. Microscopy allows enumeration of total (culturable and nonculturable) microorganisms, unlike culture analysis that only measures the culturable bioaerosol components. This method can provide important exposure information because some microorganisms that are nonviable or nonculturable can still elicit an immune or toxic response when inhaled. However, identification of microorganisms beyond the genus level is usually not possible without utilizing a taxon-specific technique such as immunospecific fluorescence staining (described in the following section). If information on viability or culturability is desired, microscopy can be used in conjunction with culture sampling and analysis. In addition, a variety of stains are commercially available that differentiate respiring cells from nonrespiring cells.

Microscopic enumeration is generally used for the determination of total airborne fungal spores. Air samples collected with slit impactors (e.g., Burkard spore traps, the Allergenco, and Air-o-Cell samplers) are prepared by mounting and staining the collection slide or tape, and fungal spores and pollen grains are enumerated by light microscopy. The total number of spores or pollen grains enumerated in a sample is divided by the volume of air sample to estimate the total number of spores or pollen grains per cubic meter of air. When the sample is collected onto a moving surface, time discrimination of fungal spore concentration is possible by enumerating spores present between specified points along the collection surface that represent discrete time intervals. Several stains, including lactolphenol cotton blue, phenosaffranin, and basic fuchsin, are commonly used to facilitate discrimination of spores or pollen grains from debris (43). Data may be reported as the total spore concentration, the concentration of a specific target genus, or the percent composition of fungal genera. However, differentiation of certain fungal genera is not possible by spore morphology alone (e.g., *Aspergillus* and *Penicillium* spp.). Therefore these genera are grouped when reporting percent composition of bioaerosol samples.

For the determination of total airborne bacteria, liquid impingement or filtration sampling is generally used with microscopic analysis. Aliquots of collection buffer or the buffer used to elute cells from the filter membrane may be stained for epifluorescence microscopy by the acridine orange direct count method (35,51,52). Fungal spores may also be enumerated using the method. However, some fungal spore types may resist staining or have dark pigmentation that masks fluorescence (43). Cells and endospores may also be enumerated by bright-field or phase-contrast microscopy using a hemocytometer or some other cell counting chamber.

A disadvantage of microscopic analysis of air samples is the labor-intensive nature of microscopic enumeration. Computerized image analysis systems that overcome this limitation are available and can be used for enumeration. An alternative to microscopic enumeration of total cells is the use of flow cytometry, in which cell concentrations can be measured by light scattering and fluorescence emitted from fluorochromes bound to cells. Impinger samples labeled with DAPI yielded comparable results when enumerated by microscopy or flow cytometry (53).

Another difficulty of microscopic analysis is the level of expertise required to identify fungal spores and pollen. Misidentification and the inability to distinguish biological from nonbiological particles are common sources of error in this method (43).

Immunoassay

The limitations of traditional analysis methods and the need for human exposure data for bioaerosol risk assessment have lead to the development of enhanced detection methods for air sample analysis. Immunoassay methods have been recognized for their potential application to bioaerosol analysis (19). Immunoassays rely on the binding of antibodies to a specific target antigen. Target antigens may be cell surface–associated proteins, polysaccharides, or human allergens. The development of a specific antibody to the target antigen is required for these assays. The advantages of immunoassay methods for quantification of airborne allergens are their specificity and sensitivity. The major limitation of immunoassays is that specific antigens for microorganisms are difficult to define and standardize (54). Variations of this method that have been applied to bioaerosol analysis include fluorescence immunoassay, enzyme immunoassay, and radioimmunoassay.

For fluorescence immunoassays, samples are stained with a fluorescence-labeled antibody that binds specifically to the antigens on the surfaces of the target organisms. The samples are then analyzed by epifluorescence microscopy. Fluorescent labeling dyes include fluorescein, fluorescein isothiocyanate, and rhodamine isothiocyanate (12). Radioimmunoassays utilize radioactive-labeled antibodies and enzyme immunoassays utilize enzyme-labeled antibodies or antigens. The concentration of antigen is measured by radioactivity or enzyme activity. These methods have been applied to the measurement of airborne allergens, such as dust mite allergen, animal dander, and β-1,3-glucan (55–58). Impaction, impingement, and filtration samples may be analyzed using immunoassays (59).

Biochemical Assay

Numerous cellular components or metabolites, such as endotoxins and mycotoxins, may produce adverse health effects when inhaled (60,61). Biochemical assays have been developed to measure these compounds directly in an effort to relate environmental exposure to human responses.

Endotoxins are lipid polysaccharides (LPS) present in the cell walls of gram-negative bacterial cells. Elevated levels of endotoxin due to the presence of airborne gram-negative bacteria have been measured in bioaerosol samples from a variety of agricultural, industrial, and office environments (62). The concentration of endotoxin in a sample may be measured using the *Limulus* amebocyte lysate (LAL) test. The lysate of amebocytes from the horseshoe crab, *Limulus polyphemus*, gels in the presence of LPS, and a variety of test systems have been developed to quantify endotoxin using this method. Filtration sampling is most often used to collect airborne endotoxin; however, certain filter materials have been shown to inhibit the LAL assay (63). In addition, interference with the LAL reaction by inhibitors present in environmental samples must be accounted for in the measurement of endotoxin content (64).

Mycotoxins associated with dusts from fungus-contaminated grains are a known source of illness (65). Exposure to *Stachybotrys chartarum* mycotoxins has been associated with toxicoses in contaminated home and office environments (66–68). Filtration sampling using glass-fiber filters or polycarbonate membranes has been used to measure aerosolized mycotoxins of *S. chartarum* in the laboratory (69,70) and in the field (71). Other biochemical methods that may be applied to the analysis of airborne fungal exposure include ergosterol (72,73) and β-1,3-glucan (56,74,75) assays.

Polymerase Chain Reaction

Polymerase chain reaction (PCR) is an example of a molecular biological technique that has been applied to the detection of target microorganisms in air samples (76–78). PCR is an enzymatic procedure used to rapidly amplify specific DNA sequences (79). Following amplification, the target DNA is present in sufficient quantity to allow detection as low as the level of a single microorganism. The authenticity of the amplified DNA can be confirmed by sequencing, restriction analysis, or gene probe hybridization. The requirement for PCR detection of target microorganisms is that unique, non-cross-hybridizing sequences are available to serve as primers for amplification. Quantitative PCR methods have been developed and are commercially available for the measurement of the concentration of the DNA segments present in the original sample.

The primary advantages of using PCR for the analysis of bioaerosols are sensitivity and speed. Because PCR detection is not dependent on the culturable state of a microorganism, PCR can be used to detect microorganisms that are nonculturable, difficult to culture, or grow slowly. For example, positive results with the PCR technique were demonstrated for the detection of bacteria aerosolized in a greenhouse when culture data were negative (76). Using PCR, it is possible to obtain results within hours of sample collection, compared with days or weeks for culture methods. If there are multiple organisms of interest in a sample, multiplex PCR may be performed in the same reaction mix to simultaneously amplify several DNA targets of interest. Liquid impingement and filtration sampling methods have been used with PCR analysis for the detection of target microorganisms (76–78).

A limitation of the PCR assay is the inability to distinguish between culturable and nonculturable microorganisms. In addition, the presence of PCR inhibitors in environmental samples may reduce sensitivity or result in false negatives (80). A nucleic acid purification step or dilution of the sample may be required to remove environmental interference to PCR amplification (81).

Data Analysis

Data generated from air sampling studies can be used to test hypotheses and answer scientific questions pertaining to environmental biocontamination, biocontaminant dispersal, human exposure, and efficacy of remediation. For data to be useful, quality assurance and statistical considerations should be addressed before sample collection. A quality assurance plan should be developed to minimize errors in sample collection and analysis (82,83). Statistical considerations include determination of appropriate data reporting methods, statistical tests for data analysis, and sample sizes. Statistical tests can be used to compare means from various sampling locations and from different sampling or analysis methods.

There are several commonly used methods for data reporting (83). Often descriptive statistics, such as means, standard errors, and confidence intervals, are used for interpretation of bioaerosol concentration results. Expressing data as the percent composition of genera or groups is often helpful for population comparisons. There are several acceptable approaches for reporting and analyzing bioaerosol data, and consideration of these factors in advance will increase the likelihood of obtaining meaningful data.

CONCLUSION

There are many sampling and analysis methods available for bioaerosol monitoring. Increased awareness of the variety of health effects potentially arising from exposure to airborne microorganisms has led to the development of numerous new analytical techniques that can provide rapid, reliable data for bioaerosol exposure monitoring. Therefore it is important for the investigator to consider carefully the objectives of sampling before any samples are taken. After determining what information is desired, an appropriate sampling and analysis method can be selected and incorporated into the monitoring design. Reliable bioaerosol data are needed to further the understanding of the effects of human exposure to airborne microorganisms

and aid in the development of standardized monitoring protocols.

BIOAEROSOLS IN AGRICULTURAL AND OUTDOOR SETTINGS

ESTELLE LEVETIN
The University of Tulsa
Tulsa, Oklahoma

Bioaerosols are biological agents carried in the air as large molecules, volatile compounds, single particles, or clusters of particles that are living or were released from a living organism. Included in this broad classification are viruses, bacteria, fungal spores, algae, pollen grains, arthropod particles, mammalian particles, complex metabolites, and volatile compounds. Particle sizes of bioaerosols range from approximately 0.05 to 100 μm and they occur both indoors and outdoors with the greatest diversity typically occurring outdoors.

A tremendous variety of bioaerosols in the atmosphere have been studied since the nineteenth century. Some of the early investigators include C.H. Blackley in England, who first described chest tightness and "bronchial catarrh" brought on by inhaling fungal spores on moldy straw and D.D. Cunningham, who attempted to relate airborne organisms to the incidence of disease in India. During the early twentieth century, advances in aerobiology (the study of bioaerosols) were made by plant pathologists interested in the spread of agricultural pathogens, specifically the movement of stem rust of wheat in the United States.

The development of the volumetric spore trap by Hirst in 1952 was probably the most important catalyst in the scientific study of bioaerosols because it made it possible to accurately estimate spore and pollen concentrations in the air at any given time. Nearly 50 years later, spore traps based on Hirst's design are among the most widely used instruments for studying bioaerosols. Analyses of air samples have shown that fungal spores are the most abundant types of bioaerosol particles (1). This entry will discuss fungal spores in the atmosphere and their importance in agricultural settings. Other bioaerosols are addressed in other sections of this volume.

SOURCES OF AIRBORNE FUNGI

Fungal spores are a normal component of the atmosphere, and they occur in large numbers whenever the ground is free of ice and snow. Atmospheric concentrations may exceed 200,000 spores/m^3 of air (2), although the levels are typically an order of magnitude lower. Spores are produced by fungal saprobes, pathogens, and symbionts; and they are dispersed into the atmosphere by various methods through the action of both wind and rain. The enormous number of spores that are produced has been well documented for many species (3–5).

Although fungi are everywhere in the environment, the major sources of the airborne spores are considered to be from fungi growing on living plants and those growing on leaf litter (1). *Cladosporium* and *Alternaria*, which frequently colonize both substrates, are typically the two most abundant genera of spores registered during atmospheric sampling. Lacey (6) found that natural and

cultivated grasslands were important spore reservoirs. He showed that spores from *Cladosporium*, *Alternaria*, and *Epicoccum*, which colonize senescent and dead grasses, reached high concentrations in the atmosphere (up to 10^6 spores/m^3) when a wheeled spore trap was drawn over an area of grass. Yeasts and yeast-like fungi are also abundant on leaf surfaces, and are the sources of yeasts in the outdoor air (7). Soil also contains many fungi; soil moisture and wind speed appear to be the critical environmental factors that control their dispersal. Spores will only become airborne when soils are dry and wind speeds high enough to entrain soil particles into the atmosphere (1).

DISPERSAL MECHANISMS

The entrainment of spores into the atmosphere is dependent on the method of discharge by individual types of fungi as well as meteorological factors such as temperature, humidity, and wind speed. Spores are discharged into the air either passively (relying on outside forces) or through active mechanisms (relying on drying or the development of osmotic pressure). Although both wind and rain play an important role in some dispersal mechanisms, wind appears to be the major factor (11). The literature on this topic is extensive. Lacey (8) provided a general review, and McCartney and Fitt (9) recently described the dispersal mechanisms for foliar fungal pathogens.

Passive Mechanisms

Wind dispersal is well studied and is the method resulting in the most abundant fungal spore types occurring in the atmosphere. Many wind-dispersed spores are produced on erect sporangiophores or conidiophores, which position the spores above the substrate and its boundary layer, thereby facilitating dispersal. Others are produced on leaf surfaces, which are well above the ground so that the spores are liberated directly into the turbulent layer of the atmosphere (8).

For many of these wind-dispersed spores, the atmospheric concentration depends upon the ease with which spores are detached from the reproductive structure or hyphae at different wind speeds and levels of turbulence. Minimum wind speeds needed to remove spores range from 0.2 to 2.0 m/second (8,10). Wind gusts facilitate their removal, as does the movement of the leaf itself. Aylor (11) and Pedgley (12) have suggested that strong gusts are able to disperse spores from leaf surfaces even when the average wind speeds are too low to accomplish this. Warm, dry weather promotes wind dispersal for both pathogenic and saprobic fungi, and the entrained propagules are referred to as the *dry air spora*. They include the most abundant fungi in the atmosphere and include conidia of *Cladosporium*, *Alternaria*, *Botrytis*, *Drechslera*, *Epicoccum*, smut teliospores, and rust uredospores. Spores of the *dry air spora* usually peak during the afternoon hours under conditions of low humidity and maximum wind speeds (5). Although there are similarities in the dry air spora worldwide, at any one time the air spora may be dominated by nearby sources of spores (2). During crop harvesting or mowing, remarkable levels of spores (up to 10^9 spores/m^3) are released into the atmosphere with *Alternaria*, *Cladosporium*, and *Epicoccum*, typically the most abundant taxa (2,8,13).

Rain can passively disperse spores by various mechanisms. Members of the dry air spora may be removed by raindrops, as they strike a leaf surface causing vibration and puffing (8). This generally occurs with the initial raindrops, and it may result in increased atmospheric concentrations of *Cladosporium*, *Alternaria*, and other conidia. This may explain some anomalous results of air sampling that show increases of these spores during rain events (14,15). A similar tapping mechanism occurs among puffballs. These fungi are unique among the basidiomycetes as their spores are passively dispersed. They are released in a puff when a raindrop strikes the peridium of the mature fruiting body.

Spores of many fungi are dispersed by rain splash (9,16–18). Splash-borne spores are usually formed in mucilage, which inhibits their dispersal by wind and protects them from desiccation. During rain, the first drops dissolve the mucilage and leave a spore suspension available for splash dispersal by additional raindrops. For example, in *Colletotrichum gloeosporioides* (19), the number of conidia was found to vary from drop to drop. Splash droplets from the first drop released some mucilage and only a few conidia; the largest number of conidia occurred in the fifth drop. The size of the droplet may also affect the number of conidia as the smallest droplets are unable to carry spores. Studies show that most spores are carried by droplets greater than 100 μm in diameter (8,12). In addition to precipitation, which is the most important medium for splash dispersal, overhead irrigation can also disperse fungal spores using the same mechanisms.

Many splash-dispersed spores have thin colorless walls and elongated shapes, such as conidia of *Fusarium* and *Pseudocercosporella*. Many frequently have adhesive properties that enable them to stick to the new host surface. Although these spores lack the protective features of thick, pigmented walls commonly found in members of the dry air spora, they are protected from desiccation by their mucilage during dry periods and by wet conditions during dispersal and deposition (16). For plant pathogenic fungi, splash dispersal is second to wind in importance for pathogen dispersal, but is only of significance for local dispersal (16).

Raindrops are also efficient spore collectors, and even a light rain can cleanse most spores from the atmosphere (20). The surface properties of the spore are important for determining the outcome of this washout. Spores with a wettable surface are incorporated within the raindrop, while those that are nonwettable remain on the surface of the drop. Wettable spores will stay with the drop and settle when the raindrop comes to rest, while the nonwettable spores may be left on leaves or other surfaces as the raindrop rolls over the surface (4).

Active Mechanisms

Spores of many fungi are dispersed by a variety of active discharge mechanisms that propel spores into

the turbulent layer of the atmosphere. The ballistics of some species are quite amazing, and these have been studied by many researchers throughout the twentieth century (3,4,8).

In the majority of ascomycetes, the explosive discharge of ascospores from the ascus is linked to available moisture. The absorption of water within the ascus leads to swelling and the development of high osmotic pressure (21). The resulting pressure causes the ascus to burst, explosively propelling the spores into the turbulent layer of the atmosphere. Characteristic bursting methods (apical slit, hinged lid, apical cap, or minute pore) are related to the taxonomic position of individual species (4). The osmotic force can be assessed by examining the distance the spore is propelled, which ranges from less than 1 mm to 40 cm. Because of moisture requirement, ascospores are usually abundant in the atmosphere during and after rainfall or even during times of high humidity. Diurnal rhythms among the ascomycetes are complicated by this water requirement. Provided the water supply is not limited, ascomycetes with a perithecium (flask-shaped fruiting body) tend to be either diurnal or nocturnal (4).

Many ascomycete fruiting bodies are xerotolerant but only release ascospores under wet conditions (4). During dry periods, the fruiting bodies dry out and become inactive. When wetted again, the fruiting bodies recover quickly releasing spores into the atmosphere soon after rainfall. This explains spectacular increases in spore levels soon after rainfall. The amount of moisture necessary for this recovery is highly variable, and in some ascomycetes such as *Mycosphaerella* moisture from dew is sufficient for spore liberation. In *Venturia inaequalis*, as little as 0.2 mm of rain will lead to the release of abundant ascospores, but dew is not effective. In other fungi more than 1.2 mm of rain are needed (4).

Ascomycetes also show differences in the speed of response following wetting. *Ophiobolus* begins spore release within 15 minutes (4). Release of *Mycosphaerella musicola* ascospores began within 10 minutes after wetting infected leaf tissue, with 85% of the spores being released from the perithecia within 2 hours (24). Similar results were seen in *Mycosphaerella citri* and *V. inaequalis* (25). Ascospore release in *M. citri* began a few minutes after rain and continued for about 1 hour. However, a second rain event 3 hours later released few spores, suggesting a depletion of mature spores after the initial rain. In *V. inaequalis*, ascospore release began 5 minutes after the start of rain and the maximum release was approximately 1 hour later. In addition to spore release directly related to wetting, other ascospores are released only as the fruiting body begins to dry following a rain event (4).

The moisture requirement can be met by several different sources of water. For example, Richardson (22) found that *Didymella* spores were present in the Edinburgh atmosphere following rain as well as during periods of high humidity, but spore release only occurred at night. *Leptosphaeria* is abundant in the atmosphere following rain (4); however, a background level of *Leptosphaeria* was found in the Tulsa, Okla., USA, atmosphere on rainless days as well (23). The average daily concentration of *Leptosphaeria* spores in the Tulsa atmosphere during 1994 and 1995 was 69 spores/m^3. On rainless days the average concentration was 44 spores/m^3 but on rainy days it increased significantly to 109 spores/m^3 ($t_{728} = -7.52, p < 0.01$). These spores were present on 607 days during the 2-year period, but rain only occurred on 271 days. The data suggest that dew is effective in stimulating spore release in some *Leptosphaeria* species. Water stored within the organism can also play a role in spore release. *Daldinia concentrica* fruiting bodies were shown to release ascospores during the night throughout the summer even in the absence of rain. In fact, when a mature fruiting body was detached from its substrate and brought indoors, spore discharge continued for weeks from water stored in the stromal tissues (4). Other species not dependent on direct wetting by rain include *Epichloe typhina* and *Bulgaria inquinans*. The former, a grass pathogen, is apparently able to obtain sufficient moisture for spore release from the transpiration stream of its host, whereas the later is able to obtain sufficient moisture from the mucilaginous layer of the apothecium to sustain spore release for several days (4).

Discharge of basidiospores from most basidiomycetes requires moisture but the mechanism is quite different than that found in the ascomycetes. Money (26) has recently reviewed this topic, which has been of intense interest to mycologists for over 100 years. Basidiospores form externally on basidia, with four basidiospores typically produced by each basidium. Each basidiospore develops asymmetrically and is attached to the sterigma by a hilar appendage. Moisture from the atmosphere condenses around a crystal of mannitol and hexoses excreted at the hilar appendage, and the resulting drop of fluid, called *Buller's drop*, quickly increases in size (26). The moisture in Buller's drop ultimately fuses with a film of water that surrounds the basidiospore and produces a shift in the center of gravity (27). The result of this transfer is that the spore is violently shot from the basidium. This mechanism has been described as a surface tension catapult. Although the discharge only propels spores a fraction of a millimeter, the spores are liberated from the basidial layer and able to fall free under gravity and be swept into the turbulent layer of the atmosphere.

The need for atmospheric moisture confines basidiospore discharge to periods of high humidity. The presence of rain, however, may be a deterrent because liquid water would disperse the solutes from the hilar appendage. Various studies have shown peak basidiospore concentrations during nighttime or early morning hours when humidities are high (14,28–30). Haard and Kramer (28) studied spore discharge in a number of mushrooms and bracket fungi and found three patterns of spore discharge. Many species exhibited a peak during the middle of the night, while others showed a double peak with spore release in the early morning and also in the evening. A third group composed of small mushrooms exhibited continuous spore release with the peak 24 to 48 hours after the onset of discharge.

The active discharge of both ascospores and basidiospores requires increasing atmospheric moisture; however, the active dispersal of some oomycete sporangia occurs during drying conditions. Rapid decreases in relative humidity during the morning hours are thought to be responsible for the hygroscopic twisting of the sporangiophores in species of *Phytophthora* and *Peronospora* (4,8). It is believed that during twisting, the sporangia from these fungi are flung into the air. Recently, it has been suggested that electrostatic repulsion may also be involved, as the leaves and the sporangia become charged and repel each other during rapid drying conditions (31).

TRANSPORT IN THE ATMOSPHERE

When spores are discharged from the parent hyphae or fruiting bodies, they pass through several layers of the atmosphere. An extremely thin film of still air exists at the surface of the ground and on the surface of objects; air in this zone is held to the surface by molecular forces. The laminar boundary layer occurs above this zone. Here, airflow is typically parallel to the surface. The laminar boundary layer is usually thin, 1 mm, but the thickness will vary with wind speed and topography (5). During the night when air is very still the thickness of the laminar layer increases exponentially; however, during high wind speeds the thickness of the layer decreases to less than 1 mm. Above the laminar layer is the turbulent layer in which air movement is constantly shifting and unpredictable. The turbulence depends on wind speed and direction, temperature, and the roughness of the terrain. Bioaerosols are carried in the turbulent layer and the dispersion is related to the intensity of the turbulence (5,32).

Plant pathogen spores within a crop must first pass from the laminar layer on the leaf surface into the turbulent layer within the crop. Wind gusts and turbulence enhance spore removal, but before spores reach the open air above the crop they must also pass through the boundary layer surrounding the crop (11). Under normal turbulence as much as 90% of the spores are deposited within 100 m with greater escape occurring under more turbulent winds (8). The location of lesions within the canopy will also affect escape of the spores. Spores produced high in the canopy will have greater chance of atmospheric entrainment as they are exposed to high winds and greater turbulence than spores lower in the canopy. Consequently, disease will spread more rapidly through the field if infection occurs in the upper canopy than if the pathogen is confined to the bottom or middle of the canopy (11).

Spores are transported vertically and horizontally by wind. Spores can be carried upward by thermals and have been recovered from various altitudes up to 5,000 m (5). Pady and coworkers (33) reported the recovery of rusts, smuts, *Alternaria*, *Helminthosporium*-type, and many unidentified spores on slides exposed during flights over Canada at 1,200 to 1,500 m. Gregory (5) reviewed the numerous studies from the 1920s through the 1960s that recovered a variety of fungal spores, especially plant pathogens, from various altitudes. Horizontally, bioaerosols can be carried downwind for thousands of kilometers. One of the best-studied examples of long-distance transport is the movement of *Puccinia graminis* uredospores from southern United States and Mexico to the wheat belt in the northern United States and Canada. This and other instances of long-distance dispersal of rust spores have been reviewed by Nagarajan and Singh (34) and Pedgley (12).

During airborne transport, fungal spores are vulnerable to various types of environmental damage. Exposure to harmful UV radiation and extremes of temperature and humidity can decrease viability of pathogenic species. Damage may be greater for species with thin-walled, colorless spores that are easily plasmolyzed and lack the protection provided by melanin found in pigmented spores (32). Despite the environmental hazards, a small percentage of spores are able to survive long-range transport and cause infection (34). Although pathogenic spores may lose viability during transport, it should be emphasized that spores probably retain their allergenic properties even when no longer viable.

DEPOSITION

Spores can be deposited by sedimentation, impaction, boundary-layer exchange, turbulent deposition, electrostatic deposition, and through rainfall (34). In still air, spores would fall to the ground in response to gravity at a rate (based on Stokes' law) that is proportional to the square of the spore radius (5). However, in the natural environment air is seldom calm, and the effect of sedimentation is insignificant at wind speeds at or above 2 m/second. Under normal atmospheric wind speeds, impaction and turbulent deposition are the most important mechanisms for deposition. Impaction occurs when air currents approach a leaf or twig or other objects and are deflected around it. Spores carried in the air diverge from the deflected air stream by amounts depending on the size of the spore and the size of the object. Impaction is most efficient when large spores impact on small objects at high wind speeds (8). Very small spores, at or below 5 μm, would require wind speeds of 25 m/second for impaction to occur. Impaction may be one of the most important methods for spore deposition in crops. Turbulent deposition occurs when air blowing over a horizontal surface deposits spores at a greater rate than would occur by gravity. Turbulent deposition increases at higher wind speeds, although some bounce may occur as well (5,8).

TYPES OF FUNGAL SPORES IN THE AIR SPORA

Many fungi are cosmopolitan; as a result, there are similarities in the air spora worldwide. From agricultural to urban areas, and from arctic to tropical areas, it is possible to find many of the same types of spores in the atmosphere whenever the ground is free of ice or snow. Although some spore types are common throughout the year, other taxa may peak in the spring, summer, or fall. In addition to seasonal variation, most fungi show a diurnal rhythm with peaks occurring at specific times of the day.

Examination of air samples from most areas of the world will show that many of the spore types are ones that potentially have an impact on humanity as allergens, potential human pathogens, and devastating crop pathogens. Approximately 20% of the human population suffer from respiratory allergies and many of these individuals are hypersensitive to fungal spores. While exposure to airborne fungal spores is typically associated with asthma and allergic rhinitis (hay fever), spores are also known to cause hypersensitivity pneumonitis (2). Allergens have been reported from every major group of fungi, but the most widely studied allergens are the asexual spores that are components of the dry air spora (35,36). In 1952, Gregory and Hirst (37) suggested airborne basidiospores as possible allergens, and in the past two decades, clinical evidence has been collected on the occurrence of basidiospore-induced allergies (36,38). Far less is known about the allergenicity of ascospores although anecdotal evidence has suggested these are also important triggers of allergic disease (39).

Although the focus of this entry is outdoor bioaerosols, especially related to agricultural applications, concentrations of fungal spores in farm buildings are also of interest as they may impact respiratory diseases in farm workers and their families as well as storage disease in crop plants. Wherever crops or hay are stored, airborne concentrations of storage fungi are high, with levels up to 10^{10} spores/m^3 recorded (2,40). *Penicillium* and *Aspergillus* are frequently the dominant fungi found; however, the taxa depend on the actual storage conditions. Pasenen and coworkers (41) studied the airborne spore load in urban and rural areas in Finland. They found that cow barns had levels up to 10^9 spores/m^3, with the highest levels associated with areas where hay was handled. Airborne concentrations up to 10^5 spores/m^3 were found in farmhouses; these levels were 10 to 1,000 times higher than levels measured in urban dwellings. Pasenen and coworkers (41) suggested that many of the fungal spores were introduced into the farmhouses on the person or clothing of the residents.

Many fungal spores are allergenic, but only a small group of fungi are considered human pathogens (42). The majority of mycoses (human fungal infections) are infections of the skin or mucous membranes, such as athlete's foot and thrush, with only a few fungi considered systemic human pathogens. However, many common airborne fungi can also cause serious human infections in immunocompromised-compromised individuals. Species of *Aspergillus* and *Fusarium* are two of the more common types of fungi in this category (36). These infections are of special concern because fungi do not respond to conventional antibiotic treatment, and mortality rates are high.

The majority of plant diseases are caused by fungi with approximately 10,000 fungal species recognized as plant pathogens. Although many important plant diseases are caused by soil fungi, these seldom cause sudden, widespread epidemics (43). By contrast, fungal pathogens with an airborne dispersal phase can quickly spread from the initial infection focus and cause widespread epidemics. The remainder of this section will examine the most prominent components of the air spora, especially focusing on those implicated in plant diseases.

Dry Air Spora

In dry weather the atmosphere in temperate areas is dominated by spores of fungal saprophytes and pathogens, which are passively dispersed by the wind. *Cladosporium*, *Alternaria*, *Epicoccum*, *Drechslera*, *Bipolaris*, *Pithomyces*, *Curvularia*, smut teliospores, and rust uredospores are among taxa typically found in the dry air spora (Fig. 1).

Cladosporium. *Cladosporium* is a large genus of anamorphic fungi with a wide variation in spore size and shape (44,45). Several species of *Cladosporium* are anamorphs of *Mycosphaerella* or *Venturia* spp. Spores are typically ellipsoidal to cylindrical and slightly pigmented (Fig. 2). Spores may be unicellular or have one or two septa. The size range of spores in the genus is seen in common species. Spores of *C. sphaerospermum* and *C. cladosporoides* range from 3–4.5 μm in diameter for the former to $3–7 \times 2–4$μm, for the latter; while those of *C. macrocarpum* average $15–25 \times 7–10$ μm.

Conidia of *Cladosporium* species are generally the most abundant airborne spore type in temperate areas of the

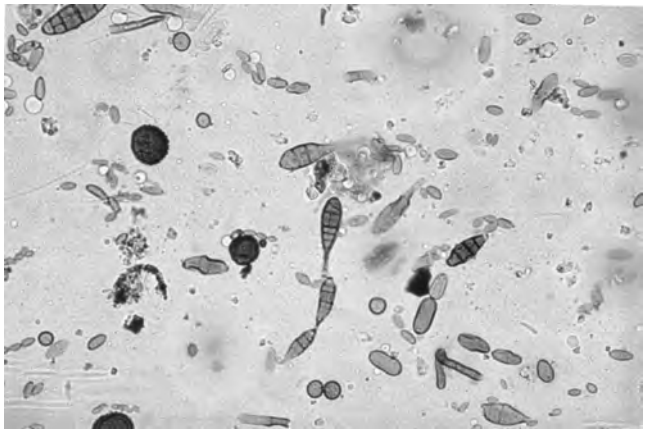

Figure 1. Components of the dry air spora from Tulsa, Okla., air sample.

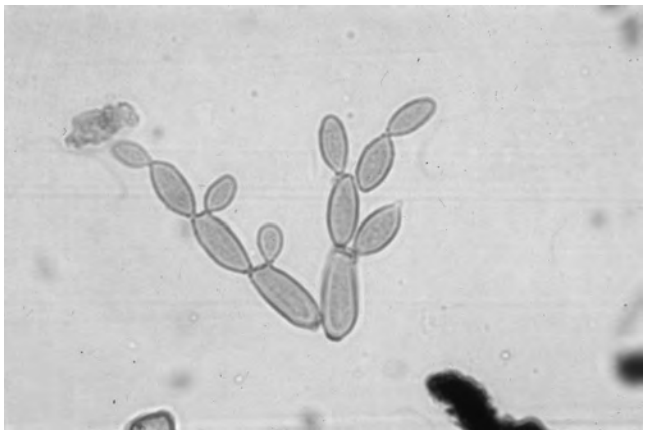

Figure 2. *Cladosporium cladosporoides* conidia from air sample.

world. *Cladosporium* species are common saprobes on leaf surfaces, dead herbaceous and woody plants, soil, foods, fabrics, and paint (44). Several species are plant pathogens causing various diseases such as leaf spots, scabs, and fruit rots. In addition, spores of *Cladosporium* are well known to be important aeroallergens (35). Aerobiological surveys including those conducted by the Aeroallergen Network of the American Academy of Allergy, Asthma, and Immunology (AAAAI) (46) routinely report the presence of *Cladosporium* conidia in the atmosphere. This network consists of a group of 84 certified air sampling and reporting stations, primarily in the United States. In the 1999 network report, airborne fungal spore concentrations were reported from 35 of the network sampling stations. *Cladosporium* spores were the most abundant airborne spore type reported at 23 stations and among the top six at all 35 stations.

In many areas, airborne *Cladosporium* spores can be detected year-round with the highest levels occurring from late spring though early fall. Summer peaks have been found in England (47), Sweden (48), and Colorado (49). However, Halwagy (50) showed year-round occurrence of *Cladosporium* in the atmosphere of Kuwait with highest levels found in the spring and secondary peaks occurring in the fall. Similar results were shown by Cosentino and coworkers (51) in Italy. These differences may result from moisture and other climatic growth factors. In the Tulsa, Oklahoma area, *Cladosporium* spores are also present in the atmosphere year-round with the highest concentrations typically occurring in the late summer or fall (46). At times, hourly concentrations of *Cladosporium* have exceeded 100,000 spores/m^3. Atmospheric concentrations of *Cladosporium* spores typically peak around noon (14).

Although generally considered a member of the dry air spora (8,47,49), various researchers have also described dispersal by mist droplets in this genus. Experimental studies with both mist-laden and dry air showed that mist was no more efficient in dispersing spores than the dry air for *Cladosporium herbarum* (4). In addition, studies have shown transient increases in the concentration after the start of rainfall (14,15). It has been suggested that an electrostatic release or the vibration and puffing from the first raindrops may be responsible for this increase (8). Others have suggested that washout is responsible for this increase in concentration (49). Wind gusts associated with the frontal system may also play a role in this increase; however, different species of *Cladosporium* may respond differently to precipitation.

Alternaria. *Alternaria* spores are frequently the second most abundant component of the dry air spora. *Alternaria* species are anamorphs of ascomycetes including members of the genus *Pleospora*. The genus is characterized by distinctive large multicellular dictyospores, which are beaked and produced in chains (Fig. 3). *Alternaria* spores are commonly found in atmospheric concentrations of several hundred to several thousand spores/m^3. In some areas, these spores may be present throughout the year; however, peak concentrations usually occur in late summer or fall (46).

Figure 3. *Alternaria* sp. conidia from air sample.

Alternaria conidia are passively released from infected leaves or other substrates by moderate to strong gusty winds with minimum velocities of 2 to 3 m/second required. Dispersal typically occurs during midday when conditions are warm and dry with high wind speeds. Rotem (52) reported that the greatest dispersal occurs during dry weather, which immediately follows periods of rain or heavy dew. Dry windy periods can eventually deplete spore reserves on the leaves and inhibit sporulation, which requires moister conditions. Spores can also be dispersed into the atmosphere when washed or splashed from leaf surfaces by raindrops or irrigation. Timmer and coworkers (53) showed large numbers of conidia were released by simulated rainfall in an environmental chamber, but they found no correlation between spore concentration and rain during field studies. By contrast, high humidity inhibits the release of spores from wet leaves and airborne spores are washed from the atmosphere by rain and irrigation (52).

Species of *Alternaria* are pathogenic to a number of crop plants, causing early blight, black spots, brown spots, seedling blight, black rots, or leaf spot diseases. They also occur as saprobes on a large variety of organic substrates including leaf surfaces, stored foods, soil, and textiles (44). Most pathogenic species have a cosmopolitan distribution including *A. solani* on potato and tomato, *A. brassicae* on members of the Brassicaceae, *A. porri* on onions, and *A. alternata* on a variety of host species (52). *Alternaria* pathogens are often secondary invaders attacking plants under stress, especially those stressed by drought, insect infestation, senescence, or even other fungi.

Crop losses caused by *Alternaria* pathogens tend to be less than losses owing to more serious pathogens such as rusts or downy mildews; however, this genus is prominent in the aerobiological literature because it is also recognized as an important airborne allergen. Although there is no nationwide network of plant pathologists conducting air sampling for the detection of fungal pathogens, data from the Aeroallergen Network show that *Alternaria* conidia were among the top 10 spore types (in terms of atmospheric concentrations) reported from all 35 stations in 1999. At 19 stations *Alternaria* spores were among the top five spore types identified from the atmosphere (46). While some of

the *Alternaria* conidia may be from saprobic species, these spores are a significant component of the air spora and represent a ubiquitous threat to many crops.

Helminthosporium/Drechslera-Type Spores. Several genera of anamorphic fungi form similar thick-walled, pigmented, cylindrical conidia with rounded ends and a distinctive attachment scar at the base. The conidia are pseudoseptate but vary in shape with some being long (up to 160 μm) and tapering, while others are relatively short (44) (Fig. 4). For many years, fungi with this type of spore were classified as species of *Helminthosporium*; however, in the past 20 years the taxonomy in this group has undergone revision and several genera are now recognized (54). The best known genera in this group are now *Helminthosporium*, *Drechslera*, *Bipolaris*, and *Exserohilum*. Teleomorphs are species of *Cochliobolus* (for *Bipolaris*), *Pyrenophora* (for *Drechslera*), and *Setosphaeria* (for *Exserohilum*). The genus *Helminthosporium* is generally reserved for saprobic members of this group, and no teleomorph is recognized. Other genera are delimited by the shape of the conidium, morphology of the attachment scar, and the number and location of germ tubes produced by the conidium. It should be noted that the separation into these genera is generally acknowledged by mycologists and plant pathologists, but it is not universally accepted. Some books and journals still use the *Helminthosporium* binomials and others use *Drechslera* for all taxa (54).

This group of fungi is known to cause leaf spots and blights and other diseases on wild and cultivated members of the Poaceae; they are especially important pathogens on cereal crops (54). Some fungi in this group are able to cause sudden, devastating diseases that have resulted in major famines and great economic loss (55). Although many other host plants are infected by these fungi, the major losses have been to cereals. In addition to their role as plant pathogens, members of this group are allergenic and are the leading cause of fungal sinusitis. In addition, they are capable of causing fungal infections in livestock and are also toxigenic (42,54).

The great Bengal famine of 1943 was owing to the destruction of rice plants by brown spot of rice, which is caused by *Cochliobolus miyabeanus* (*Bipolaris*). During the famines that resulted from this plant disease, two million people died of starvation. Southern corn leaf blight caused by *Cochliobolus heterostrophus* (*Bipolaris maydis*) is another species in this group capable of causing devastating crop loss. The fungus causes small lesions on the leaf that may be so abundant they almost cover the entire leaf surface (55). An epidemic of one race of this species quickly destroyed approximately 15% of the U.S. corn crop in 1970. The fungus attacked all corn hybrids with the Texas male sterility gene and the resulting crop loss was estimated at $1 billion.

Tan-spot caused by *Pyrenophora tritici-repentis* (*Drechslera*) is a serious disease of wheat throughout the Great Plains and is considered the most economically important wheat disease in North Dakota (56). Epidemics are initiated by both ascospores and conidia that are found on overwintered crop debris. The conidia form the repeating stage, which can rapidly spread the disease when environmental conditions are suitable. Francl (56) showed that the greatest numbers of conidia were produced after rains as the wheat neared maturity. Conidia develop in the dark, but peak dispersal occurs in the afternoon after leaf surfaces have dried.

Conidia from these fungi are common in the atmosphere. They are reported among the top 10 spore types at 12 stations from the Aeroallergen Network in 1999 (46). Moderate winds disperse the conidia that can travel through microscale or mesoscale transport (9,56).

Curvularia is a closely related genus with a *Cochliobolus* teleomorph. Conidia have three or more transverse septa and are typically curved owing to an enlarged central cell (Fig. 5). Like the other genera in this group, *Curvularia* is responsible for a number of leaf spot diseases and is a common component of the dry air spora.

Smuts. Smut fungi are plant pathogenic basidiomycetes in the order Ustilaginales. There are approximately 1,200 species of smut fungi classified in 50 genera; however, the majority of species are classified into two large genera, *Tilletia* and *Ustilago* (57). About 4,000 species of host plants are attacked by smut fungi including both crops and native plants. They are especially serious pathogens on cereal crops.

Figure 4. *Drechslera*/*Bipolaris* type spore from air sample.

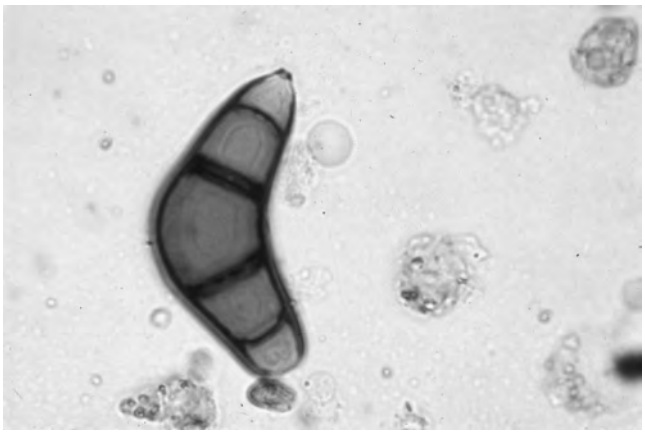

Figure 5. *Curvularia* sp. spore from air sample.

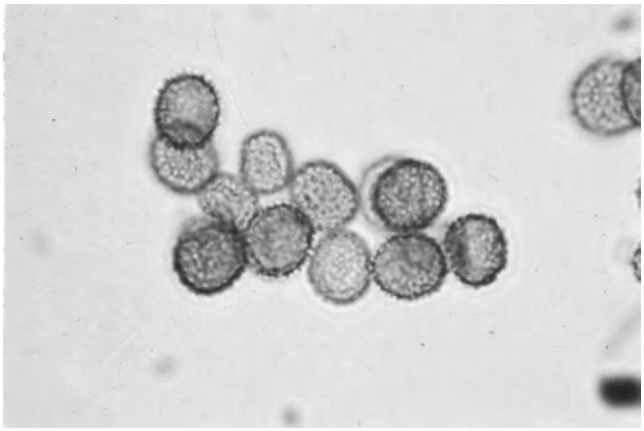

Figure 6. *Ustilago maydis* teliospores from infected corn.

The major dispersal phase of smut fungi is the asexual stage, which produces teliospores (55). Extraordinary numbers of teliospores develop and are passively dispersed by wind (Fig. 6). Smut fungi have no repeating stage; host plants produces only one generation of teliospores per growing season (55). Spores of various smut species are produced during different seasons. Hamilton (47) found that airborne spores of *Tilletia* showed highest levels in late August and early September in England, while *Ustilago* spores peaked from mid-June and late July. She also showed that the atmospheric concentrations of these genera depended on several meteorological variables. Levels decreased during rain or high humidity and increased during periods of abundant sunshine, strong winds, and high barometric pressure, typical condition for release of dry air spora (47). Smut spores typically show a mid-day peak but here the rhythm seems entirely owing to environmental conditions. Teliospores of an infected plant tend to mature all at one time; however, their release is spread over a long period and appears to be closely correlated with wind velocity, which is often higher around noon (4).

Various other studies have also reported the presence of smut spores in the atmosphere. Halwagy (50) showed that *Ustilago* spores were the second most common spore type identified in the Kuwait atmosphere. Misra (58) noted that smut spores peaked in India during dry conditions in December and January, while Rubulis (59) reported peaks during the late spring and fall in Sweden. In both of these studies, smuts were basically considered as one spore category with no attempt to differentiate the species involved. Likewise, the data from the Aeroallergen Network from the AAAAI also report smut spores as a single category. In their 1999 report (46), smut spores were among the top 10 spore types, in terms of atmospheric concentration, reported from 32 out of 35 sampling stations that provided counts for fungal spores.

Crotzer and Levetin (60) examined the atmospheric levels of smut spores in Tulsa, Okla., during 1991 and 1992 and attempted to identify the most abundant smut spores. The authors found that smut spores were present in the atmosphere every day from May through October in both 1991 and 1992. The average daily concentration generally ranged from 100 and 1,000 teliospores/m^3 during both seasons with, the mean daily concentrations at 291 spores/m^3 and 356 spores/m^3 for 1991 and 1992, respectively. Peak concentrations were 1,874 spores/m^3 on July 5, 1991 and 5,906 spores/m^3 occurring on May 12, 1992. Daily concentrations during the study period experienced many fluctuations owing to variable climatic conditions as well as the phenologies of both the host species and pathogens (60). This last factor was especially important because it resulted in different species of smuts occurring at different times of the year. In May and June, teliospores found in the atmosphere included those belonging to species, which infect Bermuda grass (*Ustilago cynodontis*), Johnson grass (*Sphacelotheca occidentalis*), oat (*U. kolleri*), and wheat (*U. tritici*). Smut spores identified during September and October included *U. maydis*, which infects corn, and *U. brumivora* and *U. bullata* pathogenic to several native Oklahoma grasses (60). Although this study was limited to the period of May to October for both years, other data from Tulsa show that atmospheric smut spores are not limited to this 6-month period (46).

In addition to the significance of smut fungi as plant pathogens, smut spores serve as important aeroallergens as they are abundant in the atmosphere for extended periods of time (35,61). However, the full extent of allergenicity to smut spores and the clinical significance of various smut species is not known (60). Data from the Aeroallergen Network showed that smut spores represent a significant component of the air spora and are, therefore, a significant source of aeroallergens as well as a significant source of plant pathogen inoculum (46).

Rusts. Members of the basidiomycete order Urediniales are commonly called *rust fungi*. About 6,000 species of rust fungi have been identified; these fungi attack a wide range of seed plants and can cause destructive plant diseases. Many rust fungi have complex life cycles with several spore stages. Probably the most important spore state is the uredial stage, which typically causes reddish (or rust-colored) lesions on plants and is the source of the common name for these pathogens. Spores produced in these lesions are known as *uredospores* (also called *urediospores* and *urediniospores*). Thousands of years before scientists knew that fungi could cause plant disease, rust epidemics were recognized and the reddish lesions noted on plants. The epidemics were described in the writings of Aristotle and Theophrastus who also realized that different plants varied in the susceptibility to these diseases. The rust fungi are responsible for some of the most important diseases of cereal crops, and it is estimated that 10% of the world grain crop is lost to rust fungi each year (55). In addition to the cereals, rust fungi have caused devastation to coffee, apple, pine trees, and other crops.

Because of the economic importance of these fungi, the long-distance transport of rust spores, especially wheat rust, has been studied more extensively than that of any other fungal pathogen (34). Worldwide, rust fungi are the most important and damaging diseases of wheat, with stem rust (*P. graminis* f.sp. *tritici*) and leaf rust (*P. recondita* f.sp. *tritici*) the most prevalent types. In North

America, leaf rust is currently the more important species, but historically major epidemics of stem rust have been more damaging. In recent decades, the widespread use of resistant wheat varieties has prevented major epidemics of stem rust. Nevertheless, approximately one million metric tons of wheat are lost to stem rust in North America each year, and in other wheat growing areas the losses are far greater (55).

Puccinia graminis f.sp. *tritici*, the fungus responsible for stem rust of wheat has a complex life cycle that involves five spore stages on two separate host plants, wheat and barberry (55,62). This fungus typically overwinters as teliospores that give rise to basidiospores in the spring. Basidiospores are capable of infecting young barberry leaves and giving rise to spermatia and receptive hyphae and later to aeciospores, also on barberry. Aeciospores become airborne and can transfer the infection to wheat on which the spores germinate, and hyphae enter the plant through stomata. Once established in wheat, the fungus produces uredia within 2 weeks; these appear on the stem as long narrow pustules, which produce dark red powdery masses of uredospores. Large numbers of spores are produced during the uredial stage (Fig. 7). It is estimated that a mature uredium is capable of producing about 10,000 uredospores per day over a period of several weeks and an even mildly infected plant with 50 uredia would produce 500,000 spores/day (63). Uredospores become readily airborne and infect new wheat plants, thereby forming the repeating stage of this fungus. Near the end of the growing season, the uredia turn black as two-celled overwintering teliospores replace the uredospores (55,62). Wheat plants infected by *P. graminis* are severely weakened, but not destroyed, and the grain yield is significantly reduced (55).

Efforts to eradicate barberry plants from wheat growing areas have reduced the risk of infection from stem rust of wheat. Also, the alternate host for leaf rust, meadow rue apparently does not occur in North America. However, for both pathogens the alternate host is less important than uredospores as a source of inoculum. Uredospores are easily carried by wind from one plant to another giving rise to rust epidemics. In fact, uredospores can be transported by prevailing winds for hundreds or thousands of kilometers (10,34). In southern Texas and Mexico where the climate is mild, the uredial stage can continue all winter and give rise to spring infections in northern states when the uredospores are carried by prevailing southerly winds. Uredospores can also be transferred back to southern areas in late summer and fall. Initially demonstrated in 1923 by Stakman, the movement of rust uredospores along the "*Puccinia* Pathway" in North America is one of the best known examples of long-distance dispersal (64). In addition to *P. graminis* and *P. recondita*, other fungal pathogens and the insect vectors of viral diseases are all linked to dispersal along this pathway (34). In a review, Nagarajan and Singh (34) also described the long-distance transport of *Puccinia* uredospores in other parts of the world including parts of Europe, India, and Australia. They also provided evidence for the transoceanic transport of uredospores between Australia and regions in southern Africa.

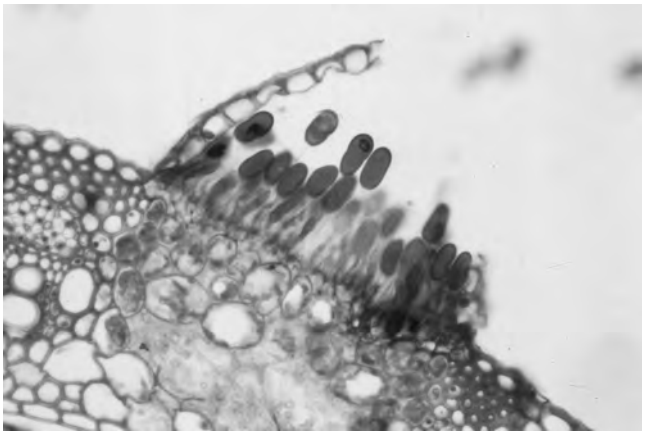

Figure 7. *Puccinia graminis* uredium with uredospores on infected wheat.

In addition to suitable wind patterns, successful long-distance dispersal of rust spores is also contingent on source strength and viability. Nagarajan and Singh (34) estimated that a field of wheat moderately infected with stem rust would produce 4×10^{12} uredospores/day/hectare (34). They suggested that uredospores must reach a suitable host within 5 days after discharge to remain infectious. However, Eversmeyer and Kramer (65,66) examined the survival of *P. graminis* and *P. recondita* uredospores under a variety of temperature conditions in the field and in environmental chambers. In field experiments, they found that during freezing or subfreezing temperatures spore viability quickly declined; but during the warmer temperatures in spring, 10 to 20% of the spores remained viable after 5 days. In addition, 1% of the spores remained viable for 19 days. In their chamber studies, spores exposed to constant temperatures between 10 and 30 °C remained viable for up to 36 days (66). While environmental conditions during transport may be severe, these studies suggest that at least a small percent of the enormous number of spores may survive long enough to reach a suitable host.

Other Members of the Dry Air Spora. Other fungal spores are also commonly found in the dry air spora. These include conidia of *Epicoccum*, *Pithomyces*, *Nigrospora*, *Botrytis*, *Torula*, *Stemphylium*, *Oidium*, *Aspergillus*, *Penicillium*, and many others. Although many of these genera are widespread saprobes, others are well known plant pathogens. The genus *Oidium* represents the anamorphic state of the powdery mildews, which are important pathogens on many crops, especially the cereals (55). *Botrytis* diseases are possibly the most common diseases of vegetable crops, responsible for gray mold and rots of fruits and vegetables in the field as well as in storage (55). *Epicoccum* is a cosmopolitan genus of asexual fungi that occurs as saprobes on a wide variety of substrates, but it is also a secondary invader on many types of plants and is frequently found on leaf spots (44).

Moist Air Spora

In damp or wet weather, the atmosphere is typically dominated by ascospores and basidiospores. As described

earlier, both spore types are actively released from the fruiting body through mechanisms that require moisture. *Leptosphaeria* ascospores are often abundant along with *Venturia*, *Didymella*, and spores from members of the family Diatrypaceae (39,67). Many ascospores found in the air spora are produced by important agricultural pathogens. Basidiospores that are typical components of the atmosphere include those from saprobic species of mushrooms, bracket fungi, and puffballs (38) although spores from a number of tree pathogens can also occur in the atmosphere (30). In addition to ascospores and basidiospores, asexual conidia of *Fusarium*, *Cercospora*, and *Colletotrichum* are also abundant in moist weather. This section will briefly consider two representatives of the moist air spora. For a fuller review of this topic, see Fitt and coworkers (16) and Huber and coworkers (17).

Apple Scab. The ascomycete, *V. inaequalis* Scab is responsible for apple scab, the most important disease of apples with all commercial varieties susceptible to infection (55). This pathogen occurs worldwide wherever apple trees are cultivated; similar scab diseases also affect pear and hawthorn. The principal symptoms are the development of scab lesions on both leaves and fruit; however, the disease can also cause premature defoliation, premature fruit drop, and poor bud development for the following year (55). Control of apple scab requires repeated applications of fungicides (8 to 20 times per season) to protect the crop. Without fungicidal protection, 70 to 100% of the crop would be unsalable.

In the spring, the primary inoculum consists of ascospores that develop in overwintered fruiting bodies. Immature fruiting bodies are found in dead leaves that overwinter on the ground in the orchard. They mature in the spring, and ascospores are actively discharged from these ascocarps during rain (16) (Fig. 8). *Venturia* ascospores are a major component of the air spora in orchards during the spring and are carried by wind to young leaves in which they cause a primary infection (68–70). Ponti and Cavanni (70) showed that the ascospores could typically be found in the air of Italian apple orchards during periods of rainfall from mid-March to mid-June. In the northeastern United States, ascospores were found in orchards from mid-April to early-June (71). Once the primary infection is established, conidia of the anamorphic stage (*Spilocaea pomi*) begin developing leading to further disease spread. The more primary inoculum present, the more rapidly the disease will build up and the more serious the epidemic will ultimately become. Several studies have recently focused on modeling the aerial dispersal of *Venturia* ascospores to help evaluate the risk of infection and optimize the application of fungicides to the periods when it is absolutely necessary (43,68,70,72).

Fusarium. *Fusarium* species are well known soil fungi with several species responsible for a variety of plant diseases. Vascular wilts and other diseases caused by *Fusarium oxysporum* have been recognized for over 100 years. Many subspecies of *F. oxysporum* attack a wide variety of crop plants. Although typically considered a soilborne pathogen, there is considerable evidence of airborne dispersal of conidia in many races and subspecies. Katan and coworkers (73) described the airborne collection of viable *F. oxysporum* f.sp. *lycopersici* conidia in greenhouses from diseased tomato plants. They also obtained similar results with a variety of other subspecies on other vegetables. Splash dispersal of *Fusarium* macroconidia has been generally accepted as the major vehicle of disease spread (8,74) (Fig. 9).

Fusarium head blight (FHB) of wheat and other small grains is caused by *Fusarium graminearum*. FHB, also known as *scab*, is increasing throughout the world and during the past decade there were several epidemics on wheat in the United States and Canada (74). *Fusarium graminearum* regularly forms its sexual stage, *Gibberella zeae*, in nature, and both conidia and ascospores are involved in disease spread. Ascospores are formed in perithecia and are forcibly shot into the air, while macroconidia are formed on sporodochia and are splash dispersed. Both stages occur on over-wintered crop debris and both require rainfall for dispersal. Spores infect the anthers on wheat inflorescences and the fungus spreads in the developing grains. Symptoms are evident in two to three weeks and include the premature senescence of spikelets (74). The fungus survives on the wheat residue

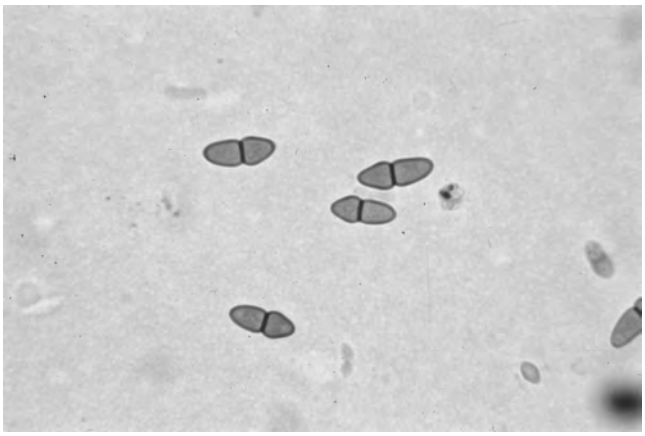

Figure 8. *Venturia* sp. ascospores from air sample.

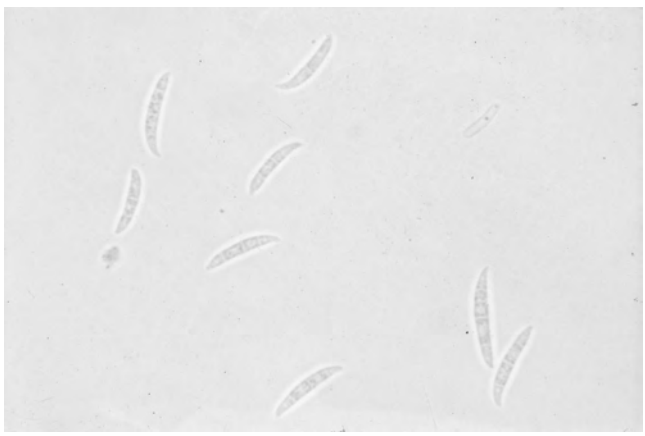

Figure 9. *Fusarium* sp. macroconidia from culture.

and gives rise to new infections the following spring. *Fusarium graminearum* also can exist as a saprobe on other residue especially corn stalks. The increased cultivation of corn in wheat growing areas and reduced tillage agricultural systems are both possible reasons for the recent epidemics.

Other Pathogens

The spore types described earlier are common components of the air spora and are often present in the atmosphere year-round. However, spores of other plant pathogens are not normally seen in the air spora unless the disease is epidemic in the area. Two diseases of this type are late blight of potato and tobacco blue mold.

Late Blight of Potato. *Phytophthora infestans* is the pathogen responsible for late blight of potato (and also tomato). This oomycete occurs wherever these crops are grown, and all cultivars are susceptible. Late blight of potato has been the most important disease of potato since the 1840s, when it caused the destruction of the potato crop in Ireland and the resulting widespread famine. *Phytophthora infestans* can invade all parts of the plant resulting in the rapid death of infected parts. Productivity of the potato plants is quickly reduced and tuber destruction frequently occurs as well. Sporangia are produced on aerial hyphae, which grow out of the stomata and are dispersed by wind, possibly carried for tens of kilometers (75). At low temperatures (10 to 15 °C) and high humidity, sporangia germinate by producing numerous zoospores, while at higher temperatures each sporangium gives rise to a single germ tube that develops into hyphae. As a result, during cool, wet periods, the production of zoospores leads to an amazingly rapid spread of the disease. Without fungicidal protection, a blighted field can be destroyed within a couple of days. Similar disease progression also occurs in infected tomato fields (70). Forecasting models have been used for over 40 years to help optimize the timing of fungicide application to periods when weather conditions promote the disease spread (76).

Generally, *Phytophthora infestans* overwinters as mycelium in infected tubers. In countries where both mating types have been identified, it can also overwinter as oospores in the soil. In the 1840s, when the disease first appeared in Europe and the United States, only one mating type (A_1) of the fungus was present. The second mating type (A_2) was identified in 1950 in central Mexico and was confined to Mexico until 1980 when outbreaks began occurring in Europe. It has been suggested that the A_2 mating type was introduced in a shipment of potatoes from Mexico to Europe in the late 1970s. In the past 20 years, the A_2 type has spread throughout the world (77,78). This has raised anxieties about the possibility of sexual reproduction occurring in the field leading to new strains developing at a faster rate. The implications for potato breeders searching for blight resistance are obvious. These concerns have been strengthened by the recent outbreaks of late blight in the United States and Canada. The strains of *P. infestans* involved were nearly all resistant to metalaxyl, the most widely used fungicide to control late blight (77,78).

Long-distance dispersal of *P. infestans* has been well documented by two different modes of transport (75). Intercontinental migration has been associated with the transport of infected plants or tubers by humans. This occurred in the 1840s and again before the 1980 outbreak of the A_2 mating type. Dispersal over tens of kilometers is attributed to airborne sporangia, which are able to survive for hours at the reduced humidity encountered during transport (75). The rapid progress of blight epidemics in the 1840s and in the 1990s illustrates the effectiveness of airborne dispersal.

Blue Mold. *Peronospora tabacina* (syn *P. hyoscyami* f.sp. *tabacina*) is an oomycete that is responsible for tobacco blue mold. This disease was first described in Australia during the nineteenth century, and the fungus was identified by Baily in 1890 (79). The first serious epidemic in North America occurred in 1979. Prior to this time the disease was confined to seedbeds. In 1979 and again in 1980, the infection rates were especially severe, with the epidemic advancing northward at rates of 10 to 32 km/day in the eastern United States to southern Canada and with crop losses estimated at $350 million.

Blue mold is able to attack both wild and cultivated species of tobacco. Host plants and pathogen exist year-round in tropical areas such as the Mediterranean and Caribbean basins. However, in temperate regions, tobacco is grown as an annual. Also, *P. tabacina* is not able to overwinter in temperate zones. As a result, reappearance of the pathogen is owing to either contaminated seedlings or the long-distance transport of inocula from tropical regions.

The asexual propagules of *P. tabacina* are the sporangia. Infection can begin within four hours after a sporangium lands on the leaf surface. A symptom-free incubation period, typically five to seven days, ends with the appearance of yellow lesions and the development of new sporangia. Unlike many other oomycetes, no zoospores are produced by *Peronospora* and the sporangia themselves (often referred to as *sporangiospores* or *conidia*) are the only asexual stage. As described earlier, sporangia are released from the sporangiophore by the twisting movements of the sporangiophore that occurs during the drying of the leaf in the morning as humidity decreases and temperature increases (11,80). Because the sporangia are subject to desiccation during transport, cool, wet, overcast weather, favors the rapid advance of the fungus, while clear, hot, dry weather halts disease spread (80).

Each spring in the eastern United States, weather conditions are favorable for the northward transport of *Peronospora* sporangia with two possible pathways of disease spread (80). Along one pathway, the pathogen can spread northward from Cuba into Florida and Georgia. In the other pathway, the source of inoculum is on wild *Nicotiana repanda* south central Texas or from cultivated tobacco in Mexico. From here the disease spreads to Kentucky and then east to North Carolina. These pathways show that long-distant transport of

sporangia can lead to blue mold outbreaks, and suggest that forecasting systems can potentially provide time for tobacco farmers to apply fungicides. This is the aim of the North American Plant Disease Forecast Center from the Department of Plant Pathology at North Carolina State University (81). Since 1995, this center has used the HYSPLIT trajectory model to predict outbreaks of blue mold in North America. Documented sources of blue mold are used in the model along with meteorological data from NOAA's ETA or AVN Models. This modeling system predicts the short-term weather and plots the trajectories of inoculum-laden parcels of air. The daily forecast produced with HYSPLIT trajectories describes weather conditions at the source and along the anticipated pathway with emphasis given to those atmospheric conditions that favor sporulation at the source, survival during transport, and deposition. An overall outlook describes the likelihood of blue mold spread over the subsequent 48 hours. The forecasters anticipate that the use of this model will continue to provide valuable information in the efforts to control blue mold epidemics (81). A recently developed numerical model encompasses the release, transport, and deposition of blue mold sporangia (82). Since 1996, the daily blue mold forecasts have been available on the Internet during the growing season (81) to provide on-line forecasts for tobacco blue mold outbreaks throughout continental North America. In 1998, the center was expanded to also include forecasts for downy mildew of cucurbits.

CONCLUSION

A tremendous variety of fungal spores are present in the atmosphere. While many of the spores originate from saprobic species, spores of plant pathogens are often a significant component of the air spora. These spores pose a constant threat to crops throughout the world. Control of plant diseases often requires extensive use of fungicides. To optimize the application of fungicides, timing of the applications should be tied to periods of peak spore dispersal. This requires a thorough understanding of the aerobiology of the pathogen. Aerobiological studies should be part of any effort to understand the distribution and epidemiology of agricultural pathogens that rely on air currents for dispersal. Unfortunately, no regional or national sampling network exists for agricultural pathogens. The Aeroallergen Network of the AAAAI maintains a national network of air sampling stations, and a similar network is needed for the plant pathology community. Studies during the last half century have provided an understanding of the dispersal mechanisms used by fungi; however, research is still needed on many aspects of fungal biology to fully understand the effects of meteorological conditions on dispersal, transport, and survival in the atmosphere. This knowledge will help in the development of better computer models for forecasting disease epidemics. These models are in place for forecasting of blue mold and downy mildew of cucurbits from the North American Plant Disease Forecasting Center. More systems of this type are needed.

BIOAEROSOLS IN INDUSTRIAL SETTINGS

KENNETH F. MARTINEZ
DOUGLAS TROUT
RICHARD KANWAL
NIOSH
Cincinnati, Ohio

Microorganisms are normal inhabitants of the environment; they exist in the soil on which we walk, in the air that we breathe, in the water that we drink, and even in the food that we eat. The saprophytic varieties (those utilizing the organic products of other organisms, living or dead, as a food source) generally predominate. Under appropriate conditions (optimum temperature, pH, and with sufficient moisture and available nutrients), saprophytic populations can be amplified. In the air, they can exist as discrete particles (e.g., as individual fungal spores) or they can be attached to other particles or substrates in a medium (solid, liquid, or gas). Many microbial species have been documented to tolerate various environmental extremes of temperature and pressure, allowing them to acclimate to the most extreme conditions. Bacteria have been identified in the lower depths of the ocean, growing amidst intense volcanic activity. Mycobacteria have been found in mummified tissues. It is clear that microorganisms

(fungi, bacteria, and viruses) are ubiquitous occupants throughout many types of diverse environments.

Many species of microorganisms are beneficial to the environment and to our existence. Microorganisms have been used for centuries to produce alcoholic beverages and to leaven bread. More recently, the metabolic systems of specific microbial populations have been used to produce pharmacologically important products (e.g., penicillin and citric acid) and a limited number of other chemical agents. Unique uses of the microbial community include the application of bacterial species in the decontamination of hazardous substances (i.e., oil spills in the ocean) and as an insecticide (i.e., *Bacillus thuringiensis*) to control cabbage worm, cotton boll worm, and chicken louse. Our everyday encounters with the microbial community generally do not pose a significant health risk to the immunocompetent population (healthy adults). However, select occupational environments present unique exposure concerns because of the nature of the microorganisms encountered, the microbial concentrations observed, and the susceptibility of the exposed population. Within the health care industry, attention has been focused on human infections or infectious agents, of which the obligate parasites and facultative saprophytes (including the primary pathogens and opportunistic pathogens) are primary concerns (1).

Exposure to bioaerosols (defined here as microorganisms and/or their products entrained in/on airborne particles) has been a well recognized safety and health issue in agricultural settings, and more recently, in nonindustrial indoor environments. However, bioaerosols are also important health and safety issues in nonagricultural industrial work settings, the topic of this article. Bioaerosols include microorganisms (both alive and dead) and their fragments or products. Among the specific components of bioaerosols that have been studied include microorganisms (such as bacteria, fungi, and viruses), endotoxins, and [1 → 3]-Beta-D-glucans. Endotoxins are lipopolysaccharide (LPS) compounds, which are part of the outer cell wall of all gram-negative bacteria. [1 → 3]-Beta-D-glucans are glucose polymers, the structural components of most fungal cell walls.

Occupational exposure limits have not been established for bioaerosols or for any of the specific components of bioaerosols (2), although several reports have proposed guidelines for occupational exposure limits to endotoxins (3–5). One factor that limits our ability to establish guidelines for exposure to endotoxins (and for bioaerosols in general) has been laboratory variation in analysis; this issue has recently been addressed for endotoxins in a collaborative study that found that both intra- and interlaboratory variation remain important problems (6).

We will now review several industries in which exposure to bioaerosols is an important safety and health issue.

BIOTECHNOLOGY

Biotechnology has been broadly defined as any technique that uses living organisms (or parts thereof) to make or modify products, to improve plants and animals, or to develop microorganisms for specific uses (7). Within the focus of this article, biotechnology will be presented in terms of the production of goods using industrial processes, specifically, fermentation technology. Aseptic fermentation techniques have been employed to produce a variety of commodities on a large scale, including single-cell proteins, antibiotics, acetic acid, citric acid, lactic acid, amino acids, vitamins, and enzymes. During industrial fermentation, microbial inocula (fungi or bacteria) are used to convert a substrate to a desired product typically using a batch processing system in three main stages: laboratory and inoculation, (or microbial preparation and growth), fermentation (or product biosynthesis), and process recovery (or product extraction and purification).

During the laboratory and inoculation stage, cultures of microorganisms are developed, prepared, and grown prior to the transfer to large-scale fermentation. All pertinent microbiological operations within the laboratory are conducted using sterile equipment with aseptic transfer techniques. To reduce the risk of contamination with foreign microbial strains, successive recultivations of cultures and numerous propagation steps are held to a minimum.

During the fermentation stage, multiple propagation steps are again held to a minimum to reduce the risk of contaminating large quantities of culture media and to optimize the use of process equipment. The seed tank, containing a sterile nutrient medium, is inoculated with the selected microbial culture prepared in the laboratory. The seed tank is designed to promote the growth of the microorganism population to a level necessary for proper inoculation of the fermentor tank. The batch mixture in the seed tank is aerated and mechanically agitated until the optimum level of culture growth is achieved. On completion of the cycle, the contents of the seed tank are aseptically transferred to a larger seed tank or, as is generally the case, directly into the fermentor tank. The fermentor tank is where "fermentation" occurs and the product of interest is biologically synthesized. A submerged, batch fermentation process is typically employed using a deep-tank reactor vessel with a top-mounted agitator and bottom air sparger. Proper temperature conditions are maintained with cooling coils inside (or a cooling jacket outside) the reactor vessel. The fermentor tank, containing the presterilized nutrient medium from a batching tank and the inoculant microbial culture broth mixture from the seed tank, is aerated and mechanically agitated for continued microbial growth and biologic synthesis of the product.

The mechanical equipment components used in the process recover stage are largely determined by the product and the microorganism used in the biosynthesis. Products that are produced extracellularly are extracted via solid/liquid separation techniques, which might employ the application of simple unit operations such as centrifugation and filtration. In some instances, concentration and purification (polishing) may be required and can be achieved with such processes as ultrafiltration, vacuum evaporation, or the precipitation of proteins. The separation of intracellular products is more complicated because the cells must first be disrupted. These processes

generate bioaerosols, which can be released to the surrounding area.

The etiologic agents of disease may be a contaminant that has found a suitable environment to proliferate (as in agricultural environments) or may be an active component of the manufacturing process. Topping and coworkers (8) documented sensitization among workers in a biotechnology plant producing citric acid using *Aspergillus niger*. The results of this study indicated that the risk was from exposures to not only fungal spores but also proteinaceous products found in the culture fluid. A follow-up longitudinal survey study of the same workforce indicated no new skin sensitizations believed to be the result of the implementation of control strategies, that is, process enclosure, the application of local exhaust ventilation, the use of respiratory protection, and worker/management education (9). In the pharmaceutical industry, Lagier and coworkers identified a case of occupational asthma in a worker exposed to penicillamine (10). The primary occupational biological hazards in the biotechnology industry is the potential for process microorganism and their metabolic products to produce an immunologic response in susceptible individuals (11). Intermediate processing chemicals used during the manufacture of specific products of biotechnology can also pose occupational exposure hazards (e.g., amyl acetate used to extract penicillin). It has also been suggested that although infections from microbial production systems based on the use of recombinant DNA technologies are plausible, the risk is considered extremely low (12).

The effective containment of the potential hazards in the biotechnology industry is dependent on the equipment designs employed in existing chemical process technology. The equipment designs must provide for containment of the microorganisms (viable and nonviable forms), biologically active products or intermediates, and processing chemicals such as extraction solvents. The level of containment is determined by the anticipated risks associated with these agents. Specific factors affecting containment include the selection of appropriate fermentor and associated equipment, suitable exhaust gas treatment, design considerations for vessel overpressurization and relief, suitable inoculation and sampling systems, and the collection and inactivation of condensate that may contain viable microorganisms (13). Consideration to these factors are categorized as primary physical containment, which offers protection from the microbial agent to the process operator through isolation. Protection of the general environment is achieved through the application of secondary physical containment, which includes consideration of the building design, the appropriate use of ventilation systems, and waste disposal concerns.

Anticipating this reliance on chemical process technology, a 1988 study characterized the engineering controls used in conventional enzyme fermentation processes (14). Sample locations selected to reflect worker exposures to process microorganisms included the laboratory (where culture transfers were conducted), inoculum and fermentor tanks (sample ports and agitator shafts), filtering operations, and background locations (Fig. 1). The study

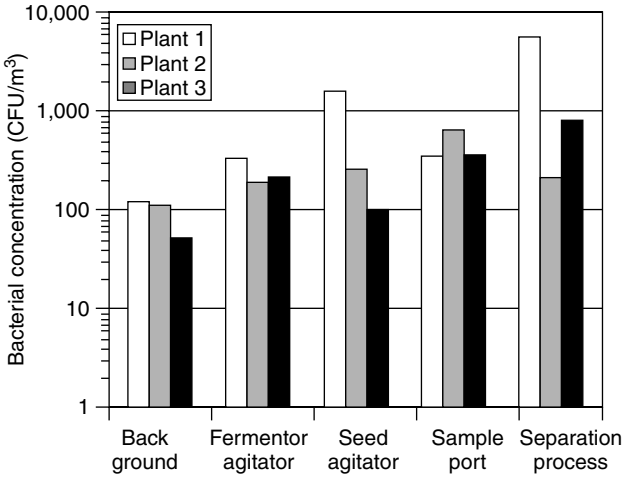

Figure 1. Sample locations reflect worker exposures to process microorganisms.

results indicated that controls are most needed around high-energy operations, including separation equipment (i.e., filters and centrifuges), fermentor agitator shafts, and manual sampling ports. These operations may not be amenable to complete sealing, enclosure, or isolation. Significantly lower bacterial concentrations were observed at a rotary vacuum drum filter compared with concentrations at the filter press (1). These differences appeared to have resulted from the application of local exhaust ventilation, the inherently better containment characteristics of drum filters, and operator work practices (dislodging filter cake from the filter press plates at the end of each cycle). Rotary vacuum drum filters have been reported to be the most widely used filters in the fermentation industry (15). In contrast, a centrifuge would be expected to produce large concentrations of microbial aerosols. However, as reported in the enzyme manufacturing study, effective process enclosure and the application of local exhaust ventilation at the biomass discharge point resulted in bacterial concentrations significantly below those of the filter process (although above those of the rotary vacuum drum filter).

Alternative methods of solids removal include precipitation, coagulation, floculation and chromatography, electrophoresis, and ultracentrifugation. These methods should be applied only after consideration of the agent risk and the inherent containment abilities of the technology. Rapid advancements in the biotechnology industry and use of microorganisms that pose significantly increased risks have resulted in large-scale equipment that offers improved containment capabilities. In a study of biohazards using a large-scale zonal centrifuge on moderate risk oncogenic viruses, it was determined that minimal risks to laboratory personnel existed during optimum operation (16). However, faulty seals did result in the detection of high concentrations of phage in the turbine air exhaust and the seal coolant system.

Exhaust gases from the fermentor tanks can be another major emission source for the production microorganisms. The aeration of fermentor broths produces a foam on

the surface of the liquid that results in the continuous production of bursting bubbles. It has been demonstrated that the droplets of dilute solutions formed by the bursting of bubbles can enrich the concentration of microorganisms by factors of 10 to 1,000 times (17,18). The control of vented bioaerosols within the fermentor tanks produced by this and other mechanical aerosolization processes is achieved primarily by the application of sterilizing (i.e., high efficiency) filtration systems preceded by "roughing" systems (e.g., cyclones, scrubbers, and/or condensers) (19). Data from the enzyme manufacturing study revealed that scrubbing systems alone may not be effective in controlling vented bioaerosols from the fermentors. The seals around the agitator shafts may be another emission source for the process microorganisms. Double mechanical steam seals appeared to provide inherently better containment than packed seals.

The work practices of the operators can also be a determining factor in the potential for occupational exposure. During the collection of fermentor tank sample volumes in enzyme manufacturing, operators were observed purging the sample port with a "blast" of pressurized steam prior to the collection of a broth sample. The steam served to clean and decontaminate the interior surfaces of the pipes to ensure a pure sample for subsequent analysis. However, the contact time between the steam and residual microbial populations in the sample line were not adequate to kill the microorganisms and therefore resulted in a dissemination of viable aerosols into the surrounding environment. Work practices are most reliable when used in combination with effective engineering measures such as isolation or automation. For example, microbial exposures during the separation of solids can be reduced by limiting operator interaction with those processes or, if this is not possible, the observance of proper and safe work practices.

Large-scale spills of fermentor tanks can be effectively controlled by concrete dikes constructed around the periphery of the tank. Spilled material is directed to a sump and subsequently pumped to a holding tank for inactivation of the microorganisms. In-line sterilizers may also prove effective prior to the disposal of the biological material. Bulk samples of the inactivated material should be microbiologically examined to validate the efficacy of the sterilization techniques. Spill responders should be equipped with personal protective equipment (PPE), including impervious clothing, gloves, autoclavable boots, and appropriate respirators (e.g., a self-contained breathing apparatus).

MACHINING

Machine tools use metalworking fluids (MWFs) during grinding, forming, treating, and machining operations. These fluids extend the life of the bits, blades, or other cutting components of the machine tool by cooling and lubrication of the machined surface. The application of the fluid also assists in the removal of the metal chips, swarf, fines, and other residues and may serve to protect or treat the material surfaces being machined. The fluids are disseminated from a dedicated sump located proximal to the machine or, as is found in larger machine shops, from a central sump that distributes fluids to multiple machines. Occupational exposures to the fluids or contaminants within the fluids are influenced by the fluid composition, the tool type and speed, the method of fluid application, the use of engineering controls (such as enclosure and local exhaust ventilation), and the fluid maintenance program.

There are four major types of MWFs — straight oils, water-soluble oils, semisynthetic, and synthetic. Straight oils (neat oils) are solvent-refined petroleum oils not designed to be mixed with water. The other three types are water-based. Soluble oil MWFs are emulsions or are composed in part of water-soluble oils (30% to 85% by concentration); the concentrate is diluted with water prior to use. Semisynthetic MWFs are composed of 5 to 30% petroleum oils. Synthetic MWFs contain no petroleum oils. MWF aerosol refers to the mist generated during grinding and machining operations, and may contain a mixture of substances. Water-based MWFs are suitable growth environments for many types of microbes owing to the abundance of water and organic substrates. As a result, many MWFs and MWF aerosols are routinely contaminated by bacteria and/or fungi.

Historically, microbial contamination of MWF has been a problem, primarily because it can affect fluid quality and performance. Fluid degradation from microorganisms can cause changes in fluid viscosity, and the acid products of fermentation may lower the pH of MWF, causing corrosion and leaks in the MWF system (20). The predominant microbial species routinely recovered from MWFs are frequently the same as those recovered from natural water systems (20). Although most bacterial species found in MWFs are gram-negative, the microbial populations within such MWF samples are continually changing (20,21). The species identified in MWFs are generally characterized as nonpathogens or opportunistic pathogens, of which the bacterial genus *Pseudomonas* is the most frequently isolated (22,23).

Bacterial concentrations in MWFs often range from 10^5 to 10^8 colony forming units per milliliter (CFU/mL), but they can be as high as 10^9 CFU/mL (24–28). It has been suggested that well-maintained MWF systems should have bacterial concentrations of less than 10^6 CFU/mL (29). Only recently have gram-positive bacteria and *Mycobacterium* species been identified as predominant species in the MWF of some plants (30). Data regarding airborne concentrations of mycobacteria from contaminated fluids are limited, but one study has reported concentrations ranging from 1,300 to 9,200 CFU/m^3 (31). Occupational disease syndromes have been suggested in workers exposed to metalworking fluids, some of which have been reported to be contaminated with mycobacteria (32,33). Similarly, recent evidence in the scientific literature suggests an association between the aerosolization of mycobacterial laden hot tub waters and the development of respiratory disease in the exposed population (34). However, although the acid-fast organism *Mycobacterium chelonae* has been found to be present in MWF associated with outbreaks of hypersensitivity pneumonitis (HP) (30), the significance of finding any

particular fungal or bacterial species in MWF is not clear at this time.

Due to the limited nature of microbial sampling, results of bulk sampling of MWFs at any given time may only represent a portion of the microecology in the MWF. Most water-based fluids have low concentrations of fungi, except when a bloom (which is often caused by a dramatic decrease in bacterial contamination) occurs (28,35). MWFs that have high concentrations of gram-negative bacteria frequently have high levels of endotoxin, which have been quantified in machining operations where water-based MWFs are used.

Exposure to MWF aerosols is known to be associated with increased prevalence of respiratory symptoms, decreases in pulmonary function, and the occurrence of occupational asthma and HP (22). The significance of reported respiratory and irritant symptoms among MWF-exposed workers in relationship to loss of pulmonary function or illnesses such as asthma or HP is unclear at this time. HP, which is an immunologically mediated inflammatory disease of the lung that occurs after repeated inhalation and sensitization to a wide variety of microbial agents (bacteria, fungi, amoebae), animal proteins, and low-molecular weight chemical antigens, has been associated with exposure to MWFs in several recent reports (30,36,37). Aerosolized endotoxins are suspect causative agents of occupationally related respiratory effects (e.g., chronic bronchitis, abnormal cross-shift declines in pulmonary function, and asthma) among workers exposed to MWF aerosol (22).

Limited information has been published regarding the concentrations of disseminated bioaerosols from MWF operations. However, questions regarding the development of occupationally related respiratory disease and exposure to MWF have prompted continued research focused on environmental characterization of the microbiological component. In one study evaluating worker exposures to MWFs (including synthetics, mineral oil, and rapeseed oil), airborne concentrations of gram-negative bacteria and endotoxins from contaminated fluids ranged up to 41,000 CFU/m^3 and 600 nanograms (ng) per cubic meter, respectively (38). Additionally, MWF workers responded with higher IgG antibody levels to *Stenotrophomonas maltophila*, *Pantoea agglomerans*, and *Comamonas acidovorans*, the most common bacterial contaminants in the fluids, than did controls. In a separate study characterizing MWF exposure indices and acute respiratory effects, a thoracic fraction sampler [that permitted the collection of personal breathing zone (PBZ) samples for bioaerosols] was used to enumerate airborne bacteria and endotoxin (39). PBZ bacterial concentrations of personnel working around MWF processes were reported to extend up to 26,600 bacteria/m^3. Sampling for endotoxins resulted in PBZ concentrations ranging to 234 endotoxin units per cubic meter of air (EU/m^3).

To prevent or greatly reduce the risk of adverse health effects due to MWF exposure, the National Institute for Occupational Safety and Health (NIOSH) recommends that airborne exposures to MWF aerosols be limited to 0.4 milligrams per cubic meter of air (mg/m^3) for thoracic particulate mass* as a time-weighted average (TWA) for up to 10 hours per day during a 40-hour week (22). The NIOSH recommended exposure limit was established primarily to eliminate or reduce respiratory health effects. Neither the Occupational Safety and Health Administration (OSHA) nor the American Conference of Governmental Industrial Hygienists (ACGIH) have exposure limits for MWF aerosols, although both have an eight-hour TWA limit of 5 mg/m^3 for mineral oil mist.

Currently, there are neither specific microorganisms in MWFs linked to specific, exposure-related health effects nor specific criteria concerning the level of total microbial contamination that may be related to potential health effects. Because the ecology of MWF systems fluctuates, documenting the microbial exposures at the time of symptom (or disease) onset is difficult. This points to the need for ongoing evaluations of the MWF environment, which may be correlated with ongoing surveillance of health effects among exposed workers. Proper management of the MWF and ventilation systems in machining areas, as components of an overall MWF health and safety program, plays an important part in reducing exposures to MWF aerosols and minimizing potential illness.

WASTE TREATMENT AND HANDLING

Because many types of waste inherently contain potentially infectious organisms, persons working in both wastewater and solid waste systems have potential exposure to bioaerosols. Important components of bioaerosols present in waste systems include a variety of microorganisms (viruses, bacteria, fungi, and protozoan) and components of microorganisms (endotoxin, [1 → 3]-Beta-D-glucan) (40). Airborne exposures that have most commonly been monitored include total and respirable dust (sometimes including analysis of particle size distribution), bacteria, and endotoxin. Recent data have shown that aerosols generated by various types of wastewater treatment processes include varying concentrations of microorganisms (including bacteria, fungi, and viruses) (41,42). Generally, the solids-handling aspects of waste systems (the typical household and industrial sewage treatment process) are thought to involve the most likelihood for bioaerosol exposure (40). However, the relationship between bioaerosols produced in sludge production, processing, and handling steps and potentially related health effects is not well described. In one study, a variety of clinical and laboratory effects among sludge workers were associated with aerosolized sewage sludge or a dust of dried sludge, both probably containing substantial concentrations of endotoxin (43).

Recently, the process of land application of biosolids (sewage sludge treated to significantly reduce pathogen levels) has received considerable attention. In the United States, land application of biosolids is a process regulated

* Thoracic particulate mass is the portion of MWF aerosol that penetrates beyond the larynx and may be deposited in the lung airways and/or gas exchange region.

by the Environmental Protection Agency (EPA) in which biosolids are applied to farmland, surface mines, and other lands, following specific requirements (44). However, potential occupational exposures during biosolid application are not directly considered by the EPA. One case study by NIOSH found that reports of gastrointestinal illness among five workers were temporally related to work in a land application process (45). In that survey, air concentrations of bacteria ranged from 412 CFU per cubic meter (CFU/m^3) to 2,356 CFU/m^3, with a small percentage of the organisms being enteric organisms. Endotoxin levels ranged from 23 to 39 endotoxin units per m^3 (EU/m^3). Another survey of bioaerosol concentrations at a land application site found concentrations of bacteria in the air of 10^5 CFU/m^3; those investigators noted that their data may not be relevant when considering occupational exposures in areas or processes in which workers are performing job tasks involving sludge agitation (46). Although direct contact with potentially infectious material is likely to be the greatest potential hazard for biosolid application workers, there is potential for respiratory exposure to bioaerosols. NIOSH is currently drafting recommendations, including eliminating potential hazards where possible and using appropriate engineering controls and personal protective equipment, to help minimize occupational exposures of workers exposed to biosolids (47).

Handling of solid waste also involves exposure to bioaerosols. A recent exposure study of workers at a refuse-derived fuel (RDF) plant found mean air concentrations of total bioaerosol (measured by epifluorescence microscopy) to range from 10^6 to 10^8 organisms per m^3, with endotoxin concentrations ranging from 5 to 346 EU/m^3 (48). Composting is another area of solid waste treatment that has been evaluated. In a case study evaluating exposure and respiratory illness of a worker handling composted wood chips and leaves, high levels of fungi (10^6 to 10^8 CFU/m^3), total bacteria (10^5 to 10^8 CFU/m^3), and endotoxin (636 to 16,300 EU/m^3) were documented (49). Another type of solid waste handling process has recently been found to present potential hazards to waste workers. As a component of an evaluation of exposures at a medical waste processing facility, where at least one employee was epidemiologically determined to have acquired tuberculosis due to occupational exposure, investigators conducted bioaerosol sampling. Air concentrations of total bacteria in the area of the process with the highest concentrations ranged from 183 to 256 CFU/m^3. Speciation of bacteria was limited to three organisms (*Pseudomonas aeruginosa*, *Escherichia coli*, and *Staphylococcus aureus*), which were considered atypical environmental organisms and utilized as indicators of aerosolization of waste materials. Although air sampling for *Mycobacterium tuberculosis* was not conducted, the investigators concluded that employees in that facility could be exposed to this pathogen as a result of occupational bioaerosol exposure; recommendations were made to minimize the potential for exposure and infection (50).

In summary, waste handling and treatment of a variety of types of waste involves potential exposure of workers to bioaerosols, which may contain a variety of potentially infectious or toxic substances.

WOOD PROCESSING

Various wood processing operations can place workers at risk for health effects due to bioaerosols. The degree of risk depends on the particular operation (logging, sawmilling, furniture manufacturing, carpentry), the types of woods utilized, the conditions in which the wood is stored before use, and the particular treatments applied to the wood (for example, fungicides) (51). A number of studies assessing the relationship between exposure of wood processing workers to bacteria, fungi, endotoxins, and (1 → 3)-Beta-D-glucan, and respiratory and mucus membrane symptoms were conducted by Alwis and coworkers (52–54). The workers in the studies worked in logging sites, sawmills, wood chipping mills, and joineries. Maintenance workers were used as controls. The lowest fungal concentrations were observed in the sawmills (3,000 CFU/m^3) and joineries (4,000 CFU/m^3). These process operations were equipped with the most efficient and well-maintained exhaust ventilation systems and used vacuuming to remove dust from machinery and the floor. Workers in the woodchipping mill were exposed to the highest concentrations of fungi (74,000 CFU/m^3). *Aspergillus fumigatus* and *Penicillium* spp. were the predominant genera at the logging sites where debarking was conducted; *Penicillium* spp. predominated in sawmills and the woodchipping mill. Joinery, sawmill, and chip mill workers showed significant correlations between mean personal exposure and work-related symptoms after controlling for smoking and age. The investigators pointed out that, although the exposures were considered low, they were still associated with symptoms. A dose-response relationship was shown between (1 → 3)-Beta-D-glucan exposure and the occurrence of chronic bronchitis, throat irritation, and regular ear inflammation and infections. A significant correlation was also found between mean personal exposures to endotoxin and chronic bronchitis. Pulmonary function testing showed that respiratory symptoms were correlated with cross-shift decreases in lung function.

Similar occupational exposures to microbiological agents have been described in related industries, that is, cellulose and paper manufacturing, which use timber as a raw material resource. Pulp logs absorb moisture during water-driven transport or during storage prior to processing. During storage, the ample supply of water and organic nutrient material provide an optimum environment for the development of microbiological communities, especially, thermotolerant species. The inner wood of logs are less likely to contain levels of fungi that would pose a significant biohazard; however, bacteria are more likely to develop in this "core" wood (55). Fungi appear to develop more prominently during the processing of waste wood and during removal of bark. The debarking of the pulplogs and subsequent storage of the resulting biomass can result in the release of bioaerosols, including fungi, bacteria, and endotoxins. A NIOSH study of a paper manufacturing process revealed elevated

concentrations of thermoactinomycete species during the debarking and subsequent transport and storage of removed biomass material (56). Concentrations of bacteria were two orders of magnitude greater in the transfer tower and the biomass storage area than those observed in outdoor control samples with thermoactinomycetes comprising greater than 90% of the genera identified. The lower concentrations of bacteria in the debarking process were attributed to the application of water, which reduce the dissemination potential of bacterial spores. Another reported study of a cellulose factory described elevated exposure concentrations of bacteria and fungi to barking workers of 46,000 and 5,900 CFU/m^3 (geometric means), respectively (57). Caterpillar drivers operating in wood chip piles were exposed to concentrations of bacteria averaging 1,500 CFU/m^3 and fungi averaging 45,000 CFU/m^3. Additionally, IgG antibody levels were significantly higher among the wood chip workers as opposed to the barking workers. It was suggested that dry wood chip material can penetrate to the lower parts of the lung more readily than wet aerosols generated in the barking process.

Exposure to bioaerosols have also been documented in the paper recycling industry. In a Danish study of six recycling plants, two plants were reported with very high counts of airborne microorganisms noting that several values exceeded the Danish threshold limit value of 10,000 CFU/m^3 (58). The highest microbial concentrations were observed in the effluent water treatment area with a mean concentration of 261,000 CFU/m^3; lesser mean concentrations of 34,000 and 8,700 CFU/m^3 were observed around paper machines and near winding and cutting machines, respectively. Samples for endotoxins at one plant near the paper machine revealed concentrations, which exceeded the Danish threshold limit value of 100 ng/m^3 (mean value of 294 ng/m^3). High endotoxin concentrations may have been the result of intensive reuse of process water.

Health effects associated with exposure to wood dust include occupational asthma, HP, organic dust toxic syndrome (ODTS), chronic bronchitis, and upper respiratory and mucus membrane irritation (59). Although exposures to the dusts of many different woods are thought to be associated with occupational asthma, a specific sensitizing agent directly related to the occurrence of asthma has been identified for only one type of wood (plicatic acid in the case of western red cedar) (59). A variety of fungi have be found to be associated with HP among workers in this industry, including *Cryptostroma corticale* (maple bark), *Aureobasidium pullulans* (redwood), and *Alternaria*, *Aspergillus*, and *Thermoactinomyces* (moldy wood chips) (59). *Penicillium*, *Graphium*, *Pullularia*, and *Trichoderma* species have also been found to be causative antigens (60). ODTS is characterized by the occurrence of a flulike illness (fever, chills, myalgia, malaise, nonproductive cough) within a few hours of inhalation of wood dusts contaminated with fungi, bacteria, and/or endotoxins. Although the clinical picture differs in some respects from HP (59,61), it has been postulated that HP and ODTS may represent parts of a spectrum of responses to exposure to bioaerosols (49).

Avoidance of exposure to the offending agent(s) is the primary means of prevention of these disorders and can usually be accomplished through product substitution or engineering controls. PPE may be suitable for occasional brief exposures. If symptoms persist despite engineering controls and PPE, an affected worker will need to be removed completely from the exposure situation (61). This has been shown to be particularly important for HP as repeated episodes of HP can lead to chronic lung disease and recurrent low level exposures can lead to the insidious development of chronic interstitial lung disease with fibrosis.

TEXTILE INDUSTRY

Recognition of adverse respiratory effects related to work in the textile industry dates back many years (62). Byssinosis is an occupational lung disease caused by inhalation of cotton, hemp, or flax dust, which in the early stage is characterized by distinctive chest tightness associated with decreased lung function. The relationship of respiratory effects and workplace exposures to cotton dust vary depending on the stage of processing workers are performing, with higher risk areas being those areas where the cotton is first processed (4,63). OSHA has regulations, directed primarily at the prevention of byssinosis that limit occupational exposure to cotton dust (64,65), and decreases in exposure to cotton dust in the textile industry has been associated with a decrease in the incidence of byssinosis (62). There has been ongoing research related to bioaerosol exposure in the textile industry. Important issues being addressed by some of that research include the issue concerning byssinosis occurring among persons with exposures below the limits set by OSHA and the issues of other respiratory disorders such as chronic bronchitis and long-term decrements in pulmonary function, which have been associated with exposure to cotton dust. Many investigators have evaluated the role of endotoxin as the etiologic agent within cotton dust, and acute pulmonary responses (decreased pulmonary function) have been related to the endotoxin concentration within the cotton dust (4,66). More recently, results of an 11-year longitudinal study indicate that chronic lung function decrements are more closely related to cotton dust exposure than exposure to associated endotoxins (67). This raises the question of whether exposure to bioaerosol components (e.g., endotoxin) and vegetable components of dusts such as cotton dust may lead to different health effects.

Studies designed to characterize occupational exposures to microbiological agents in cotton mills have been reported. In a study of two cotton mill plants in China, samples for airborne dust and endotoxins were collected using vertical elutriators and 5 micrometer (μm) polyvinyl chloride filters (68). Dust concentrations were similar for the two plants ranging from 0.15 to 2.34 mg/m^3 at the first plant and 0.19 to 2.50 mg/m^3 at the second plant. However, endotoxin concentrations between the two plants were different, with the first plant exhibiting higher levels, ranging from 20 to 920 ng/m^3, and the second plant, ranging from 2 to 550 ng/m^3. In a separate study of two

cotton mills in England (one mill was characterized as new while the other had been long established), air samples were collected for culturable fungi, actinomycetes, and bacteria and for spores counts of fungi, actinomycetes, and bacteria (69). Bulk samples of the cotton were also collected and microbiologically analyzed. Cotton dust samples revealed spore counts averaging 2,400,000 spores per gram (spores/gm) of material, with approximately two-thirds comprising "actinomycete + bacteria" classified spores. Culture techniques revealed predominance by bacteria with lesser numbers of actinomycetes, including *Faenia rectivirgula*, *Streptomyces albus*, *S. griseus*, and *Thermoactinomyces* spp., and fungi, including species of *Aspergillus*, *Penicillium*, and *Cladosporium*. As with the bulk sample analyses, "actinomyces + bacteria" classified spores were the most numerous spores identified with a mean concentration of 220,000 spores/m^3 for "actinomyces + bacteria" and 50,000 spores/m^3 for fungi in the new mill, and 2,770,000 spores/m^3 for "actinomyces + bacteria" and 50,000 spores/m^3 for fungi in the long established mill. This was consistent with the culturable air sample analyses, with bacteria being the most numerous on most culture plates.

FOOD PROCESSING

The relationship of bioaerosol exposure as a cause of health effects has been evaluated in a variety of food processing plants, including trout processing facilities (70) and beet sugar refineries (71). The latter survey documented exposure to fungal bioaerosol in a workplace where employees had been diagnosed with occupational asthma, and provided recommendations for detailed engineering controls designed to minimize bioaerosol exposure. Respiratory effects related to exposure to flours and grains have been researched for many years; it is clear that work-related respiratory symptoms and illnesses have been documented among workers in both agricultural and nonagricultural industries in which exposure to flours and grains occurs. A broad range of etiologic agents are thought to be involved with these health effects, including many types of microorganisms (such as bacteria, fungi, wheat weevils, and mites) and additives (such as enzymes and other proteins) (72). A series of evaluations have been performed concerning the potato processing industry (73,74) and a recent report evaluating workers in that industry demonstrated that decrements in lung function were associated with endotoxin exposure above 53 EU/m^3 (75). In addition to the components of bioaerosols mentioned earlier, another area of research relevant to the food processing industry includes evaluation of microbial volatile organic compounds as etiologic agents for respiratory and other symptoms.

CONCLUSION

The preceding discussions demonstrate that exposure to bioaerosols can occur in a wide variety of nonagricultural industrial settings and that occupational safety and health professionals in these settings must continually consider the potential for bioaerosol exposures. The discussions provided here are not meant to be an exhaustive review; for example, in-depth studies at other types of industrial sites have provided information useful in characterizing exposures and health effects related to bioaerosol exposure (76,77). Further research is needed to help clarify the health implications of exposure to bioaerosols in many industrial settings.

BIOAEROSOLS: MODELING.

See MODELING THE TRANSPORT OF BIOAEROSOLS

BIOAEROSOLS: TRANSPORT AND FATE

FRANCES L. STITES
Dugway Proving Ground
Dugway, Utah

The study of bioaerosols (microorganisms aerosolized by natural or artificial means) and how they behave in the environment has long interested the scientific community. In the late 1800s, it was discovered that diseases could spread from person to person through the air. The process of how diseases were actually transmitted was not understood however, and the effort to elucidate that process was the birth of the scientific study of aerobiology. Aerobiology is defined as the study of the transport and fate of aerosolized microorganisms. Since then the study of bioaerosols has continued and much has been learned in the last century. However, as with many subjects of scientific interest, there is still much to learn and understand with regard to the transport and fate of bioaerosols. Within the last decade, interest in bioaerosol studies has grown considerably because of the increase in perceived threats of biological warfare and biological terrorism. Therefore, the study of bioaerosols has two purposes, the prevention and prediction of the spread of airborne contagious diseases and the detection of aggressive biological warfare/terrorism threats.

A large number of human pathogens are aerosolized from a wide variety of sources. Airborne human pathogens and common airborne microbes that cause opportunistic infections are listed in Tables 1 and 2, respectively.

The physics of biological aerosol stability and transport have long been established. Modern efforts are geared toward clarifying some of the more obscure effects the environment has on the bioaerosol as a whole. As the data from current efforts are collected and added to the body of knowledge it helps to increase our understanding of a very complex subject that has perplexed scientists for many decades.

Transport and fate are two fundamental parameters of bioaerosols that must be understood by aerobiologists. Transport involves the origin of the bioaerosol and meteorological influences, as well as physical obstacles that may affect the path the bioaerosol travels. The second parameter of interest is bioaerosol fate. This relates to the biological survival or viability of the aerosolized microorganism and all of the external factors that influence that survivability. These two parameters of biological aerosol study are interrelated. Both transport and fate are influenced by many of the same parameters including meteorology, forces involved in aerosol generation and dispersion, and time of day.

Table 1. Airborne Human Pathogens from Nonhuman Sources

Agent	Disease	Source
Bacillus anthracis	Woolsorter's disease, pneumonic and cutaneous anthrax	Contaminated hides, bone meals
Histoplasma capsulatum	Histoplasmosis	Soil enriched with bird droppings
Coxiella burnetii	Q fever	Contaminated meats, animal products
Chlamydia psittici	Ornithosis	Dried droppings from infected fowl

Source: Table Reproduced from Burrell (1991) with permission of the publisher (1).

Table 2. Common Airborne Opportunistic Infections from Nonhuman Sources

Agent	Disease	Source
Cryptococcus neoformans	Cryptococciosis	Pigeon dropping contamination
Acanthamoeba spp.	Various amoebic infections	Natural water sources
Legionella spp.	Legionaires' disease	Natural water sources
Atypical mycobacteria	Tuberculosis like illnesses	Water vegetation
Aspergillus spp.	Allergy, bronchopulmonary aspergillosis, mycetomas, hypersensitivity pneumonitis	Widespread in decaying vegetation

Source: Table Reproduced from Burrell (1991) with permission of the publisher (1).

In this article, the transport and fate of bioaerosols are investigated with an in-depth examination of their contributing factors, as they are currently understood. It is important to note that all of the studies cited in this chapter used culture-based analysis, and this assay method favors the results discussed.

TRANSPORT

According to Bartlett (2), there are three distinct stages involved with the transport of biological aerosols: dispersal, diffusion, and deposition. Dispersal is the aerosolization of the microbe, diffusion is the movement of the microbe over a distance, and deposition is the settling of the microbe onto a surface. All of these stages are influenced by meteorological conditions. In order to fully

appreciate their functions in aerosol transport, each of the three stages will be investigated.

Dispersal

Dissemination of microorganisms occurs when adhesion (i.e., electrostatic) forces attracting a particle to a surface are overcome by wind, mechanical, or other forces. This action is termed dispersal. Any activity or event that provides the energy necessary to elevate a microorganism into the atmosphere is capable of producing a bioaerosol.

Naturally occurring bioaerosols are generated by a variety of means. One example of natural aerosolization is injection into the atmosphere by a bubble traveling through a liquid and bursting on the surface (i.e., waves breaking on the shore, wastewater treatment plants). Aerosol particles generated by bursting bubbles have a higher concentration of microorganisms than a sample of the same volume taken from the liquid suspension that the bubble traveled through (3–8). Aerosol droplets containing *Serratia marcescens* generated by the bubbling action contain concentrations of bacteria greater than the source solution by a factor of 1,000 (4). Other studies indicated that viruses could be concentrated up to 50 times with respect to the source solution concentration (6,7). During the bubbling action the microbes collected in the resulting aerosol particle are concentrated in the surface microlayer and are drawn into the particle during formation (5).

Additionally, it was found that aerosols generated from five-day-old *Escherichia coli* cultures, showed an aerosol particle concentration 15 times greater than those generated from one-and-a-half-day-old cultures (5). However, the researchers did not observe this same effect with all of the bacteria used in their study. They felt that increased lipid content in the cell envelope could account for the organisms being present in the surface microlayer. They theorized that the lipid content of the cell envelope in *E. coli* might increase as the organism ages, which would account for the increase in particle concentration over time.

Bioaerosols can be dispersed by natural events including rain or snow impacting on the surface of pooled water (4) and wind blowing across a surface where microorganisms are present. For this last mechanism the force required to remove a particle from a surface increases as the particle size decreases (9). Bartlett (2) explains that almost all naturally occurring organisms are released within three to four meters from the ground with a majority being released less than 1 meter from the surface. It is this region that is most strongly affected by the daily cycle of heating and cooling. During the day this region can become very unstable so organisms will be rapidly mixed vertically through a substantial depth of the atmosphere. After dark, strong inversions develop and the movement of particles in the lower atmospheric layers is restricted. Material that finds its way above the inversion becomes entrained in a low-level jet of air and can be transported to substantial distances (2).

In a three-year study of the natural fluctuation of aerosolized microbes in four localities (agricultural districts, coastal areas, city parks, and city streets) several patterns were observed (10). The average counts of aerosolized bacteria in the four locations were: agricultural areas, 99 bacteria/m^3; coastal areas, 63 bacteria/m^3; city parks, 763 bacteria/m^3; and city streets, 850 bacteria/m^3. In all areas, the highest counts were observed in summer and autumn with the lowest counts observed in winter. Rain and low relative humidity (RH) corresponded to decreased bacterial counts.

Humans also generate natural bioaerosols as they go about their everyday activities. General movement (e.g., bed making, closing curtains, dressing, walking, talking, coughing, or laughing), can generate significant amounts of bioaerosols. A cough can generate 3,000 droplets, talking for five minutes may also generate 3,000 droplets, and sneezing can generate as many as 40,000 droplets (11,12). Table 3 lists a variety of sources for bioaerosols of health significance and the activities creating the aerosols.

Artificial bioaerosols can be generated using equipment specially designed to serve that purpose. Some examples and uses of aerosol generators include, atomizers used for the generation of mondisperse aerosol standards for the calibration of particle size analyzers (13) and atomizers used in the agricultural industry for spraying trees and plants for pest control (14). Other aerosol generators include the Collison nebulizer commonly used to generate aerosols used in respiratory studies (15), the vibrating orifice aerosol generator (16) and the spinning top aerosol generator (17), both used to generate monodisperse aerosols for calibration.

Artificial bioaerosol generation is sometimes an unfortunate by-product of industrial and agricultural activity. In one community, in which contaminated wastewater was used for spray irrigation, the number of enteric communicable diseases was two to four times higher than in communities that did not use wastewater for irrigation (18). It was determined that the bacterial levels in the air were directly related to the bacterial levels in the wastewater being sprayed. Wastewater treatment plants are also a significant source of bioaerosols. Aerators used to oxygenate the wastewater generate bubbles that burst creating aerosols (19) as described earlier.

Artificial bioaerosols are intentionally generated in the agricultural industry for use in pest and disease control. For example, *Erwinia* sp. are commonly sprayed onto fruit trees in an aerosol form to help control fire blight (20–23).

Generation of bioaerosols by either natural or artificial means exerts some degree of stress on the microbes. Strange and Cox (24) state that the injury to an aerosolized microbe results mainly from shear and impaction forces with the extent of the injury depending on the method of aerosol generation, the microbial species being generated, and the physiological state of the microbe. However, in a more recent study using *Pseudomonas syringae* and *Erwinia herbicola* and an aerosol generation method dissimilar to that discussed by Strange and Cox, it was found that the mechanism of aerosol generation itself did not seem to adversely affect the organisms being aerosolized (25). This information could lead one to conclude that the damage to an aerosolized microbe occurs after aerosolization; however, further study is needed in this area.

Table 3. Health Significance of Various Sources of Indoor Aerosols

Sources	Activities Creating Aerosols	Examples of Organisms of Health Significance	Potential Risk to Human Health
Human:			
Desquamated skin	Motion (clothed and unclothed), showering, bed making	Staphylococci	Low
Respiratory tract	Talking, coughing, sneezing, blowing nose	Staphylococci, streptococci, respiratory viruses, *Mycobacterium tuberculosis*, *Yersinia pestis*, *Haemophilus pertussis*	Moderate to high
Gastrointestinal tract	Toilet	*Escherichia coli*, enteroviruses	Low
Ventilation:			
Penetration from exterior	Air movement from cooling towers and other exterior aerosols	*Legionella* species, *B. anthracis*, and various others	Low to high
Interior systems	Operation	*Pseudomonas* species, staphylococci, fungi	Low
Humidifiers	Operation	*Pseudomonas* species, *Acinetobacter* species, *Serratia* species, *Actinomycetes* species	Moderate
Industrial:			
Wool, goat hair, cotton	Textile and furniture manufacture	*Bacillus anthracis*, *C. burnetii*, gram-negative organism	High
Slaughtered animals and birds	Meat packing and rendering plants	*Coxiella burnetii*, *Brucella* species, *Chlamydia psittaci*	High
Vegetables	Freezing, canning, drying	*Streptococcus* species	Low
Dairies	Milk processing	*Coxiella burnetii*, streptococci	Low to high

Diffusion

After dispersion into the surrounding atmosphere, the aerosol diffuses by natural meteorological means. Diffusion is the spreading of aerosol particles caused by thermal energy possessed by all particles, expressed as Brownian motion, or by the action of meteorological conditions (e.g., wind mixing). Bioaerosols can be transported very long distances if the conditions are right. To enable long-distance transport of naturally occurring aerosols, it is necessary that the aerosol source be abundant, the microbes must be resistant or protected from the atmospheric environment, the aerosol particle size not too large (e.g., <10 μm), and the meteorological conditions be favorable (e.g., high wind speed and suitable stratification) (26).

Terrestrial-based bacteria have been found 160 km out to sea and marine-based bacteria found 54 km inland (27). There are also reports of various plant pathogens (28) and the causative agents of Foot and Mouth disease (FMD) (29–31) and New Castle disease (31) traveling great distances. Bacterial spores aerosolized during a sand storm near the Black Sea were found to have traveled 1,800 km to Sweden and Finland (32). Stem rust disease has been documented to travel from the Mississippi Valley to central and northern Canada (33).

One group of researchers (34) theorize that influenza viruses are transmitted over large distances from the far east because of seasonal atmospheric circulation patterns that may help explain the absence of influenza on the North American continent in summer. They feel this may also explain the ubiquity and persistence of the disease. Cold temperatures at high atmospheres, where the virus is theorized to travel, may increase the survival of the virus. An important factor in long-range transmission is the ability of the microbe to survive in the aerosolized state (26); this issue will be further explored in the fate section of this chapter.

The particle size of the generated aerosol is very important in the diffusion process. Not only does it determine how far a particle will travel but it influences the survival of the bioaerosol. As the aerosol particle increases in size, the survival rate of the microbes contained within the particle also increases (24). However, if a particle is too large it will not travel a great distance. A 100-μm particle has a gravitational settling velocity of 10 to 50 cm per second, whereas a particle less than 1 μm has a gravitational settling velocity of 0.003 cm per second (33). Small particulates of 1 to 2 μm can remain suspended in room air for more than 90 minutes (12). However, a large particle can remain airborne and travel a significant distance if the atmospheric turbulence has a velocity component with updrafts exceeding one meter per second (33). These updrafts will counteract gravitational settling of larger particles.

Cool humid weather, and overcast skies seem to favor the transport of bioaerosols. This effect may be due to the protection afforded microbes from the damaging conditions of desiccation, heat, and UV radiation (31).

Deposition

Deposition (the settling or impaction of an aerosol particle onto a surface) and terminal velocity (the rate at which a particle settles influenced by gravitational force) are both governed in part by the mass and size of the particle (9). Particles 1–5 μm generally follow the streamlines of the surrounding air, whereas larger particles have the momentum to deviate from the streamlines and impact surrounding surfaces resulting in deposition of the particle (9). When particles enter the region near a surface, van der Waals forces (weak attractions among electrically neutral molecules or parts of molecules) and electrostatic forces (electrical charge forces of attraction and repulsion) can influence deposition (9).

Deposition of bioaerosols is also influenced by meteorological conditions. For example, they will be restricted from deposition if vertical mixing and winds are strong enough to keep the particles aloft. Particles are washed from the atmosphere by precipitation, both rain and snow (10). It has been shown that the rate at which particles are removed by rain increases as the particle size increases (2). It was shown with FMD that when winds are blowing from infected areas, outbreaks tend to occur where rain has fallen (31). It is theorized that this may be a result of the FMD virus-bearing particles being washed out of the atmosphere.

Deposition in the respiratory tract depends on the size of the particle (27,35). 0.5–15 μm is the optimum size for deposition in the lungs (12,24,31). Respirable particles are considered to be in the size range of 1 to 5 μm (the size of most bacterial and fungal spores). These particles will penetrate as far as the distal alveoli and respiratory bronchioles (1). Therefore, it is easy to see that the infectivity of a given microorganism is in some ways dependent on the aerosol particle size. Particle size can also influence the dose of an organism required to cause infection. As the particle size increases, so does the dose required to cause disease (36). This may be due to the fact that the size of the particle determines where in the respiratory tract the particle is deposited (27,36).

FATE

Before 1965, there was little understanding of the survival of microbes in aerosols (33). Since then important research has been completed to explore the effects various factors have on bioaerosols. According to Theunissen, and coworkers (37) the fate of aerosolized microorganisms depends on five factors: (*1*) relative humidity (RH), (*2*) temperature, (*3*) oxygen concentration, (*4*) presence of UV radiation, and (*5*) constituents of the aerosol itself. In addition to these five factors, the type of microorganism being aerosolized and how much time the microbe spends in the aerosol are important. Interactions among these factors complicate interpretation making it difficult to ascertain the effect each individual factor has on the aerosol stability of the microbe. However, it is generally agreed that the factor that most influences the survival or viability of the bioaerosol is the RH level.

Relative Humidity

RH is defined as the ratio of the amount of water vapor actually present in the air to the greatest amount possible at the same temperature. In a study performed by Walter and coworkers (25), it was found that the RH level was more detrimental to bacterial survival than temperature or the physical stress of aerosolization.

Changes in water content represent the most fundamental potential stress experienced by airborne microbes. In general, aerosolized bacteria have an increased survival/viability at low and high RH levels than at mid-range humidities (24). The actual effect of desiccation on an aerosolized microbe is difficult to determine because of concurrent inactivation of the microbe by oxygen and other factors (33). In order to negate the effect of oxygen on aerosolized microbes, researchers conducted studies in enclosed chambers in which oxygen was replaced by an inert gas such as nitrogen. They were then able to observe the effect of different levels of RH on bioaerosols.

In the early to mid 1960s it was a common practice to evaluate aerosol survival at only three RH values corresponding to high (80%), medium (50%), and low (30%) RH. During a study using *E. coli*, it was observed that critical narrow RH bands exist where loss of viability of *E. coli* was much greater than in adjacent regions (24,33,38). Figure 1 displays the data from that study (33). The aerosols were generated in a nitrogen atmosphere and RH was increased in 2% increments. This phenomenon of narrow bands of instability was also seen with freeze-dried bacteria and viruses (24).

Many theories exist regarding the effect desiccation, caused by low RH, has on aerosolized microbes. In 1959, Webb (39) proposed that cell death, after aerosolization, was due to water molecule movement in and out of a cell in

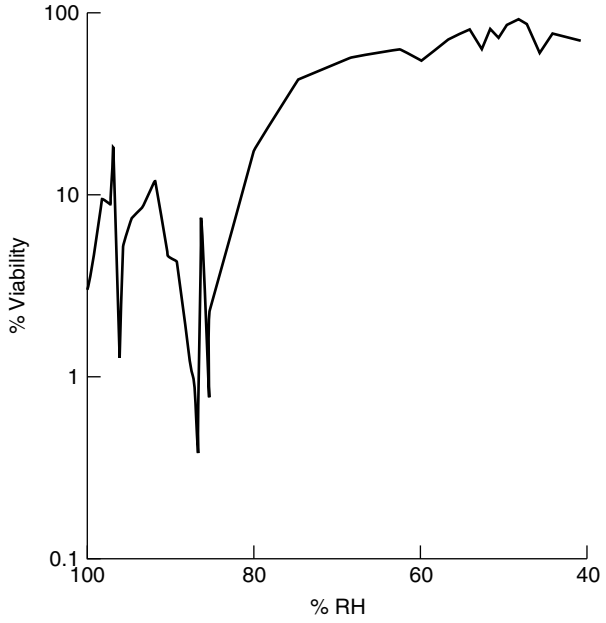

Figure 1. Aerosol survival of *E. coli* B sprayed suspension in distilled water and stored in nitrogen atmospheres. Reprinted from Cox (1989) with the permission of the publisher (33).

an equilibrium system resulting in the collapse of natural cellular protein structures. He also reported at that time that sensitivity of a bacterium to RH differed markedly from organism to organism.

In the 1960s, more specific knowledge regarding the effect of RH was attained. Webb and coworkers (40,41) suggested that the death of airborne bacteria was the direct result of the loss of water, bound to nucleoproteins. Anderson and Cox (27,42) published results supporting that theory. They went on to propose that the structures of macromolecules such as proteins, structural elements, and nucleic acids are affected by water loss. They theorized that the physical structure of proteins and deoxyribionucleic acid (DNA) and ribonucleic acid (RNA) depend on water content. However, Cox (27) stated that desiccation does not markedly denature nucleic acid but instead inactivates surface proteins. At low RH levels water loss might increase the concentration of toxic compounds inside the cell or crystallize them, potentially damaging the metabolic processes of the airborne microbe (27,37,42).

The reactions of bacteria and viruses to the relative humidity of the environment are different. This is most likely due to the difference in structural makeup of the bacterial cell wall and whether or not the viral envelope contains lipids. Envelopes on viruses, which are composed of a phospholipid bilayer, with inserted protein molecules, are analogous to the outer phospholipid membrane of gram-negative bacteria and mycoplasmas (33). Generally, these phospholipid membranes have an inherent thermodynamic instability that can lead to structural changes with little agitation (33). For bacteria, sensitivity to stress appears to be related to gram stain reaction. Gram-positive organisms are more stable in aerosols than gram-negative organisms. Gram-positive organisms are impermeable to ions and small molecules unlike gram-negative organisms, which may account for the differences in sensitivities between the two groups (41). Interestingly, in one study it was observed that culturable gram-positive cocci outnumbered gram-negative organisms of any kind in samples taken from urban air (43).

Gram-negative bacteria and viruses with envelopes containing lipids demonstrate phase changes in the outer phospholipid bilayer membrane when exposed to various RH levels (33). In viruses, those with envelopes containing lipids survive better at a low RH levels and those viruses without lipids in their envelopes survive better at a high RH(44–46) (Fig. 2).

Israeli and coworkers (48) studied freeze-dried microorganisms and concluded that for many bacteria, the phospholipid bilayer biomembrane undergoes conformational changes from the liquid-crystalline phase to gel phase as a result of water loss. The physical change of cell protein conformation leads to a loss of viability of the airborne microbe. Theunissen and coworkers (37) also state that the transition of lipids from a liquid-crystalline phase to a gel phase is a possible inactivation mechanism. They believe this phase change would occur when the airborne microbe is exposed to an environment of low temperature and low RH.

Cox (33) found that aerosolized gram-negative and lipid-containing viruses demonstrate phase changes in the outer phospholipid bilayer leading to a cross-linking reaction between protein moieties, thus enhancing inactivation. This occurs mainly at mid to high RH levels (27). Conversely, the reactions of the surface proteins of lipid free enveloped viruses occur most rapidly at low RH levels. In bacteria, Cox (27,33) proposed that the lipoproteins found in gram-negative organisms denature most readily at mid to high RH levels and other proteins denature most readily at low RH levels.

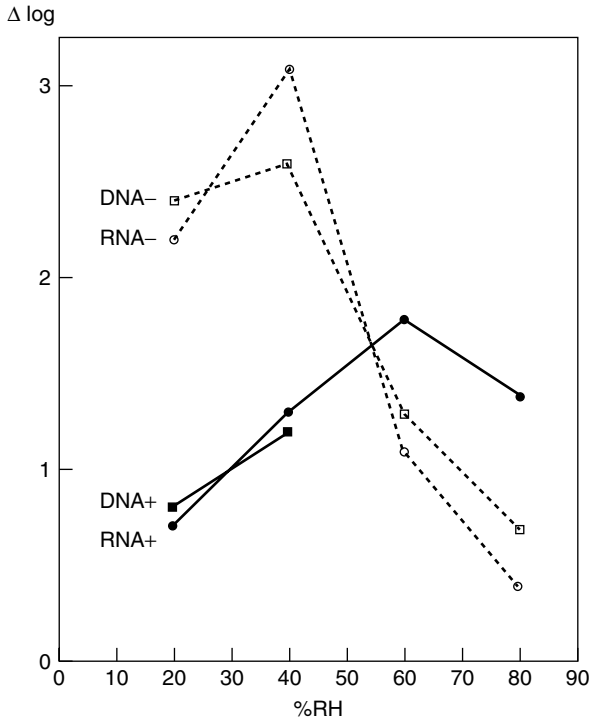

Figure 2. Inactivation of aerosolized viruses after one hour of storage in aerosol at a given RH. DNA– are lipid free-enveloped DNA viruses, DNA+ are lipid containing-enveloped DNA viruses, RNA– are lipid free-enveloped RNA viruses, and RNA+ are lipid containing-enveloped RNA viruses. Δ log: the difference between log of titre calculated and log of titre one hour after atomization. Reprinted from De Jong, et al. (1973) with the permission of the publisher (47).

Another inactivation mechanism is Maillard reactions (37). Maillard reactions are reactions between lipids and proteins or proteins and proteins and result in the removal of water. These reactions occur at low to medium (0% to 50%) RH levels and may possibly increase with increasing temperature.

Webb (39) reported that the death of a bacterial population in an aerosol proceeds in two stages. The first stage is a rapid initial kill within the first second after aerosolization and the second stage is a subsequent slower death. The research of many others (37,45,49–51) supports Webb's initial finding, in both aerosolized bacteria and viruses. Akers (45) expanded on Webb's theory by proposing that the quick initial death may be due to the osmotic shock resulting from the humidity change.

From the earlier discussion, it is apparent that RH directly plays an integral role in the survival and viability of airborne microbes. RH also affects the response of the

aerosol to other factors such as temperature and UV radiation (42). In a study with *Mycoplasma pneumoniae*, a high RH (95%) was observed to increase recovery by approximately ten percent after exposure to UV radiation (52).

Oxygen and Pollutants

In 1914, it was observed that oxygen could cause a loss of viability in freeze-dried bacteria (24). Enhanced bacterial survival was observed when oxygen was replaced with nitrogen (42) or helium (24), resulting in inert atmospheres.

Oxygen inactivation is only seen in some species of vegetative bacteria and algae (27). Oxygen susceptibility usually increases with the degree of desiccation of the aerosolized bacteria, increasing oxygen concentration, and the length of exposure time (27,48). The toxic effect of oxygen was observed to occur below 70% RH (53). Atmospheric oxygen is not toxic to viruses in the aerosol state (46). Figure 3 illustrates the results from a study conducted in which *Serratia marcescens* was aerosolized into different combinations of nitrogen and oxygen at 30% RH and 25 °C (54). As the amount of oxygen in the atmosphere decreased, the viability of *S. marcescens* increased. In this same study little or no toxic action of oxygen was detected at RH levels above 65%.

Lighthart and coworkers (55) observed that the sulfur dioxide (SO_2) found at urban air concentrations affects the survival/viabilility of *S. marcescens*. Exposure of *S. marcescens* to urban levels of SO_2 resulted in a marked decrease in viable bacteria. They also found that cells in recently generated aerosols (i.e., aerosols aged 0 to 1 hours) generally were more sensitive to SO_2, than cells in older aerosols (aerosols aged 1 to 5 hours). SO_2 at 3.6 ppm, in combination with simulated solar radiation, significantly reduced the viability of the Venezuelan Equine Encephalitis (VEE) virus in aerosol (56). It was observed in one study that inactivation due to the combination of RH and SO_2 was greater than the sum of the separate effects (45).

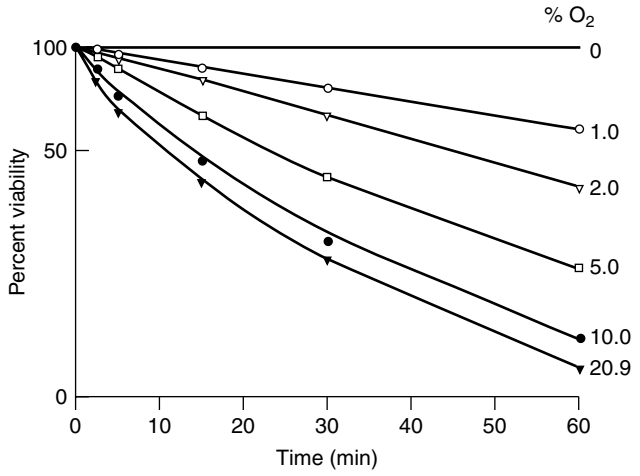

Figure 3. Aerosol survival (log scale) of *S. marcescens* 8UK sprayed different nitrogen + oxygen mixtures at 30% relative humidity and 25.0 °C. Points are experimental; lines are calculated. Reprinted from Cox, et al. (1974) with the permission of the publisher (54).

Carbon monoxide (CO) has been observed to provide protection to aerosolized *S. marcescens* at 88% RH and higher but at other RH levels, mainly below 75%, the death rate was increased (57). The protection by CO at high RH levels may be due to the inhibition of a small energy-requiring death mechanism or the rerouting of conserved energy to repair mechanisms, although the article did not describe or name the small energy-requiring death mechanism (57).

In a study with *Flavobacterium*, a dependence of nitrous dioxide (NO_2) toxicity on the RH level was observed (58). At lower RH levels, more NO_2 was needed to produce equivalent losses that were observed at higher RH levels. At 85% RH it is possible for atmospheric water to convert NO_2 to nitric or nitrous acids, both of which are known to denature proteins (45).

Open-Air Factor (OAF)

The term open-air factor (OAF) is derived from the fact that significant increases in biological inactivation were observed when aerosols were exposed to HEPA-filtered outdoor air compared with clean, inert laboratory-supplied air (9).

For many decades the causative agents of the OAF and the action of these agents have been speculated upon. The death action of the OAF is still not fully understood. Currently, the OAF is thought to be the result of olefins reacting with the ozone (24,27,33). Olefins are unsaturated open-chain hydrocarbons that come from a variety of sources. The question of why the OAF is observed on bioaerosols outside and not inside is addressed by Cox (33). However, the components of the OAF may require time to condense or buildup on the surface of the particle.

Druett (59) observed, through experimentation, that germicidal action arose from the reaction of the ozone with the olefin fraction of unburned fuel. Testing the OAF effect on aerosolized microbes is very difficult because the influence is rapidly lost once outside air is enclosed in a test chamber (60). This loss is presumably due to the adsorption of the ozone + olefin gaseous complex to the walls of the holding container (60). Ozone + olefin products have been reported (27,60) to have short half-lives that may explain loss of reactivity as outside air travels through pipes and particulate filters.

The concentration of OAF, at a given location depends upon wind direction, factors influencing vertical mixing of air masses, time of day, etc. (27). OAF toxicity is at its greatest in air masses that have crossed urban and industrial areas (27,59). In an OAF study of air passing over industrial areas, urban areas, and the sea it was found that the OAF was absent in air passing over the sea and the highest microbial death rates were observed when air passed over cities and industrial areas (61). Because of the many variables involved, the toxicity of OAF can vary from one day or minute to the next (62). The effect of the OAF is increased by high RH levels (33).

The toxic effect of OAF on some bacteria and viruses results in the inactivation of coat constituents and nucleic acids (27). The effectiveness of the OAF is due less to high

toxicity than to the readiness of the components of the OAF to condense on aerosol particles (27).

In some microbes, nucleic acids and coat proteins are seriously affected by the OAF (33). However, microbes that tend to be resistant to UV radiation also appear to be resistant to the OAF (33). Cox (33) believes this may be related to the lipid content, whereas, organisms without surface lipids have a greater resistance to OAF and UV radiation than those with surface lipids, namely, gram-negative bacteria and viruses with envelopes containing lipids. The causative virus of FMD, a lipid free enveloped virus, has been given as an example of a microbe that can travel great distances (at least 100 miles) while retaining its viability and infectivity. This is possibly because of its OAF resistance (33).

Temperature

The sole effect of temperature on aerosolized microbes is difficult to ascertain because RH levels are related to environmental temperature. However, several studies with airborne viruses, in which the RH level was held constant, show the rate of aerosol decay increasing with increased temperature (10,24,42,45). In general, as the temperature decreases the survival/viability of aerosolized microbes increase.

Repair

According to Cox (33), the ability of microbes to survive the airborne state depends on their ability to repair damage. This ability depends on the chemical environment as well as the genetic makeup of the microbe (27). Repair of damage caused by solar radiation may be activated by exposure to wavelengths of light longer than the damaging wavelength (photo reactivation repair) or spontaneously in the dark (dark repair) (63). This may account for the rise in the airborne bacterial concentration seen in the late afternoon or after sunset.

UV Radiation

Electromagnetic radiation can reduce the survival of microbial aerosols (42). Hypothetically, airborne inactivation of bacteria after UV light irradiation is due to ruptured hydrogen bonds among water molecules or between water molecules and cellular nucleoproteins or thymine dimers (42,45). UV radiation is also known to increase the mutation rate of bacteria in aerosols (42), possibly leading to inactivation.

Many factors determine whether or not an aerosolized microbe is sensitive to UV radiation. UV radiation effects are dependent on bacterial or viral species, physiological state, light intensity and duration, and wavelength (64). For example, many viruses (especially enveloped viruses) are sensitive to visible light of short wavelength (31), but a FMD virus is less sensitive (more resistant) to sunlight (30).

Larger particles survive solar radiation better than smaller particles (42). This may be because of the protective action provided to organisms located in the interior of the particle. Bacterial aerosols generated from the dry state are less sensitive to radiation than those generated from the wet state (42). No explanation for this effect has been determined. However, it has been shown that dry disseminated aerosols undergo a spontaneous reactivation when held in the dark after UV radiation. This may have something to do with the increased survival of bioaerosols generated from the dry state.

In a study in which airborne bacteria were collected continuously (64), microbes collected at night were more sensitive to solar radiation than those collected on cloudy days. Bacteria collected during sunny days had the lowest sensitivity to solar radiation. As the solar radiation intensity increased, the time to reach a lethal dose decreased and cells died more rapidly. The organisms that were the most resistant to solar radiation were found in the upper atmosphere where the least amount of atmospheric protection exists (i.e., ozone). However, these UV-resistant organisms are rare.

Bacteria with pigmentation survive UV radiation exposure better than those without pigmentation (43,65). When taking culture samples of indigenous background microbes, pigmented bacteria are more prevalent than nonpigmented bacteria (43).

Berendt and coworkers (56,66), in the course of their research, saw a reaction between sulfur dioxide and UV radiation. They found that under certain circumstances, sulfur dioxide (0.4 ppm concentration) reduced the virucidal properties of UV radiation. They theorized that this effect was due to the radiation and the sulfur dioxide acting in an antagonistic manner, thereby reducing a possible enhanced combined effect. Some of the wavelengths of solar radiation may be absorbed by sulfur dioxide or sulfur dioxide may react with UV radiation, leading to the production of sulfuric acid that has little influence on viral inactivation (56,66).

Protection

The survival of aerosolized microbes can be related to the method of propagation (11), the spray fluid (24,40,42,45,46,67,68), culture age (24,44,69–71), growth media (24), and suspending media (40,45,71). For instance, at high RH levels, it was observed that aerosolized *E. coli* survival was better if the organism was grown on agar rather than in liquid media (42). The survival response of an aerosolized virus to RH levels is dependent greatly on the composition of the spray fluid (45,46,71).

The stage of growth of an organism also affects the aerosol stability. *Escherichia coli* and *S. marcescens* both exhibit increased decay rates when the organisms are harvested in the transition from lag to log phase, during growth (42). Organisms harvested during the stationary phase of growth survive the best (38,69,72). Aerosols generated from *E. coli* harvested during the stationary phase displayed a survival rate of 40%–50% in contrast to cells generated during the exponential or declining growth stages in which survival rates of 6% and 1% were respectively observed (70). Aged organisms have a greater resistance to osmotic shock than log phase organisms (42,44). This may be because of the "mature" cells having low metabolic activity (70). Organisms that

grow slowly are more resilient than those that grow quickly (24,70).

Adding a variety of compounds to either the growth media or to the slurry before aerosolization, can affect the survival of an aerosolized organisms. At low RH levels, the addition of salts to the slurry has been shown to protect enteric viruses (73). Polyhydroxy and amino compounds (41,45) as well as proteins (45), and sugars (24,27,33,38,42) can enhance aerosol survival of bacteria and viruses. These compounds replace water in protein structure during periods of desiccation. Raffinose and trehalose stabilize desiccated phospholipid membranes and inhibit membrane fusion (27,33). Cox and coworkers (24,42) lists amino acids, antibiotics, aromatic compounds, dyes, metal-chelating agents, polyhydric alcohols, salts, spent growth media, and sugars as protective additives. They state that relatively simple compounds such as inositol and sugars (di- and trisaccharides) offer the best microbial protection over the widest range of conditions. Israeli and coworkers (74) observed that trehalose, added to drying media, protected biomembranes and proteins from inactivation during the freeze-drying process. In their study with *E. coli* it was found that trehalose protected bacteria from known environmental hazards such as visible light, air, and RH levels. They stated that trehalose imparts protection by stabilizing the liquid-crystalline phase of the outer bacterial membrane, probably replacing the water molecules in the phospholipids. This prevents these molecules from denaturing, thus inactivating the bacteria. In a similar study conducted by Larson (75), using *Francisella tularensis*, it was observed that the effect of RH levels on biological decay was essentially eliminated by the additives raffinose and dipyridyl. Inositol has been shown to provide a broad range of protection from RH effects, specifically in aerosols of *E. coli* and *S. marcescens* (76). Inositol in the absence of water can form strong reversible hydrogen bonds with cellular proteins, thereby stabilizing the protein structure (41). Catalase added to collection media caused a significant increase (>63%) in the colony forming abilities of airborne bacteria (77). Catalase acts by removing or degrading hydrogen peroxide that is lethal to cells. Cellular catalase activity is reduced by stress that results in the accumulation of hydrogen peroxide.

Webb found that some bacteria that possess antibiotic resistance have a protein alteration that affords them increased aerosol stability (41). He further discovered that challenging an aerosol-sensitive species to certain antibiotics resulted in adaptations in which the organism became considerably more stable during air storage. Antibiotics that produced this effect were those that interfered with protein synthesis.

CONCLUSION

Table 4 is a summary of bioaerosol stressors and most probable target molecules. It is generally agreed upon that the major stressor of any bioaerosol is desiccation but it is difficult to isolate the effect of this stressor because of the complicating factors that are invariably present.

Table 4. Bioaerosol Stressors and Most Probable Target Molecules

Stress	Most Probable Target Molecules
RH and temperature	Outer membrane phospholipids, proteins
Oxygen	Phospholipids, proteins
Ozone	Phospholipids, proteins
Open-Air Factor (O_3 + olefins)	Phospholipids, proteins, nucleic acids
γ-rays, X rays, UV radiation	Phospholipids, proteins, nucleic acids

Source: Table Reproduced from Cox (1989) with the permission of the publisher (33).

Although many of the processes involved with bioaerosol inactivation are unknown, some generalizations regarding these microbes can be made (37):

1. Gram-negative bacteria survive best in conditions of low temperature and high RH levels.
2. Gram-positive bacteria survive better and longer than gram-negative bacteria in aerosols.
3. The sensitivity of gram-negative bacteria to oxygen depends on species.
4. Viruses with lipids in the envelope are more stable than viruses without lipids in the envelope. Viruses with lipid-containing envelopes survive better at RH levels less than 50%, whereas viruses without lipid-containing envelopes survive better at RH levels greater than 50%.
5. Normal survival characteristics can be altered by the addition of certain compounds.

It is obvious that the interactions affecting the transport and fate of bioaerosol particles have many variables resulting in very complex relationships. Each of these variables affect the survival and viability of the aerosolized microbe making it difficult to determine exactly what effect each variable actually has on the bioaerosol particle. Even the mechanisms and affects of factors that have been studied extensively are, in many instances, not fully understood. Further research and study is necessary to add to the body of knowledge that currently exists. Advances in technology, which helps us to design equipment and execute tests, make attaining this information possible.

BIOAUGMENTATION

MARY F. DEFLAUN
ROBERT J. STEFFAN
Envirogen, Inc.
Lawrenceville, New Jersey

Bioaugmentation is the addition of exogenous organisms to an environment to complement or replace an indigenous population. In the context of remediating polluted environments, bioaugmentation typically involves the addition of bacteria that have been selected for their ability to transform a target contaminant. In the last several years, bioaugmentation for pollution remediation has become increasingly popular. Consequently, the relative conceptual simplicity of the technology has spawned an industry involved in the sale of mixed or pure cultures of bacteria with the promised ability to degrade nearly any contaminant in virtually any environment. In actuality, the rational selection of bioaugmentation as a remedial alternative for a given site requires a detailed evaluation of the pollution profile (i.e., chemicals and their concentrations) and the hydrogeology of the site, as well as nontechnical driving forces such as regulatory demands, property owner interests, and ultimately the cost of cleanup in terms of both money and time.

The remediation of sites contaminated with chlorinated volatile organic compounds (CVOCs) has been a focus area for the development of bioaugmentation technologies. CVOCs are a family of chemicals that have been used extensively as industrial solvents and cleaning agents, and include perchloroethylene (PCE), trichloroethylene (TCE), dichloroethylene (DCE), vinyl chloride (VC), trichloroethane (TCA) dichloroethane (DCA), carbon tetrachloride (CT), and chloroform (CF). The widespread use of CVOCs, improper disposal practices, and their chemical properties and stability have led to them becoming common groundwater contaminants throughout the United States (1).

REMEDIATION HIERARCHY

Within the group of in situ bioremediation technologies there has developed a hierarchy of alternative remedies based on ease of cleanup and cost. The first level of the hierarchy is intrinsic biodegradation whereby indigenous microflora destroy the contaminant of concern before it creates a significant risk to downgradient receptors. This has become a natural first choice of remediation alternatives where applicable because it requires no intervention; just monitoring of contaminant concentrations and modeling of the groundwater flow and natural degradation rates.

The second choice in the hierarchy, biostimulation involves the stimulation of indigenous microbial populations to allow them to destroy the target chemicals. In this case, the observation is made that a natural population exists within the contaminated zone; however, specific nutrients, growth substrates, inducers, and/or oxygen are insufficient for microbial activity. Thus, through the introduction of the correct co-substrate, the native degradative population can be stimulated to grow and destroy the target contaminant.

In cases in which natural attenuation or biostimulation do not work because of insufficient or unacclimated indigenous microflora, bioaugmentation of the subsurface is an option. Selected strains of bacteria with the desired catalytic capabilities can be injected directly into the contaminated zones along with any required nutrients to effect the biodegradation of the target chemicals. Two distinct approaches have developed in the area of bioaugmentation for remediation of CVOCs. In the first approach (Type 1), degradative organisms are added to complement the native microbial population. The added microorganisms can be selected for long-term survival and the ability to occupy a selective niche within the contaminated environment, and stimulants or selective co-substrates, can be added to aid survival. Thus, the goal of the Type 1 approach is to achieve prolonged survival and growth of the added organisms and the concomitant prolonged degradation of the target pollutants.

In the second approach (Type 2), large numbers of degradative bacteria are added to a contaminated

environment as catalysts that will degrade a significant amount of the target contaminant before becoming inactive or perishing. Attempts can be made to increase the expression of the degradative enzymes or to maximize catalytic efficiency or stability, but the long-term survival, growth, and establishment of the biocatalyst are not the primary goals of the treatment approach. Additional microbial catalysts can be added as needed to further the degradation process. Although this review focuses on bioaugmentation for the remediation of chlorinated solvents, in particular TCE, examples of field-scale applications of bioaugmentation for other compounds are discussed.

ORGANISMS FOR BIOAUGMENTATION

Several classes of microorganisms can degrade TCE under the proper conditions (2). TCE can be biodegraded by aerobic bacteria, which oxidize aromatic hydrocarbons (3–6), methane (methanotrophs; 7–10), ammonia (11), and propane (12). All of these bacteria initiate the degradation of growth substrates and CVOCs by incorporating atmospheric oxygen through the action of enzymes known as oxygenases, and in each case the degradation appears to be co-metabolic; that is, the degradative organism does not gain sufficient metabolic energy from the oxidation of the CVOC to support growth of the organisms, but rather, the CVOCs are fortuitously oxidized by enzymes that have evolved to degrade other substrates. Furthermore, the oxygenase enzyme systems typically are only induced by growth in the presence of the specific hydrocarbon (e.g., toluene-4-monooxygenase is induced by toluene).

Anaerobic microorganisms can reductively dechlorinate and ultimately mineralize many of the CVOCs. This can occur co-metabolically or by dehalorespiration, a process that involves the chlorinated compound acting as the electron acceptor (13). Dehalorespiration in particular can effect dehalogenation at relatively high rates (14). Some of the lower chlorinated CVOCs can also be used as sole sources of carbon and their degradation does not require a co-substrate. There is only one strain that has been identified to date, that can degrade PCE all the way to ethene (15). In general, the stepwise pathway of degradation is mediated by a number of different bacteria. A number of these consortia have been enriched from environments in which reductive dechlorination is occurring (16–19).

IMPROVING ORGANISMS FOR BIOAUGMENTATION

The successful application of bioaugmentation for remediation of contaminated aquifers is limited by several physiological characteristics of CVOC-degrading organisms. For example, many bacteria in nature produce a glycocalyx layer and/or a variety of surface structures or polymers that aid in their adhesion to surfaces (20). As a result, bacteria tend to be very adhesive and they resist migration through tight matrices such as those existing in aquifer soils. Also, the initial oxidation of CVOCs is an energy and reductant requiring process, and thus, cofactors such as NADH are required for degradation (2). Furthermore, because the oxidation of CVOCs does not allow regeneration of sufficient energy to continue the oxidation process, supplemental energy substrates are needed to prolong degradation. Finally, the production of oxygenase enzymes known to transform CVOCs is typically tightly regulated at the genetic level. That is, degradative genes must be induced, and the inducers are typically the natural substrate for the enzyme. For example, CVOC-degrading toluene monooxygenase genes are induced by toluene. Thus, in addition to supplying a substrate for energy production, an inducing substrate must also be available.

To circumvent these limiting characteristics of natural CVOC-degrading microorganisms, the organisms may be modified to improve their utility for bioaugmentation. These modifications can often be accomplished by chemical mutagenesis and/or natural selection, or they can be made by using recombinant DNA techniques.

CONSTITUTIVE DEGRADATIVE ACTIVITY

A significant breakthrough in the development of organisms for remediating CVOC-contaminated aquifers has been the selection of organisms that constitutively produce degradative enzymes. In these organisms degradation of the target pollutant is uncoupled from growth of the organisms, thereby allowing the organisms to grow on alternative substrates while degrading the pollutant. Problems of competitive substrate inhibition or the requirement for using toxic or explosive co-substrates can potentially be eliminated.

In the first example of creating organisms that degrade CVOCs constitutively, Shields and Reagin (1992) (21) used transposon mutagenesis to generate insertional toluene-*ortho*monooxygenase (TOM) mutants of *Burkholderia cepacia* G4, and then selected spontaneous revertants of the mutants that expressed TOM constitutively. TOM is an enzyme that catalyzes the degradation of certain CVOCs. One resulting variant of this selection process, *B. cepacia* PR1, degraded TCE in the absence of inducing substrates such as phenol and toluene, and was extremely stable over more than 100 generations of growth. In further studies by the same group (22) a similar variant, *B. cepacia* $PR1_{301}$, was developed by traditional chemical mutagenesis. The latter strain is more applicable for bioaugmentation because it is not considered genetically engineered, and it has been evaluated in a series of laboratory and field demonstrations of bioaugmentation (see below).

In similar studies, a constitutive soluble methane monooxygenase (sMMO) variant of *Methylosinus trichosporium* OB3b was developed by chemical mutagenesis and revertant selection (23). The resultant strain produced sMMO, a broad-substrate range CVOC-degrading enzyme, even in the presence of relatively high copper concentrations, and during growth on methanol. Constitutive variants of CVOC-degrading phenol hydroxylase-producing organisms (24), toluene oxidizers (25) and isopropylbenzyne-degrading organisms (26) have been developed by using various recombinant DNA techniques.

Like *B. cepacia* $PR1_{301}$, any of these mutants could potentially be added to contaminated aquifers and fed noninducing, noncompetitive, growth substrates to prolong their degradative activity in situ.

In related work, McClay and coworkers (1995) (27) showed that TCE could act as an inducer of TCE degradation activity in the toluene-oxidizing bacteria *P. mendocina* KR1 and strain ENVPC5. Likewise, if *P. putida* F1, *P. pickettii* PKO1, or *B. cepacia* G4 were grown in the presence of TCE, the toluene oxidation genes were induced (28), and a wild-type toluene dioxygenase-producing *P. putida* degraded TCE in the absence of inducing substrates (29). Either of these strains could potentially be used for bioaugmentation where noninducing substrates are added to support degradative activity and TCE acts as the inducing substrate. Again, competitive inhibition between the growth substrate and the target CVOCs should be limited, but the added substrate could increase competition from nondegrading organisms.

ENHANCED TRANSPORT

Adhesion-deficient variants of CVOC-degrading bacteria should allow improved distribution of the biocatalysts throughout contaminated aquifers, and minimize problems of wellhead plugging during injection of organisms. Previous studies have demonstrated the feasibility of generating adhesion-deficient variants of a number of different bacterial strains by transposon mutagenesis, chemical mutagenesis, or by selection of naturally occurring adhesion-deficient variants from a population (30–35). In one study, greater than 91% of a highly adhesive strain of *Pseudomonas fluorescens* (Pf0–1) was consistently retained by a 3 cm tall, 12 g sand column (36). With this degree of attenuation, in situ transport would be limited to approximately 0.2 m in an unconsolidated sand aquifer. However, an adhesion-deficient variant (Pf0–5) with 40% retention in the same sand column would be capable of traveling approximately 1 m in a sandy aquifer.

By using this simple adhesion assay, transposon-generated adhesion-deficient mutants and natural variants of *P. cepacia* G4, *M. trichosporium* OB3b, *P. cepacia* $PR1_{301c}$, *P. mendocina* KR1, and *P. cepacia* ENV BF1 have been selected (37). Some of the variants adhere to the sand columns at less than 10%, while the wild-type strains adhere at greater than 90%. Model aquifer studies have demonstrated that several of these strains migrate through a 25 cm sand column at approximately the same rate as a conservative tracer. Thus, these metabolically proficient, adhesion-deficient strains are more suitable for in situ applications than the wild-type organisms because they are less likely to plug the injection well during application and they should travel farther into the subsurface, thereby increasing the effective zone of remediation.

In a related approach, Rothmel and coworkers (1998) (38) used surfactant foams to distribute strain ENV435 throughout a model aquifer. Because of their viscosity and scouring properties, surfactant microbubble foams (a.k.a. colloidal gas aphrons) are useful for removing dense nonaqueous liquids (DNAPLs) from aquifers. The foams flow effectively around heterogeneities in the aquifers, and remove more DNAPL than either water or liquid surfactant. By incorporating strain ENV435 into the foam, the strain was distributed evenly throughout a model aquifer, and it resulted in significantly greater TCE removal than treatment with foam only. Incorporating growth substrates, important nutrients, inducing substrates, or oxygen-generating compounds into the foam, even greater degradation might be expected.

Liquid surfactants and low ionic strength solutions also have been tested for enhancing transport of bacteria for bioaugmentation. Early work using glass beads as a model porous media indicated that a significant increase (0.16 to 60 m) in bacterial transport would result from some of these chemical treatments (39). However, subsequent work using the same bacteria and chemical additions, but with soils as the porous media, resulted in only moderate increases in transport (40). These moderate increases in transport would be sufficient to create small bioactive zones (~1 m), but would not be sufficient for dispersion of the bacteria throughout a plume.

Other efforts to enhance bacterial transport have shown that under conditions of controlled starvation bacterial cells become significantly smaller than active vegetative cells. These "ultramicro" bacteria produce less of a biofilm than vegetative cells and are able to penetrate deeper into consolidated materials than full-size cells (41,42). Once in place, the cells can be revived by adding the appropriate nutrients and/or carbon source. A similar approach could be applied with spore-forming cells (43).

Others have evaluated the use of encapsulation to improve survival and transport of bacteria added to the environment. In a study by Crawford and coworkers, the encapsulation of a PCP-degrading *Flavobacterium* improved its survival in groundwater (44). In this study, encapsulation procedures were modified from previously used techniques in order to create much smaller capsules that would both improve oxygen diffusion to the cells and improve the transport of the encapsulated bacteria in the subsurface.

ENERGY ENRICHMENT

All known aerobic CVOC-degrading microbes require a cosubstrate for sustained enzyme activity and metabolic survival. However, adding a cosubstrate to an aquifer can stimulate the growth of other non-TCE-degrading organisms and create problems with biofouling and oxygen depletion. Furthermore, some of the desired cosubstrates for CVOC degradation may be explosive (e.g., methane, propane, or butane) or toxic (e.g., phenol, toluene, or isopropylbenzene) and their use may be regulated or require the use of expensive equipment or excessive monitoring.

An alternative approach for enhancing and maintaining biological activity in situ is to utilize biocatalysts that are enriched in energy reserves. The production of energy storage polymers, most commonly poly-beta-hydroxybutyric acid (PHB), by bacteria is a long-studied phenomenon (45). PHB is produced naturally by many bacteria, typically under conditions of a nutrient limitation

and the presence of excess carbon, and it may account for up to 80% of the bacterial cell dry weight. Utilization of PHB as a reducing power substrate by methanotrophic bacteria degrading TCE has been demonstrated (46,47). Likewise, cells containing PHB may survive longer in groundwater than cells without PHB (48). Thus, selecting a degradative organism that produces storage polymers may be advantageous over selecting an organism that does not produce such polymers. In work performed by Steffan and coworkers (1999) (49), *B. cepacia* ENV435 was grown to optical densities ($O.D._{550}$) of greater than 65 (100 g/L wet weight) and so they contained as much as 60% dry weight of PHB.

An additional advantage of using energy-enriched organisms for in situ remediation, versus feeding indigenous or introduced organisms, may be that it forces more efficient utilization of added oxygen and inorganic nutrients. The degradative organisms carry an internal food reserve with them into the aquifer. The food reserve is not available to less efficient indigenous organisms and thus should not stimulate increased oxygen demand or biofouling associated with feeding indigenous microbes. The only additional oxygen that may be needed is that required to support oxidation of target contaminants and cellular respiration of the added strain.

MIXED CULTURES AND CONSORTIA

Most commercial-scale bioremediation applications of bioaugmentation involve the addition of mixtures or consortia of bacteria. This is particularly true in the area of hydrocarbon treatment where a number of vendors market products composed of uncharacterized mixtures of bacteria that have been cultured and prepared for application in the field. Few mixed cultures or consortia of organisms have been developed for remediation of CVOCs. This may be due, in part, to the fact that bacteria are not known to use CVOCs as a growth substrate. Therefore, it is difficult to enrich degradative organisms by using target CVOCs as a selective substrate. It may be feasible, however, to create stable mixtures of CVOC-degrading organisms by enrichment on substrates known to co-metabolize CVOCs. Such stable mixtures have been maintained for extended periods on methane, propane, toluene, and phenol (50–52) in the laboratory. Likewise, the stimulation of indigenous microbial communities by adding selective substrates to a contaminated environment undoubtedly selects for the enrichment of stable consortia that can sustain prolonged co-metabolic degradation of CVOCs. The use of such mixtures in bioaugmentation may provide more stable populations of organisms to help prolong degradation in situ.

EXAMPLES OF TYPE 1 BIOAUGMENTATION

Type 1 bioaugmentation involves the addition of degradative organisms to a contaminated environment with the goal of establishing an active degradative microbial population. Although this technique has been used extensively for destroying contaminants that can act as growth substrates for the added organisms, it has been applied less often for destroying targets that are only degraded co-metabolically. In the latter case, an additional substrate must be added to support the growth and degradative activity of the added organism.

A laboratory study performed by Krumme and colleagues (53) compared the TCE degrading activity and survival of wild-type *B. cepacia* G4 (54), with that of a transposon-generated mutant, strain PR1 that constitutively expresses the TCE-oxidizing enzyme toluene-*o*-monooxygenase (TOM). Both strains survived for extended periods (>10 weeks) in sterile aquifer material, but the population of each strain decreased by about three orders of magnitude during the same period. When PR1 was added to microcosms at an initial cell concentration of 5×10^8 CFU/g of aquifer material, it degraded TCE from 60 μM to less than 0.1 μM within 24 hours. When PR1 was added at lower cell densities, it continued to degrade TCE over the entire 10-week incubation, but the observed degradation rates were low relative to those observed with the high cell density inoculum.

In a related laboratory study, Munakata-Marr and coworkers (1996) (22) coupled bioaugmentation with biostimulation in aquifer microcosms. Aquifer microcosms were augmented with either *B. cepacia* G4 or a chemically induced mutant of the strain, *B. cepacia* $PR1_{301}$, which constitutively produces TOM. The augmented microcosms were then supplied with either phenol or sodium lactate, and TCE degradation in the microcosms was compared to degradation in microcosms that did not receive the degradative organisms.

When strain G4 and phenol were added in small columns to sterile aquifer material containing 250 μg/L TCE, there was no breakthrough of TCE during the first 37 days of incubation and several exchanges of TCE-contaminated water. Without the addition of G4, TCE degradation was not observed until approximately 19 days after biostimulation with phenol. The TCE concentration in microcosms augmented with strain $PR1_{23}$ and lactate, however, were not significantly different than in sterile controls. These results suggested that bioaugmentation could be effective, but that in this system, the constitutive expression of TOM during lactate feeding was not an effective mechanism for maintaining degradative activity.

In related experiments, microcosms were augmented continuously with lower concentrations of degradative organisms (22). Bioaugmentation with phenol-grown G4 alone generated TCE removals similar to those observed in microcosms fed only phenol. However, if lactate was added with the phenol-grown G4, TCE degradation was 70% greater than in microcosms receiving only G4 or only phenol. Similarly, if strain $PR1_{301}$ was added to microcosms with phenol, TCE degradation was about twice that observed in phenol-only microcosms, and it proceeded without a lag period. In each case, the addition of organisms resulted in a significant oxygen demand that could potentially limit the effectiveness of the technology.

Field Application — TCE

In an early in situ bioaugmentation field study, *B. cepacia* G4, was injected directly into a TCE-contaminated sandy aquifer with tryptophane added as an inducing

substrate (55). Data from the study strongly suggested that, although the organisms degraded TCE, movement of the microorganisms was severely retarded by the aquifer material, thereby limiting the effective treatment area. Tracer test results estimated the hydraulic flow of the aquifer to be approximately 48 feet per day. Nonretarded organisms, therefore, should have appeared in the nearest down gradient recovery well (10 ft.) about 8 to 10 hours after injection, but none of the injected microorganisms were observed in the monitoring well until six days after injection. No injected organisms were detected at a monitoring well located 75 feet downgradient from the injection well. Thus, it appears as though the injected cells acted essentially as an in situ biofilter. Clearly more aquifer material could be treated if the organisms or the aquifer conditions were altered to reduce adsorption and retardation of bacterial movement.

Despite the poor distribution of the biocatalysts, TCE degradation by the injected strain G4 reduced groundwater TCE concentrations from 2,500 μg/L to 466 μg/L for a period of about eight hours. TCE concentrations increased, however, to 3,280 μg/L the following day, presumably due to a nutrient feed pump failure. After another eight hours, TCE concentrations again declined and remained below 300 μg/L with a mean TCE concentration of 135 ± 72 μg/L over the first five days following G4 injection. The mean TCE concentration during the following 10 days was 78 ± 64 μg/L.

Although the authors did not estimate the total amount of TCE degraded, their data suggests that degradation was significant. The groundwater flow rate was 48 ft/day and the receiving zone (area in which bacteria were injected) was 20 ft wide and 14 ft thick with a porosity of 25%. The authors thus concluded that approximately 25,000 gallons of groundwater went through the test area per day. The average decrease in TCE concentration during the first five days (2,500 μg/L to 135 μg/L) represents an apparent TCE removal of about 1,100 g TCE. However, because the authors estimated that the nutrient addition system diluted the groundwater by 30%, the apparent amount of TCE degraded was approximately 800 g. Applying the same calculation for data obtained during the subsequent 10 days during which TCE declined to an average of 78 μg/L, the apparent amount of TCE degraded during the 10-day period was 1,600 g. Thus, the total amount of TCE degraded during the 15 days could have been as much as 2,400 g.

Survival of Introduced Bacteria

The ability of an exogenous organism to survive and compete for resources against indigenous organisms has long been an area of interest in both macro- and microbial ecology, and in most cases added organisms do not fare well. When three well-characterized toluene-degrading bacteria, *P. putida* PaW1, *B. pickettii* PKO1, and *B. cepacia* G4 were added to a fluid bed bioreactor with toluene as a feed source, strain PaW1 became the predominant organism in the reactor (56). When groundwater strains were allowed to enter the reactor, however, even strain PaW1 was rapidly replaced. Thus, even precolonization of the reactor with the added strain did not prevent it from being rapidly outcompeted by native microbes.

The oxidation of CVOCs might further hinder the ability of an added strain to survive in a natural environment. The oxidation of CVOCs is known to result in toxicity to the degradative organisms, presumably due to the production of highly reactive epoxide molecules that can react with and harm cellular components causing cellular inhibition (50,57,58). When four strains of toluene-oxidizing bacteria were placed in a reactor with a low feed rate of toluene, each strain was maintained at relatively constant levels (59). When TCE was added to the reactor, however, *P. putida* mt-2, which does not degrade TCE rapidly, became the dominant organism in the reactor. Kinetic analysis of the three strains that perished revealed that their affinity for toluene was greatly reduced after exposure to TCE. Remarkably, this same selection did not appear to occur when toluene was used to stimulate TCE degradation during a prolonged field study, as indicated by continuous TCE degradation for more than one year (60). In a related study, the addition of toluene or phenol to a TCE-contaminated aquifer resulted in the selection of a native toluene oxidizing bacterial population in which 55% of the strains contained toluene-ortho-monooxygenase, which is known to oxidize TCE. A more detailed analysis of the native strains revealed that a significant number of the strains (20%) were poor TCE degraders, and none degraded TCE as well as strain G4 (61). Nonetheless, CVOC degradation in the aquifer was relatively constant through several months of biostimulation (62).

An area that has not been well investigated is the selection of organisms with an inherent selective advantage for long-term survival, or the development of organisms, which have a selective advantage or that can be provided with an environment that gives them a selective advantage. For example, carbon tetrachloride (CT) degradation by *Pseudomonas* sp. strain KC was found to be greater under denitrifying conditions than aerobic conditions (63,64). Furthermore, degradation was inhibited by iron, but by adjusting the pH of growth media to 8.3, conditions under which iron is precipitated, this inhibition could be overcome (65). Thus, strain KC had a competitive advantage over other aquifer organisms if grown under nitrate-reducing conditions at high pH. By adjusting the pH and redox potential of a contaminated aquifer, one could create a selective niche for added strain KC. These characteristics allowed Criddle and coworkers (66) to demonstrate the use of bioaugmentation for the remediation of a CT-contaminated aquifer in School Craft, Michigan.

In the School Craft demonstration, NaOH-amended groundwater was used to maintain slightly alkaline conditions (pH>7.6), KC was injected, and acetate was added in weekly pulses to maintain degradative activity. During a period of poor chemical delivery incomplete degradation of CT occurred and chloroform concentrations increased. However, data from downgradient monitoring wells indicated that as long as the appropriate amendments were maintained, bioaugmentation was effective for CT remediation (66).

In a related approach, Lajoie and coworkers (1992) (67) isolated a bacterial strain, termed "field application vector," that was resistant to a surfactant that it could also use as a carbon source. By cloning degradative genes into the resistant organism, the researchers could add surfactants to an environment to create a selective niche, and then add the resistant strain containing the degradative genes (68). Such strains may be of use in bioaugmentation of aquifers during or after surfactant or foam flushing designed to remove free product contaminants (69,70).

Field Application — MTBE

Type 1 bioaugmentation is most applicable to contaminants that can serve as a sole source of carbon and energy for the degradative strain so that the addition of a carbon source is not necessary for growth and maintenance of the added strain in situ. Methyl *tert*-butyl ether (MTBE), a component of reformulated gasoline, is a contaminant that can serve as a sole substrate for bacteria (71–73), but these bacterial strains are not ubiquitous. Biostimulation approaches for MTBE degradation have utilized propane to stimulate indigenous propane-oxidizing bacteria to degrade MTBE co-metabolically, but this approach is not applicable to every site (74). Bioaugmentation, therefore, has been utilized to remediate this highly soluble contaminant.

Three demonstrations of this technology have been conducted at Port Hueneme Naval Facility in Oxnard, California. In the first demonstration, injection of a microbial consortium (MC-100) along with oxygenation of the aquifer, was compared to oxygenation only and no treatment, in three adjacent test plots (75). Although oxygenation alone appeared to stimulate indigenous MTBE-degrading strains after a considerable lag time, the plot with added bacteria had a faster and greater decrease in MTBE concentrations than in the oxygen-only plot. Two other demonstrations are currently being conducted with pure cultures of MTBE-degrading bacteria (76,77). Strain PM-1 was injected into a test plot in November 1999 next to an oxygen-only plot (77). Difficulties in oxygen delivery and degradation of MTBE by indigenous populations stimulated by the oxygen injection have made data interpretation difficult, and the contribution by PM1 to degradation of the MTBE in this demonstration has yet to be determined. Strain ENV425 is a propane-oxidizing bacteria that degrades MTBE co-metabolically. Bioaugmentation with this strain coupled with oxygen and propane injection is also being tested at Port Hueneme (76).

Hydrogenophaga flava ENV735 is an isolate that degrades MTBE as a sole food source (73). This strain was injected into a fractured bedrock aquifer contaminated with MTBE that previous tests had shown did not a decrease in concentration during previous tests when only oxygen was added (76). The addition of ENV735 with oxygen was shown to effect immediate decreases in the concentration of MTBE throughout the injection zone (unpublished results).

Anaerobic Bioaugmentation

For some sites and contaminants anaerobic degradation is more applicable than aerobic. This may be because one or more of the contaminants only degrades anaerobically or because the site is already anaerobic and adding enough oxygen to reverse this condition is technically infeasible. PCE only degrades anaerobically to TCE and by successive dechlorinations these chlorinated solvents can be degraded to the innocuous product ethene. If PCE is present, or if the aquifer is already anaerobic, anaerobic biostimulation is a viable remedial option. Often the addition of an electron donor (substrate) will be sufficient to stimulate the complete degradation of the higher chlorinated solvents to ethene, especially if there is some evidence of dechlorination already occurring. In a previously aerobic aquifer at Dover Air Force Base, DE, the addition of a substrate (lactate) and nutrients (nitrogen and phosphorus) were successful in turning the aquifer at the test site anaerobic and also stimulating the anaerobic dechlorination of TCE to *cis*-1,2 dichloroethene (cDCE). Further dechlorination, however, was not observed until the site was inoculated with an ethene-forming microbial consortium (78). A lag period of 90 days occurred between injection of the bacteria and the first appearance of VC, the degradation product of cDCE, and an additional 60 days before complete conversion to ethene. This lag period can be attributed to the small amount of bacterial inoculum ($<$35 g dry weight) and the slow growth rate of this culture.

EXAMPLES OF TYPE 2 BIOAUGMENTATION

Type 2 bioaugmentation involves the addition of degradative organisms as biocatalysts that can degrade a significant amount of target compound and then perish. The assumptions are made that the added organisms will not compete well against native organisms, and/or that the added organisms can be grown more efficiently ex situ (e.g., in a fermentor) than in situ.

In Situ Biofilter

In one field-scale demonstration of Type 2 bioaugmentation (79), approximately 5.4 kg (dry weight) of the CVOC-degrading methanotroph *Methylosinus trichosporium* OB3b were injected into a TCE-contaminated aquifer near Chico Municipal Airport in Chico, California. The cells were used to establish an in situ biofilter (a.k.a. biocurtain or biobarrier) of attached resting state cells (i.e., the cells were not fed after injection) through which contaminated groundwater was directed. Analysis of groundwater extracted from the aquifer indicated that approximately 50% of the bacteria injected into the aquifer were extracted by the pumping action, whereas the other 50% presumably became attached to the aquifer solids surrounding the extraction well.

TCE degradation by the in situ biofilter was very limited. Initially, the TCE concentration in the extracted groundwater was reduced from about 425 μg/L to less than 10 μg/L, but it remained at these low concentrations for only about two days. The TCE concentration then increased until, after 21 days, it was near the initial

(untreated) concentration. Integration of the TCE concentration over time revealed that only about 20 g of TCE were degraded during the 40-day study. This represented approximately 40% of the TCE extracted through the in situ biofilter, and only about 4% of the calculated degradation capacity of the injected organisms.

One of the greatest apparent limitations of the in situ biofilter approach is that contact between the added organisms and the contaminant is limited by the same physiochemical properties that limit any pump-and-treat technology, namely, the TCE present in the aquifer must undergo repeated sorption and desorption as it moves toward the biofilter and its associated extraction system (80). The rate-limiting step, as in any pump-and-treat system, therefore, is transport of the TCE to the treatment system. The biofilter in effect becomes the treatment process for the pumping system, and in order to be a viable technology it must be as reliable and inexpensive as competing treatment technologies. Given the long treatment times associated with pump-and-treat systems, it is unlikely that in situ biological systems can become as reliable or cost-effective as a standard ex situ stripping tower and/or activated carbon adsorption system. In fact, in the demonstration reported by Duba and coworkers, regulatory treatment standards were met for only two days.

In situ biofilters are an attractive remedial option, however, because they rely on the natural tendency of bacteria to stick to solid surfaces, and because the bacteria are immobilized, addition of cosubstrates, nutrients, or oxygen and contact between the bacteria and the additives is easily implemented. One strategy that has been developed to overcome the pump-and-treat limitations of this technology is the use of an electric current to deliver the contaminant to treatment zones created by hydraulic fracture injection. In two field tests of this technology for TCE remediation (81,82) the treatment zones were composed of carbon and iron filings. However, bench scale studies have demonstrated that inoculation of these treatment zones with degradative bacteria is an effective technology for the biodegradation of the electrokinetically-delivered contaminants (83).

Field Application — Bedrock Aquifer

In another field-scale demonstration of bioaugmentation, strain ENV435 was injected directly into a bedrock aquifer (84). Strain ENV435, is a variant of the toluene/TCE-degrading strain *B. cepacia* G4 (54). The strain had been mutated to select a new strain, *B. cepacia* $PR1_{301}$ that constitutively expressed the toluene monooxygenase genes that were responsible for TCE degradation (22). An adhesion-deficient variant of strain $PR1_{301}$ was selected by successive passage of the culture over a sand column (85). Finally, before introduction into a contaminated aquifer, the strain was grown to high cell density under conditions that promoted the production of high levels of poly-β-alkonoates that can serve as a high-energy storage material to prolong degradative activity (46).

To facilitate injecting the strain into the aquifer, pneumatic fracturing was used to expand bedrock fractures. Approximately 550 L of a high cell density culture ($\sim 10^{10}$ CFU/ml) of strain ENV435 was injected into the aquifer formation during the fracturing process, and results of plate count analysis demonstrated that the organisms were dispersed throughout the aquifer in a radius of about 25 feet from the fracture/injection well. Cell numbers in groundwater collected from monitoring wells were as high as 10^8 CFU/ml almost immediately after injection.

TCE concentrations in the formation rapidly decreased from between 20 to 30 mg/L to less than 5 mg/L within a few days after injection. A decrease in TCE degradation rate with time correlated with decrease in the viable ENV435 population during the same two-week period. It was estimated that during that study approximately 825 g of TCE were degraded by approximately 46,000 g (wet weight) of ENV435 cells. This corresponds to an apparent transformation capacity (Tc) of about 0.018 mg TCE/mg cells, which is greater than that estimated for a toluene-degrading enrichment culture (0.0073) but lower than that reported for a phenol-degrading enrichment culture (0.031) (51,52).

Field Application — Porous Aquifer

In a related study, strain ENV435 was injected during four separate tests into a semi-confined CVOC-contaminated aquifer located in Central New Jersey (49). The groundwater within the treatment zone was contained by recirculating groundwater from a downgradient recovery well into a series of upgradient injection wells. A hydraulically-isolated control plot was operated identically to the test plot, but without the addition of microorganisms. Results of the study indicate that in situ bioaugmentation can be an effective treatment alternative for CVOC-contaminated aquifers.

In the first field experiment, ENV435 was injected into six injection wells located approximately 12 m upgradient of the recovery well. Groundwater samples were recovered from monitoring wells located 2, 5, and 8 m downgradient from the injection wells. Strain ENV435 was enumerated by selective plating, and CVOC concentrations were determined by gas chromatography. In another experiment, strain ENV435 was injected into each of nine monitoring wells (2 depths each) throughout the test plot.

During the first experiment, the adhesion-deficient strain ENV435 was distributed throughout the test plot aquifer in a pattern similar to the distribution of a bromide tracer. Sodium bromide was distributed throughout the test plot within about 13 days after injection, whereas strain ENV435 was distributed throughout the plot within 20 days. The calculated retardation factor for ENV435 in the fine sand layer of the aquifer was only 1.25. These results suggested that adhesion-deficient bacteria can be effectively dispersed throughout an aquifer. However, even better distribution is likely when the adhesion-deficient strain is injected into multiple injection points throughout the contaminated aquifer (e.g., experiment 2). In this case, the radius of influence of the strains can be calculated to determine the spacing required between injection points (49).

When CVOC concentrations were monitored in the ENV435-amended test plot, a rapid decrease in CVOC concentrations followed the injection of ENV435. An analysis of the ratio of degradable CVOCs in the groundwater (TCE, DCE, and VC) to nondegradable CVOCs (PCE and TCA) confirmed that the observed decrease in CVOC concentrations was caused by biodegradation and not other factors such as dilution. During the first experiment, this ratio was lowest at the first monitoring well and increased at the downgradient wells suggesting that the degradative activity of the injected cells decreased with time and distance during the 15-day travel time through the aquifer.

When the strain was injected into monitoring wells spaced across the entire test plot (experiment 2), CVOC concentrations were reduced throughout the entire test plot within only a couple of days after injection. Furthermore, the ratio of degradable CVOCs to nondegradable CVOCs decreased at every monitoring point. Thus, if economically and logistically feasible, it appears that the best treatment strategy for applying Type 2 bioaugmentation is to use multiple biocatalyst injection points spaced to allow rapid dispersion of the organisms throughout the contaminated zone of an aquifer.

The bacterial transport and CVOC degradation data gathered during the field demonstration allowed the development of treatment and cost models. The treatment model incorporated ENV435 transport characteristics to determine the required spacing of injection points, and knowing the spacing requirements, allowed the calculation of cost of system installation. For a site with the dimensions of 152 m × 152 m × 6 m, and a CVOC concentration of 1,000 μg/L, estimated cleanup costs would be approximately $\$7/m^3$ ($\$5/yd^3$) and it would require only about one year to remediate the site. These costs are comparable to or less than competitive technologies including air sparging/soil vapor extraction with off-gas treatment.

CONCLUSION

Bioaugmentation, like most remedial technologies, is site- and contaminant-specific. In other words, whether or not bioaugmentation will be effective and how it will be implemented depends of the hydrogeology and geochemistry of the site as well as the mixture and concentration of the contaminants. Extremely high concentrations and free product contamination can be toxic or inhibitory to bacteria and not amenable to bioaugmentation without pretreatment to lower concentrations. For contaminants that are strongly sorbed to aquifer solids, injecting bacteria that will disperse or grow throughout the contaminated zone would be more effective than an in situ biofilter because of the length of time, that it would take for desorption of the contaminant from the aquifer solids to occur. If bacteria are dispersed throughout the contaminated zone, the ongoing degradation will increase the concentration gradient and desorption will occur more rapidly. On the other hand, if there is an ongoing source, or if the contaminants are highly soluble, an in situ biofilter may be an effective application of this technology. As with all in situ remedial technologies, contact of the bacteria and any needed additions (cosubstrates, nutrients, oxygen, etc.) with the contaminants is key to the effectiveness of the remedy.

Studies in environmental microbiology are often limited by the inability to unambiguously identify and directly quantify the enormous diversity of natural microbial populations. Our perspective on microbial diversity has improved enormously over the past few decades. In a large part, this has been due to molecular phylogenetic studies of related organisms. Phylogenetic tree based on gene sequences are maps that are used to articulate the elusive concept of biodiversity. The phylogenetic classification of microbes based on rRNA gene (rDNA) sequences offers a well-defined framework, which can be used to develop molecular tools for microbial identification. The rDNA molecules typically consist of highly conserved sequences interspersed with regions of more variable sequences. Together with the development of the PCR technique and a number of high-resolution molecular typing systems, this knowledge has provided an approach for microbial community typing. Many devices and methods have been developed and applied for microbial community typing, which include biosensors (1) capillary electrophoresis (2), the biochip technology (3) and others (4). The traditional typing methods used in microbiology consist of (*1*) Culture followed by morphological and physiological analysis, (*2*) Molecular biology methods [such as polymerase chain reaction (PCR), restricted fragment length polymorphism (RFLP), amplification fragment length polymorphism (AFLP), and PCR-RFLP of polymorphic loci, etc.]. Compared with the newly developed biochip methods, the traditional methods are laborious and time-consuming. The advantages of the biochip-based systems are obvious: sensitive, specific, fast, portable, and parallel sample analysis capability. In this article, we will first present a brief overview of microbial community ribotyping in environmental microbiology and then focus on the application of biochip-based devices and methods in microbiology, especially in microbial community ribotyping in environmental microbiology.

BACKGROUND OF MICROBIAL COMMUNITY RIBOTYPING

Microbial Community Typing

Modern taxonomic approaches often employ technically more complex methodologies and are concerned with profiling the structural composition of bacteria. This often involves approaches based on "molecular biology" or "analytical chemistry." It is now recognized that many of the classical schemes for differentiation of bacteria provide little insight into their genetic relationships and to some extent are scientifically incorrect. The new information has resulted in renaming of certain bacterial species and, in some instances, in the complete reorganization of relationships within and among many bacterial families.

The aim of typing is to identify stable groups in a population of the same species using markers that are reproducible, accurate, and conveniently detected. The complex characteristics (phenotypic patterns) are intuitively recognized as good indicators of relationship. The characters of bacteria that are traditionally used for typing include biotypes, antigenic structure, phage susceptibility, and so forth. Genotypic information or sequence information is superior to phenotypic information in two ways for relating and classifying microorganisms: (*1*) the results can be more readily, reliably, and precisely interpreted, and (*2*) the results are innately more informative of evolutionary relationships than the phenotypic information. The elements of a sequence, nucleotides, or amino acids are restricted in number and are well defined. The subjectivity that goes into the judgments "same," "similar," and so forth at the phenotypic level is replaced by simple, more objective judgments and mathematical definitions.

In the past several years, sequence analysis of the entire genome of one representative (i.e., a strain) out of a few bacterial species has been achieved. For species identification, it would be ideal to compare the sequences of the entire bacterial chromosomal DNA. However, this is currently not a practical approach, because enormous amount of efforts has to be put in to sequence millions of nucleotides for each strain. An alternative way is to assess the genomic similarity by the content of guanine (G) + cytosine (C), usually expressed as a percentage (% G+C). This has lately been replaced by two different approaches, namely, hybridization or sequence analysis of the genetic coding segment for 16S rRNA.

Ribosomal RNA

The story of the ribosomal RNA (rRNA) begins in 1960s, but not much progress was made until the early 1970s, when Woese realized that rRNA is universal to life and that much historical information could be stored in it. Comparative analyses of small-subunit (SSU) rRNA (16S or 18S rRNA) and other gene sequences show that life falls into three primary domains — Bacteria, Eukarya, and Archaea (5). Since then, the three-domain theory based on rRNA has been widely accepted.

The ribosome is a molecular machine in which all the proteins are synthesized. In the past few years, sequence analysis of 16S rRNA has become the "gold standard" in bacterial taxonomy. This is due to its molecular ubiquitousness and the functional constancy. The 16S rRNA changes very slowly in sequence and can be easily traced through experimentation. Moreover, as the central component of the highly complex translation apparatus, rRNA is among the most refractory of molecules to the vagaries of horizontal gene flow and so was considered

likely to avoid the phylogenetic hodgepodge of reticulate evolution (6).

The nucleotide sequence of the 16S rRNA gene is about 1,500-letters long, and consists of many domains. The 16S rRNA changes very slowly in sequence, which makes it an accurate chronometer. The sequence of 16S rRNA provides a measure for genomic similarity above the level of the species and allows comparison of relatedness across the entire bacterial kingdom. Closely related bacterial species often have identical rRNA sequences. The technique thus provides complementary information to DNA-DNA hybridization. Exploiting this basic research in the clinical laboratory has allowed the development of probes for improved identification of bacterial pathogens.

A large collection of SSU rRNA-targeted DNA probes has been developed for studies in environmental microbiology. They have been designed to identify phylogenetic groups of different evolutionary depths, corresponding in general to the taxonomic ranks of species, genus, family, and higher. In particular, the use of group-specific DNA probes complementary to the SSU rRNA has provided a comprehensive framework for studies of microbial population structure in complex systems. However, to fulfil such studies, it is highly desirable to conduct independent hybridization of multiple environmental samples to multiple DNA probes. Biochip as a new platform can meet just this requirement.

BIOCHIP-BASED DEVICES AND METHODS

Biochip is a fingernail-sized solid device used for the analysis of biomolecules (e.g., DNA, RNA protein etc.) in parallel. A typical analytical system usually consists of three classical steps, for example, sample preparation, chemical reaction, and detection. The total integration of these three steps has been the dream for many years for both academic researchers and entrepreneurs. The marriage between molecular biology and the semiconductor industry for the first time brings this hope to the scientific community. The use of biochips will substantially increase the research speed in molecular biology and they will find their way in environmental microbiology, especially in bacteria community typing, which is now mainly based on the analysis of sequence diversity of 16S rRNA. Biochip-based systems can be made small and compact and thus suitable for field and point-of-care use for which hand-held analyzers are required.

Classification of Biochips

Passive Biochip. The passive biochip specifically refers to devices on which no functional elements have been fabricated to actively generate forces for molecule manipulation. The reaction takes place simply on the basis of the specific binding of complementary DNA or RNA and the specific recognition of antigen and antibody via random diffusion process. The results obtained from the passive biochip are displayed in an arrayed format. When compared with the traditional single-probe hybridization method, DNA microarray technology demonstrated its advantage of being able to perform nucleic acid hybridization analysis in a high-throughput and low-cost way.

Active Biochips. The active biochip (7) refers to devices on which elements with different functions have been fabricated to generate forces (i.e., electric force, magnetic force, acoustic force, etc.) for active manipulation of cells and molecules.

Most biological molecules are charged and can be moved and concentrated by electric fields. Cells or microparticles with molecules attached can be manipulated by inducing the dipole on the particles, which is independent of the native charges carried by these materials. Research reports on active biochips are currently limited. Companies such as Nanogen, Caliper technologies, Aclara, and AVIVA Biosciences are the leaders in this category. Among these, AVIVA is the only company making chips capable of producing multiple forces either sequentially or simultaneously depending on the actual needs of the experiment. The advantage an active biochip has over a passive chip is the speed, accuracy, and sensitivity in reaction and detection. Using active biochip-based analytical systems, the entire sample-to-result process could be completed in minutes.

Chip-Based Sample Preparation

Traditionally, the sample preparation step involves numerous operations (e.g., pipetting, centrifugations, extraction, precipitation, etc.) on a large quantity of samples. They are often labor-intensive and time-consuming. Recently, chip-based small disposable devices have been developed for handling biological samples. Many reports (8,9) have been dedicated to cell manipulation and nucleic acid extraction, that is, separation and transportation of cells and isolation of DNA and RNA molecules.

An effective microscopic sample preparation method should be sensitive to certain cell properties and selective for cell types to allow for discrimination and separation of target cells, requiring little or no sample pretreatment. So far, only a few microscopic-scale cell-manipulation concepts have been demonstrated including diffusion-based particle separation and detection; microtitration of cell samples that exploits the cell size and mechanical properties (10); and electronic separation of cells that makes use of the electrical properties of cells (11). Figure 1 shows the separation of *Escherichia coli.* from blood using a microfabricated dielectrophoretic chip.

The San Diego–based company AVIVA Biosciences is known for its unique multiple-force chips (Fig. 2). These

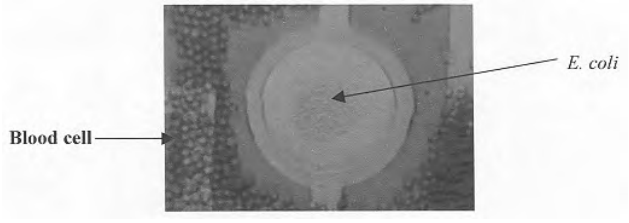

Figure 1. The separation of *E coli.* from blood using a microfabricated dielectrophoretic chip. See color insert.

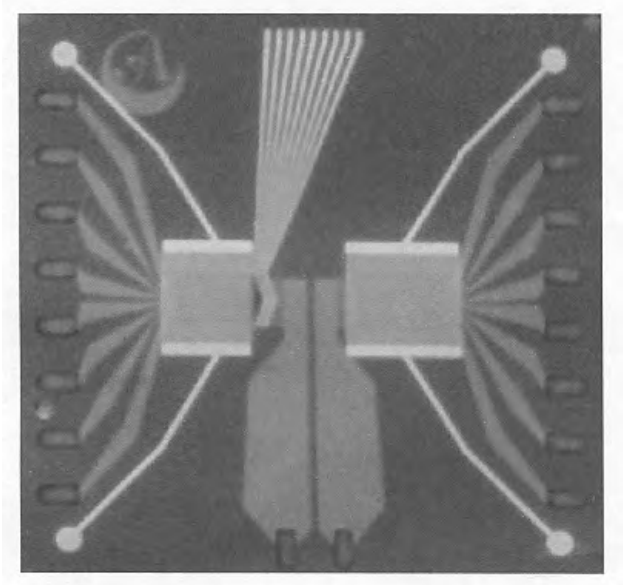

Figure 2. A microfabricated multiple-force active biochip capable of isolating various bioanalytes from a complex biological sample. With permission from AVIVA Biosciences. See color insert.

chips can produce a variety of physical forces and are useful for actively manipulating a variety of bioanalytes such as cells, proteins, DNA, and RNA. The combined use of AVIVA biochips with microbeads provides the capability for separating and manipulating diversified bioanalytes from crude biological samples. Extraction, purification, and concentration of nucleic acids from complex biological samples are the initial steps in any nucleic acid–based assay. This is necessary because the nucleic acids from live organisms are protected inside the living cell. Once the cell is broken open, nucleic acids will be released into solution and become accessible for analysis. However, other biological chemicals may also be present in the solution. Many of these biochemicals, such as proteins and metal complexes, tend to bind with the nucleic acids and therefore interfere with the followed DNA or RNA amplification reaction. Hence, to successfully carry out nucleic acid amplification, it is essential to eliminate those contaminating materials.

Oxidized silicon surface is useful for capturing nucleic acids. Christel described such a system for rapid nucleic acids analysis (12). The extraction, purification, and concentration of DNA from test samples have been accomplished using fluidic microchips with high surface area to volume ratios. Short (500 bp) and medium size (48,000 bp) DNAs have been captured, washed, and eluted using the silicon dioxide surfaces of these chips. DNA quantities approaching 40 ng/cm^2 of binding area were captured from input solutions in the 100 to 1,000 ng/ml concentration range. The extraction efficiency was about 50% with diluted samples of interest for pathogen detection.

Chip-Based Reactions

Chip-based reactions are usually represented by various enzymatic reactions such as PCR amplification reaction, or proteinase K digestion, chemical labeling reaction, and so on.

The nucleic acids extraction studies can be divided into two types: high-concentration inputs and low-concentration inputs (at or below 10^5 copies/mL). These two regimes have relevance to different clinical situations. Samples involving genomic DNA, such as whole blood, typically possess large quantities of DNA. On the other hand, samples for diagnosing infectious diseases often contain minute amount of pathogenic nucleic acids of interest. Serum, plasma, and urine are examples for the latter case. For studies on high concentration, the quantities of DNA are large enough to conduct direct fluorescence assay. For low concentrations, however, amplification reactions such as PCR must be used to first amplify a target sequence.

PCR chips shown in Figure 3 have been used to perform nucleic acid amplification (13). It has been assumed since the first illustration of microchip-based PCR in the early 1990s that features such as low reagent consumption, low-volume sample requirement, and rapid cycling would be a consequence of this technology. PCR reactions previously taking up to three hours were shown to be feasible with time as little as 20 minutes (14). It will require considerable effort to overcome many difficulties in fluidic control, efficient thermocycling, surface chemistry, specimen introduction, and quantitation of amplicons. However, it is quite clear now that microchip-based amplification will play a major role in molecular biology and find wide application in environmental microbiology.

Chip-Based Detection

The detection of nucleic acids is usually achieved by using two approaches. One approach is a "separation-based detection" such as electrophoresis, chromatography, spectrometry; the other one is a hybridization-based approach.

Chip-Based Electrophoresis Systems. Capillary electrophoresis (CE) is an attractive technique. In the last decade, chip CE has been made possible in separating and analyzing DNA samples within a few minutes or even seconds. It may eventually prove to be a valuable tool for microbiologists.

Different materials (e.g., silicon, glass, and plastics) have been used as substrata for fabricating chip CE devices. A variety of fabrication processes have been developed to accommodate the complicated requirements. Biochip-based CE systems have demonstrated their uses

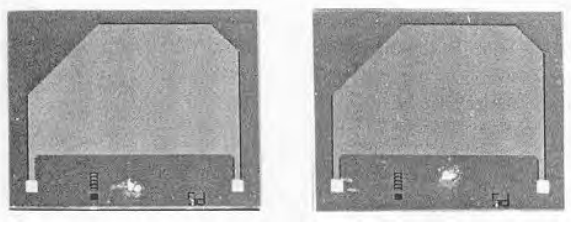

Figure 3. Microfabricated silicon-glass PCR chips. See color insert.

in diverse applications such as the separation of amino acids, DNA or RNA fragment sizing, DNA sequence analyses and CE-based laboratory-on-a-chip systems.

A fused silica CE chip has been fabricated and used for fast-DNA profiling (15) with a replaceable denaturing polyacrylamide matrix. Baseline resolution was achieved with four amplicons representing loci of the *CSF1PO*, *TPOX*, *THO1*, and *vWA* genes in less than two minutes. This represents a 10- to 100-fold increase in the speed of separation compared with the conventional capillary or slab gel electrophoresis systems. Ribosomal RNA samples were reportedly separated in an injection-molded plastic microchannel with a cross section of 100×40 μm and with an effective length of one centimeter.

Hybridization-Based Biochips. Hybridization analysis offers many advantages over other methods of DNA identification, such as comparative size or relative migration determination, by providing insight into the specific nucleotide sequence being investigated. Specifically, with hybridization, spatial position of sequence-specific probes the corresponding signal intensity generated by these probes provide the basis for analyzing complex genetic mixtures for sequence-specific characteristics.

Microchip-based nucleic acid arrays now permit the rapid analysis of genetic information by hybridization. Many of these devices take advantage of sophisticated silicon manufacturing processes developed by the semiconductor industry over the last 40 years. With these devices, parallel hybridization was made possible with immobilized capturing probes. Stringency and rate of hybridization are generally controlled by temperature and salt concentration of the solutions used for hybridization and wash. The passive microarray approaches have the following limitations: (*1*) All nucleic acids are exposed to the same conditions simultaneously — capture probes should be made with similar melting temperatures to achieve similar hybridization stringency; (*2*) The rate of hybridization is proportional to the initial concentration of the interrogated solution — high concentrations are therefore required to achieve rapid hybridization; (*3*) Hybridization conditions are difficult to control — single base discrimination is generally restricted to oligomers of 20 bases or less.

Many of the limitations with passive hybridization techniques can be overcome by using active biochips, which can generate desired forces, thus facilitating (*1*) the rapid transport and selective addressing of DNA molecules to the test on the chip surface; (*2*) speedy hybridization process; and (*3*) rapid discrimination of single base mismatches in target DNA sequences.

A research group at Yale University has produced an RNA-based microarray that promises to put a powerful diagnostic lab on a dime-sized chip (16). To create the prototype, they placed the RNA switches (a molecular switch is a molecule that can be turned on or off by another molecule or compound) on a gold-coated silicon surface and arranged them in clusters. Each switch was designed to bind only to a specific molecule — its "target" — and then release a signal that identifies the target molecule. They tested the array of RNA switches on a variety of complex mixtures. In one experiment, they successfully identified different strains of *E. coli* found in bacterial cultures. This array is able to simultaneously identify a potentially large number of compounds and, combined with the precise exclusivity of each switch, adds up to a recipe for a powerful and wide-ranging laboratory on a dime-sized slice of silicon.

Micro-Total Analysis System

The detection of microorganisms is important in disease diagnosis, in guaranteeing the safety of food and water supply, and in ensuring public safety from the threat of biological warfare agents. In many of these applications, the time taken to provide the result is a critical issue. A portable system that is easy-to-use, and yet would provide a rapid result, would be of great benefit. A fully integrated biochip-based micro-Total Analysis System (μTAS) or "lab-on-a-chip" possessing the aforementioned merits usually consists of (*1*) chip-based sample treatment, such as cell separation, cell fractionation, and nucleic acid extraction; (*2*) chip-based biochemical reaction, such as PCR, immunoassay, and fluorescent labeling; (*3*) chip-based detection, such as electrophoresis, chromatography, spectrometry, and "hybridization-based" approaches. However, to complete such a system will require the use of other microelectromechanic system (MEMS)-based devices including microheaters, valves, pumps, and detectors. Such a system, once constructed, would allow for the generation of very sophisticated biochemical and biomedical information with simplified steps. Figure 4 is the schematic of such a system.

The first Lab-on-a-Chip system was developed and reported by Cheng and coworkers (17). Using the same type of photolithographic and deposition techniques employed in the microelectronics industry, Cheng and colleagues have created a $1\,cm^2$ silicon chip that functions as a lab. The manufactured bioelectronic chip consists of an addressable array of 25 platinum 80-μm diameter microelectrodes covered by an agarose permeation layer in a 4.84-μl flow cell. The alternating current field that is set up in the chip separates cells by dielectrophoresis. Different cell types locate to different regions of the microelectrode array. Weakly held cells located in interelectrode regions of low field strength

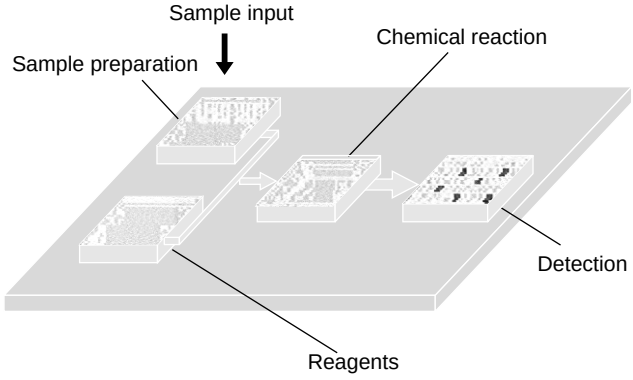

Figure 4. Illustration of a lab-on-a-chip system.

can be selectively removed by washing. The chip isolates *E. coli* cells from a whole blood sample in about 4 minutes through the use of dielectrophoresis, followed by electronic lysis and proteolytic digestion. The lysate contained a spectrum of nucleic acids including RNA, plasmid DNA, and genomic DNA and was further examined by electronically enhanced hybridization assay on a second bioelectronic chip. Cultured cervical carcinoma cells were similarly isolated from normal human blood cells by this group using the same device in a modified manner.

THE APPLICATIONS OF BIOCHIPS IN MICROBIOLOGY

Study the Relationships Between the Microbes and the Hosts

For more than a century, microbiologists studied pathogens in pure culture, whereas cell biologists studied mammalian cells in tissue culture. A few years ago, researchers realized that these laboratory methods of growing pathogens and their hosts were quite artificial and had very little in common with real life, wherein pathogens and hosts coexist, interact, and compete in conditions that are often far from optimum. To better mimic what happens in real life, the study of the interaction between microbes and host cells was proposed, taking advantage of technological progress that allowed cocultures of microbes and cells to be handled together. For this reason, a new discipline (cellular microbiology) was born (18) and a powerful new approach to cellular microbiology was described (19). Instead of studying one parameter at a time, microarray-based methods allow the study, within a single experiment, of all the host genes and those of the bacteria whose expression is modified during host–pathogen interaction: the global picture of the dialog between the pathogen and the host in one experiment.

High-density genome-wide microarrays of eukaryotic cells are commercially available. Homemade chips can also be printed when the genes are available. In the past few years, sequencing of the entire genome of one representative (i.e., a strain) of a few bacterial species has been achieved. These include *Helicobacter pylori*, *Neisseria meningitidis*, *Mycobacterium tuberculosis*, and *E. coli.* Chips containing all genes of the sequenced bacterial genomes are either commercially available or homemade, and many more will be available in the near future.

A typical microarray experiment is shown in Figure 5 (20). RNA is prepared from bacteria culture in standard laboratory conditions (a), from host cells grown under optimum conditions in tissue culture (b), and from cells that have been infected with bacteria (c). RNA is converted into fluorescent cDNA by incorporation of different fluorochromes during the reverse-transcription reaction (typically by using Cy3- and Cy5-dCTP). The labeled cDNAs are then hybridized to microarrays containing bacterial probes (d) or eukaryotic probes (e).

In the experiment shown in Figure 5e, the RNA prepared in (b) and labeled with Cy3 (green) is mixed with the RNA prepared in (c) and labeled with Cy5 (red). The two fluorescent cDNAs are then mixed together and hybridized to the chip. Sometimes, RNA prepared from a pool of control conditions or cells is used to prepare

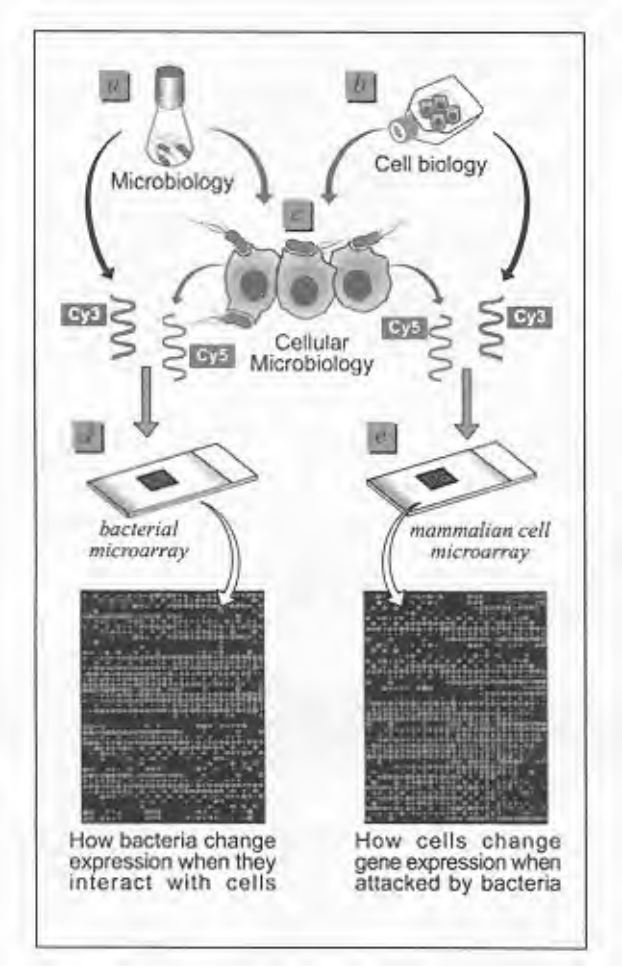

Figure 5. Schematic description of how microarrays can be used to study host cell–pathogen interactions (20). See color insert.

a Cy3-labeled reproducible control, which is then mixed with Cy5-labeled cDNA prepared from the experimental condition, including uninfected cells. This allows an invariant comparator, so that any experimental profile can be compared with any other. After hybridization, laser scanning, image detection, and analysis of each chip, the ratio of the targets in Figure 5b and c provides a precise indication of the relative expression of the genes of the mammalian cells grown in the conditions in Figure 5b and c. More specifically, for the labeling reaction [RNA in Figure 5b (Cy3) or RNA in Figure 5c (Cy5)], the red spot indicates gene activation after bacterial addition to the cells, and a green dot refers to the downregulation of the gene, whereas a yellow spot indicates no change in gene expression. The final results of the analysis are the expression ratios of Figure 5b or c obtained from the mean value of two labeling conditions.

Biochip may be used in the study of infected tissues and whole organisms. The possibility of studying pure cultures of pathogens while they interact with pure cultures of mammalian cells is exciting and represents a major step forward from traditional studies, in which pathogens and host cells were studied separately. However, even the in vitro infection of host cells is far from a real-life

scenario in which pathogens infect animals and their tissues. There is no doubt that the technology is available for studying host cell and pathogen-gene expression in whole organisms. For instance, bacteria recovered from infected tissues (blood, cerebrospinal fluid, etc.) should be suitable for sample preparation. Similarly, macrophages and lymphocytes from infected organisms and tissue from patients with chronic infections can be recovered and used for sample preparation.

So far, published studies describe only the host response to infection. Many studies regarding the bacterial response to host cell contact are in progress.

As an example (19), DNA microarray has been used for studying the transcriptional responses of respiratory epithelial cells to *Bacillus pertussis*. *Bacillus pertussis* is the causative agent of whooping cough, which has many well-studied virulence factors and a characteristic clinical presentation. Despite this information, it is not clear how *B. pertussis* interacts with host cells in disease generation. In this example, the authors examined the interaction of *B. pertussis* with a human bronchial epithelial cell line (BEAS-2B) and measured host transcriptional profiles by using high-density DNA microarrays.

The results showed that *B. pertussis* induces mucin gene transcription by BEAS-2B cells and then counters this defense by using mucin as a binding substrate. A set of genes is described for which the catalytic activity of pertussis toxin is both necessary and sufficient to regulate transcription. Host genomic transcriptional profiling, in combination with functional assays to evaluate subsequent biological events, provides insight into the complex interaction of host and pathogen.

Biochip-Based Microbial Community Ribotyping

Current analytical techniques used for the determination of microorganisms are rarely automated, usually require incubation in a suitable medium to increase the number of organisms, and generally employ visual and/or chemical methods to identify the strain or subspecies of interest. The inherent delay in such methods frequently necessitates medical intervention before definitive identification of the nature of an infection. In industrial, public health, or clinical environments, such delays may have unfortunate consequences. Therefore, there is a concrete need for any possible convenient systems that are capable of rapid detection of microorganisms. Ribotyping is mainly based on the sequence information of the bacterial 16S rRNA and, once combined with oligonucleotide microchip techniques, should have widespread applications in environmental and medical microbiology.

Oligonucleotide microchips are the widely used format for determinative and environmental studies in microbiology. Oligonucleotide microchips were originally developed for rapid sequence analysis of genomic DNA, that is, sequencing by hybridization with oligonucleotides in a matrix. For example, a single-stranded DNA fragment about 200-bases long could be hybridized in parallel with all the 65,536 possible DNA 8-mers. In principle, the DNA sequence of the fragment can be reconstructed from the pattern of hybridization to the chip. However, this method has not yet been adapted for large-scale sequencing projects because of the problems resulting from inefficient discrimination between perfect and mismatched duplexes, secondary structure within the single-stranded DNA (or RNA), and the presence of tandem repeats in the DNA to be sequenced. Yet, it has proven to be an excellent method for sequence analysis of mutations, gene polymorphisms, and other genetic changes and has been further extended to the studies in microbial ecology.

Nitrifying Bacteria Typing. Nitrifying bacteria have proved particularly difficult to study using cultivation techniques because of their long generation times and poor counting efficiencies. Thus, a rapid, culture-independent enumeration technique for nitrifiers could greatly facilitate research in their ecology.

Guschin and coworkers (21) described the utility of parallel hybridization of environmental nucleic acids to oligonucleotides immobilized in a matrix of polyacrylamide gel pads on a glass slide (oligonucleotide microchip). Oligonucleotides complementary to small-subunit rRNA sequences of selected microbial groups, encompassing key genera of nitrifying bacteria, were shown to selectively retain labeled target nucleic acid derived from either DNA or RNA forms of the target sequences. The utility of varying the probe concentration to normalize hybridization signals and the use of multicolor detection for simultaneous quantitation of multiple probe-target populations were demonstrated. The technique should provide a powerful format for the systematic exploration of natural microbial diversity.

Mycobacterium Species Identification and Rifampin Resistance Testing. One of the applications of high-density DNA probe arrays for bacteriology focuses on fastidious bacterium diagnostics. Using oligonucleotide as the probe, the potential of the microarray strategy for parallel testing of different targets has been demonstrated in this study, as the same hybridization conditions could be used for the three genes tiled on the mycobacterial array (16S rRNA, *rpoB, katG*).

Tuberculosis (TB), caused by members of the *M. tuberculosis* complex, is one of the most common human infectious diseases, causing three million deaths a year worldwide. Although the disease is associated with impoverished economic conditions, TB is on the rise in many industrialized nations. The spread of TB is due to immigration, the emergence of drug-resistant strains, and the AIDS epidemic. Reduced and compromised immune function as found in newborns, infants, and immunosuppressed individuals allows opportunistic infections caused by mycobacteria other than *M. tuberculosis*, such as *M. avium-intracellulare*, *M. chelonae*, *M. fortuitum*, *M. Kansasii*, *M. xenopi*, *M. marinum*, *M. scrofulaceum*, and *M. zxulgai.*

The increasing number of mycobacterial infections has made it clinically important to quickly identify mycobacteria at the species level. The diagnosis of a pathogenic versus a nonpathogenic species not only has epidemiological implications but also is relevant to the demands of patient management. Individuals with highly contagious infections may be isolated to prevent the spread

of the disease. Antibiotic treatments may vary according to the species encountered.

The emergence of drug-resistant *M. tuberculosis* has created additional concern in the event of TB diagnosis. Recently, a number of genetic changes leading to rifampin, isoniazid, pyrazinamide, and ethambutol resistance have been characterized and allowed for the development of probe-based assays for antibiotic resistance.

Traditionally, species identification within the genus *Mycobacterium* and subsequent antibiotic susceptibility testing rely on time-consuming, culture-based methods. Despite the recent development of DNA probes, which greatly reduce assay time, there is a need for a single-platform assay that is capable of answering the multitude of diagnostic questions associated with this genus.

Troesch and coworkers (22) described the use of a DNA probe array on the basis of two sequence databases: one for the species identification of mycobacteria (82 unique 16S rRNA sequences corresponding to 54 phenotypical species) and the other for detecting rifampin resistance (*rpoB* alleles). They designed an array that contained all the 16S rRNA polymorphisms over a 200-bp region present in a mycobaterial database. The array also contained 51 *M. Tuberculosis* rifampin resistance-causing *rpoB* mutations in a 200-bp region and 2.2 kb of the *M. Tuberculosis* wild-type *katG* gene—this fragment spanning codons in which mutations were previously shown to confer resistance to isoniazid. An experimental protocol was optimized to perform hybridization on the probe array, scanning, and data analysis in one hour. The hybridization-based probe array assay used here showed a specificity matching the sequence polymorphisms of the 16S rRNA marker. In this study, a total of 26 out of 27 species were correctly identified and so were all of the *rpoB* mutants, with the only discrepancy being an artifact because of an error in the reference sequence. This parallel testing format opens new perspectives in terms of patient management for bacterial diseases by allowing a number of genetic tests to be simultaneously run.

Portable System for Microbial Sample Preparation and Oligonucleotide Microoarray Analysis. The limitation with microarray technology is the lack of portability and inexpensive devices for the acquisition of hybridization patterns. The group headed by Mirzabekov has developed a three-component system and a rapid inexpensive procedure for analysis of different microorganisms based on microchip biotechnology (23).

The system consists of three main components: (*1*) a universal syringe-operated silica minicolumn for successive DNA and RNA isolation, fractionation, fragmentation, fluorescent labeling, and removal of excess free label and short oligonucleotides; (*2*) microarrays of immobilized oligonucleotide probes for 16S rRNA identification; and (*3*) a portable battery-powered device for imaging the hybridization of fluorescently labeled RNA fragments with the arrays.

The minicolumn combines a guanidine thiocyanate method of nucleic acid isolation with a newly developed hydroxyl radical-based technique for DNA and RNA labeling and fragmentation. DNA and RNA can also be fractionated through differential binding of double- and single-stranded forms of nucleic acids to the silica. The procedure involves sequential washing of the column with different solutions. No vacuum filtration steps, phenol extraction, or centrifugation is required. After hybridization, the overall fluorescence pattern is captured as a digital image or is recorded by a polaroid camera.

This three-component system was used to discriminate *E. coli*, *Bacillus subtilis*, *Bacillus thuringiensis*, and human HL60 cells. The procedure is rapid: beginning with whole cells, it takes approximately 25 minutes to obtain labeled DNA and RNA samples and an additional 25 minutes to hybridize and acquire the microarray image using a stationary image analysis system or the portable imager. This is the first passive chip-based total analysis system for environmental microbiology; the portable system may be further used in microbial identification in medical, agricultural, or environmental applications. Although the system is not perfect, it has demonstrated the promise of applying biochip technology in environmental microbiology.

PERSPECTIVE

It is increasingly evident that only a small fraction of the microbial world has been characterized, although there is little agreement about the full extent of undescribed diversity. The development of rRNA-targeted probes that selectively target characterized phylogenetic groups now provides a format to systematically address this question. These probes are fully compatible with the microchip format.

Biochip is one of the most promising biotechnologies for the twenty-first century, which has the advantage of combining a rapid, high-throughput and portable platform for nucleic acid hybridization. In addition to their use in identifying described phylogenetic groups, the great capacity of the microchip array could be used to evaluate sequence motifs of the novel microbial populations. Thus, we anticipate that the microchip will have application not only to microbial community ribotyping but also in ongoing studies of global diversity.

BIOCONTROL, MICROBIAL AGENTS IN SOIL

ILAN CHET
LEONID CHERNIN
The Hebrew University of Jerusalem
Rehovot, Israel

Plant pathogens affect crops throughout the world and are a major obstacle to effective food supplies worldwide. Losses due to plant diseases may be as high as $30 to $50 billion in cultivated and stored crops and 20% of total food production annually. The most efficient way of preventing crop diseases caused by these pathogens is to use chemicals to disinfect the soil against pathogens and pests. However, pesticides, common in agricultural practice, create a health hazard for many nontarget organisms. Their use becomes more limited every year because of concern of legislators for human and animal health, as well as for quality of life and the environment. In addition, excessive application of pesticides has led to an increased proportion of pathogens, which are resistant to the chemicals. Thus, each year, diseases cause millions of dollars worth of crop damage, despite extensive use of pesticides. Moreover, many nonspecific chemical pesticides currently widely used against soilborne diseases (e.g., methyl bromide) are soon to be taken off the market as a result of registration cancellation (1). Therefore, the development of safer, environmentally friendly control alternatives that promote sustainable agroecosystems is urgently required and has become a research priority in developed countries. Agricultural biotechnology offers a new approach to the problem: the development of alternative, efficient, and ecologically safer biological methods of plant disease control (2–6).

Biological control can be defined as "any conditions under which survival or activity of a pathogen is reduced through the agency of any other natural or modified living organisms and genes or gene products (delivered by organisms) as well, with the result that there is reduction in incidence of the disease caused by the pathogen" (2). Chemicals produced and delivered by living organisms represents biological control, whereas chemicals extracted from living organisms represents chemical control. A beneficial organism used to protect plants is referred to as a "biological control agent" (BCA), "biopesticide," "microbial pesticide" or, simply as "antagonist," because it "antagonizes," or interferes with, the target organisms that are damaging the plant.

Antagonists are generally naturally occurring, mostly soil microorganisms, which have some trait or characteristic that enables them to interfere with pathogen or pest growth, survival, infection, or plant attack. Usually, they have little effect on other soil organisms, leaving the natural biology of the ecosystem more balanced and intact than would a broad-spectrum chemical pesticide. Several plant diseases caused by soilborne plant pathogens have been shown to be inhibited by soils. Soil suppressiveness may be constitutive, an inherent property of the soil regardless of its cropping history, or adaptive, whereby soil suppression is only achieved after a specific cultural practice, such as monocropping, has been adopted. Soil suppressiveness of *Fusarium* wilt of melons (7) and of *Gaeumannomyces graminis* var. *tritici* (*Ggt*)-take-all of wheat (2) are examples of constitutive and adaptive soil suppression, respectively. Soil suppression is considered a rather complex phenomenon in which the antagonists establish themselves in the soil and interfere with the growth or survival of the pathogenic microorganism. Several microorganisms can be involved in soil suppression of a single disease. Studies of why some soils can naturally suppress plant diseases while others cannot have provided the basis of most research on BCAs.

Biological approaches to the control of soilborne plant pathogens were discovered more than 70 years ago in the classical works of G. Sanford and R. Weindling, however, it was only in the 1960s that biological control research took on a more practical approach (8). Since that time, many agrochemical and biotechnological companies throughout the world have increased their interest and investment in the biological control of plant diseases and pests. The current market for BCAs is estimated at only $500 million, which is about 1% of the world's total output for crop protection. The largest share of this market involves biopesticides marketed for insect control (mainly products based on *Bacillus thuringiensis* strains which produce a protein toxin with strong insecticidal activity) and these bioinsecticides represent around 4.5% of the world's insecticide sales. Other agents used for biocontrol exist on a much smaller scale commercially. However, the biopesticides market is expected to grow over the next 10 years at a rate of 10 to 15% per annum, versus 1 to 2% for chemical pesticides (1). Despite the fact that the total register of commercially available

biocontrol products is still small, their number has increased more than twofold in the last few years. For plant pathogens alone, the current list of microbial antagonists available for use in commercial disease biocontrol includes around 40 preparations (3,5). These are all based on the practical application of several species of nonpathogenic bacteria and fungi able to suppress plant pathogen growth (Table 1). The main topics discussed in this review are the following: the: biocontrol of soilborne diseases and nematodes by fungal and bacterial biocontrol agents, mechanisms of biological control, formulation, and delivery of biocontrol agents, combined usage of biocontrol agents, integrated pest management, and molecular approaches for improvement of biocontrol agents.

BIOCONTROL OF SOILBORNE DISEASES

Fungi as Biocontrol Agents

Fungi are relatively easy to grow and formulate for large-scale application. The first fungal antagonist to have been introduced commercially was *Peniophora* (Phlebia) *gigantea*, used for the control of *Heterobasidium* (*Fomes*) *annosum* root rot on pines (9). Since then several other fungi have been marketed as BCAs (Table 1). Among them, the necrotrophic mycoparasitic fungus *Gliocladium virens* Miller, Giddens, and Foster (=*Trichoderma virens* Miller, Giddens, Foster, and von Ark) is a common soil saprophyte and one of the most promising and studied fungal BCAs. *Trichoderma*, a genus of hyphomycetes and an anamorphic Hypocreaceae (class Ascomycetes) closely related to *Gliocladium*, is also common in the environment, especially in soils. Species of this genus have been used in the production of cellulolytic and hemicellulolytic enzymes, biological control of plant disease, biodegradation of chlorophenolic compounds, and soil bioremediation. The first report on a biological control experiment using *Trichoderma* spp. under natural field conditions came from Wells and coworkers (10), who used *Trichoderma harzianum* grown on an autoclaved mixture of ryegrass seeds and soil to control *Sclerotium rolfsii* Sacc. Since that time, more *Gliocladium* and *Trichoderma* isolates have been obtained from natural habitats and used in biocontrol trials against several soilborne plant pathogenic fungi under both greenhouse and field conditions (11,12). In particular, isolates of *G. virens*, *Gliocladium roseum*, *Trichoderma viride*, *T. harzianum* Rifai, and *Trichoderma hamatum* have been reported to be antagonists of many phytopathogenic fungi, including *Botrytis cinerea*, *Fusarium* spp., *Phytophthora cactorum*, *Pythium ultimum*, *Pythium aphanidermatum*, *Rhizoctonia solani*, *Sclerotinia sclerotiorum*, *S. minor*, *S. rolfsii*, and several other fungal pathogens that cause soilborne and foliage diseases in a wide variety of economically important crops under a wide range of environmental conditions. The antagonists kill the host by direct hyphal contact, causing the affected cells to collapse or disintegrate; vegetative hyphae of all species have been found susceptible. Thus, treatment of soil infested with propagules of *R. solani* or *P. ultimum* with *G. virens* resulted in a significant reduction in the number of viable *R. solani* sclerotia. Several isolates of *T. harzianum*, capable of lysing mycelia of *S. rolfsii* and *R. solani* by application to pathogen-infested soil, significantly reduced the diseases caused by these fungi in bean, cotton, tomato, and eggplant seedlings under greenhouse conditions. A seed treatment was developed to reduce the amount of *Trichoderma* added to the soil to control soilborne plant pathogenic fungi. *Trichoderma hamatum* conidia applied in the laboratory to seeds of pea and radish provided protection to seeds and seedlings from *Pythium* spp. and *R. solani*, respectively, almost as effectively as fungicide seed treatment. A *T. harzianum* isolate applied to either soil or rooting mixture efficiently controlled damping-off induced by *P. aphanidermatum* in several crops with disease reduction of up to 85%. Commercial preparations based on strain *T. harzianum* T-22 (Table 1) are sold to the greenhouse, row crop, and turf industries. Applied as a seed treatment, as a drench or incorporated into the soil as granules, the strains significantly increase yield of field corn, wheat, potato, and other crops. Granules of T-22 added to potting materials used in the production of vegetables and ornamentals reduced the incidence of diseases caused by *Fusarium* and other pathogens. The strain was shown to be highly rhizosphere competent, resulting in long-term root colonization and substantial advantages to plant growth and productivity (13).

Biological control of wilt pathogens that penetrate the vascular system of their hosts (e.g., *Fusarium oxysporum* or *Verticillium dahliae*) and that may attack the plant at various growth stages is considered to be less feasible than control of plant pathogens, which induce damping-off. In the latter case, the host is only susceptible to the pathogen for a limited time, at the early growth stage of the plant, after which it is not susceptible to infection. Thus, for biocontrol of damping-off, protection is required for only a limited time. This might be the reason for the slower progress in developing introduced antagonists for biocontrol of wilt pathogens. Nevertheless, *T. harzianum* T-35 isolated from the rhizosphere of cotton plants grown in fields infested with *Fusarium* significantly reduced the disease incidence caused by *F. oxysporum* f. sp. *vasinfectum*, *F. oxysporum* f. sp. *melonis* and *F. roseum* Culmorum in cotton, melon, and wheat, respectively, in greenhouse trials when applied as a peat-bran preparation, a conidial suspension or a seed coating. In trials over two successive growing seasons against *Fusarium* crown rot of tomato in fields naturally infested with *F. oxysporum* f. sp. *radici lycopersici*, this isolate provided a significant increase in the total yield of tomatoes (11). This and several other isolates of *Trichoderma* are produced commercially for the biocontrol of soilborne and aerial fungal diseases (Table 1).

Other fungal BCA, *Pythium nunn*, a necrotrophic fungus with a limited host range, was isolated from soil suppressive to a plant parasitic *Pythium* sp. The fungus efficiently suppresses growth of *P. ultimum*, *P. aphanidermatum*, *R. solani*, and *Phytophthora parasitica* by penetration and/or lysis of the host cell wall at the site of interaction. It can be used alone or in combination with *T. harzianum*. The fungus *Talaromyces flavus* (Klocker) A.C. Stolk and Samson is a mycoparasite of several soilborne plant pathogenic fungi, including

Table 1. Examples of the Microbial Products Containing Living Organisms Currently Employed for Biocontrol of Crop Diseases and Nematodes

Biocontrol Organism	Trade Name	Formulation	Application	Examples of Target Pathogens/Effects	Examples of Target Crop
Bacteria					
Agrobacterium radiobacter strain K84	Galltrol-A, Nogall, Diegall, Norbac 84 C	Culture grown on agar, culture suspensions	Bacterial suspension applied to seeds, seedlings, cuttings, roots, stems, and as soil drench	Crown gall disease caused by *A. tumefaciens*	Fruit, nut, and ornamental nursery stock
Bacillus subtilis strains GB03, FZB24 and others	HiStick N/T, Kodiak, Kodiak HB, Kodiak AT, Rhizo-Plus, Rhizo-Plus Konz, Serenade, Subtilex, System 3	Dry powder usually applied with chemical fungicides	Water-based slurry seed treatment; water-based suspension for in-furrow treatments, hopper box treatment, seed treatment, soil drench, dip, and addition to nutrient solutions	*Alternaria* spp., *Aspergillus* spp., *Fusarium* spp., *R. solani*, *Streptomyces scabies Verticillium*	Barley, beans, corn, cotton, peanut, pea, potatoes, rice, soybean, ornamental plants
Burkholderia cepacia	Dany, Intercept	Peat-based dried biomass from solid fermentation; aqueous suspension	Applied to seeds with a sticking agent in planter box (aqueous suspension formulation is for use in drip irrigation or as a seedling drench)	*Fusarium* spp., *Pythium* sp.; *R. solani*, nematodes	Alfalfa, barley, beans, clover, cotton, peas, sorghum, vegetables, wheat
Pseudomonas aureofaciens strain Tx-1	Spot-Less	Liquid	Over-head irrigation	Anthracnose, Dollar spot, Michrochium patch (pink snow mold), *P. aphanidermatum*	Turf grass
Pseudomonas chlororaphis	Cedomon	Seed treatment	Seed dressing	*Fusarium* sp., Leaf stripe and spot.	Barley and oats; potential for wheat and other cereals
Pseudomonas fluorescens A506	BlightBan A506	Wettable powder	Bloom time spray of the flower and fruit	Frost damage, *Erwinia amylovora*, and russet-inducing bacteria	Almond, apple, apricot, blueberry, cherry, peach, pear, potato, strawberry, and tomato
Pseudomonas syringae strains ESC10, ESC11	Bio-save 100, Bio-save 1000	Frozen cell concentrated pellets	Pellets added to water to produce liquid suspension, postharvest application to fruit as drench, dip, or spray	*Botrytis cinerea*, *Geotrichum candidum*, *Mucor pyroformis*, *Penicillium* spp.,	Pome fruit, citrus
Streptomyces griseoviridis strain K61	Mycostop	Powder	Drench, spray, or through irrigation system	*Alternaria brassicola*, *Botrytis* spp., *Fusarium* spp., *Phomopsis* spp., *Phytophthora* spp., *Pythium* spp., and	Field, ornamental, and vegetable crops
Fungi					
Ampelomyces quisqualis	AQ10	Water-dispersible granules	Spray	Powdery mildew	Apples, cucurbits, grapes, ornamentals, strawberries, and tomatoes

(*continued overleaf*)

Table 1. (*Continued*)

Biocontrol Organism	Trade Name	Formulation	Application	Examples of Target Pathogens/Effects	Examples of Target Crop
Coniothyrium minitans	Contans, Kony	Water-dispersible granule	Spray, granules incorporated into soil or soilless mix	*Sclerotinia sclerotiorum*, *S. minor*	Canola, sunflower, peanut, soybean, vegetables, and ornamental flowers in greenhouse production
Fusarium oxysporum, non-pathogenic	Biofox C Fusaclean	Spores, dust, or alginate granules	In drip to rock wool; incorporate in potting mix; soil incorporation; seed treatment	*Fusarium oxysporum*, *Fusarium moniliforme*	Asparagus, basil, carnation, cyclamen, gerbera, and tomato
Gliocladium catenulatum	Primastop	Wettable powder	Drench and incorporation	*Botrytis* spp., *Didymella* spp., *Pythium* spp., *Rhizoctonia* spp.,	Greenhouse crops
Gliocladium virens strain GL-21	SoilGard	Alginate granules	Granules incorporated in soil or soilless growing media prior to seeding	*Pythium* spp. and *R. solani*	Ornamentals, food crops
Paecilomyces lilacinus	Paecil	Dry spore concentrate	Seedling or soil drench	Various nematode spp.	Banana, wheat, and potatoes
Phlebia gigantea	Rotstop, P.g. Suspension	Spores in inert powder	Spray, chain saw oil	*Heterobasidium annosum*	Trees
Pythium oligandrum	Polyver-sum	Wettable powder	Root and stem drench, spray	*Aphanomyces* spp., *Alternaria* spp., *Botrytis* spp., *Fusarium* spp., *G. graminis* , *Pythium* spp., *Phytophthora* spp., *R. solani*, *S. cepivorum*, *Tilletia caries*	Canola, Cereals, fruits, forest nurseries, legumes, vegetables, and ornamental plants
Talaromyces flavus isolate V117b	Protus WG	Water-dispersible powder	Soil or seed treatment, soil drench, root dip application	*Rhizoctonia solani*, *V. dahliae*, *V. alboatrum*	Cucumber, tomato, and rapeseed oil
Trichoderma harzianum strain Y	Trichoderma-2000	Peat-bran preparation	Incorporated into soil or potting medium	*Fusarium* spp., *Pythium* spp., *R. solani*, *S. rolfsii*	Nursery and field crops
Trichoderma harzianum strain T-22 (KRL-AG2)	PlantShield, RootShield, RootShield Home and Garden, T-22 Planter Box, Turf Shield,	Wettable powder, granules, or dry powder	Granules added in-furrow, by broadcast application to turf, mixed with greenhouse soil, or by mixing powder with seeds in planter box, or in commercial seed treatment slurry	*Fusarium* spp., *Pythium* spp., *R. solani*, *Sclerotinia homoeocarpa*	Bean, cabbage, corn, cotton, cucumber, peanut, potato, sorghum, soybean, sugar beet, tomato, turf, greenhouse ornamentals
T. harzianum strain T39	Trichodex	Wettable powder	Spray	*Botrytis cinerea*, *Collectotrichum* spp., *Fulvia fulva, Monilia laxa, Plasmopara viticola, Pseudoperonospora cubensis, Rhizopus stolonifer, S. sclerotiorum*	Cucumber, grape, nectarine, soybean, strawberry, sunflower, tomato
T. viride Pers ex Gray	EcoSOM, Trieco	Powder	Dry or wet seed, tuber, or set dressing or soil drench, spread/broadcast over field	*Fusarium spp., Pythium spp.*, *Rhizoctonia spp.*	Tobacco, cereals, citrus, coffee, cotton, grapes, oilseeds, soybean, tea, tomato, vegetables, and others

(*continued overleaf*)

Table 1. (*Continued*)

Biocontrol Organism	Trade Name	Formulation	Application	Examples of Target Pathogens/Effects	Examples of Target Crop
Trichoderma harzianum other strains, *Trichoderma* spp.	Bio-Fungus, Root Pro, Supresivit	Granular, wettable powder, sticks, and crumbles	Applied after fumigation; incorporated in soil; sprayed or injected	*Armillaria*, *Botryosphaeria*, *Chondrosternum*, *Fusarium*, *Nectria*, *Phytophthora*, *Pythium* spp.,*Rhizoctonia*, *Sclerotinia*, *Verticillium*	Flowers, strawberry, trees, vegetables
Mixture of *T. harzianum* and *T. viride*	Trichopel, Trichoject, Trichoseal, Trichodo-wels				
Mixture of *T. harzianum* and *T. polysporum*	Binab T	Wettable powder and pellets	Spray, mixing with potting substrate, mixing with water and painting on tree wounds, inserting pellets in holes drilled in wood	Pathogenic fungi that cause wilt, take-all, root rot, and internal decay of wood products and decay in tree wounds	Flowers, fruit, ornamentals, turf, and vegetables

Modified from D. Fravel's list of commercial biocontrol products for use against soilborne crop diseases, updated on September 20, 2000 and available through the Internet (*http://www.barc.usda.gov/psi/bpdl/bpdlprod/bioprod.html*).

S. sclerotiorum, *R. solani*, and *Verticillium* spp. The mechanism by which *T. flavus* controls plant pathogenic fungi is not always clear and in some cases, it may involve a combination of antibiosis and mycoparasitism. The necrotrophic mycoparasite *Coniothyrium minitans* Campbell has been found to be a natural destructive mycoparasite of *S. sclerotiorum*, which kills both hyphae and sclerotia of this phytopathogen. Infection by *C. minitans* actually provided natural biological control of *S. sclerotiorum* and *Sclerotium cepivorum* under greenhouse conditions and in the field. *Coniothyrium minitans* could be recovered from the soil more than a year after its application, and during this time it spread throughout the greenhouse, indicating its potential for long-term control. The fungus *Fusarium chlamydosporum* was shown efficient against groundnut rust caused by *Puccinia arachidis*, whereas the soilborne fungal BCAs, *Trametes versicolor*, and *Pleurotus eryngii* were effective against *F. oxysporum* f. sp. *lycopersici* race 2 on tomato. The fungus *Penicillium purpurogenum* protected peach and tomato against the plant pathogens *Monilinia laxa* and *F. oxysporum* f. sp. *lycopersici.* Isolates of *T. flavus* and *Stenotrophomonas maltophilia* were shown to antagonize *S. rolfsii* and *P. ultimum*, respectively. The biotrophic mycoparasite *Sporidesmium sclerotivorum* Uecker, Ayers, and Adams is a dermatiaceous hyphomycete, which was isolated from field soil. The fungus has been found to be an obligate parasite on sclerotia of *S. sclerotiorum*, *S. minor*, *S. trifoliorum*, *Sclerotium cepivorum*, and *B. cinerea* under natural conditions (14). The fungus *Ampelomyces quisqualis* Ces. has been reported as a biotrophic mycoparasite and BCA of many fungi, which cause powdery mildew. An isolate of *A. quisqualis* M-10 obtained from an *Oidium* sp. infecting *Catha edulis* in Israel was developed as a BCA (preparation AQ10–Table 1) of several powdery mildew fungi belonging to the genera *Oidium*, *Erysiphe*, *Sphaerotheca*, *Podosphaera*, *Uncinula*, and *Leveillula* (15).

Bacteria as Biocontrol Agents

Many strains of soilborne and rhizospheric bacteria have been used for biocontrol of plant disease. The bacteria are easy to grow and can be applied as a seed treatment or as a soil drench, and mechanisms by which they reduce disease have been studied. The bacteria appear to protect plants against a wide range of pathogens and the potential for commercial utilization is promising. Bacterial BCAs can reduce disease by different modes of action, including production of antibiotics, toxins and lytic enzymes, direct parasitism of pathogen hyphae or propagules, competitive exclusion by occupation of infection sites and/or depletion of nutrients, plant growth enhancement and induction of host resistance mechanisms (3).

Most bacterial BCAs are gram-negative. Among them, *Agrobacterium radiobacter* strain 84 is probably the best example of the application of a bacterial antagonist for the biocontrol of an economically important plant pathogen *Agrobacterium tumefaciens*, a causal agent of crown gall disease in a large number of crops and considered one of the most destructive agricultural pathogens. Introduction of this strain into agricultural practice was the first case of successful commercialization of a BCA (16).

Rhizospheric bacteria belonging to the fluorescent *Pseudomonas* spp. are receiving increasing attention for the protection of plants against soilborne fungal pathogens (3). These bacteria, defined as root-inhabiting, plant growth-promoting rhizobacteria (PGPR) have been shown to improve plant health and increase yield. PGPR may exert their effect directly and/or indirectly by the suppression of plant pathogens, thereby providing biological control (17). Direct promotion of plant growth may be exerted by several mechanisms, for example, via the production of auxin and other plant hormones, synthesis of siderophores, biological nitrogen fixation, solubilization of minerals such as phosphorus, or via

enzymatic activities such as 1-aminocyclopropane-1-carboxylate (ACC) deaminase, an enzyme, which decreases the endogenous concentration of ethylene. PGPR strains producing this enzyme may have a competitive edge over other microorganisms in the rhizosphere because they can use ACC as a source of nitrogen (18). Several other mechanisms have been proposed to account for PGPR's disease-suppressive ability, including antagonism, and induced resistance. However, before the deliberate use of PGPR and other bacteria as biofertilizers and BCAs, it is necessary to know some key parameters, such as root colonization capacity, location of infection site, and degree of persistence of the inoculum. The most suitable techniques for studying these parameters are microscopical and immunological.

One of the most intensively studied biocontrol systems using rhizobacteria was generated after the isolation of *Pseudomonas fluorescens* strains from a soil naturally suppressive to Gtg-take-all of wheat. These fluorescent rhizosphere-colonizing bacteria, when applied as seed treatments to a soil conducive to the diseases, provided significant disease control. Other pseudomonad species with biocontrol activity have been described. Among them strains of *Burkholderia* (*Pseudomonas*) *cepacia*, *Pseudomonas aureofaciens*, *P. chlororaphis*, *P. corrugata*, *P. putida*, and *P. syringae* (3,5).

Besides *Pseudomonas* spp., several other gram-negative bacteria exhibit highly efficient biocontrol activity. For example, the bacterium *Enterobacter cloacae* was shown to be a capable BCA of different rot and pre-emergence damping-off diseases incited by *Pythium* spp., as well as of fusarium wilt and of some other plant diseases caused by fungal pathogens (19,20). Biocontrol potential was also demonstrated for strains of *Serratia marcescens* and *Enterobacter agglomerans* producing chitinolytic enzymes (21,22).

Gram-positive bacteria of *Bacillus* spp. are widely dispersed in nature, easy to reproduce, have a long shelf life when sporulated, and are nonpathogenic. The ability to produce endospores provides bacilli with a high tolerance to heat and desiccation. Therefore, they have a significant ecological advantage over other bacterial antagonists (23). Several strains of *Bacillus* are now produced commercially as BCAs (Table 1). Because *Bacillus subtilis* is a spore-forming organism, it is extremely tolerant of environmental stresses, including seed treatment pesticides, soil and seed pH, cultivar effects, edaphic factors, and long-term storage. It is readily produced with current fermentation technology. Other BCAs, such as *Pseudomonas* spp., do not readily adapt to large-scale production methods, and stability is a limiting factor.

BIOCONTROL OF NEMATODES

Nematodes are small, round worms, which are common inhabitants of many natural environments. Some of them are pathogenic to plants. Plant parasitic nematodes are major agronomic pests, with the annual global loss in agriculture of U.S. $100 billion worldwide caused by nematode damage to plants. The most important nematodes are root-knot (*Meloidogyne*), which have multiple generation per year and are the leading cause of crop loss due to plant parasitic nematodes, and cyst (*Heterodera* and *Globodera*) nematodes that have a single generation per year and cause damage mainly in the early root-infection process.

Natural enemies of nematodes include viruses, rickettsias, bacteria, and nematophagous fungi. Antagonists most likely to be receptive to management for the biocontrol of nematodes are trapping fungi, fungal egg pathogens or parasites, endoparasitic fungi, fungal pathogen or parasites of females, endomycorrizial fungi, plant growth-promoting bacteria, obligate bacteria parasites. The parasitoid endospore-forming bacterium *Pasteuria penetrans*is able to survive in the soil under extreme conditions and destroys nematodes by parasitic action. This bacterium is an obligate parasite of many nematode species thought to be responsible for the decline in nematode populations in some stable monocultures (e.g., sugarcane) and perennial cropping systems (e.g., grapes). *Pasteuria penetrans* has been an effective biocontrol agent against root-knot nematodes. An application of endospores to soil prevent juvenile females attacking roots. The limitation of the bacterium practical sense is that it can be cultured only in its nematode host or in association with host cells.

Other genera of bacteria known to reduce nematode populations mainly by colonizing the rhizosphere of the host plant include *Agrobacterium*, *Alcaligenes*, *Bacillus*, *Clostridium*, *Desulfovibrio*, *Pseudomonas*, *Serratia, Streptomyces,* and *Telluria.* spp. Application of some of these bacteria has shown very promising results (24). Fungi described as efficient for nematode biocontrol include mainly nematode-trapping species (e.g., *Arthrobotrys oligospora*) possessing the ability to capture, kill, and utilize nematodes by using specially adapted mycelial structures called traps, and egg-parasitic species (e.g., *Verticillium chlamidosporium*, *Paecilomyces lilacinus T. harzianum*, and *Fusarium* spp.) whose action in reducing the nematode populations is rather dramatic compared with other parasitic or predacious fungi. However, the endoparasitic fungi are most specific for their nematode host. They produce conidia or resting spores that are surrounded by adhesive material that allows the spores to attach to the nematode cuticle.

The most important obligate parasites of female cyst nematodes of the genus *Heterodera* are *Nematophthora gynophila* and *Catenaria auxiliaris*. Thus, *N. gynophila* takes up to seven days to kill female cyst nematodes. The resting spores can survive at least five years in the absence of cyst nematode females. Combined activities of *N. gynophila* and facultative parasite of females *V. chlamidosporum* are largely held responsible for natural reduction in *Heterodera avanae*, a cereal cyst nematode.

Endomycorrhizial fungi limit the densities of plant parasitic nematodes on a broad range of host plants. Mycorrhizial fungi *Gigaspora* and *Glomus* decrease damage caused by root-knot nematodes, especially where transplants are used in crop production. Endotrophic mycorrhizial fungus *Glomus mossea* was shown efficient toward

Meloidogyne incognita and *Rotylenchulus reniformis* in cotton, cucumber, tomato and so on (25,26).

MECHANISMS OF BIOLOGICAL CONTROL

Biocontrol strategies may be divided into two broad categories. One follows a fundamentally ecological approach. This strategy has been termed classical biocontrol or biocontrol with one-time introduction (27). The other uses microorganisms as biopesticides and resembles, in some important respects, the approach similar to chemical pesticide treatment (which aims at control for a limited period of time). This strategy has also been referred to as augmentative biocontrol. In the ecological approach, selected organisms must be able to function in the same environmental niche as that of the pathogen they are meant to control. Biological control of plant diseases can be achieved directly, through introduction of specific microbial antagonists into the soil or plant material, or indirectly, by changing the conditions prevailing in the plant's environment, and thus the microbiological equilibrium of its ecosystem. In some cases, a combination of indirect and direct approaches leads to the best biocontrol results.

Direct Biological Control

The direct approach includes four general direct mechanisms of biological control of plant diseases by soil antagonistic microorganisms: (*1*) "competition" with the pathogen for limited resources, such as space or nutrients, this is considered an important mechanism of biocontrol by bacterial and fungal antagonists; (*2*) "antibiosis," which is the inhibition or destruction of an organism by the secondary metabolites produced by another organism; (*3*) "production of lytic enzymes" (e.g., chitinases, glucanases, cellulases, and proteases) able to degrade the pathogen cell wall and/or to destroy its metabolic activities; (*4*) "predation or parasitism," the phenomenon that occurs when one fungus exists in intimate association with another from which it derives some or all its nutrients while conferring no benefits in return.

Competition. Many plant pathogens require exogenous nutrients to successfully germinate, then penetrate and infect the host tissue. In the rhizosphere, competition for space and nutrients is of major importance. Therefore, competition for limiting nutritional factors, mainly carbon, nitrogen, and iron, may result in the biological control of plant pathogens. Indeed, competition is one of the main mechanisms involved in controlling plant pathogens. Most work on bacterial competition has concentrated on iron (Fe). Many plant-beneficial rhizospheric bacteria, for example, those that belong to the pseudomonads (*P. fluorescens* and *P. putida*, to name a few) produce fluorescent siderophores, that is, low molecular weight microbial iron-transport cofactors. These high-affinity ferric iron (Fe^{3+}) chelators specifically enhance the bacteria's iron acquisition by binding to membrane-bound siderophore receptors. Siderophore production by the fluorescent pseudomonads leads to severe iron depletion in the rhizosphere and can limit the growth of some phytopathogenic fungi (e.g., *Fusarium* spp.) and bacteria (e.g., *Pseudomonas syringae*). As a result, these plant pathogens end up in an iron-deficient environment deleterious to their growth.

A competitive exclusion mechanism was shown responsible for the biological control of *P. ultimum* -incited seed infections by *E. cloacae* in which *E. cloacae* prevents the germination of the seed-rotting oomycete *P. ultimum* sporangia by the efficient metabolism of fatty acid components of seed exudate and thus prevents seed infections. It was conclusively demonstrated (a) that unsaturated fatty acids from seeds and roots are required to elicit germination of *P. ultimum* around planted seeds, and (b) that very rapid metabolism of unsaturated fatty acids that leach from seeds is the primary mechanism by which *E. cloacea* controls *Pythium* seed rot (28).

Antagonists capable of more efficiently utilizing essential resources (e.g., carbon, nitrogen, volatile organic materials, plant residues, iron, and microelements) effectively compete with the pathogen for its ecological niche and colonization of the rhizosphere and/or phyllosphere, leaving the pathogen less efficient to grow in the soil or colonize the plant. An important attribute of a successful rhizosphere BCA is the ability to remain at a high population density on the root surface, providing protection of the whole root for the duration of its life. The ability of a microorganism applied as a seed treatment to proliferate and establish along the developing root system has been termed "rhizosphere competence" (29). For example, competition for carbon and nitrogen in the rhizosphere, as well as rhizosphere competence, may be involved in the biocontrol of *F. oxysporum* by *T. harzianum* (11).

Antibiosis. This mechanism includes small toxic molecules, volatiles, and lytic enzymes that kill the target organism. Antibiosis is restricted for the most part to those interactions that involve a chemically heterogeneous group of low molecular weight (less than 1 kDa) diffusible organic compounds (known as antibiotics) produced by a microorganism, which at low concentrations, inhibit the growth or metabolic activities of another microorganism (30,31). In recent years, genetic and molecular studies, specific and sensitive assays, and detection systems have provided evidence of the contribution of antibiotics to pathogen suppression and disease reduction in vitro and in situ, under greenhouse and field conditions. Under natural conditions, antibiotics participate in soil suppressivenes and the antagonism of phytopathogens. However, even in cases where antifungal metabolite production by an agent definitely reduces disease, other mechanisms may also be operating.

Antibiotics Produced by Bacterial Biocontrol Agents. A large number of antibiotics produced by bacterial BCAs appear to be involved in the biocontrol of plant pathogens. Many individual strains can produce a set of antibiotics and secondary metabolites important in biocontrol. One of the best known is biocontrol of *A. tumefaciens* strains carrying the nopaline-type Ti plasmids, which are causative agents of crown gall disease in many dicotyledonous plants (16). The soilborne nonpathogenic

strain *A. radiobacter* K84 produces the bacteriocin agrocin 84, a low–molecular weight adenosine derivative with a very specific host range against pathogenic *A. tumefaciens*.

A large number of pseudomonads active as biocontrol strains are able to produce a diverse array of potent antifungal metabolites. The most well-characterized are simple metabolites such as phenazines (Phz), 2,4-diacetylphloroglucinol (Phl), pyoluteorin (Plt), pyrrolnitrin (Prn), hydrogen cyanide (HCN), and some others (30,32–35).

Pnz are nitrogen-containing heterocyclic molecules, two of the main ones being phenazine-1-carboxylic acid (PCA) and 2-hydroxy-phenazine-1-carboxylic acid (2-OH-PCA). The antibiotics have fungistatic effect on *G. graminis* var. *tritici* (take-all disease of wheat) growth. They act as electron donor or acceptors, which interfere with normal membrane function in target organisms resulting in increased level of toxic intracellular active oxygen products. Phz production by strain 30–84 of *P. aureofaciens* contributes to its ecological competence on plant roots in competition with indigenous microflora in natural soils. Therefore, Phz production was shown to be required for both BCA survival and pathogen inhibition.

Phl, a member of the phloroquinoline class of compounds, is a major factor in the biological control of *Thielaviopsis basicola* (black root rot), *G. graminis* var. *tritici* (take-all disease of wheat), and a range of other plant pathogens. Its antifungal activity may be realized via disruption of the fungal membrane. Phl was found in the rhizosphere of plants inoculated with Phl-producing bacteria and in the rhizosphere of wheat grown in suppressive soil. Production of Phl by bacteria may activate the host plant's defense systems.

Prn, or 3-chloro-4-(2′-nitro-3′-chlorophenyl)-pyrrole, synthesized from tryptophan, possesses wide range of antimicrobial activity. This secondary metabolite may interfere with normal membrane function in the target organism. Prn-producing strains of *Burkholderia cepacia*, *P. fluorescens*, *E. agglomerans*, and *Serratia plymuthica* were shown able to control *P. ultimum*, *R. solani*, and some other fungi. However, Prn is highly sensitive to sunlight and therefore was found to be unsuitable for use as an agricultural fungicide. Derivatives of Prn, called fenpiclonil and fludioxonil, with increased stability under light due to substitution of the chlorine on the pyrrole ring with a cyano group, were developed by Ciba-Geigy (Novartis) company as environmentally safe agricultural fungicides.

Plt, an antibiotic that consists of a resorcinol ring linked to a bi-chlorinated pyrrol moiety, is produced by biocontrol strains Pf-5 and CHAO of *P. fluorescens*, and has been shown to be most toxic to *Pythium* spp. However, the role of Plt in biological control varies depending on the patterns of its gene expression and production by the bacteria, which differ in the rhizosphere and spermosphere of various plant hosts.

HCN is a volatile compound shown to be enzymatically generated from glycine by several *P. fluorescens* strains and this trait is linked to the bacteria's ability to suppress the black root rot disease of tomato and tobacco, caused by the fungus *T. basicola*. Production of HCN is stimulated by iron. HCN has a direct effect on plant roots (stimulates root hair formation) and may induce plant defense mechanisms.

Antibiotics providing strain-producer biocontrol activity have been described in several gram-positive bacteria, mainly of *Bacillus* spp. Thus, *B. subtilis* strains with antifungal activity have been shown to produce the antifungal lipopeptides iturin A and surfacin. Antibiotics active against various plant pathogens have also been found in strains of *Bacillus cereus*, *Bacillus pumilus*, and *Bacillus licheniformis*. Many of these bacilli are generally soil-inhabiting bacteria or exist as epiphytes and endophytes in the spermosphere (23). For this reason, *Bacillus* species among other strains in the genera *Pseudomonas*, *Burkholderia*, *Enterobacter,* and *Trichoderma* spp. known as excellent root colonizers, both internally and externally, are good candidates for use as BCAs against soil borne pathogens. Examples of bacterial antibiotics that may be involved in disease biocontrol are presented in Table 2.

Antibiotics Produced by Fungal Biocontrol Agents. Species of *Gliocladium*, and *Trichoderma*, *T. flavus*, *Chaetomium globosum*, and some others produce a range of antibiotics, which are active against pathogens in

Table 2. Examples of Bacterial Antibiotics and Other Secondary Metabolites That May Be Involved in Crop Disease Biocontrol

Metabolite	Pathogen	Disease
Phenazines	*Gaeumannomyces graminis* var. *tritici*	Take-all of wheat
Pyrrolnitrin	*Alternaria* spp., *B. cinerea*, *Pythium* spp., *R. solani*, *S. sclerotiorum*, *Fusarium sambucinum*, *V. dahliae*	Seedling diseases, gray mold, root rot and damping-off, white mold, dry rot of potato, wilt
Oomycin A	*Pythium* spp.	Damping-off
Pyoluteorin	*Pythium ultimum*	Damping-off
2,4-Diacetylphloroglucinol	*Rhizoctonia solani*, *P. ultimum*, *T. basicola*	Root rot and damping-off, Black root rot of tobacco
Hydrogen cyanide	*Thielaviopsis basicola*	Black root rot of tobacco
Agrocin 84	*Agrobacterium tumefaciens*	Crown gall of fruit trees
Pseudobactin 10	*Fusarium oxysporum lini*	Flax wilt
Ammonia	*Pythium* spp.	Damping-off

Source: Modified from N. Dowling and F. O'Gara, *Trends Biotech.* **12**, 133–141 (1994), J. M. Ligon et al., *Pest Manage. Sci.* **56**, 688–695 (2000).

vitro and, consequently, antibiosis has been suggested to be involved in biological control by fungal antagonists (31,36). Several secondary metabolites produced by *Gliocladium* (= *Trichoderma*) *virens* were shown to be important in mycoparasite biocontrol activity. Thus, production of the antifungal antibiotics gliotoxin (an epidiothidiketopiperasine) and gliovirin (a diketopiperazine) has been associated with efficacy of *G. virens* as a BCA of seedling diseases incited by *Pythium* spp. and *R. solani*, which cause seedling damping-off and root rot, respectively, of many host plants. Gliotoxin appears to be the key factor in *G. virens* biocontrol activity against both these fungal pathogens, whereas gliovirin appears to kill the first fungus but not the last. Strains of *Trichoderma* produce more than 40 compounds with antibiotic activity. Many of them, including volatile alkyl pyrones, peptaibols, diketopiperazines, isonitriles, polyketides, and steroids are thought to be responsible for biocontrol activity of some *Trichoderma* isolates. Some antibiotics are synergistic with cell wall–degrading enzymes in their action against fungal phytopathogens. It is worth noting, however, that some highly effective biocontrol strains of *Trichoderma* may not produce the antibiotics shown to be important for the biocontrol efficiency of other *Trichoderma* strains. To illustrate, gliotoxin has been shown to be important for activity of the *G. virens* strain, which is the active component of SoilGard (Table 1), but it is not produced by *T. harzianum* T-22, which is described as one of the most efficient BCA (13).

Cell Wall Lysis. Most fungal plant pathogens have cell walls, which contain chitin as a structural backbone and laminarin (β-1,3-glucan) as a filling material. The other minor cell wall components are proteins and lipids. Chitin, an unbranched insoluble homopolymer consisting of β-1,4-linked N-acetylglucosamine (GlcNAc) units, is the second (after cellulose) most common biodegradable polysaccharide in nature, being the main structural component of cell walls of most fungi and arthropods (insects, nematodes, and other invertebrates) including many agricultural pests. Many species of bacteria, streptomycetes and actinomycetes, fungi, and plants produce chitinolytic enzymes, which catalyze the hydrolysis of chitin (37). Chitinolytic enzymes (chitinases) cleave a bond between two consecutive GlcNAc units. These enzymes play an important physiological and ecological role in ecosystems as recyclers of chitin, by generating carbon and nitrogen sources. In recent years, soilborne microorganisms that produce chitinases have become considered as potential BCA against fungal pathogens, insects, and nematodes, which cause diseases and damage in agricultural crops.

Lytic Enzymes Produced by Bacterial Antagonists. The ability to produce lytic enzymes is a widely distributed property of soil, marine, and rhizospheric bacteria. Many of these are potential BCA of chitin-containing plant pathogens. The list of chitinolytic bacterial antagonists includes *Aeromonas caviae*, *E. agglomerans*, a *Streptomyces* sp., *Pseudomonas stutzeri* and *P. fluorescens*, *S. marcescens*, and *S. plymuthica*, among others. Chitinase production may be part of a lytic system, which enables the bacteria to use living hyphae rather than chitin as the actual growth substrate, because chitin is an important constituent of most fungal cell walls. For example, a strain of *S. marcescens*, isolated from the rhizosphere of plants grown in soil infested with *S. rolfsii* Sacc., was found to be an effective BCA under greenhouse conditions against this pathogen and *R. solani* Kuhn. A chitinase(s) produced by the bacterium caused degradation of *S. rolfsii* hyphae in vitro, which provides evidence that this enzyme plays a role in biocontrol. Chitinolytic strains of *A. caviae* and *E. agglomerans* were able to control *R. solani* and *F. oxysporum* f. sp. *vasinfectum* in cotton and *S. rolfsii* in beans under greenhouse conditions. In many cases, however, the inhibition of fungal growth was not accompanied by bacterial chitinase production, indicating that other cell wall–degrading enzymes (β-1,3-glucanase and protease) and/or antibiotics may also be involved in the antagonistic activities of chitinolytic bacteria against fungi (38).

Lytic Enzymes Produced by Fungal Antagonists. The ability to produce lytic enzymes has been shown to be a crucial property of the mycoparasitic fungi *G. virens* and *Trichoderma* spp., and many bacterial antagonists of plant pathogenic fungi. In general, chitinolytic enzymes are not only involved in the destruction of the host cell wall; they may also play a role during the initial stages of mycoparasitism. However, the relevance and role of enzymes and toxic metabolite(s) of the mycoparasitic fungi's antagonism toward plant pathogens can vary among independent isolates and should be reinvestigated for each individual case. Moreover, the ability of lytic enzymes to provide biocontrol depends on the type of plant being protected and the fungal pathogen. Thus, the cell walls of basidiomycetes (e.g., *R. solani* and *S. rolfsii*) and ascomycetes (e.g., *Sclerotinia sclerotiorum*) contain mainly β-glucan and chitin, but no cellulose. In contrast, oomycetes (e.g., species of *Pythium* and *Phytophtora*) are composed of β-glucan (laminarin), cellulose and less than 1.5% chitin. Therefore, the cell wall lytic enzymes chitinase and β-1,3-glucanase have frequently been associated with biocontrol activity against the first groups of fungal phytopathogens, whereas β-1,3-glucanases and cellulases (β-1–4-glucanases and β-1–4-glucosidases) can provide biological control of the fungi belonging to the second group (38). Protease production is common in microorganisms, including fungi, among them *Trichoderma* strain T39 that serves as a BCA of the fungus *B. cinerea* (39) and is commercially produced as the biopreparation "Trichodex" (Table 1).

Chitinases and other lytic enzymes also play an important role in the biocontrol of plant pathogenic nematodes. The inhibition of *Globodera rostochiensis* egg hatch by the chitinase-producing bacteria *S. maltophilia* was suggested as a biocontrol strategy for the defense of potato crops against potato cyst nematodes (40). Another approach to controlling plant parasitic nematodes involves amending the soil with chitin that stimulates chitinolytic activity. This treatment drastically increases the populations of chitinolytic bacteria and fungi (41). The nematode's surface is composed of a multilayered cuticle, which consists mainly of collagen. Collagenolytic

activity was shown therefore to play a role in the antagonism of some fungi and bacteria toward plant pathogenic nematodes. Soil amendment by collagen sharply decreased the root-galling index of tomatoes inoculated with *Meloidogyne javanica*. This led to the enrichment of collagenolytic microorganisms, which drastically reduced the number of galls caused by *M. javanica*. The effect was even more pronounced when the amendment was supplemented with the collagenolytic fungus *Cunninghamella elegans* (42). The proteases produced by the fungus *P. lilacinus* and some others were shown to play a role in this fungal nematode-parasitic activity (43). Some of the fungal parasites of plant parasitic nematodes act by triggering induced resistance in the plant, by inhibition of the nematodes's host-recognition process or by producing toxins able to immobilize the nematode, following by penetration of hyphae through the cuticle (25,26).

Predation or Parasitism. This is a complex mechanism, which occurs when the BCA feeds directly on or inside the pathogen. Parasitism is defined as a direct attack on fungal cells followed by feeding by the parasite. When one fungus feeds on another fungus, it is generally called mycoparasitism. Competition for substrates already taken up by other fungi is an ecological feature shared by many mycoparasites. Briefly, mycoparasitism is a complex process, which involves "recognition" of the host, positive chemotropic growth, attachment, and de novo synthesis of a set of cell wall–degrading enzymes that aid the parasite in penetrating the host and completing its destruction. Lectins, the sugar-binding proteins or glycoproteins of nonimmune origin, which agglutinate cells and are involved in interactions between the cell's surface components and its extracellular environment, have been shown to play a role in the recognition and contact between necrotrophic mycoparasites of *Gliocladium* and *Trichoderma* spp. and soilborne pathogenic fungi. This contact, in turn, initiates a signal transduction cascade toward the second most important step of mycoparasitism, the induction of lytic enzymes able to degrade fungal cell walls (4).

Barnett and Binder (44) divided mycoparasitism into: (*1*) necrotrophic (destructive) parasitism, in which the relationship results in death and destruction of one or more components of the host thallus and (*2*) biotrophic (balanced) parasitism, in which the development of the parasite is favored by a living rather than dead host structure. Necrotrophic mycoparasites tend to be more aggressive, have a broad host range extending to wide taxonomic groups, and are relatively unspecialized in their mode of parasitism. The antagonistic activity of necrotrophic mycoparasites is attributed to the production of antibiotics, toxins, or hydrolytic enzymes in proportions that cause the death and destruction of their host. Necrotrophic mycoparasitic fungi, being more common, saprophytic in nature and less specialized in their mode of action, are easier to study. As a result, most mycoparasites (*P. nunn*, *T. flavus*, *C. minitans*, *Gliocladium* spp., and *Trichoderma* spp.), used as BCA in greenhouse or field trials to date have been necrotrophs. The biotrophic mycoparasites, in contrast to necrotrophic ones, tend to have a more restricted host range and produce specialized structures to absorb nutritients from their host. Because of their nature, only a few examples of biotrophic mycoparasites (*S. sclerotivorum* and *A. quisqualis*) as BCA exist (45).

Indirect Biological Control

Indirect approaches include: (*1*) use of organic soil amendments which enhance the activity of indigenous microbial antagonists against a specific pathogen and where changing conditions in the plant's environment may affect the parasite, its host, or the saprophytic microorganisms potentially involved in disease control (46); (*2*) plant growth promotion by root-colonizing bacteria and fungi which are able to stimulate plant growth and to increase tolerance to biotic and abiotic stresses through enhanced root and plant development (17); (*3*) induced resistance, which involves the stimulation of plant self-defense mechanisms against a particular pathogen by prior inoculation of the plant with a nonvirulent strain.

Successful induced resistance has been documented for both bacterial and fungal pathogens. Induced resistance is a plant response to challenge by microorganisms or abiotic agents, such that following the induced challenge, de novo resistance to pathogens is shown in normally susceptible plants. Induced resistance can be "localized" when it is detected only near the inducing factor, or "systemic," when resistance occurs subsequently at sites throughout the plant. Both localized and systemic types of induced resistance are nonspecific and can act against a wide range of pathogens. The difference between these two types of induced resistance is that localized resistance occurs in many plant species, whereas systemic resistance is limited to some plants. During localized resistance, the plant reacts to the environmental stimulus by activating a variety of defense mechanisms, which manifest themselves in various biochemical and physical changes. The general plant defense response consists of the induction of pathogenesis-related (PR) proteins and the deposition of structural polymers, such as callose and lignin.

Little is known about the distribution and/or the biochemistry of the interaction. Special emphasis has been placed on the accumulation of hydrolases such as chitinases and glucanases with antimicrobial potential. Another group of enzymes includes peroxidases, which play a key role in the plant resistance process, being involved in phenolic compounds synthesis and structural barrier formation. In some systemically protected plants (e.g., tobacco and cucumber), increases in newly formed PR proteins have also been recorded, and these may be chitinase-, glucanase-, or osmotin-like proteins. The induction of systemic resistance responses by sometimes only a single local lesion indicates involvement of an immunity signal(s), which are appeared at the induction site and then transduced to the target parts where it conditions the plant for resistance. Several endogenous plant compounds, salicylic acid, and jasmonic acid among them are promising candidate signals for induced systemic resistance. For example, application of exogenous salicylic

acid elicits PR protein patterns similar to those induced by pathogens, and the treated plants develop resistance to viral, bacterial, and fungal pathogens (47,48).

All known BCAs utilize one or more of these general indirect or direct mechanisms. At the product level, this includes the production of antibiotics, siderophores, and cell wall–lytic enzymes, and the production of substances that promote plant growth. Additionally, successful colonization of the root surface is considered a key property of prospective antagonists (17). The best BCAs may use two or three different mechanisms. Antagonists can also be combined to provide multiple mechanisms of action against one or more pathogens. Plant genes also play a role in biocontrol efficiency. Plant health depends, in part, on associations with disease-suppressive microflora, but little is known about the role of plant genes in establishing such associations.

Selection of Biocontrol Agents

Despite the increasing interest in studying the basic and applied aspects of biocontrol of plant pathogens, the commercial usage of biocontrol facilities is still very limited. The development of reliable biocontrol systems depends on an accurate assessment of the problems and on the limiting factors that interfere with them. One of the most prominent problems associated with biocontrol appears to be the inconsistent performance of microbial antagonists under field conditions. Several reasons can be attributed to this phenomenon, including screening techniques, ecological factors, mechanisms of control, and problems associated with formulation and large-scale production (11).

Different screening methods for the selection of BCAs have been described. Hence, using in vitro methods many strains of microorganisms with antagonistic properties have been isolated. In planta, screening methods have been developed to optimize selection of antagonists effective against a range of soilborne pathogens. Screening in the field follows screens in the laboratory or greenhouse. Ecologically adapted antagonists against seed and soilborne pathogens can be isolated from the surface of seeds and roots of the plants susceptible to the desired pathogen. A frequently used approach is to look for healthy plants in a field with diseased plants of the same species. Thus, effective isolates have been found in soils suppressive to take-all of wheat caused by fungus *G. graminis* var. *tritici* (49), or to *Fusarium* wilt (7). However, knowledge about the origin of an antagonist will always be relevant in connection with risk evaluation, and wild-type candidates isolated from natural locations can be expected to give less complications in the registration process (50).

Screening methods can be focused mainly on information about mechanisms of antagonism obtained in vitro or try to mimic greenhouse or field conditions. For example, two-component screening methods (e.g., dual cultures of a candidate antagonist and a pathogen on agar) are based on interaction studies. The potential antagonists are typically ranked according to their ability to inhibit the growth of the pathogen, as expressed by an inhibition zone. Dual cultures on agar are able to reveal the mycoparasitism of the pathogen (e.g., *R. solani*) by the antagonists (e.g., *T. harzianum*) (Fig. 1) or antibiosis causing the inhibition of the pathogen (e.g., *P. aphanidermatum*) by the antibiotics or siderophores produced by the antagonists (e.g., some bacteria) (Fig. 2). However, the results obtained with such plate tests do not necessarily indicate that a strain with good antagonistic activity in vitro will serve as an efficient BCA under natural environmental conditions. A soil plate method revealed a good correlation between the competitive saprophytic ability of a range of mycoparasitic *Trichoderma* isolates and their ability to destroy host (target) fungi in soil. In this method, an agar plate is first colonized by a host fungus, then particles of soil or plant material are placed on the surface. Only fungi that are able to derive nutrients from the precolonizing fungus and to tolerate its waste products will be able to grow. Mycoparasites isolated by this method include *G. roseum*, a *Papulaspora* sp., *Pythium* spp., and *Verticillium biguttatum* (50).

The introduced microbial antagonist will have to overcome competition from the indigenous soil microflora. Therefore, mechanisms other than those that can be

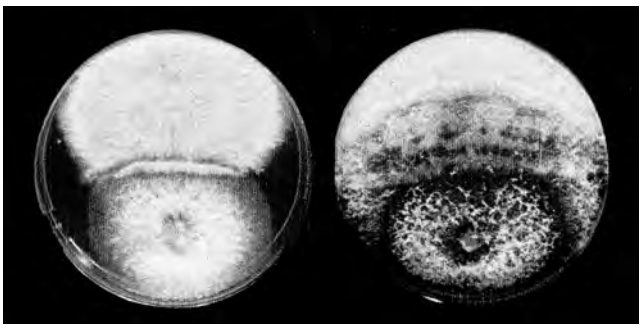

Figure 1. Dual cultures of mycoparasitic fungus *T. harzianum* (lower part) with the plant pathogenic fungus *R. solani* (upper part) growing simultaneously at 28 °C in a petri plates with potato-dextrose agar (PDA). Left and right plates are two and seven days after contact.

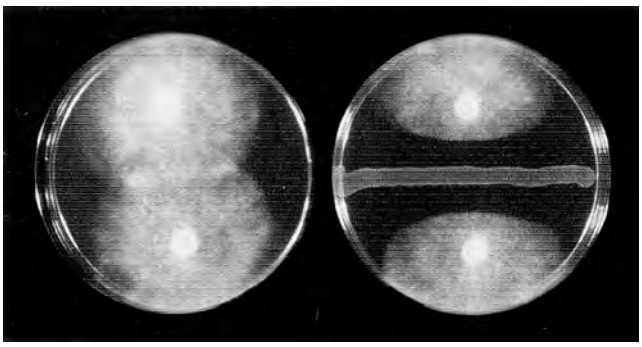

Figure 2. Assay of antifungal activity on petri plates. Two agar disks from an actively growing culture of *P. aphanidermatum* were placed on either side of the bacterial growth area, and the plates were incubated at 28 °C for two days. A suspension of bacterial strain *E. agglomerans* was seeded in a line through the center of a PDA plate and incubated at 28 °C for 24 hours (right plate). In a control plate (left plate) where sterile water was used instead of bacteria, the fungal mycelium covered the entire agar surface.

assessed in in vitro assays are important under field conditions. The ability of the antagonist to metabolize the exudate molecules produced by a protected plant, to colonize the plant rhizosphere and to protect infection sites in situ appears to be key factors in the biocontrol of soilborne plant pathogens. Soil pH may also be an important factor determining the success or failure of introduced antagonists. Competition and other antagonistic interactions (e.g., antibiosis and parasitism), between the introduced BCA and the pathogen may also take place in the rhizosphere. Other mechanisms, such as induced resistance and plant growth promotion, can also be taken into account by screening programs on the basis of approaches related to the plants.

FORMULATION AND DELIVERY OF BIOCONTROL AGENTS

Maintaining adequate viability of microorganisms throughout processing, storage, and application for biocontrol is critically important for commercial reasons. Unlike chemical pesticides that begin to degrade after application, BCA must survive and begin to proliferate. To compete with chemical pesticides, appropriate technology must be developed to improve the BCA stability, bioactivity, and shelf life. Therefore, formulating biocontrol organisms effectively is the key to their successful use. The formulation must be compatible with the requirements of the microorganisms, and even enhance their performance, and it should be compatible with regular agricultural practice, to be both acceptable and useful to the farmer. To be distributed through the normal commercial chain, the preparation should ideally have a shelf life of one to two years. The right formulation can help protect the microorganisms biologically and physically. To achieve this protection, the formulation should be able to induce low metabolic activity in the microorganism involved. This is usually brought about by reducing moisture potential by drying or by incorporating the agent into an oily microaerophilic environment. Surfactants, stickers, emulsifiers, and spreaders are added to formulations to improve their application to the target.

Commercial formulations of microbial agents have been used in the biocontrol of plant diseases and plant parasitic nematodes. Products aimed at soil pathogens can be formulated for bulk application in the plant growth media or for seed treatment, with or without a food base. The type of delivery system used to apply the BCA to its specific habitats important for its success. For example, a mixture of peat and wheat bran (1 : 1) was shown efficient medium for *T. harzianum* growth and sporulation. This formulation has been applied to seedlings before planting, to seeds in furrows, and in broadcast applications (51). The most extensively and successfully used bioencapsulation material is alginate. A method of forming alginate beads for encapsulation of biocontrol strains of *Trichoderma* and *Gliocladium* was developed. The fungal conidia, chlamydospores, or fermentation biomass are mixed in a 1% sodium alginate solution and added dropwise into a 2 to 5% calcium chloride solution. The formed pellets or granules are dried for use as a BCA. The resultant alginate-encapsulated cells or spores survive well in the soil. Encapsulation of microorganisms in an alginate matrix was considered to be an effective way of delivering useful microorganisms slowly into the soil for prolonged periods.

Various BCAs have been encapsulated in amylopectin (pregelatinized starch) to improve their survival under severe environmental conditions. Several other granular formulations, including 'Pesta' granules in which fungal propagules are encapsulated in a wheat gluten matrix, peat or alginate prills, vermiculite, and application onto crop residue were evaluated (52). Some formulations provide rapid release of bacteria early in the growing season whereas other formulations provide slow-release of bacteria, particularly for weeds that emerge later in the growing season. Industrially available products include formulated preparations of biocontrol fungi, bacteria, and streptomycetes (Table 1). For example, *G. virens*, formulated in alginate prill form (preparation GlioGard^{TM}) and incorporated into soilless potting media was shown effective for disease control of bedding vegetable plants and ornamental seedlings against *P. ultimum* and *R. solani*. Another example is alginate prill formulations of *T. flavus* with organic carriers for biocontrol of *V. dahliae*. In this case, pyrophyllite clay (Pyrax) and milled corncobs used to make alginate prill with ascospores of *T. flavus* consistently enhanced the biocontrol activity of the fungus.

COMBINED USAGE OF BIOCONTROL AGENTS

Most approaches for biocontrol of plant diseases use a single BCA as antagonist to a single pathogen. Indeed, microorganisms as BCAs typically have a relatively narrow spectrum of activity compared with synthetic pesticides and often exhibit inconsistent performance in practical agriculture resulting in the limited commercial use of biocontrol approaches for plant pathogens suppression (49). Usually, it is very difficult to find a single strain that is able to control a wide spectrum of pathogens under various rhizospheric and soil conditions. However, this goal can be achieved by genetic modification of the BCA by adding disease suppression mechanisms (e.g., genes encoding additional antibiotics or cell wall lytic enzymes), which operate against more than one pathogen, or by developing strain mixtures with superior biocontrol activity. Several strategies for forming mixtures of BCAs have been proposed, including mixtures of organisms with differential plant-colonization patterns; mixtures of antagonists that control different pathogens; mixtures of antagonists with different mechanisms of disease-suppression; mixtures of taxonomically different organisms; mixtures of antagonists with different optimum temperature, pH, or moisture conditions for plant colonization. Mixtures of antagonists are considered to account for the protection afforded by disease-suppressive soils. In the absence of cross-inhibition of antagonists, combining antagonists results in improved biocontrol. Therefore, successful development of strain mixtures requires compatibility of the coinoculated microorganisms (53).

Combinations of BCAs for plant diseases include mixtures of fungi, mixtures of fungi and bacteria, and mixtures

of bacteria. Thus, combined usage of bacteria and fungi for plant disease control have been shown in some experiments to be more efficient than a single antagonist. For example, *E. agglomerans* together with some *Trichoderma* spp. strains were shown to be the most promising antagonists from suppressive soils against *Phythophtora capsici* in pepper. *Enterobacter cloacae* and *Pseudomonas* spp. strain–induced suppression of *Rhizoctonia* damping-off were consistently more effective in combinations with *T. hamatum* relative to the fungal isolate alone. The integrated approach based on using binuclear *Rhizoctonia* spp. and *E. cloacae* strains in combination, led to protection of cucumber against the disease in greenhouse. Several bacterial and fungal BCAs, including *Trichoderma, Gliocladium, Pseudomonas, Bacillus, Agrobacterium, Enterobacter,* and *Serratia*, may protect plants against diseases via synergistic action. Therefore, it has often been stated that mixtures of BCAs are required for successful long-term control because the individual components that colonize different crops are adapted to different environments or have different functions (49). However, single isolates of *Trichoderma* and other microbial antagonists efficient for biocontrol of a number of plant pathogens also have been described (11,13).

INTEGRATED PEST MANAGEMENT

Biological control is just one component of a strategy termed integrated pest management (IPM). IPM is defined as the reduction of pest populations by natural enemies, and it typically involves an active human role. IPM strategy involves the coordinated use of pest and environmental information with available pest management methods to prevent unacceptable levels of pest damage by the most economical means, and with the least possible hazard to humans and the environment. In short, the goal of the IPM approach is to manage pests and the environment so as to balance costs, benefits, human health, and environmental quality. Thus, IPM is biologically based, cost-effective, and its site-specific risk-reduction system makes use of multiple methods in the decision-making process (54). Combinations of BCAs with low, otherwise inefficient doses of chemical pesticides are often considered an important IPM approach to achieving the most capable protection of crop disease. For example, under field conditions, a combination of lowered doses of methyl bromide (MB) and *T. harzianum* exhibited a significant synergistic effect on damping-off of carrot seedlings caused by *R. solani*, and its effect on growth, yield, and disease control was similar to that of the much higher recommended MB dosage. Integrated control of *V. dahliae* in potato by *T. harzianum* and the fungicide captan increased both marketable and total potato yield (36). Integration of induced systemic resistance into pest management systems can further lead to the decreased usage of the conventional pesticides (48). Combinating BCAs with soil solarization (solar heating) technique is an additional efficient way of using natural conditions to protect crops against pathogens and to enhance plant growth, even in the absence of known major pathogens. The rapid establishment of fluorescent pseudomonads was observed in the rhizosphere of plants that were grown in solarized soils and was found to be due to the improved capacity of these bacteria to compete for the plant exudates (55).

MOLECULAR APPROACHES FOR IMPROVEMENT OF EXISTING, AND CREATION OF NEW BIOCONTROL AGENTS

Improvement of Bacterial Biocontrol Agents

Some BCAs have been genetically modified to enhance their biocontrol capabilities or other desirable characteristics. Strain improvement is one of the most exciting ways of achieving highly efficient biocontrol of plant diseases. Molecular approaches and genetic engineering techniques have recently been applied to gain a better and more basic understanding of the mechanism of action of BCAs, and to develop superior and improved strains of BCAs with enhanced activity (18,32).

For example, synthesis of agrocin 84 by the BCA *A. radiobacter* K84 is directed by a gene located in the extrachromosomal DNA known as plasmid pAgK84. This plasmid also carries the genes needed for resistance to agrocin 84 and is able to transfer from one bacterium to another by a mechanism known as conjugation. Consequently, pAg84 may be transferred to pathogenic *A. tumefaciens*, which would then be resistant to agrocin 84. To prevent this resistance, a transfer-deficient mutant of strain K84 was constructed. *Agrobacterium radiobacter* strain K1026 is identical to the parental strain, except that the agrocin-encoding plasmid cannot be transferred from cell to cell (16).

In systems in which antibiotics play a primary role in the strains biocontrol activity, molecular approaches can be used to enhance the bacteria's biocontrol efficacy by increasing levels of antibiotic synthesis, either by increasing the copy number of the biosynthetic genes or by modifying the regulatory signals that control their expression. This is particularly interesting for bacteria in which the biosynthetic genes are arranged in either operons or clusters, as was shown for the genetics of Phz, Phl, and Prn production in *Pseudomonas* spp. strains (56). For example, increased production of Plt and Phl and superior control of *P. ultimum* damping-off of cucumber was achieved by increasing the number of antibiotic biosynthesis genes in *P. fluorescens* strain CHAO. Constitutive synthesis of oomycin A in *P. fluorescens* strain HV37a was achieved by insertion of a strong *tac* promoter from *Escherichia coli* upstream of the *afuE* locus encoding the antibiotic. The resultant recombinant strain produced a significantly higher level of oomycin A than the parental strain and provided greater control of *P. ultimum* infection (57). Another approach is to introduce biosynthetic genes into a strain deficient in antibiotic production, or into one that produces a different antibiotic, to increase the spectrum of activity. Thus, cloned Phz biosynthetic genes were transferred from *P. fluorescens* 2–79, which exhibits poor rhizosphere competence, into *P. putida* and *P. fluorescens* strains, which exhibit superior rhizosphere competence. The recombinant strains that synthesized

Phz in vitro are potentially superior BCAs of pathogenic fungus *G. graminis* var. *tritici* because of their ability to colonize the wheat rhizosphere. When genes conferring Phl synthesis were mobilized from a *P. aureofaciens* strain into a *P. fluorescens* strain that normally produces only Phz and inhibits this fungus, the obtained recombinant strain was shown to be additionally suppressive against *P. ultimum* and *R. solani* through expression of an additional antibiotic (49).

The chitinase gene *chiA* encoding one of the chitinases from biocontrol strains of *S. marcescens* and *E. agglomerans* was isolated and cloned into *E. coli* (58,59). *Escherichia coli* strains transformed with the *chiA* gene expressed and excreted the corresponding protein into the growth medium. Transformed *E. coli* was effective in inhibiting *S. rolfsii* on beans and *R. solani* on cotton, but to a lesser degree than the original chitinolytic strains. The genetically engineered *E. coli*, a nonsoil bacterium, served here as a model system to demonstrate the role of chitinase in controlling a chitin-containing plant pathogen. It is suggested that the introduction of such engineered genes into soil bacteria will increase control efficiency by combining high expression of a gene encoding a lytic enzyme with rhizosphere competence.

The current knowledge of regulatory mechanisms governing the expression of various antifungal substances may help in the construction of strains with enhanced biocontrol activity. Manipulation of regulatory systems responsible for the production of lytic enzyme and antibiotics has resulted in significant improvement of the bacteria's biocontrol potential. The advantages of this approach were demonstrated by increasing the doses of genes encoding the GacA-GacS system of global regulation or sigma factors of transcription in some biocontrol strains of *P. fluorescens* (35,56). The findings supported the idea that regulatory signals from the environment may contribute to the success of a bacterium in competition with plant pathogens and other rhizosphere inhabitants under natural conditions (33).

Improvement of Biocontrol Potency of *Trichoderma* spp.

Introduction of foreign genes that could potentially enhance the biocontrol capacity of *Trichoderma* (4). For example, genes encoding cell wall lytic enzymes were used as a tool to increase the chitinase activity of one of the most potent biocontrol species, *T. harzianum*. Two different strategies were used. According to one approach, the chitinase gene of *S. marcescens* was introduced into the genome of *T. harzianum* under the control of a constitutive eukaryotic promoter, providing a high level of expression of the foreign bacterial gene into a new fungal host. Following another strategy, a *T. harzianum* strain was transformed by a vector that contained the coding region of the 42-kDa endochitinase gene of this fungus under the control of a strong cellulase promoter from a relative fungus *Trichoderma reesei* (=*T. longibrachiarum*). A 10-fold increase in chitinase activity was achieved. Using the same the endochitinase gene of *T. harzianum* with its own regulatory sequences, transformants of *T. hamatum* with an approximately fivefold increase in chitinase activity were obtained. The 42-kDa endochitinase encoding gene of *T. harzianum* has been shown to be triggered in mycoparasitic interactions. Therefore, duplication of this highly conserved gene appears to be a potential means of improving the biocontrol capability of *Trichoderma* species.

Proteinases were also overexpressed in *Trichoderma* with the aim of improving the isolate's biocontrol activity. Under greenhouse conditions, *T. harzianum* transformants with an increased copy number of the basic proteinase gene *prb1* that were incorporated into pathogen-infested soil reduced the disease caused by *R. solani* in cotton plants up to fivefold as compared with the wild-type strain. In all these studies, the *Trichoderma* strains were genetically improved to serve as better BCAs of fungi, such as *R. solani*, that contain chitin and β-glucan as major cell wall components (4). A similar approach was approved for obtaining *Trichoderma* strains with high activity against plant pathogenic oomycetes, such as *Pythium* spp., containing cellulose as the main cell wall component. The difference in this case, however, was that the *Trichoderma* strains were designed to overproduce cellulytic enzymes instead of chitinolytic ones. Hypercellulolytic strains of *T. longibrachiatum* obtained by genetic engineering methods were shown to be significantly more effective in controlling *Pythium* damping-off disease on cucumber than the wild-type strain (60).

The major advantage of such genetic manipulations is the ability to isolate genes from one strain and to introduce them into other varieties of fungi or bacteria. This enhances the potency of BCAs and makes a single strain effective, stable, and consistent against more than one plant pathogenic fungus, without the hazardous effects of chemical pesticides.

The current strategies to improve BCAs activity through genetic engineering technology are summarized in Table 3.

CONCLUSION

Because of their beneficial activity, BCAs can serve as suitable alternatives to some commercial fungicides. However, more studies are required to develop screening techniques, appropriate formulations, and delivery systems to enhance application and survival, and to elucidate the molecular basis of their mode of action against plant pathogens. This, in turn, will yield genetic information to produce superior biocontrol strains, and give a better understanding of ecological factors that may interfere with biocontrol activity. Because these developments are time-consuming and often, do not produce immediate results, more emphasis should be directed to extending the use of integrated control as part of a comprehensive IPM program, thus introducing biocontrol into mainstream agriculture. The biocompatibility of these agents with fungicides is expected to enhance their efficacy, and there are a few examples available to demonstrate this.

Most microorganisms selected as potential BCAs never become products because of problems related to their production and downstream processing. The antagonistic activities in vitro or in vivo considered important for the

Table 3. Examples of Genetic Engineering Approaches to Improve Biocontrol Agents by Enhancement of Antimicrobial Compound Production

Strategy	Approach	Mechanism of Biocontrol Enhancement
Altered expression	Insertion of biosynthesis genes upstream of a stronger promoter; introduction of new/or additional regulatory genes, construction of regulatory mutants	Constitutive and/or increased production of antibiotics, siderophores, or lytic enzymes
Gene dosage	Increase copy number of gene(s) in wild-type strains	Overproduction of antibiotics and other antimicrobial compounds
Heterologous expression	Introduction of new genes encoding antimicrobial compounds	Conversion of non-producing strains to producing strains, expansion of assortment of antimicrobial compounds produced by a single biocontrol agent
Deletion	Specifically delete transfer (*tra*) genes from plasmid encoding agrocin 84	Eliminates potential transfer of agrocin 84 resistance gene to target pathogen

Source: Modified from N. Dowling and F. O'Gara, *Trends Biotech.* **12**, 133–141 (1994).

biocontrol potential of these strains are, in fact, often not sufficient to develop an efficient biocontrol product. To become a product, the microorganisms have to fit the following requirements. They must be easily produced in fermentors, that is, a high amount of cells produced per unit volume in a short time with low-cost culture medium; they must be easily converted to an appropriate form for longer shelf life; they must maintain biocontrol properties after large-scale production and drying. Because of their high production costs, biotechnological products require a large market to be beneficial. Therefore, it is worth being able to use the same product against a large number of diseases.

The greatest value of biocontrol agents versus chemical pesticides is that chemicals usually give a high level of protection but strongly rhizospheric competent organisms, in particular, can provide a somewhat lower level of benefit for extended periods, that is, up to several months. The point is that biologicals and chemicals both have strong points and neither can do what the other does best (13). The introduction or application of BCAs for pest and disease control will result in yields that are pesticide-free and hence biosafe. Pesticide-free products have already been introduced into the marketplace, particularly in developed countries. The market share of environmentally friendly fresh produce is constantly increasing, and pesticide-free fruits and vegetables are achieving being in higher prices than conventional produce. At present, biological control may lack, in some cases, the rapid protective effect exhibited by the best pesticides, and it may also result in somewhat lower efficiency and narrower host specificity than chemical control. Currently however, several BCAs with a rather wide range of biocontrol activity are available. The most extensively studied bacterial organisms, including *Pseudomonas* spp., *B. subtilis*, and *Enterobacter* spp., have been reported to reduce several soilborne and aerial diseases on various crop species. Fungal BCAs, including the extensively studied *Gliocladium* and *Trichoderma* species, in addition to other weakly virulent or saprophytic fungi, have been reported to reduce infection or reproduction of many pathogens. Most of the applications of these fungi are for soilborne diseases, with a few reports of reduction of foliar fungal pathogens. It is worth noting, however, that even the most efficient BCAs can be overcome by heavy disease pressure. BCAs cannot cure already existing infections; hence they must be used strictly as a preventive measure (13). There are several areas, in which additional research is required, and these include further improvement of the agents to achieve long-term effects and to enhance their survival and efficiency for routine application in agricultural practice for the benefit of the farmers.

BIOCORROSION: ROLE OF SULFATE REDUCING BACTERIA

IWONA B. BEECH
University of Portsmouth
Portsmouth, United Kingdom

In natural environments and artificial systems, corrosion reactions under a biological influence usually involve surface-associated microbial growth, namely, a biofilm. Terms such as microbially influenced corrosion (MIC) or biocorrosion are frequently employed to describe metal deterioration in the presence of microorganisms (1).

Corrosion under a biological influence frequently occurs as a localized attack, which results from the activity of physiologically diverse microbial species associated

with the metal substratum. Microorganisms implicated in biocorrosion have frequently been grouped by their metabolic demand for different respiratory substrates. Sulfate-reducing bacteria, sulfur-oxidizing bacteria, iron-oxidizing/reducing bacteria, manganese-oxidizing bacteria, as well as bacteria secreting organic acids and exopolymers or slime have all been named as culprits in MIC failures. These organisms coexist within biofilms, often forming synergistic communities able to affect electrochemical processes through cooperative metabolism, which individual species have difficulty initiating.

The first documented case describing biocorrosion dates to 1891. This report proposed that the increase of corrosion of lead cable could be due to bacterial metabolic products. However, it was not until 1934 that the corrosion of ferrous metal buried in anaerobic clay soil was solely attributed to the activity of obligate anaerobic microorganisms known as sulfate-reducing bacteria (SRB) (2). Since then SRB became the most investigated group of microorganisms implicated in corrosion damage of iron and ferrous alloys in a broad range of aquatic and terrestrial habitats varying in nutrient content, temperature, pressure, and pH values.

Biocorrosion of metals and their alloys is of great importance to many industries such as oil and gas, shipping, power, and water distribution sectors. In particular, the activity of sulfate-reducers can have considerable impact on oil and gas industry, leading to severe economical losses due to system failures and equipment deterioration and resulting in serious health and safety hazards and environmental risks (3,4). It has been proposed that approximately 20% of all corrosion damage to materials fabricated with metal is microbially influenced or enhanced (5). MIC is therefore the subject of intense research efforts aiming to develop environmentally acceptable prevention and protection measures and to improve the effectiveness of already existing control strategies.

Several theories have been presented to explain mechanisms by which sulfate-reducers can influence corrosion of metallic materials. In this article all proposed models of SRB-mediated corrosion are described along with the current hypothesis based on the identified reactions of primary importance leading to the coupled electrochemical and biotic electron transfer processes (6).

FUNDAMENTAL ASPECTS OF CORROSION

The term corrosion is defined as the physicochemical interaction between a metal and its environment, which results in changes in the properties of metal (7). These changes may lead to impairment of the function of the metal, the environment, or the technical system of which these form a part. Corrosion is an electrochemical process defined as a chemical reaction involving the transfer of electrons through a series of oxidation and reduction reactions.

For electrochemical corrosion to occur, the following components have to be present:

- An anode site
- A cathode site
- An electrolyte (a solution capable of conducting electrical flow).
- A cathodic reactant
- An anodic reactant
- Electronic contact between the anode and cathode

Schematic diagram of a basic corrosion cell for a ferrous metal under anoxic conditions is represented in Figure 1.

The process of corrosion consists of two half-reactions: an anodic reaction involving the ionization (oxidation) of the metal and a cathodic reaction involving the reduction of a chemical species in contact with the metal surface. At the anodic site the metal dissolution occurs and metallic ions are formed. A cathodic site is required as an electron sink for the return of current to the metal. This reaction is a reduction reaction or an electron-consuming reaction. The rate of corrosion is determined by the rate of the cathodic reaction, and as the electric current must migrate through the solution to the metal at the cathode; the cathodic current must be equal to the anodic current.

In aerated and oxygen-free solutions the anodic reaction is metal dissolution:

$$\mathrm{Me} \rightarrow \mathrm{Me}^{2+} + 2\mathrm{e}^- \tag{1}$$

For aerated solutions at neutral or alkaline pH, the main cathodic reaction is the reduction of oxygen

$$\mathrm{O_2} + 2\mathrm{H_2O} + 4\mathrm{e}^- \rightarrow 4\mathrm{OH}^- \tag{2}$$

In acidic or deaerated solutions, protons or, when present, hydrogen sulfide may act as electron acceptor, as demonstrated in reactions (3) and (4):

$$2\mathrm{H}^+ + 2\mathrm{e}^- \rightarrow 2\mathrm{H} \rightarrow \mathrm{H_2} \tag{3}$$

$$2\mathrm{H_2S} + 2\mathrm{e}^- \rightarrow 2\mathrm{HS}^- + \mathrm{H_2} \tag{4}$$

In an intermediate pH solution, that is, one of low pH but aerated, protons are more readily available than oxygen and, therefore, proton reduction will be the main electron-consuming route.

Although the anodic and cathodic reactions can occur at different locations on the metal, typically they are adjacent to each other. The sites of the anodic and cathodic reactions

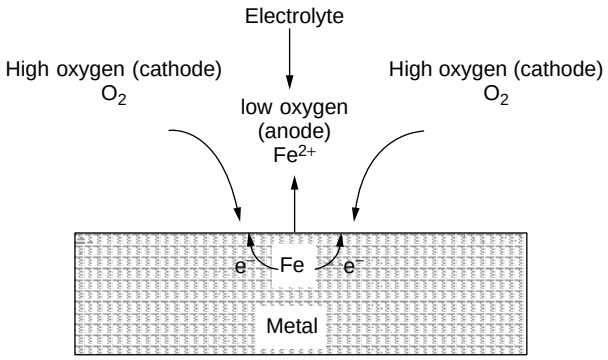

Figure 1. Basic corrosion cell for iron-based alloy under aerated conditions.

are referred to as the anode and cathode, respectively. The irregular distribution of corrosion cells across the metal surface causes localized attack in the form of pitting and/or crevice corrosion. When the half-cells are closely spaced, a general corrosion is observed.

As already stated, corrosion process causes materials fabricated of pure metals and/or their mixtures (alloys) to undergo chemical oxidation from ground state to an ionized species. The oxidation reaction, in most instances, slows to a low rate after a period of time because the oxidation products (corrosion products) adhere to the metal surface and form a layer, which serves as a diffusion barrier to other reactants. These products form a protective barrier to further oxidation of the underlying metal. Changes in the environmental conditions can affect the stability of the protective layers and, hence, the overall susceptibility of the metal to corrosion.

BIOCORROSION

Due to their presence on the surface and their ability to carry out specific biochemical reactions, microorganisms can alter the physical/chemical conditions at the metal/substratum interface and modify electrochemical reactions, which are fundamental to all corrosion processes. Microbial colonization of the surface is facilitated by the production of extracellular polymeric substances (EPS) that are composed of a mixture of macromolecules such as proteins, polysaccharides, nucleic acids, and lipids. EPS facilitate bacterial attachment to the substratum and form the biofilm matrix ((8) and references therein). The presence of exopolymers on the metal surface can modify both morphology and chemistry of corrosion products altering their corrosion characteristic, often rendering these products more aggressive.

The selective binding of different metal ions by EPS leading to the formation of metal concentration cells within the biofilm matrix has been proposed as one of the mechanisms of biocorrosion. The presence of such cells could promote electron transfer processes between the biofilm and base metal (9,10). A number of studies have demonstrated the involvement of exopolymers secreted by different genera of aerobic bacteria in metal deterioration (11,12).

Microbial metabolic processes, including the consumption of oxygen and production of acids and sulfides, promote the establishment of localized chemical gradients at the metal surface. The existence of such gradients leads to the formation of electrochemical cells, which stimulates anodic and/or cathodic reactions, the ultimate consequence being loss of metal from the discrete locations on the surface. A number of biocorrosion mechanisms have been identified that reflect the variety of physiological activities carried out by different types of microorganisms (13,14).

The interaction of a biofilm harboring many species of aerobic, facultatively anaerobic, and strictly anaerobic microorganisms and the underlying substratum produces a unique physical and chemical environment. Thus, conditions at the substratum surface can differ significantly from those in the bulk phase or at a biofilm-free surface. In the presence of biofilms, the following factors are likely to affect metal deterioration (1):

- Microbial activity and microbial metabolic products.
- The passage of charged entities through the exopolymer matrix.
- The degree of conductivity of the EPS matrix.
- The binding of metal ions by the EPS matrix.
- Destabilization of corrosion inhibitors.

The main importance to the corrosion process is the control the biofilm exerts on the transport of ions, namely, regulating the exchange of ions between the metal surface and the aqueous environment by either promoting or retarding metal ion transfer. Although in most natural and artificial environments, microorganisms and products of their metabolism, including EPS, are present in greater quantities at the metal surface compared to the bulk phase, water still constitutes 95% or more of the biofilm matrix. The biofilm can, therefore, still act as a modified electrolyte. The high growth rates, varied metabolic products, many of which are corrosive, and the high surface-to-volume ratio of microorganisms can result in interactions, which would modify physicochemical parameters at metal solution interfaces to such a degree that corrosion rates can be accelerated by factors of 10^3 to 10^5 (15). In contrast, certain types of biofilms may produce a barrier effect resulting in a reduction of the chemical activity and hence a substantial decrease in the corrosion rate of the metal (1).

SULFATE-REDUCING BACTERIA

Sulfate-reducing bacteria are readily isolated from biofilms formed on different type of surfaces in natural habitats and industrial systems. These bacteria thrive within anoxic niches, which exist within biofilms as a result of oxygen depletion due to the respiration of aerobic or facultatively anaerobic microorganisms.

Phylogeny

The family of taxonomically diverse SRB is currently distributed within two domains: *Archaea* and *Bacteria* (16). In the former domain, sulfate-reducers are represented by microorganisms of the *Archaeglobus* genus. In the Kingdom *Bacteria*, SRB are divided into three distinct groups, the gram-positive spore-forming SRB with *Desulfotumaculum* being a predominant genus, the gram-negative mesophilic SRB (δ-subclass of the *Proteobacteria*) of which *Desulfovibrio* is one of the better characterized genera and the thermophilic SRB represented by two genera *Thermodesulfobacterium* and *Thermodesulfovibrio*. Although SRB are currently divided into four phylogenetic groups, new divisions could be added, as several new genera of psychrophilic SRB were recently isolated from permanently cold Arctic marine sediments (17).

Physiology

Lactate, pyruvate, and malate are frequently used as carbon source and electron donors and are oxidized

to acetate and carbon dioxide (18,19). Some SRB can utilize high molecular weight fatty acids or simple aromatic compounds such as benzene or phenol and are known to participate directly or indirectly in the degradation of variety of substances, including saturated hydrocarbons (20). During their growth, SRB produce a large amount of hydrogen sulfide that assure the maintenance of an anoxic atmosphere.

Although all SRB species known to date have been described as strictly anaerobic, some genera are able to survive for long periods in the presence of oxygen, indicating the existence of enzymatic defense mechanisms against oxygen radicals (21,22). Indeed, the presence of enzymes catalase and superoxide dismutase, which prevent accumulation of H_2O_2 and eliminate toxic respectively, constitutively expressed during anaerobic growth of *Desulfovibrio gigas*, was recently confirmed (23).

Respiration

Sulfate-reducing bacteria are chemolithotrophic organisms that are able to carry out dissimilatory reduction of sulfur compounds such as sulfate, sulfite, thiosulfate, and even sulfur itself to sulfide by a series of energy-conserving reactions (Fig. 2; 18).

The initial step in the dissimilatory sulfate reduction is the transport of exogenous sulfate across the bacterial membrane into the cells. This process may be inhibited by selenate, which is the structural analog of sulfate. Once inside the cell, sulfate dissimilation proceeds by the action of adenosine triphosphate (ATP)-sulfurylase which combines sulfate with ATP to produce the highly activated molecule adenosine phosphosulfate (APS), as well as pyrophosphate (PP) that may be subsequently cleaved to yield inorganic phosphate.

$$ATP + SO_4^{2-} \rightarrow APS + PP$$

APS is rapidly converted to sulfite and AMP by the cytoplasmic enzyme APS reductase.

$$APS \rightarrow AMP + SO_3^{2-}$$

A number of different sulfite reductases have been identified in SRB (24). The most commonly recognized types, particularly among the genus *Desulfovibrio*, are the biosulfite reductases, desulfoviridin, and desulforubidin. Sulfite is reduced via a number of intermediates, including metabisulfite ($S_2O_5^{2-}$), dithionite ($S_2O_4^{2-}$), trithionate ($S_3O_6^{2-}$), and thiosulfite ($S_2O_3^{2-}$), to form the sulfide ion. The latter can be further converted to hydrogen sulfide (H_2S) in the presence of external hydrogen (H^+) ions.

Apart from sulfate, some *Desulfovibrio* species can grow with nitrate or fumarate as alternative electron acceptors releasing ammonia and succinate, respectively (20). At low dissolved oxygen concentrations certain SRB are able to respire with Fe(III) or even oxygen with hydrogen acting as electron donor (25,26). Although some gram-negative SRB can reduce Fe(III) there are no known SRB that are capable of performing this reaction using ferric ion as a sole electron acceptor.

Hydrogenase Enzymes

Hydrogen metabolism plays a central role in energy-generating mechanisms of sulfate-reducing bacteria. The capability of SRB to produce and consume H_2 means that they possess the enzyme hydrogenase, which catalyzes the reversible oxidation of hydrogen according to the reaction (5):

$$H_2 \leftrightarrow 2H^+ + 2e^- \quad (5)$$

Hydrogenase was first discovered by Stephenson and Stickland in 1931 (27). Since then hydrogenase activity was found in a large number of anaerobic and aerobic prokaryotes, as well as in eukaryotic cells.

Two mechanisms involving H_2-metabolism have been offered for energy coupling in *Desulfovibrio* during

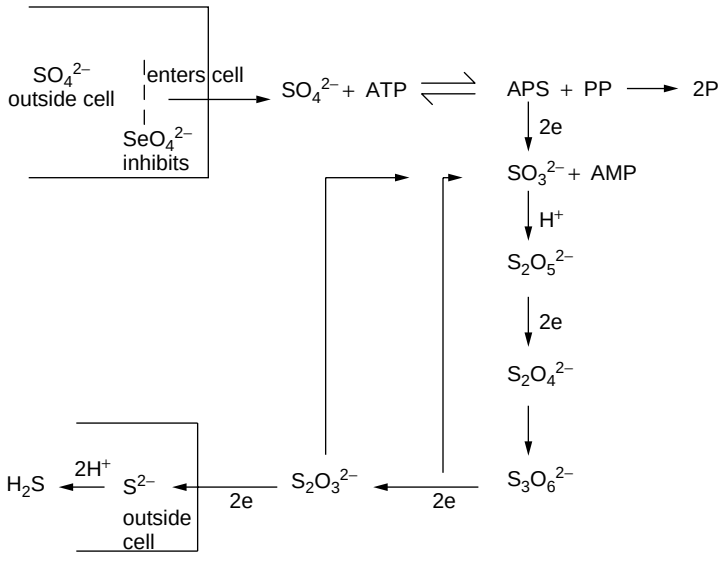

Figure 2. A proposed cyclic pathway for dissimilatory sulfate reduction (18).

growth on organic substances in the presence of sulfate: (*1*) generation of a proton gradient by the periplasmic hydrogenase itself linked to obligate H_2-cycling (28) and (*2*) proton translocation typically associated with a trace H_2-transformation model (29,30). Both models propose that bioenergetic mechanisms are dependent on the existence of at least two functionally distinct hydrogenases: one located in the cytoplasm involved in H_2-production and another in the periplasm involved in H_2-consumption.

Three types of hydrogenases have been isolated from the sulfate-reducing bacteria of the genus *Desulfovibrio*. According to the type of metal present, hydrogenases are generally divided into: the iron hydrogenase ([Fe] hydrogenase), the nickel-(iron-sulfur)-containing hydrogenase ([NiFe] hydrogenase) and the nickel-(iron-sulfur)-selenium containing hydrogenase ([NiFeSe] hydrogenase). They differ in their subunit and metal compositions, physicochemical characteristics, amino acid sequences, immunological reactivities, gene structures, and their catalytic properties (31). The [NiFe] hydrogenases have been found in all species of *Desulfovibrio* investigated to date. This class of hydrogenases can be localized in the periplasm, the cytoplasm, and/or the membrane depending on the SRB species and are particularly resistant to inhibitors such as CO and NO_2^- (32). [NiFeSe] hydrogenases, which contain nickel and selenium in equimolecular amounts, are only found in some species of *Desulfovibrio*. The [Fe] hydrogenase has the highest specific activity in the evolution and consumption of hydrogen and this enzyme is the most sensitive to CO and NO_2^-. It is not present in all species of *Desulfovibrio* (33).

The three classes of hydrogenases are not uniformly distributed in all *Desulfovibrio* and an individual species may contain one (e.g., [NiFe] hydrogenase in *D. gigas*), two (e.g., [NiFe] and [NiFeSe] hydrogenases in *D. baculatus*) or three hydrogenases (e.g., [Fe], [NiFe], [NiFeSe] hydrogenases in *D. vulgaris* Hildenborough). Most of the hydrogenases isolated from the genus *Desulfovibrio* are confined to the periplasmic space; however, membrane-bound and cytoplasm-located enzymes have also been described (34).

All three types of hydrogenases catalyze the same basic reaction, the reversible activation of the hydrogen molecule by a heterolytic mechanism. The proton-deuterium exchange reaction, the para-ortho hydrogen conversion, the hydrogen production from reduced methyl viologen and the hydrogen utilization with various artificial and natural electron acceptors can determine the activity of hydrogenases, which varies with pH and temperature (35,36).

Apart from their participation in energy production (i.e., the involvement in hydrogen cycling and the generation of a proton gradient), the hydrogenases of SRB are proposed to play an important role in biocorrosion (37).

MODELS OF SRB-INFLUENCED CORROSION

The role of SRB has been documented in pitting corrosion of iron-based alloys in both aquatic and terrestrial environments under anoxic, as well as oxygenated conditions (Figs. 3 and 4). The number of SRB detected in a system, as either suspended or attached populations, does not necessarily correlate with the extent or rate of corrosion and different types of SRB dissimilar in their physiology vary in the ability to influence metal deterioration (38–40). However, no clear consensus has yet been reached linking specific bacterial metabolic rates to observed corrosion rates.

Several key theories such as:

- The depolarizing effect of hydrogenase enzyme.
- Cathodic depolarization due to biogenically produced iron sulfide.
- Anodic depolarization due to the formation of iron sulfide corrosion products.

along with reports on the generation of corrosive phosphorous compounds and binding of metal ions by SRB exopolymers have been proposed to explain the mechanisms by which these bacteria can influence the corrosion reaction (41–43). It is now accepted that one predominant mechanism may not exist and that a number of processes are involved (44–46).

Hydrogenase Enzyme as Depolarizing Agent — Early Studies

In 1934, von Wolzogen Kühr and van der Vlugt proposed what is now referred to as the classical mechanism of anaerobic corrosion of ferrous metals in the presence of SRB, also known as the cathodic depolarization theory (2). The essential step in this theory involves the removal of hydrogen (cathodic depolarization) by the activity of the hydrogenase enzyme. The electron removal as a result of hydrogen utilization forces more iron to be dissolved at the anode. The main steps involved are listed in the following text (reactions 6 to 12) and depicted in Figure 5.

anodic reaction:

$$4Fe \rightarrow 4Fe^{2+} + 8e^- \quad (6)$$

dissociation of water:

$$8H_2O \rightarrow 8H^+ + 8OH^- \quad (7)$$

cathodic reaction:

$$8e^- + 8H^+ \rightarrow 8H \quad (8)$$

cathodic depolarization:

$$SO_4{}^{2-} + 8H \rightarrow S^{2-} + 4H_2O \quad (9)$$

corrosion products:

$$Fe^{2+} + S^{2-} \rightarrow FeS \quad (10)$$

corrosion products:

$$3Fe^{2+} + 6OH^- \rightarrow 3Fe(OH)_2 \quad (11)$$

overall reaction:

$$4Fe + SO_4{}^{2-} + 4H_2O \rightarrow 3Fe(OH)_2 + FeS + 2OH^- \quad (12)$$

Using cathodic polarization measurements, a range of studies demonstrated that the SRB species with

Scanning electron micrograph demonstrating localized corrosion on the surface of AISI 316 stainless steel following the removal of a 14-day-old biofilm formed in a pure culture of the marine sulfate-reducing bacterium *Desulfovibrio indonensensis*. Corrosion is visible as pitting attack of varying intensity.

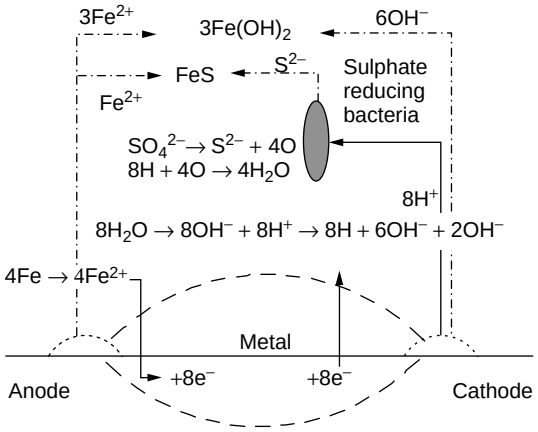

Figure 5. Schematic representation of the cathodic depolarization process of ferrous metal in the presence of sulfate-reducing bacteria.

detectable hydrogenase activity were able to depolarize the mild steel cathode. Depolarization did not occur in the cultures of SRB where hydrogenase activity was not recorded (47–49). Further support of the model was provided by demonstrating the dissolution of iron from a mild steel electrode electrically connected to a similar electrode in contact with a culture of hydrogenase-positive *Desulfovibrio* spp. on an agar surface containing benzyl viologen (BV), acting as electron acceptor. The SRB oxidized cathodic hydrogen and transferred the electrons to the redox dye, BV instead of sulfate (50,51).

However, the latter experiment met with criticisms since it was likely that hydrogenase-positive SRB catalyzed not only the consumption of hydrogen but also the liberation of hydrogen by reduced BV. The apparent hydrogenase-dependent cathodic depolarization was claimed to be an experimental artifact (15). A number of follow-up studies produced inconclusive or contradicting results leading to the revision of the proposed SRB corrosion model based solely on the hydrogenase activity.

Iron Sulfide as Depolarizing Compound

Low corrosion rates were measured in semicontinuous or continuous hydrogenase-positive SRB cultures grown with low ferrous iron concentration in lactate medium containing sulfate due to the formation of a protective iron sulfide film. When this film ruptured, much higher corrosion rates were recorded. Moreover, in the media with a high ferrous ion concentration, high corrosion rates (on the order of 1 mm y^{-1}) were observed for both hydrogenase-positive and -negative SRB strains. These results prompted investigation into the involvement of biologically generated sulfides in the SRB-mediated biocorrosion phenomenon (52). Detailed studies demonstrated that the initial sulfide film formed during corrosion was in the form of a continuous, adherent, and protective layer of mackinawite ($Fe_{1-x}S$). However, this film showed a degree of physical disruption in a time-dependent modification to greigite (Fe_3S_4). In the presence of higher soluble iron concentrations there was a similar loss of protective mackinawite film with the conversion to smythite (Fe_9S_{11}) and pyrrothite (FeS_{1+x}). In each case, this loss of the uniform protective mackinawite film generated active electrochemical cells between areas of unreacted and unprotected steel and deposits of the various ferrous sulfides, with the resulting corrosion occurring by cathodic stimulation.

Many sulfides under near-surface natural environmental conditions may only be produced by enzymatically catalyzed microbiological pathways on specific substrates such as metals. For example, formation and stability of the sulfide mineral, mackinawite, is dependent on a continuously acting hydrogen sulfide source. Although abiotic sources of sulfide may also lead to mackinawite formation in the absence of enzymatically governed biological reactions (53), the most common source of sulfide responsible for the vast majority of industrially related corrosion is that produced by SRB (54,55). Although mackinawite formation is not favored under standard thermodynamic conditions common to many corrosion scenarios, it is frequently found where SRB have been detected. On continued exposure to SRB, mackinawite alters to greigite and smythite and finally to pyrrhotite. Greigite is associated with generalized corrosion of iron, while smythite is indicative of pitting attack. The presence of mackinawite and greigite among corrosion products of ferrous materials is generally considered as proof that SRB participated in the corrosion reaction (56). Although pyrite (FeS_2) is not a common iron corrosion product, SRB can produce pyrite from mackinawite in contact with elemental sulfur.

Mineral signatures of both crystalline and amorphous iron sulfides indicative of SRB-mediated corrosion are commonly detected using X-ray diffraction (XRD) and energy dispersive X-ray analysis (EDX). Little is known about subsequent crystallization of amorphous sulfides, although biomineralization around SRB colonies, or within biofilm matrix, may be a key process.

The quantitative importance of cathode depolarization by solid FeS was demonstrated by the addition of chemically prepared FeS to mild steel test coupons in the presence and absence of *Desulfovibrio* spp. and replacing sulfate with fumarate as terminal electron acceptor for bacterial reduction processes. The extent of corrosion as assayed both by polarization and by weight loss measurements, was proportional to the FeS added and dependent on direct contact between the sulfide and the metal surface (57).

Comparison of the corrosion of mild steel by chemically prepared FeS and biogenically derived FeS indicated that, in media of high Fe^{2+} concentration, most of the corrosion in pure SRB cultures was attributed to the biogenically derived FeS (58–60). The corrosion caused by the biogenic FeS appeared identical to that caused by FeS from inorganic reactions (61).

Thus, a new model emerged, which proposed that corrosion of iron-based alloys in the presence of SRB proceeded under reduced conditions through cathodic stimulation of electrochemicals cells established between areas of unreacted metal (anode) and deposits of various biogenically generated reduced ferrous sulfide corrosion products (cathode).

Iron Sulfide and Hydrogenase as Depolarizing Agents

It has been noted that the presence of SRB is required to maintain the chemical integrity and electrochemical activity of iron sulfide species. In bacteria-free cultures the depolarizing capacity of FeS diminished with time, possibly as a result of the bonding of atomic hydrogen within the FeS crystals lattice. However, the corroding ability of the FeS was restored in active SRB cultures.

A theory was constructed proposing that the cathodic reaction, namely, H_2 evolution resulting from reaction of Fe^{2+} with bacterially produced S^{2-} occurred on the FeS deposits (41). It further postulated that SRB present as biofilms on the surface of FeS continually regenerated or depolarized the FeS by the removal of atomic hydrogen as a result of hydrogenase activity. This mechanism would explain the continued high rates of mild steel corrosion in biologically active, SRB-harboring systems.

Studies on physiology of SRB provided evidence that in oxygen-free environments bacteria were able to utilize

cathodic H_2 with sulfate acting as the sole source of energy (62–64). However, this process, which required the activity of hydrogenase, was influenced by the availability of organic electron donors. It was concluded that in the presence of SRB, anoxic aqueous environments rich in anaerobically degradable organic matter (e.g., interior of sewer pipes) should be more corrosive than environments that are mainly inorganic (e.g., in geothermal heating plants). These findings led to reevaluation of the role played by hydrogenase in the corrosion process.

Enzyme Hydrogenase as Depolarizing Agent — New Approach

Although the role of iron sulfide in the SRB-mediated corrosion process could not be dismissed, it has been argued that the oxidation of cathodically produced H_2 was the determining step. Experiments were conducted to demonstrate that the separation of bacteria from the surface by a dialysis membrane prevented the utilization of cathodic H_2 by the SRB (65). Furthermore, the current observed in the presence of biofilms formed by the hydrogenase-positive SRB did not appear when biofilms were developed by hydrogenase-negative SRB cultures. It has also been demonstrated that the hydrogenase activity did not depend on the presence of viable SRB cells and that the cell-free extracts of hydrogenase enzyme increased the corrosion of mild steel (66,67). Thus, it was determined that regardless of the presence of living cells, hydrogenase might still retain its depolarizing capabilities, which could be expressed under appropriate reducing conditions.

Studies on mixed populations of SRB in biofilms isolated from corroded and undamaged oil pipelines revealed that the biofilm with detectable hydrogenase activity was associated with a significantly higher corrosion rate (7.70 mm $year^{-1}$) than the noncorrosive biofilm (0.48 mm $year^{-1}$). Both biofilms had comparable number of SRB cells per unit area; however, no measurable hydrogenase activity could be found in the latter type of biofilm. It was therefore concluded that the susceptibility of a system to biocorrosion depended on the microbial makeup of the mixed population of SRB and the activity of the hydrogenase enzyme (68).

Subsequent investigations revealed that the hydrogenase activity of SRB is regulated by dissolved Fe^{2+} availability, which is subject to repression/derepression mechanism and depends on SRB species (69,70). It is therefore likely that apart from other parameters affecting enzyme performance, bacterial uptake of cathodically generated H_2 governed by the activity of hydrogenase, and hence the rate of cathodic depolarization, fluctuates depending on the ecology and physiology of SRB species within biofilms and the level of bioavailable Fe^{2+} ions. To date, hydrogenase contribution to the SRB-enhanced corrosion process has not been assessed in a quantitative manner.

The Influence of Oxygen

Numerous observations confirmed that the presence of dissolved oxygen played an important part in the SRB-influenced corrosion of ferrous metals (71–73). A corrosion rate recorded when the vessel containing SRB and steel foil was exposed to oxygen on an intermittent basis was 50 times higher than that reported under anaerobic conditions (74).

It is believed that under alternating aerated and anoxic conditions, the corrosion mechanism of mild steel is related to the large Fe-S pool, which provides both surface area for colonization and hydrogen to SRB, as well as potentially corrosive elemental sulfur and polysulfide (46). The latter can be produced as a result of sulfide reacting with oxygen. When anoxic sites with SRB become aerobic, new minerals are formed from the original corrosion products. The oxidation process yields lepidocrocite or goethite and rhombic or orthorhombic sulfur. Mixed reducing and oxidizing conditions, such as those commonly found in certain pipeline systems, often produce the partially oxidized iron oxide magnetite along with lepidocrocite and goethite (56).

It has been suggested that at the aerobic/anoxic interface, the corrosion reaction sequence due to accumulation of FeS might proceed in two stages. Firstly, the iron sulfide on the steel surface may form a protective film of mackinawite, thereby exerting anodic control of metal dissolution by limiting ferrous ion diffusion through the sulfide film. Subsequent breakdown of this protective film would create an electrochemical cell with sulfide-free steel acting as the anode, iron sulfide acting as the cathode, and sulfur serving as the electron acceptor to promote cathodic depolarization.

Anodic Depolarization

Careful analysis of cathodic depolarization theory and in particular the role of sulfides led to an alternative hypothesis. The latter proposed that SRB promoted corrosion by a mechanism of anodic depolarization, essentially dependent on sulfide production. This model postulates that an anode is first created by local H^+ production at a focus of SRB metabolic activity, with ensuing metal dissolution (75,76). A key element in generating the necessary kinetic conditions is a localized acidification at the anode resulting from the formation of iron sulfide corrosion products according to reaction (13):

$$Fe^{2+} + HS^- \rightarrow FeS \downarrow + H^+ \qquad (13)$$

The reaction also has the secondary effect of removing HS^-, hence reducing the effectiveness of the H_2S/HS^- buffer system, which would resist local acidification. The availability of sulfide and free iron would determine the nature of the corrosion products formed. If the local sulfide concentration was low, as would be the case with the reaction aforementioned, in the presence of high soluble iron concentration, the product formed would most likely be mackinawite, which, as already described, is considered to be nonprotective. Where sulfide was in excess, the product would be the more protective pyrite. Although pitting corrosion of steel can theoretically be explained by the mechanism of anodic depolarization, the processes under which locally acidic conditions are maintained needs to be confirmed.

Corrosive Phosphorus Compounds

It has been suggested that not only iron sulfides, but also a highly active phosphorus compound produced by SRB, could cause anaerobic corrosion of ferrous alloys (77). The corrosion reaction yielded iron phosphide as a corrosion product. Cathodic depolarization experiments on an agar surface in the absence of an electron acceptor resulted in the blackening of the agar at areas in contact with SRB. On extraction and analysis by X-ray diffraction, the black precipitate was found to contain iron phosphide (Fe_2P). It was concluded that the phosphorus compound was produced as a result of both the activities of SRB and the effect of H_2S on phosphate, phosphite, and hypophosphite. Although subsequent studies have excluded inorganic phosphate as the source of phosphorus metabolized by the SRB into the corrosive phosphorous product (78), it has been found that corrosive activity of hydrogenase can be augmented by the availability of inorganic phosphate (79). Organic phosphate in the form of phytic acid, a common metabolite of plants, was proposed as the form of phosphate metabolized by the SRB into the corrosive phosphorus product in the field. To date, however, the role of phosphorous compounds in SRB-influenced corrosion remains ambiguous.

The Role of Extracellular Polymeric Substances

The ability of SRB to produce EPS in batch cultures were first documented by Ochynski and Postgate (1963) who also reported the carbohydrate composition of exopolymer using paper chromatography (80). Subsequent investigations demonstrated that both freely suspended and surface-associated SRB are able to synthesize exopolymers varying in their chemical composition depending on SRB species and growth conditions (81–83). Electron and atomic force microscopy allowed visualization of EPS in SRB biofilms (84). Binding of metal ions, in particular Fe, Cr, Mo, and Ni by SRB exopolymers has also been documented (85). Additional study confirmed the direct involvement of a high molecular weight, thermostable protein-carbohydrate complex produced by a marine SRB in pitting corrosion of mild steel (86). Further investigation demonstrated SRB species specificity in binding of Fe^{2+} ions originating from the corroding surface of mild steel by exopolymers released into the planktonic phase of bacterial culture media (87). It is therefore conceivable that in addition to already listed processes, complex organic macromolecules excreted by SRB could contribute to corrosion at the biofilm/metal interface by mechanisms outlined in previous sections of this entry.

CONCLUSION

A hypothesis coupling electrochemical and physiological electron transfer processes has been presented to rationalize present understanding of the SRB-influenced corrosion mechanisms and to create a framework for future studies (6). The key features of this hypothesis are summarized below.

Phylogenetically and physiologically diverse anaerobic sulfate-reducing bacteria associated with mixed species microbial consortia thriving as biofilms on surfaces of metallic substrata can influence corrosion processes mainly due to the generation of sulfide ions. The production of the latter varies with SRB species and is linked to the type and activity of hydrogenase enzyme(s) present in all SRB. The enzymatically catalyzed reactions, which are influenced by bacterial ecology and physiological and environmental factors, facilitate oxidation of molecular hydrogen evolved at the cathode of the electrochemical corrosion cell, leading to cathodic depolarization. Metal that dissolves at the electrochemical anode can combine with the biogenically generated sulfide to form corrosion products such as metal sulfides. The latter will precipitate within the anoxic zones of the biofilm, causing further stimulation of either the cathodic reaction by serving as an electron sink and/or by influencing the anodic reaction, namely, further metal dissolution, due to local acidification at the anode. Depending on their physicochemical characteristics, the accumulating iron sulfides can be either protective or corrosive. A number of factors, for example, the traces of oxygen, levels of unbound iron ions, the concentration of soluble sulfide and the presence of other microorganisms such as sulfur-oxidizing bacteria, methanogenic bacteria, or iron-oxidizing/reducing bacteria determine both the metabolic activity of SRB and the type of metal sulfide species formed.

In the presence of SRB-harboring biofilms the highest corrosion rates were recorded when there are fluctuating aerobic-anaerobic (O_2/AnO_2) conditions. Under such conditions, sulfide ions and ferrous ions are prone to biotic/abiotic oxidation with oxygen acting as ultimate electron acceptor, which would lead to the development of corrosion products such as ferric oxides/hydroxides and elemental sulfur. A descriptive model of SRB-mediated corrosion is depicted in Figure 6 (46). The model demonstrates that corrosion in the presence of SRB occurs by a

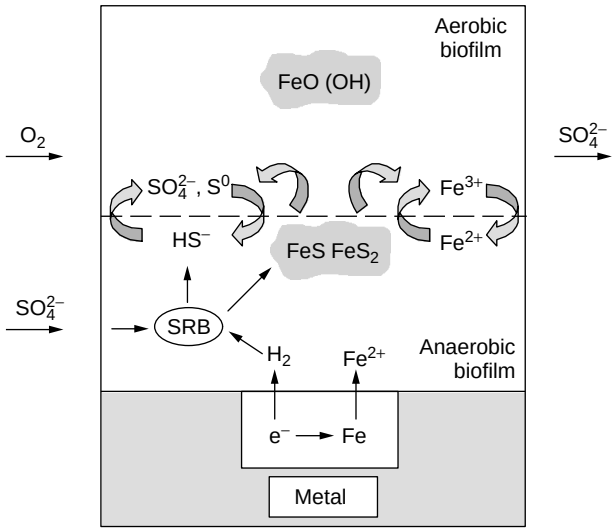

Figure 6. A diagram of the corrosion of ferrous alloys in an aerobic/anaerobic biofilm system due to the metabolic activity of sulfate-reducing bacteria. In this model oxygen acts as terminal electron acceptor (46).

process of electron transfer from the base metal to oxygen as ultimate electron acceptor, through a series of coupled redox reactions of electrochemical, biotic, and abiotic character.

It is unequivocally accepted that SRB-influenced deterioration of iron and ferrous alloys does not involve any new mechanisms of corrosion. The observed metal deterioration in SRB-active environments is due to microbially influenced changes in surface conditions of the metallic substratum that promote the establishment and/or maintenance of cathodic and/or anodic reactions not normally favored under otherwise similar conditions in the absence of these bacteria. Notwithstanding considerable research efforts undertaken to elucidate the role that sulfate-reducers play in corrosion, there is still a number of ambiguities related to the contribution of biologically catalyzed reactions, including the quantitative contribution of enzymic activities and significance of exopolymers, to the overall corrosion reaction. Undoubtedly, the better understanding of relationships, both direct and indirect, between the electrochemical corrosion reactions and spatial and temporal processes associated with metabolic activities of SRB within biofilms would aid in resolving such uncertainties.

BIODEGRADABILITY: METHODS FOR ASSESSING BIODEGRADABILITY UNDER LABORATORY AND FIELD CONDITION

EUGENE L. MADSEN
Cornell University
Ithaca, New York

Herein are described basic principles pertinent to the design, implementation, and interpretation of both laboratory and field determinations of biodegradability. The information is applicable to both organic and inorganic contamination problems whose solutions can be addressed microbiologically. However, the focus here is primarily on assessing the biodegradability of organic compounds.

DEFINITIONS OF BIODEGRADABILITY AND BIODEGRADATION

"Biodegradability" embodies qualities representing the susceptibility of substances to alteration by microbial processes (1). The substances may be organic or inorganic. The alteration may be brought about by (*1*) intra- or extracellular enzymatic attack that is essential for the growth of the microorganism(s) (e.g., the attacked substances are used as a source of carbon, energy, nitrogen, or other nutrients or as a final electron acceptor), (*2*) enzymatic attack that is beneficial because it serves some protective purpose (e.g., mobilization of toxic mercury away from the vicinity of the cells), (*3*) enzymatic attack that is of no detectable benefit to the microorganism (e.g., cometabolic reactions in which a physiologically useful primary substrate induces the production of enzymes that fortuitously alter the molecular structure of another compound), and (*4*) nonenzymatic reactions stemming from by-products of microbial physiology that cause geochemical change (e.g., consumption of oxygen, production of fermentation by-products, or an alteration in pH).

"Biodegradation" of organic compounds is the partial simplification or complete destruction of their molecular structure by physiological reactions catalyzed by microorganisms (2–7). Biodegradation is routinely measured by applying chemical and physiological assays to laboratory incubations of flasks containing pure cultures of microorganisms, mixed cultures, or environmental samples (e.g., soil, water, sediment, or industrial sludges). When attempting to measure biodegradation or judge the biodegradability of substances, the investigator must define the environmental context so that potential reactants and products can be identified. Microorganisms

can catalyze only reactions that are thermodynamically possible. Furthermore, reaction mechanisms are largely constrained by precedents set during the evolution of physiological and biochemical functions. Because of ongoing microbial evolution and biochemical research, our understanding of mechanisms by which microorganisms degrade substrates continues to expand.

LABORATORY METHODS

Principles for Measuring Biodegradability in the Laboratory

Biodegradation methodologies are designed to confirm, demonstrate, and explore both the net chemical changes and the associated intracellular details pertinent to how microorganisms influence the fate of contaminants. The procedures span a broad range of disciplines and sophisticated protocols. Figure 1 provides an overview of the variety of objectives, disciplines, and protocols that play key roles in biodegradation research. The two phases that serve as main divisions in Figure 1 result from the degree to which scientific detail is pursued. Phase 1 procedures treat samples of soil, sediments, water, or industrial effluents simply as "black boxes" that do or do not make contaminant compounds disappear, as judged by analytical chemical criteria. Phase 2 begins with the isolation of pure cultures of contaminant-degrading microorganisms. Once these have been obtained, refined physiological, enzymatic, and molecular biological assays may then be performed. As DNA sequences of genes that code for metabolic pathways become increasingly available, molecular procedures will continue to gain prominence in biodegradation protocols. One of the final goals of the procedures shown in phase 2 is understanding the molecular basis for gene expression and regulation.

Design and Implementation of Biodegradation Assays Using Environmental Samples and Pure Cultures

The traditional black-box approach to biodegradation assays asks the question, "Are microorganisms within this complex microbial community (e.g., derived from soil, water, sediment, or industrial sludge) able to metabolize the compound of interest?" To answer this question, one aseptically gathers samples from a given field location, dispenses known weights or volumes of the samples to replicated vessels, handles the samples in a variety of ways that include a treatment that

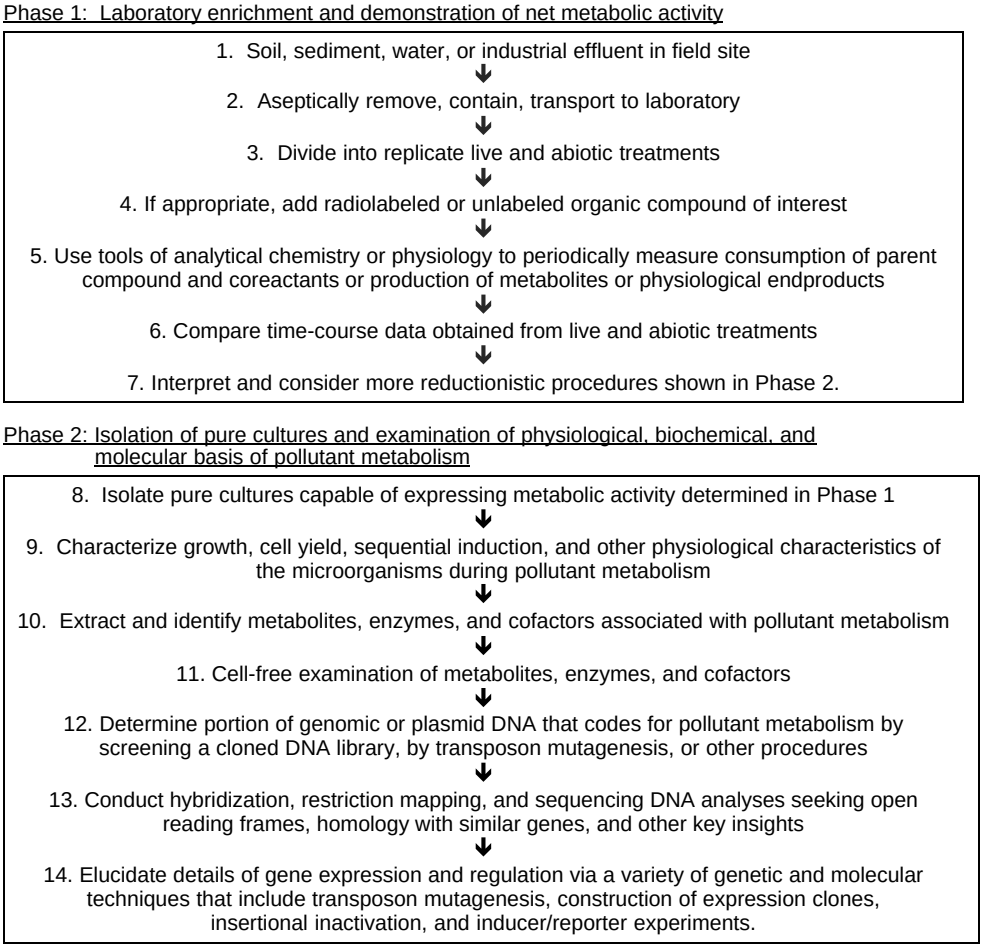

Figure 1. Two phases of procedures for understanding biodegradation processes. Phase 1 begins with environmental samples. Phase 2 proceeds through biochemical and molecular aspects of pollutant metabolism by single microorganisms (from Ref. 1).

has been either sterilized or poisoned, incubates the test samples under laboratory conditions, and employs over time both chemical and physiological assays that monitor the fate of the test compound within experimental vessels (Fig. 1; phase 1). The objective of this general experimental design for biodegradation procedures using environmental samples or pure cultures is remarkably simple, yet there is a substantial series of obstacles that must be overcome before one obtains clear data that truly test a given set of specific hypotheses. Every design parameter selected for inclusion in a biodegradation assay can influence the resultant data. Therefore, decisions made in implementing biodegradation assays should be well reasoned. Table 1 summarizes many of the practical and theoretical decisions that must be made in developing biodegradation protocols. Step 1, a background issue considering information use, is fundamental to all related experimental decisions. The degree to which experimental minutiae of a given testing protocol must be initially considered is commensurate with the scrutiny that the final data will undergo. Artifacts and biases in data are virtually unavoidable in biodegradation assays (see later); thus, it may be wise to simply accept methodological limitations rather than worry about initial potential technical design flaws that may later have no practical impact.

Once the reason for conducting the biodegradation assay has been put in perspective (Table 1, step 1), another background issue, that of physiological conditions, should be confronted. Step 2 appears in Table 1 to acknowledge

Table 1. Steps and Decisions Essential for Implementing Biodegradation Assays (After Ref. 7)

Step	Decisions
1. *Background*: Determine how the resultant data will be interpreted and used	Objectives range from information about crude "biodegradation potential" to tests of specific hypotheses about physiological or biochemical factors governing biodegradation processes
2. *Background*: Select the physiological conditions under which pollutant metabolism is to be measured	The pivotal physiological concern is defining the mechanism by which the compound(s) is metabolized. Of primary importance is discriminating among such possibilities as cometabolic reactions, its use as an electron acceptor, and its use as a carbon and energy source. Other concerns address conditions in experimental flasks such as nutrient sufficiency, which final electron acceptor regimen should dominate, what pollutant concentration ranges should be examined, and if conditions should change (batch culture) or remain constant (continuous culture) during the assay
3. *Practice*: Select and aseptically prepare or sample the microorganisms whose physiological activity is of interest	For assays using environmental or industrial samples, aseptic sampling techniques involve use of tools (such as flame-sterilized scoops, spatulas, and knives) and sample placement within sterilized glass or plastic containers. For assays using pure cultures of microorganisms, the microorganisms must be aseptically grown under conditions that carefully define the cell physiological status (e.g., stage of growth, cell numbers, induced enzyme systems, nutritional state) desired by the investigator
4. *Practice*: Select the physical apparatus and hence the physiological setting for biodegradation reactions to occur	Glass (or plastic) vessels must be assembled. These contain the test compound(s), the microorganisms being studied, and any accompanying components of soils, sediments, sludges, and water in various ratios. Experimental hardware may be fitted with a variety of gas and water exchange assemblies for maintaining physiological conditions and assaying reaction progress
5. *Practice*: Select a metabolic activity assay that is sensitive, effective, convenient, inexpensive, and compatible with experimental objectives	The general assay categories are physiological assays (e.g., respirometry or growth) and chemical assays (which include gas chromatography, gas chromatography-mass spectrometry, high-performance liquid chromatography, and radiotracer techniques)
6. *Practice*: Aseptically prepare stock solutions of ^{14}C-labeled organic compounds. Check radiopurity	The validity of the results from biodegradation assays using ^{14}C-labeled substrates is dependent on substrate radiopurity and aseptic preparation of stock solutions
7. *Practice*: Complete the experimental design parameters for the assay vessels and the assays themselves	a. Concentration of the test substrate(s) b. Number of replicated flasks per treatment c. Whether flasks can be sampled repeatedly or if they require sacrifice at each sampling period d. Frequency of sampling e. Method of preparing abiotic controls f. Methods for separating radioactive parent and product compounds from one another

the fact that biodegradation is only a small portion of the perhaps thousands of physiological reactions occurring simultaneously when both pure cultures and mixed microbial populations in environmental samples are incubated in the laboratory. These physiological processes feed one another, interact in complex ways, and can be governed by many of the sometimes inadvertent physical and chemical manipulations made while preparing, incubating, and sampling assay vessels. Uncertainties become particularly striking when one is attempting to troubleshoot failed attempts to demonstrate biodegradation activity. The interplay between fundamental knowledge of physiology and experimental design parameters demands that a variety of issues be confronted: (*1*) The mechanism by which the compound is metabolized (e.g., as a carbon source, as a nitrogen source, or as a cometabolic substrate whose transformation will occur only when another compound is supplied), (*2*) inclusion versus exclusion of potential growth-limiting vitamins and minerals, (*3*) inclusion versus exclusion of air in the headspace of the reaction vessel, (*4*) the solid-to-liquid ratios used in test vessels containing soil, sediments, or sludges, (*5*) the multiple roles of compounds in physiological reactions (for instance, nitrate can serve as both a nitrogen source and a final electron acceptor), and (*6*) the fact that the compound whose biodegradation is being tested may be toxic at high concentrations or fall below some minimum threshold value for uptake and cell growth at low concentrations. Background considerations raised in steps 1 and 2 guide most of the practical steps needed for completing the implementation of the biodegradation assays (Table 1, steps 3 to 7). Detailed considerations pertinent to steps 3 to 7 (Table 1) have been discussed previously (1,7,8).

FIELD METHODS

Assessing Biodegradation in the Field

There is a fundamental paradigm for verifying that the biodegradation processes we hope are occurring are actually occurring in field sites. The paradigm begins by modestly admitting that both microorganisms and their habitats are incomplete puzzles. Our task is to relentlessly find new ways to create the puzzle pieces describing microbiological processes and to assemble them logically. The scientific disciplines that contribute information and techniques toward creating the puzzle pieces include microbiology, geochemistry, hydrology, biochemistry, soil science, physiology, molecular biology, analytical chemistry, computer modeling, and both environmental and chemical engineering. It must be recognized that each of these disciplines is actively being advanced and therefore, contributes a dynamic spectrum of expertise to bioremediation, ranging from theoretical and basic knowledge to applied and practical instrumentation.

Verifying field biodegradation is perhaps best achieved in two mutually supportive ways (9): (*1*) succinctly using common sense and (*2*) using elaborate reasoning and analyses (see later). The succinct answer is "We know that bioremediation is taking place when all of the available information congeals as a coherent picture (it makes sense)." There needs to be consistency, redundancy, and convergence of all types of evidence from as many of the appropriate scientific disciplines as are available.

Because the key players in bioremediation are microorganisms, it is essential that the process makes sense to the microorganisms themselves, in the physiological and thermodynamic contexts where they reside. Contexts for bioremediation processes range from a variety of field sites in which organic contaminants have spilled accidentally (e.g., marine coastlines, desert soils, freshwater streams, or anaerobic deep subsurface sediments) to various aerobic or anaerobic engineered stirred and staged bioreactor systems. Regardless of the particular context, each must be scrutinized as a habitat for microbial metabolism in which individual cells can develop into populations and complex ecological communities whose fundamental physiological needs for adenosine triphosphate generation, carbon assimilation, terminal electron acceptors, other inorganic and organic nutrients, and dynamic intercellular interactions (competition, synergism, interspecies hydrogen transfer, commensalism, predation, parasitism, etc.) demand constantly improving sets of hypotheses aimed at refining our understanding of bioremediation. Once the fundamental thermodynamic, nutritional, and ecological bases for the sought metabolic functions are initially conjectured, a series of hypotheses will naturally unfold that provide a means for documenting the bioremediation process of interest on a site-specific and case-specific basis.

Table 2 contains four examples of contaminants in field sites whose physiological contexts dictate how microorganisms can metabolize the offending organic compounds. Knowledge from laboratory-based (using environmental samples, mixed cultures, and/or pure cultures) assays provides the biochemical basis for mechanisms operating in the field. Answers to key questions, such as "Are the contaminants suitable carbon and electron sources?," "Which physiological electron acceptors (oxygen, NO_3^-, Fe^{3+}, Mn^{4+}, SO_4^{2-}, carbon dioxide) are required coreactants?," "Are the contaminants, themselves, final electron acceptors?," and "What competing reactions may slow or prevent the sought biodegradation?," provide a framework that launches a broad array of possible assays that can argue for or against the successful establishment of a given biodegradation process (1,7,8). The example contaminated sites of Table 2 range from aerobic soil to aerobic and anaerobic aquifers. The assays range from field-based oxygen probes, to counts of contaminant-degrading bacteria, to laboratory biodegradation assays, and to molecular biological assays of DNA and ribonucleic acid. The following sections of this article elaborate on the reasoning and detailed analyses required for the generation and testing of hypotheses that allow bioremediation technology to be verified. Related aspects of bioremediation and biodegradation have been reviewed in several recent books (2,21–29).

A Three-Step Strategy for Verifying Bioremediation

The reasons for establishing sound scientific criteria for microbiological involvement in contaminant loss are (*1*) biodegradation processes are often unique in their

Table 2. Examples of Contaminated Sites, Hypothesized Key Bioremediation Processes, and the Corresponding Field and Laboratory Measurements that Allow Site-Specific and Case-Specific Verification of Microbiological Destruction of Contaminants (After Ref. 9)

Example Sites	Hypothesized Key Bioremediation Processes	Supportive Field and Laboratory Measurements
Aerobic soil contaminated with petroleum products	Heterotrophic microorganisms are growing using petroleum components as carbon and energy sources (10,11,12). Metabolism in this context relies on oxygen, both in the attack of aliphatic and aromatic compounds, and as a final electron acceptor in respiratory chains	• Coincident depletion of petroleum components and oxygen in the field • Corresponding production of carbon dioxide • High numbers of petroleum-degrading aerobic heterotrophs inside but not outside the contaminated areas • If petroleum has a distinctive $^{13}C/^{12}C$ ratio, this should be reflected in the carbon dioxide • Adding nitrogen or phosphorus fertilizer to replicated plots may relieve nutrient limitation, hence enhance loss from field plots compared to unfertilized controls • Genes involved in the catabolism of petroleum components should be expressed in high abundance inside but not outside the contaminated zone
Anaerobic aquifer contaminated with perchloroethylene	Dehalorespiring bacteria are using chlorinated aliphatic compounds as final electron acceptors (13,14). Dechlorination reactions are governed by: complex microbial and chemical interactions that generate physiological electron sources (especially hydrogen gas); the presence of alternative electron acceptors (NO_3^-, Mn^{4+}, Fe^{3+}, SO_4^{2-}, carbon dioxide) in site sediments and waters; and ecological and physiological competition among the microorganisms carrying out the metabolism that links electron donors and acceptors (15,16)	• Dechlorinated daughter products, trichloroethene (TCE), dichloroethenes (DCE), vinylchloride (VC) within contaminant plume • Products of complete detoxification, such as ethene, should be inside and not outside the plume • Adaptation of site microorganisms to dehalorespiration can be documented by finding dechlorination activity in site samples from inside but not outside the contaminant plume • Immunological or polymerase chain reaction–based data demonstrating the presence of dehalorespiring enzymes, genes, and characteristic bacteria inside but not outside the plume
Aerobic aquifer contaminated with TCE	TCE destruction is achieved cometabolically by aerobic microorganisms supplied with a primary carbon source. Oxygenase enzymes (involved in metabolizing primary substrates such as methane, propane, toluene, and phenol) fortuitously convert TCE to unstable compounds that spontaneously hydrolyze to nontoxic and/or readily biodegradable components (17–19)	• Microcosms prepared with site samples consume TCE only when supplied with both oxygen and the primary substrate • In recirculating field site waters, TCE loss is enhanced only when both oxygen and the primary substrate are supplied • Assays for oxygenase enzymes, genes, and appropriate metabolites (e.g., *trans*-dichloro-ethylene oxide) reveal high abundances inside but not outside the contaminated zone
Anaerobic aquifer contaminated with jet fuel	Aromatic fuel components, especially toluene, serve as growth substrates for anaerobic microorganisms that utilize sulfate as a final electron acceptor	• Microcosms containing site sediments incubated under sulfate reducing conditions produce $^{14}CO_2$ from ^{14}C-labeled toluene and benzene (20) • Sulfate is depleted along the groundwater flow path in the field site • Dissolved inorganic carbon (e.g., carbon dioxide) increases along the flow path in field sites (20) • Contaminant plume has ceased advancing despite a constantly dissolving reservoir of jet fuel (20) • A solute transport model accounts for dispersion, flow velocity, and adsorption, and produces biodegradation rate estimates that are consistent with microcosm estimates (20)

capacity to break intramolecular bonds of contaminant compounds; thus, contaminants can be destroyed and not simply transferred from one location to another, as is the case in many other pollution control technologies; (*2*) when the mechanism of pollutant destruction is certain, key site management decisions about process enhancement can be made; and (*3*) for bioremediation to meet pollution-control needs of the society, the industry must adopt some standards for uniformity and quality control so that credibility and reliability can be attained (25–27).

However, the question remains: What is an adequate proof of bioremediation? The legal system of the United States provides a variety of categories of certainty in interpreting evidence. The categories depend on the type of the case and the significance of the issues. Among the different burdens of proof are (*1*) proof beyond reasonable doubt, (*2*) proof in a clear and convincing manner, and (*3*) proof beyond a preponderance of doubt. This article neither intends, nor is able, to dictate to regulatory or legal agencies what level of proof should be deemed adequate for bioremediation technology practitioners. Nonetheless, approaches are discussed here that can be used to distinguish biotic and abiotic reactions affecting contaminants at field sites in which bioremediation technology is being applied (for additional discussion see Refs. 1,6,7,11,12,25,26,30–37).

The consensus of a National Research Council (NRC) (25) committee in recommending criteria proving in situ bioremediation is as follows:

1. Develop historical records documenting loss of contaminants from field sites.
2. Perform laboratory assays unequivocally showing that microorganisms in site-derived samples have the potential to metabolize the contaminants under expected site conditions.
3. Demonstrate that the metabolic potential measured under criterion 2 is actually expressed in the field. To achieve this, microbiological mechanisms of contaminant attenuation must be distinguished from abiotic ones. Evidence deemed suitable for these purposes will vary according to the contaminants and conditions found at each site.

Implementing Step One: Site Monitoring to Understand Site Biogeochemistry and Establish Historical Trends of Contaminant Behavior. It must be recognized that virtually all locations in the biosphere (from the poles to the equator, contaminated or pristine sites, engineered bioreactors, or the deep sea) are inhabited by microorganisms. Furthermore, whenever physiological resources are available, microbial metabolic activity will occur. Thus, site characterization is designed to assess the resources and guide the documentation of their exploitation by microorganisms. There is a critical need to relate results of geochemical measurements performed on field samples directly back to in situ processes and conditions. For details of completing in situ analyses, avoiding site-sampling artifacts, and understanding site biogeochemistry see References 7,38– 40.

All site characterization data must be interpreted in terms of the physiological processes that produce and consume geochemical constituents. Final electron acceptors that dominate the physiological reactions of field sites (or discrete zones therein) provide useful criteria for categorizing biogeochemical regimes as aerobic, denitrifying, iron reducing, manganese reducing, fermentative, dehalogenating, sulfate reducing, or methanogenic (41–43). These physiological regimes are often separated in space and/or time in field sites and largely determine the mechanisms of contaminant biodegradation. Information establishing the physiological regime(s) operating at particular field sites is provided by field measurements of the contaminants themselves, of concentration gradients of coreactant final electron acceptors (e.g., oxygen, NO_3^-, Fe^{3+} Mn^{4+}, SO_4^{2-}, halogenated compounds), and of end products of microbial metabolism (e.g., carbon dioxide, Fe^{2+}, Mn^{2+}, S^{2-}, N_2O, NH_4^+, organic acids, reductive dehalogenation daughter products, and methane) along site transects. In this regard, Lovley and coworkers (44) and Chapelle and coworkers (45) have devised a gas sampling bulb protocol for anaerobic groundwaters in the field, which, in combination with hydrogen gas determinations and Winkler titrations for oxygen (40), provides definitive information on dominant anaerobic redox couples.

The goal of establishing site-specific historical records of the behavior of contaminants, coreactants, and metabolic products is a simple one. Theoretically, compilation of such field data documents the effects of contaminant-attenuating processes over time. In conjunction with other assays (see later), field data can be interpreted in ways that may implicate biodegradation as a cause of pollutant losses. However, as in understanding in situ physiological regimes, obtaining robust, interpretable field-monitoring data may be an elusive goal if contaminant characteristics and site conditions are complex. The overall objective is to establish a site-monitoring regime using a network of consistent sampling locations, which affords the acquisition of contaminant concentration and other measurements that are comparable over time. If the distribution of contaminants at the site and factors influencing contaminant transport (e.g., climate, hydrology, commercial, or industrial activities) are erratic, then the pertinent database on contaminant behavior may be so noisy as to mask any trends. However, in many sites the type of contaminant monitoring protocols required by concerned regulatory agencies can be integrated over time and can sometimes produce a clear historical record of diminishing contaminant concentrations from year to year. When such data exist, they assist in meeting the first criterion for proving in situ bioremediation.

Implementing Step Two: Laboratory Assays Demonstrating That Microorganisms in Site Samples Have the Potential to Transform the Contaminants Under Expected Site Conditions. The biodegradation assays discussed in this article are designed to ask the question: "Are microorganisms within samples of soil, water, or sediment microbial communities able to metabolize the compound(s) of interest under conditions that are relevant to the specific field site of interest?" To answer this question, one gathers samples

Table 3. Strategies for Obtaining Evidence for Field Expression and Biodegradation Processes (After Ref. 9)

Type of Strategy	Principles and Examples	References
Internal conservative tracers	Assess loss of certain compounds relative to the persistence of less-biodegradable, but similarly transported, compounds. Examples include using ratios of straight-to-branched chain alkanes (C_{17}/pristane, C_{18}/phytane) and ratios of other compounds to hopane in crude oil; ratios of lower to higher chlorinated congeners in PCB mixtures (trimethyl benzene can serve as a conservative tracer in enzene-toluene-ethylbenzene-xylene (BTEX) plumes); ratios of nonchlorinated to chlorinated aromatics in mixed solvents; and selective metabolism of one stereoisomer of particular pesticides (e.g., σ-chlorocyclohexane)	47–57
Added conservative tracers	In some field sites, contaminant mixtures may lack internal tracers but be amenable to the addition of materials that provide a baseline measure of various transport processes. Examples include helium to assess oxygen loss or carbon dioxide production in groundwater, propane to assess toluene loss from a stream, and bromide to assess groundwater flow	25,58,59
Added radioactive tracers	In rare instances, regulatory authorities have allowed intentional field release of radioactive (e.g., ^{14}C-labeled) pollutants in field sites. Subsequent recovery of $^{14}CO_2$, ^{14}C-metabolites, and ^{14}C-parent compounds provide, definitive proof of metabolic and other field processes	60–63
Added stable isotopic tracers	Pollutant compounds that are nonradioactive, but isotopically labeled with deuterium or ^{13}C, have been released in field sites. Subsequent stable isotopic analyses of field samples for labeled CO_2, metabolites, and/or the parent compound provide proof of metabolic and other field processes	64,65
Stable isotopic fractionation patterns	CO_2 has different $^{13}C/^{12}C$ ratios depending on the $^{13}C/^{12}C$ signature of the substrates respired and the ^{13}C-enriching process of methanogenesis. When site-specific signatures of both inorganic and organic carbon reservoirs have been characterized, the relative contribution of pollutant biodegradation to the pool of CO_2 can be discerned. The radioactive (^{14}C) component of CO_2 is also revealing because petroleum contaminants contain no ^{14}C	49,66–70
Detection of intermediary metabolites	When sufficient biochemical knowledge of pollutant biodegradation has accrued, particular metabolites can be targeted using a combination of careful sampling and analytical chemistry. Detection of stable (dead-end) metabolites and transient metabolites (indicative of "real-time" biodegradation) has been reported. The metabolites include *trans*- dichloroethylene oxide, dihydrodiols of aromatic compounds, DDE, and hydroxylated pesticides	71–77
Replicated field plots	Some relatively homogeneous field sites are amenable to randomized block designs of treatments that stimulate microbiological activity. Comparing the loss of pollutants from plots with and without nutrients and/or inocula can demonstrate effectively the role of microorganisms in field biodegradation	47,53,78–81
Microbial metabolic adaptation	Naturally occurring microbial communities that grow in response to pollutant exposure have predictable characteristics relative to adjacent unexposed communities. Adaptation is reflected in laboratory or field measure of: qualitative pollutant metabolian or rates of pollutant metabolism; numbers of specific pollutant degraders; and enhanced concentrations of protozoan predators of bacteria inside but not outside contaminant plumes	16,82
Molecular biological indicators	Based on molecular biological characterization of pure cultures capable of pollutant metabolism, a variety of assays consistent with established genetic sequences and their expression can be devised. These include polymerase chain reaction (PCR) amplification of structural genes, messenger ribonucleic acid (mRNA) extracted from field sites, reverse-transcriptase PCR detection of mRNAs, nucleic acid sequencing, immunodetection of enzymes and metabolites, and 16S ribosomal RNA analysis of the composition of microbial communities	83–90
Gradients of coreactants and/or products	Ongoing *in situ* metabolism of pollutants consumes physiological final electron acceptors and generates metabolic endproducts that reflect site-specific pollutant metabolism. Chemical gradients in field sites should be apparent using measures that include oxygen, NO_3^-, Mn^{4+}, Fe^{3+}, SO_4^{2-}, CO_2, NO_2^-, N_2O, Mn^{2+}, Fe^{2+}, methane, hydrogen, pH, and alkalinity	20,91,92
In situ rates of respiration	A subset of the previous entry that has been effectively applied to engineered bioremediation of subsurface sites involves cessation of an oxygen (or air) sparging regime, followed by insertion of an oxygen probe that documents real-time oxygen consumption. This respiratory activity should be high inside but not outside the contaminated area. The conserved gas, helium, can be included in the sparging step to account for diffusional O_2 loss	93,94

(*continued overleaf*)

Table 3. (*Continued*)

Type of Strategy	Principles and Examples	References
Mass balances of contaminants, coreactants, and products (total expressed assimilative capacity)	Under well-defined hydrogeologic regimes, fluxes of water contaminants and physiological electron donors or acceptors can be quantified in a cross-sectional analysis of site sampling stations. The stoichiometry of all appropriate aerobic, anaerobic, isotopic fractionation, and inorganic equilibria reactions can serve to predict and distinguish biotic from abiotic processes and to identify contributions from a variety of microbiological groups	56,92,95–97
Computer modeling that incorporates transport and reaction stoichiometries of electron donors and acceptors	This approach considers quantitative aspects of fluid flow, dilution, sorption, volatilization, mixing, microbial growth, and metabolic reaction stoichiometries to achieve an integrated and predictive tool for understanding all processes influencing the fate of pollutant compounds. This approach resembles the previous entry, but is implemented on a larger scale and uses more sophisticated computations	92,98–101

aseptically from a given field site or bioreactor, dispenses known weights or volumes of the samples to replicated vessels, handles the samples in a variety of ways that include a treatment that has been either sterilized or poisoned, incubates the test samples under laboratory conditions, and employs both chemical and physiological assays that monitor the fate of the test compound within experimental vessels over time (Fig. 1, phase 1). These procedures have been described earlier.

Implementing Step Three: Evidence for Field Expression of Biodegradation Potential. Three sources of uncertainty must be confronted and overcome when demonstrating that microorganisms are the active agents of pollutant loss in bioremediation projects.

1. We must acknowledge that extrapolation from laboratory-based metabolic activity assays to the field is usually unwise because of the propensity of microorganisms in field samples to respond to laboratory-imposed physiological conditions that are unlikely to match those in the field perfectly (6,46).
2. The spatial heterogeneity of field sites may impede or completely prevent trends in the behavior of environmental contaminants from being discerned (12,20).
3. The action of a multitude of both abiotic and biotic processes may contribute simultaneously to pollutant attenuation (6,20).

To contend with these challenges, several strategies have been developed for verifying the success of field bioremediation efforts in truly activating pollutant-destroying microbial processes in field sites and bioreactors. These (comprehensively codified in Table 3) are simple, logical expressions of the fundamental paradigm for verifying bioremediation introduced previously and in Table 1. The strategies that appear in Table 3 are firmly based on the physiological principles that distinguish between biotic and abiotic contaminant attenuation processes. Four of the strategies involve tracers (internal conservative, added conservative, added radioactive, and added stable isotopic) that either account for or circumvent problems arising from abiotic changes in field concentrations of contaminants and related metabolites. Six of the strategies in Table 3 rely on detailed prior knowledge of specific microbiological processes (stable isotope fractionation, detection of intermediary metabolites, stimulation of microbial activity in replicated field plots, metabolic adaptation, in situ respiration, and gradients of coreactants and/or products) that are manifest as observable geochemical changes in the field. The molecular biological strategy in Table 3 is an elegant, emerging approach that is constantly strengthened by genetic links that are forged between information from pure cultures and real-world mixed microbial communities. The linkages are limited by the relatively small database of genetic sequences pertinent to pollutant metabolism and the uncertain metabolic diversity that may arise when genes of unrelated lineage may have converged on the same metabolic function. The final two strategies in Table 3 (computer modeling and mass balances of contaminants, reactants, and products) attempt to account quantitatively for both transport and metabolic processes within entire field sites or along distinct transects therein.

CONCLUSION

Understanding and proving biodegradation processes under laboratory and field conditions is a science of ongoing discovery. This discovery requires a close dialog among many disciplines. It must be recognized that only under relatively rare circumstances is a proof of field bioremediation unequivocal when a single piece of evidence is relied on. In the majority of cases, the complexities of contaminant mixtures, their hydrogeochemical settings, and accounting for competing abiotic mechanisms of contaminant loss make it a challenge to document biodegradation processes. Unlike controlled laboratory experimentation wherein measurements can usually be interpreted easily, cause-and-effect relationships are often very difficult to establish at field sites. Furthermore, certain bioremediation data that may be convincing for some authorities may not be convincing for others. Thus, in documenting bioremediation, the several approaches described previously should be independently pursued: a consistent, logical case relying on convergent lines of independent evidence should be built. The three-step strategy for verifying bioremediation described previously has been augmented recently by that of a new NRC Committee (26). What might be considered a fourth step and an overarching goal is assuring the

public that bioremediation in specific sites will be reliable, sustainable, and quantitatively complete.

BIODEGRADABLE DISSOLVED ORGANIC CARBON (BDOC).

See ASSIMILABLE ORGANIC CARBON (AOC) IN TREATED WATER: DETERMINATION AND SIGNIFICANCE

BIODEGRADABLE DISSOLVED ORGANIC CARBON IN DRINKING WATER

CHRISTIAN J. VOLK
Indiana-American Water Company, Inc.
Muncie, Indiana

Natural organic matter (NOM) present in surface waters and sometimes in groundwaters can be the root cause of various problems in drinking water. Organic material can be responsible for undesirable water taste, odor, and color. Organic material lead to the formation of disinfection by-products (after reaction with the disinfectant during water treatment) and to bacterial proliferation within distribution systems. The presence of low concentrations of organic nutrients in water is sufficient to support biofilm growth within the pipe network, potentially leading to a deterioration of bacterial water quality.

Therefore, the control of organic matter concentration is becoming recognized as an important part of the operation of drinking water plants and distribution systems. The following section will list methods available for characterizing organic matter and its biodegradable fraction, present the impact of water treatment on organic materials, and describe the role of biodegradable organic matter (BOM) in bacterial regrowth. This section focuses on one type of measurement for bacterial substrate called *biodegradable dissolved organic carbon* (BDOC). The next section is devoted to a second type of measurement for bacterial nutrients named *assimilable organic carbon* (AOC). Limited AOC data is presented to compare both measurements.

MEASUREMENT OF ORGANIC MATTER AND ITS BIODEGRADABLE FRACTION

Chemical Characterization of Organic Matter

Most organic matter are naturally present in water, but one small portion is artificial and originates from pollution and human activity. Chemical characterization of organic matter is complex. To date, it has not been possible to identify all organic molecules in water. The difficulty of this approach arises from the great complexity of the organic matrix, constituted by a mixture of hundreds of simple molecules or heteropolymers, and the very low concentration of these compounds. Consequently, organic matter characterization is only possible through various fractionations and measurement techniques that give partial information on organic matter levels, chemical functions, or molecules, depending on the methodology used (1).

Measurement of Surrogate Parameters. The measurement of total organic carbon (TOC), dissolved organic carbon (DOC), ultraviolet absorbance at 254 nm (UV254), or fluorescence provides some insight into the organic levels and properties of water. TOC and DOC measurements are the most common techniques for monitoring organic matter levels in waters. Expressed as TOC, organic matter can be fractionated into DOC, colloidal compounds, and particulate organic carbon (POC). The dissolved and particulate fractions are distinguished on the basis of the porosity of the filters used to separate these two fractions. The typical exclusion limit of the particulate form of organic matter that has been adopted ranges from 0.2 to 0.45 μm. TOC is generally composed of 90% DOC and approximately 10% POC (2). Part of the colloidal carbon is categorized as dissolved, whereas the other part is quantified as particulate matter. TOC analyzers are common instruments used to assess organic matter levels. They are based on the following principle: organic compounds are oxidized to carbon dioxide using a combination of oxidizing agents (persulfate) and UV light or high temperature. The amount of carbon dioxide produced can then be measured using nondispersive infrared absorption or conductivity. As most waters contain carbonates and bicarbonates, the concentrations of these inorganic compounds are either measured or the samples are acidified and purged with an inert gas to remove the inorganic carbon, before TOC analysis of TOC. When these are purged, the remaining TOC is referred to as nonpurgeable TOC or as nonpurgeable DOC if the sample is filtered. Organic matter levels typically range from 0.1 mg/L to 10 to 20 mg/L. UV absorbance at 254 nm, measured using a spectrophotometer, provides some information on the aromaticity of the organic matter, because aromatic rings absorb UV light (1). Fluorescence indicates the level of polymerization of organic molecules present in water (1).

Extraction Methods Through Macroreticular Resins. Extraction techniques using selective resins fractionate organic matter into two parts: humic (humic and fulvic acids) and nonhumic substances, which correspond to hydrophobic and hydrophilic fractions, respectively (3). Humic substances are complex macromolecules obtained after polymerization of organic molecules, following biodegradation and chemical, biological, and photochemical oxidation of animal and vegetable wastes. They include aromatic structures linked together with aliphatic chains. The extraction method using the XAD-8 resin (3) is the most common technique for isolating aquatic humic substances. After acidification of a water sample to pH 2, humic substances adsorb to the XAD-8 resin, whereas hydrophilic acids pass through the resin. Half of the nonextractable chemicals includes hydrophilic acids and the other half represents well-identified chemicals such as carbohydrates, amino acids and proteins, carboxylic acids, and trace compounds. After an additional step of elution with caustic soda, humic substances are divided into two fractions: humic acids precipitating in acid (pH 1) and fulvic acids that remain soluble in acidic medium. Generally, fulvic acids have lower molecular weights and a higher number of carboxyl functional groups than humic acids. Fulvic acids represent the major part (80 to 85%) of the humic substances (3). Humic substances and hydrophilic acids are responsible for 50 and 30% of the DOC, respectively. The proportion of humic material in water can also be assessed by calculating the specific UV absorbance (SUVA). The SUVA value corresponds to the ratio between UV absorbance at 254 nm and DOC concentration (SUVA = UVabs [cm^{-1}] × 100/DOC [mg/L]). SUVA values higher than 4 to 5 generally describe a relatively hydrophobic DOC, mainly containing aquatic humic substances of high molecular weight and aromaticity. On the contrary, SUVA data less than 3 indicate that the DOC is hydrophilic, low in molecular weight, and low in charge density and aromaticity (4). Elemental analysis determination that defines the percentage of chemical elements such as carbon, hydrogen, nitrogen, oxygen, or sulfur within molecules showed that humic substances are mainly composed of carbon (average of 50%), oxygen (35 to 40%), hydrogen (5%), and nitrogen (1%) (5).

Identification of Functional Groups, Structural or Molecular Size (Weight) Characterization. Up to one-third of the organic molecules common in water can be identified using various technical analyses. Certain organic molecules can be characterized by spectrophotometric measurement (^{13}C nuclear magnetic resonance) or by a pyrolysis gas chromatography/mass spectrometry (GC/MS) technique. The

pyrolysis GC/MS method reveals fingerprints indicative of specific polymers such as polysaccharides, amino-sugars, proteins, and polyhydroxy-aromatic compounds (6). Amino acids (total and free), carbohydrates (total and free), aldehydes, and carboxylic acids can also be identified and quantified by specific chemical analyses (7–9). The apparent molecular weight of organic fractions can be assessed either by gel permeation liquid chromatography (Sephadex) (10) or after ultrafiltration fractionation (1).

Biodegradable Organic Matter Estimation (BOM)

Organic matter can be divided into two fractions. The first, called BOM, can be utilized by bacteria as a source of energy and carbon. The second is refractory to biodegradation (e.g., nonbiodegradable) and has little effect on bacterial growth (11). Several biological tests have been developed to assess the level of BOM in water (11,12). The specific experimental setting varies from one assay to another; however, they all include the following steps (13).

- *Preparation of Glassware*. Carbon contamination must be avoided when performing BOM measurements because water samples generally contain low carbon levels. The glassware is rendered carbon free after heat treatment at 550 °C for several hours or by washing in strong oxidant solution (e.g., sulfochromic acid and persulfate).
- *Pretreatment of Water Samples*. Depending on the methodology and sample type, pretreatment of samples is required to inactivate indigenous bacteria present in water, remove suspended matter, or neutralize any toxic chemical-like disinfectant residuals. Inactivation of microorganisms can be performed using pseudopasteurization. Water samples are heated at 60 to 70 °C for 30 minutes to inactivate autochthonous bacteria without drastically altering the organic matrix. Sample bacteria can also be retained after filtration using a 0.2-μm pore size membrane. Filtration is also performed for raw water samples containing suspended materials. Filtration membranes used to filter water samples are made of material such as fiberglass or polycarbonate that do not release organic compounds. Treated waters often contain disinfectants that could affect the microorganisms used in the bioassay. Disinfectant residuals are neutralized using sodium thiosulfate.
- *Preparation of a Bacterial Inoculum*. There is no standard inoculum. Inoculum can be composed of pure cultures of one or several bacterial strains used at certain concentrations or mixed natural flora. Pure culture inocula involve bacterial strains well adapted to low nutrient concentration conditions in water. Natural inocula are generally composed of many unknown species. In this case, it is difficult to assess the number of active cells, the microbial species involved, and their reactivity toward organic molecules. Inoculum may also be in suspension or attached to a solid media, such as biofilms attached to sand.
- *Inoculation and Incubation of Water Samples*. Inoculum density varies from a few hundred to millions of bacteria, depending on the method. Incubation periods, which allow test bacteria to grow and to degrade organic molecules present in the water sample, vary from a few hours to one month.
- *Measurement of the Test Parameter for Biodegradation*. Bacterial growth or carbon utilization is monitored during the incubation of inoculated water samples. Increase in bacterial counts can be evaluated using bacteria numeration on agar, microscopic numeration in epifluorescence, measurement of cell energy such as adenosine triphosphate (ATP), or turbidity monitoring. Carbon consumption by bacteria is assessed by monitoring DOC concentrations using a TOC analyzer.
- *Calculation of the BOM Concentration*. Depending on the parameter used to evaluate the BOM, results can be expressed using an index of biodegradability (micrograms acetate carbon equivalents per liter), cell production (growth yield or maximum growth), or carbon consumption (expressed in milligrams carbon per liter).

There are two established categories of biological tests: (*1*) AOC and (*2*) BDOC (Fig. 1). AOC refers to the fraction of TOC that can be utilized by bacteria for growth. The inoculum is a mixture of pure bacterial strains cultivated under laboratory conditions (*Pseudomonas fluorescens* P17, *Spirillum* NOX) (14–19) and environmental bacteria (20). Bacterial growth is monitored in the water samples using colony counts or ATP measurements. The maximum growth (N_{max}) observed during the incubation is converted into AOC using the growth yield of the bacteria from calibration curves performed with known concentrations of standard organic compounds (acetate and oxalate) (Fig. 1). When turbidity is measured for monitoring bacterial growth, two parameters are determined: the growth yield (μ) recorded during the exponential growth phase and the growth factor ($\log Y/Y_o$) corresponding to the increase in bacterial population (21). The concept of AOC has generated many different methods that are summarized in Table 1. In contrast, BDOC content represents the fraction of DOC that can be assimilated and mineralized by heterotrophic microbes. The inoculum consists of environmental bacteria suspended in water or fixed on a surface. BDOC is the difference between the initial DOC of the water sample and the minimum DOC observed during the incubation period (23–27) (Table 2, Fig. 1). In general, AOC molecules correspond to the "easily" assimilable organic compounds and generally represent a relatively small portion of the BDOC.

Microorganisms need various nutrients to grow in water. The ratio in which compounds of carbon, nitrogen, and phosphorus are required is 100 : 10 : 1 (C/N/P). Both AOC and BDOC assays quantify BOM (carbon), which is typically the limiting nutrient for bacterial regrowth in drinking water distribution systems. However, some nutrients other than organic carbon (phosphorus) may limit the regrowth of heterotrophic bacteria in the humus-rich water of some boreal regions such as Finland or

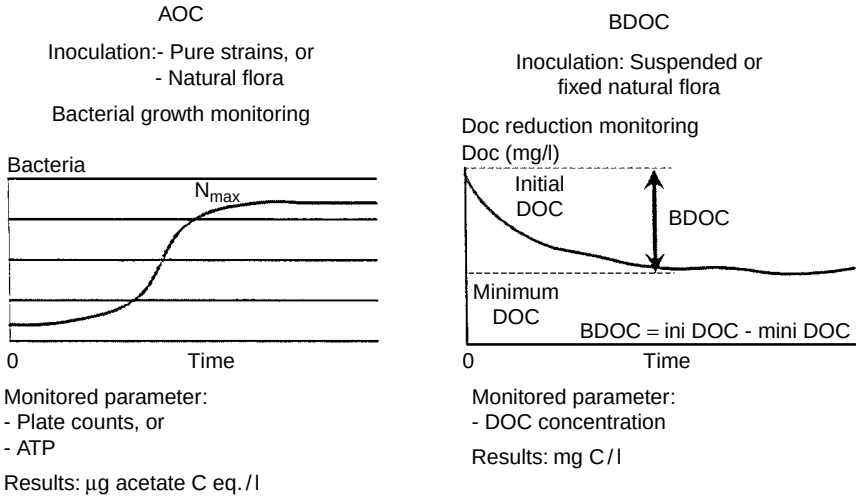

Figure 1. AOC and BDOC concepts for biodegradable organic matter determination.

Norway (28,29). In addition, a bioassay has been developed to determine if carbon or phosphorus is the limiting nutrient for regrowth (30).

BDOC Methodologies

BDOC Determination Using Suspended Bacteria. A filtered water sample (0.2-µm pore size filter) is seeded with suspended bacteria and incubated at $20 \pm 2\,^{\circ}C$ in the dark for 28 days (Fig. 2). Bacterial inoculum consists of indigenous bacteria contained in a small volume of surface water. Inoculum water is filtered through a 2-µm porosity polycarbonate membrane to remove particles and any protozoa that could graze bacteria. The inoculation ratio is 1 mL of surface water/100 mL of water sample (ratio of 1%, v/v). BDOC can be determined by two procedures. In the first one, bacterial biomass and mortality rate are monitored, the integrated flux of mortality (F) during the incubation period is then calculated and divided by the growth yield (Y) to give an estimate of BDOC (BDOC = F/Y) (24). This approach, which is very sensitive but also long, is used when BDOC levels are very low. The second procedure is simpler and is more commonly used. The decrease in DOC concentration is monitored until a plateau is reached and BDOC is the difference between the initial and final DOC values (24).

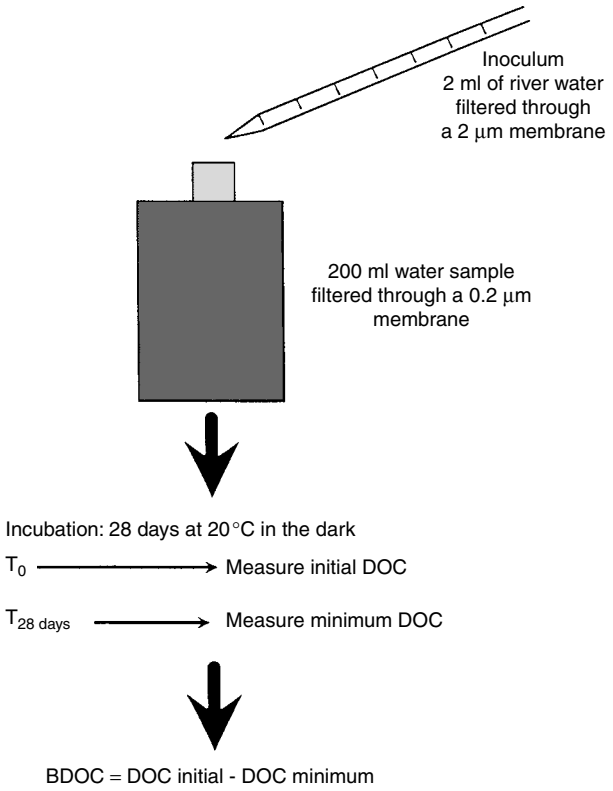

Figure 2. Experimental setup to measure BDOC levels with suspended bacteria.

BDOC Determination Using Sand-Attached Bacteria. This method is also based on the decrease in DOC concentrations, but the water sample is incubated at $20 \pm 2\,^{\circ}C$ in the presence of sand colonized by bacteria (23,31) (Fig. 3). Water samples can be aerated during incubation with organic carbon–free air. The inoculum is quartz sand (with a granulometry of 1 to 2 mm) colonized by bacterial biomass sampled from a sand filter of a water-treatment plant without a prechlorination stage (no oxidant residual present) or colonized sand from a freshwater fish tank. A sand/water sample ratio of 1 : 3 (w/v) is used for sample inoculation (e.g., 100 g of sand per 300 mL test water). Using such an abundant fixed flora allows a rapid response; the test is completed after an incubation period of a few days. The DOC values in the water sample are analyzed on a daily basis with a TOC analyzer. The incubation is continued until a minimum DOC value is reached. BDOC concentration is defined as the difference between the initial and minimum DOC values. The minimum DOC value observed after biodegradation, which corresponds to the nonbiodegradable DOC, is defined as the refractory dissolved organic carbon (RDOC).

BDOC Determination Using Bioreactors. The plug flow biofilm reactor was developed to measure BOM levels within a few hours (26,27). A BDOC reactor consists of

two glass chromatography columns (2.5 × 60 cm, Kontes, Vineland, New Jersey) containing porous glass particles (Siran; 1- to 2-mm diameter, 60- to 300-μm pore size, Schott America, Yonkers, New York) (Fig. 4). The reactor column media is heavily colonized with bacteria from the environment. Bioreactors are continuously fed with water at a flow rate of 4 mL/minute. The total hydraulic retention time of the BDOC reactor is two hours for both columns. The BDOC test begins by loading the bioreactor reservoir with a water sample. Column inflow and outflow are sampled for at least two hours after the beginning of the test. BDOC concentrations are determined from changes in DOC concentrations from the reactor inflow and outflow.

Factors Affecting BOM Results

BOM levels can be estimated using various bioassays, and each test has specific strengths and weaknesses (11,12). Most of the methods have not been standardized, and

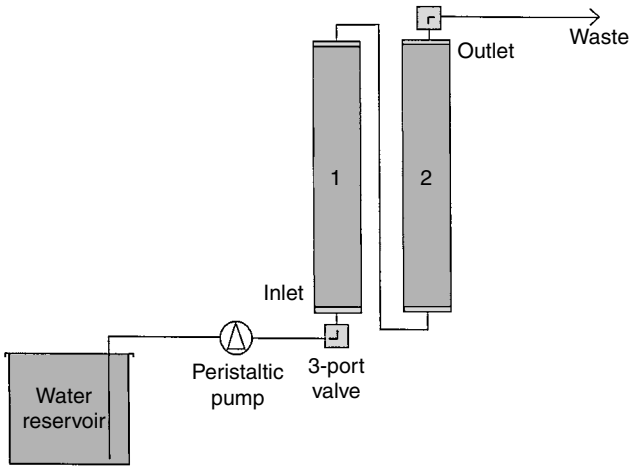

Figure 4. Experimental setup to measure BDOC levels with a biofilm reactor.

many factors such as the inoculum (pure strain versus mixed inocula from the environment), the glassware used, the monitored parameter (bacterial growth versus DOC), the use of suspended or fixed bacteria, and the experience of the laboratory performing the test can influence the final test results (12,32).

Nutrient Levels in Water. Organic matter and nutrient concentrations vary dramatically between water sources, over the seasons, and from one year to another. In general, DOC levels are low (<1 mg/L) in groundwater. Surface waters generally contain 2 to 10 mg/L of DOC (2); however, higher values (20 to 30 mg/L) have been recorded in some waters from Southeastern United States with high-humic content. BDOC concentrations typically range from less than 0.1 mg/L to 1 to 2 mg/L. For example, a study conducted on various water types showed that river waters had DOC values of 3.2 to 4.0 mg/L and BDOC concentrations above 1.2 mg/L (33). After treatment, BDOC levels ranged between 0.2 and 1.0 mg/L (DOC between 0.9 and 2.9 mg/L). Waters with low organic matter levels had BDOC levels lower than 0.1 mg/L (mineral, spring, and ultrapure waters with DOC levels less than 0.5 mg/L) (33). A large survey that evaluated BDOC concentrations in 31 surface water treatment plant effluents showed that the geometric mean of BDOC concentrations was 0.32 mg/L for all the sites (34). On an average, the BDOC represented 5 to 21% of the DOC. When the BDOC levels were tabulated site by site, the mean concentrations of plant effluents ranged between 0.03 and 1.03 mg/L, whereas the DOC levels ranged from 0.61 to 4.53 mg/L (34) (Fig. 5).

AOC concentrations typically vary from a few to several hundred micrograms per liter. Figure 5 shows AOC results of a survey conducted at 95 sites. AOC concentrations entering distribution systems were generally high. Fifty percent of the sites had plant effluent AOC levels above 100 μg/L. When data were averaged for each site, the mean AOC levels ranged from 18 to 214 μg/L, depending on the site (34). These finished water results are comparable to other AOC data collected from 53 source waters, including surface and groundwaters in North America (35). Raw water AOC concentrations varied from 18 to 322 μg C-acetate/L or from 2.4 to 44% of the DOC content. Sixty-two percent of the raw water AOC values were above 100 μg/L. Bradford and coworkers (19) reported AOC variations from 94 to 275 μg/L (mean of 168 μg/L) in a surface water reservoir and 75 to 731 μg/L (mean of 317 μg/L) in river water (Santa Ana River, California). The mean AOC concentration for three groundwater samples was 54 μg/L. Much lower AOC concentrations (<10 μg/L) were recorded after bank or slow sand filtration (14).

Parameters Affecting BDOC Results. BDOC concentrations vary, depending on the method applied and the operating conditions (inoculum size, incubation time, sample aeration) (Table 2). For the BDOC determination using bacteria fixed on sand, both inoculum size and aeration have been shown to affect the result of BDOC measurement (31,36) (Table 3). A sand/water ratio of 100 g : 300 mL (w/v) allows a rapid decrease in DOC concentration and optimum biodegradation of the organic matter. However, levels of BDOC tend to increase with the sand/water ratio, showing sorption of a low fraction of DOC (0.1 to 0.2 mg of DOC/100 g of sand). Aeration

Table 3. Factors Affecting BDOC Results

Method	Parameter	Effects on Measured BDOC Concentration
Suspended bacteria method	Inoculum size	None
	Aeration	None
	Incubation period	BDOC level increased
	Disinfectant neutralizer	BDOC level decreased
Sand method	Inoculum size	BDOC level increased
	Incubation period	None
	Aeration	Faster test, possible increase in BDOC level
Bioreactor method	Contact time	Possible increase in BDOC level

$$BDOC_{\text{suspended bacteria}} < BDOC_{\text{sand}} = BDOC_{\text{bioreactor}}$$

mixes the water and provides a more uniform exposure to the sand, promotes faster kinetics of DOC consumption, increases dissolved oxygen concentrations, and sometimes leads to a greater consumption of DOC (31).

In the method using suspended bacteria, inoculum size (from 0.04 to 5%, v/v) and aeration (4 L/hour) have not been shown to have any effect on BDOC determination (31,36). On the other hand, incubation time affects the result of BDOC measurement (Table 3). For certain water types, biodegradation may still be incomplete after one month of incubation. BDOC levels increased by 0 to 125% when the incubation was extended to 85 to 120 days (31). Finally, precautions have to be taken regarding the dechlorination agent used to neutralize disinfectants. MacLean and coworkers (37) reported that sodium thiosulfate levels higher than 20 mg $Na_2S_2O_3$/L interfered with the 30-day BDOC test using suspended bacteria. During incubation, the presence of $Na_2S_2O_3$ promoted the growth of sulfur

oxidizing bacteria resulting in the production of sulfuric acid and a depressed pH. The low pH inhibited the activity of heterotrophic bacteria in utilizing organic carbon (37).

The BDOC column method is attractive for use in water utilities because by simply measuring the DOC at the inlet and outlet of the columns, BDOC can be determined rapidly on a continuous basis. The problem with the bioreactor method, however, is that a long period (between six and nine months) is required for the columns to be colonized with the variety and density of bacteria necessary to rapidly utilize trace levels of organic carbon. Bioreactors are also highly site-specific — changing feed water source may require an acclimatization period of several months. Columns that were colonized with water from the Mississippi River required up to seven months to equilibrate once shipped to new locations with different types of source waters (34). Consequently, bioreactors must be colonized and used to perform BDOC measurements with the same water matrix. NOM is composed of a mixture of hundreds of simple molecules and complex polymers such as humic substances that are highly specific to a particular watershed. When colonization occurs, organic matter leads to the development of unique and specific populations of microbial species. This high specificity of bacteria to the site's organic material was reported to be a limitation of the BDOC-column methodology (27,38). Bioreactors do not perform well as a stand-alone analyzer for samples from various origins. During interlaboratory experiments of bioreactors colonized with different water sources, maximum biodegradation was observed at the site in which the microflora was specific to tested water samples. At the other sites, when bioreactors were exposed for a few hours to the new water conditions, the reactor biofilm could not metabolize any of the organic matter. In addition, the bioreactor columns require constant attention and maintenance. After colonization, bioreactors can operate several years, but they require a continuous flow of low-turbidity water that does not contain disinfectants (feed water can be filtered river water, granular activated carbon (GAC)-filtered water, or dechlorinated tap water). Routine checks include pump function, absence of blockage, absence of leaks, and flow through the reactor. If a feed water reservoir is used, the water within the reservoir must be periodically replenished.

Variation Between the Different BDOC Methods. The estimation of BDOC concentration depends on the applied method. BDOC concentrations obtained with a suspended and a fixed/sand inoculum are well correlated. However, the BDOC values are generally higher (twice as high) while using attached (i.e., fixed/sand) bacteria (31). Mathieu (13) also observed that the BDOC values measured using bacteria attached to sand were 1.2 to 1.5 times higher than those obtained with suspended bacteria. Several hypotheses could explain discrepancies between the suspended and fixed/sand inoculum. The bacterial concentration in freshly inoculated water samples is 100 to 1,000 times higher when using colonized sand than when using river water as the inoculum (10^7 to 10^8 bacteria per gram of sand versus 10^6 bacteria per milliliter of river water). An attached inoculum might be able to degrade a larger range of organic compounds. Thus, molecules that are refractory to biodegradation by a suspended inoculum could be biodegradable by a fixed inoculum. This observation could be because of a greater bacterial diversity in the sand biofilm than in a river sample, a higher adaptation of sand bacteria (fixed species are selected according to their ability to degrade a large spectrum of organic compounds), and an advantage caused by the fixation because cometabolism and synergy mechanisms can occur on sand particle biofilms.

Both the bioreactor and the sand methods yield similar BDOC results. A study involving 52 samples showed that the differences between the BDOC levels obtained from the bioreactor and sand methods were less than 0.1 mg/L for 50% of the samples (34). The difference was between 0.1 and 0.2 mg/L for 17% of the samples. In comparison, Joret (39) reported differences less than 0.1 mg/L and between 0.1 and 0.2 mg/L for 49 and 30% of the samples, respectively. Kaplan and coworkers (27) and Prevost and coworkers (40) found that the bioreactor results were higher than the BDOC levels determined using suspended bacteria. This observation is not surprising, as the BDOC-sand method gives higher results than the BDOC-suspended bacterial method (31).

Variation Between AOC and BDOC Data. The AOC test measures a biological response to assimilable carbon, but unlike BDOC, it is not a direct measure of the carbon level itself. Correlations observed between AOC and BDOC can be strong in some cases and weak in others (12). Figure 6 shows a comparison of the AOC and BDOC values based on a monthly analysis of 31 plant effluent samples (34). Although the AOC and BDOC values were significantly correlated ($p < .01$), the variation between the test results was high (correlation coefficient of only 0.45). When the test results were grouped, a more clear relationship was observed between the two tests (Fig. 6). Volk and coworkers (33) observed an excellent correlation ($r = 0.996$) between the AOC and BDOC levels in a series of dilutions of a particular type of river water. However, the correlation between the tests was not as strong ($r = 0.77$) when performed on 31 different water types. Kaplan and coworkers (35) reported a significant but weak correlation ($r = 0.59$) between the AOC and BDOC data in a survey involving 109 samples from 79 drinking water supplies. AOC is an index of regrowth potential, which is strongly related to specific groups of organic molecules. Moreover, the origin and changes in the characteristics of organic matter might affect the relationship between these two methods of BOM measurement. Because NOM characteristics vary from one water type to another, and seasonally for a given water type, it is not surprising that waters with similar BDOC concentrations might have low or high levels of AOC, depending on the type of organic molecules present in the water constituting BDOC. BDOC concentrations are generally much higher than the AOC levels. This is probably due to a difference in the range of metabolic capabilities contained in the AOC test, which uses just two bacterial stains (P17 and NOX), versus the

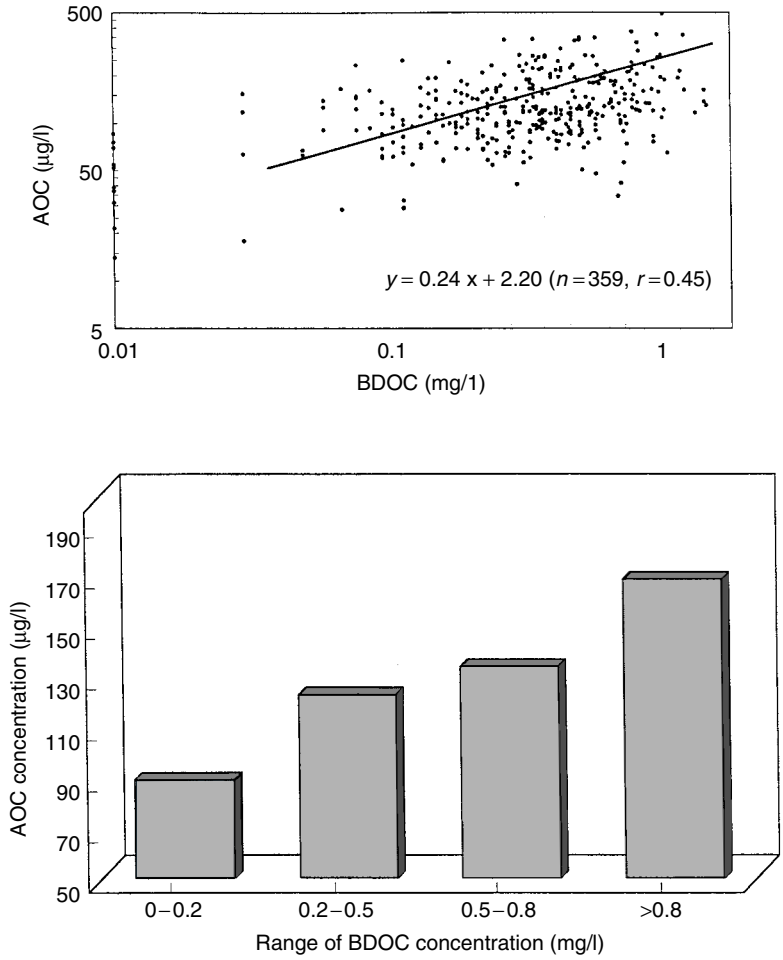

Figure 6. Relationship between AOC and BDOC concentrations (from Volk and LeChevallier (34)).

BDOC-sand bioassay with a wide variety and a greater density of microorganisms capable of degrading a large spectrum of organic compounds.

Composition of Biodegradable Molecules. AOC measures the "easily" assimilable carbon, whereas the BDOC fraction includes easily and slowly biodegradable compounds. Because of the complexity of the organic matter, it has not been possible to determine precisely the chemical characterization of the biodegradable fraction. Biodegradable organic materials have generally been considered to be carbohydrates and small molecular weight compounds, whereas complex molecules such as humic substances in water were assumed to be essentially nonbiodegradable. However, some studies have shown that this classification should be used with caution (41–43). It has been found that biodegradable compounds include both low and high molecular weight molecules. Some low molecular weight molecules can be directly utilized for metabolism. Other compounds, such as humic substances, which constitute most of the DOC, can be partially degraded by bacteria after enzymatic action. A study showed that 27% of humic substances in stream water were utilized by biofilm bacteria (43). On an average, BDOC was composed of 75% humic substances, 30% carbohydrates, 4% amino acids, and 39% of molecules greater than 100,000 Da (43). Finally, the BDOC fraction determined using the suspended bacteria assay (24) can be further fractionated into three pools of substrates (S, H1, and H2). The H1 fraction represents the macromolecular substrate that can be rapidly hydrolyzed by bacteria exoenzymes, whereas H2 includes polymeric organic molecules slowly hydrolyzed. The H1 and H2 fractions are transformed into the S fraction, including monomeric substrates directly available for bacteria. This partitioning is achieved by the use of a biomass flux technique (44) and by the use of the HBS Model (H: high molecular weight polymers, B: bacteria; S: direct substrates) (45). The polymeric BOM (H1 and H2 fractions) is hydrolyzed by the bacterial exoenzymes that are in concentrations directly proportional to bacterial biomass, according to Michaelis-Menten kinetics. The kinetics includes the maximum rates of exoenzymatic hydrolysis of H1 or H2 ($e_{1\max}$, $e_{2\max}$) and the half-saturation constants (K_{H1} and K_{H2}). The exoenzymatic hydrolysis rates for H1 and H2 are, respectively, equal to $e_{1\max}\mathrm{H1}/(\mathrm{H1} + K_{H1})$ and $e_{2\max}\mathrm{H2}/(\mathrm{H2} + K_{H2})$. The exoenzymatic hydrolysis of macromolecules yields monomeric substrates (S), such as amino acids, which are rapidly utilized by bacteria, according to another Michaelis-Menten kinetics. For substrate S, the direct substrate uptake is equal to $b_{\max}\mathrm{S}/(\mathrm{S} + K_S)B$. The kinetics is characterized by the following parameters: maximum rate of substrate uptake per

unit of bacterial biomass (b_{max}) and the half saturation constant of direct substrate uptake (K_H). The numerical values of the different kinetic parameters were determined for a large spectrum of aquatic environment and correspond to general physiological characteristics. These processes are used to describe BDOC removal during biological filtration (Model CHABROL) (46), or BDOC consumption in distribution systems (Model SANCHO) (47). These models are described later in this section.

While BDOC can include larger molecules, humic substances, and some humic bound compounds, it appears that for most water samples, the AOC is mainly composed of small (<1,000 Da) and nonhumic molecules (34).

REMOVAL OF ORGANIC MATTER DURING DRINKING WATER TREATMENT

Drinking Water Treatment and Water Quality

Most types of water require treatment to remove certain impurities and pollutants, add chemical substances, or change water characteristics in order to protect public health, improve water aesthetics, and comply with drinking water regulations. Overall, the quality of water is improved after treatment. Raw water type (ground versus surface water) and the type and levels of impurities present in the source water determine the treatment processes that need to be implemented. In general, groundwaters have a uniform quality and contain no turbidity (cloudiness), few microorganisms, and little organic matter. However, groundwaters often have high hardness and might contain various contaminants such as iron, manganese, hydrogen sulfide, and radionuclides. They can also be contaminated by synthetic chemicals, including organic solvents and herbicides/pesticides. Surface water supplies originate from creeks, streams, rivers, lakes, and reservoirs. Surface waters have the characteristic of varying quality after heavy rains or over the seasons. Surface waters must be treated to remove microorganisms and turbidity. In addition, they contain organic matter and numerous inorganic and organic contaminants related to natural or human activities (urban, industrial, and agricultural pollution). The kinds of treatment available to produce drinking water can involve aeration, adsorption, chemical oxidation and disinfection, settling, filtration, membrane filtration, softening, or ion exchange. Most surface waters are conventionally treated to remove high levels of microbes and particles. The basic conventional treatment train involves the following four steps: pretreatment, settling, filtration, and posttreatment before distribution (Fig. 7). Preoxidation is used to control bacteria and algae growth and oxidize iron, manganese, taste, odor and color molecules, as well as micropollutants. Primary oxidants include chlorine, chlorine dioxide, potassium permanganate, ozone, and hydrogen peroxide. Chlorine has been the most extensively used, but some concerns about the health effects of chlorine disinfection by-products have increased the use of alternative oxidants. Chemically enhanced settling allows removal of particulate and colloidal matter that would not precipitate within a reasonable time by gravity alone. After physicochemical reaction, the nonsettlable solids are converted into heavier and settlable solids that can be removed by sedimentation. Target elements include clay and silt particles, microorganisms, inorganic solids, as well as color

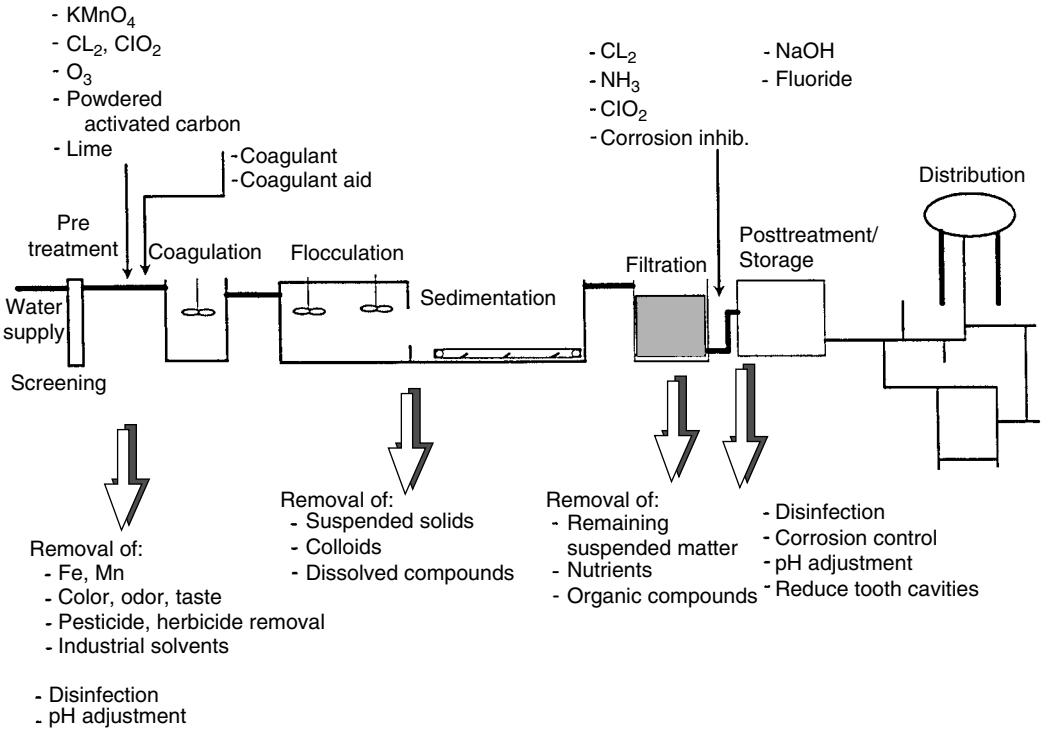

Figure 7. Conventional water treatment steps.

and organic matter. Settling involves three sequential steps of coagulation, flocculation, and sedimentation (Fig. 7). Coagulation consists of adding and rapid mixing of chemical coagulants into raw water. Alum salts, iron salts, and synthetic polymers are the most common coagulants used in water treatment. Particles in water are usually negatively charged and tend to repel one another. Positively charged coagulants neutralize particle charges and promote coagulation. Destabilized particles aggregate during flocculation. Slow mixing promotes particle aggregation and leads to the formation of bigger flocs. The flocs are allowed to precipitate out of the water by gravity during sedimentation (no mixing). Filtration is the final step in water clarification. Suspended matter remaining after settling is removed when passed through a bed of granular media filter at a certain velocity. The most common materials used in filter media are sand, anthracite, garnet, and GAC. Filter materials can be used alone (mono-media filter) or in combination (dual or multimedia filters). Following settling, a major goal of filtration is to physically remove suspended solids, remaining precipitates, and floc that did not settle, thus improving the finished water turbidity. Moreover, if media include GAC, dissolved organic compounds can be removed through adsorption and biodegradation. GAC is generally used to remove micropollutants through adsorption. However, after a few months, the adsorption capacity of GAC is exhausted and it must be regenerated or replaced. An alternative is to use GAC without regeneration, to use the benefit of microbial flora that colonize GAC grains in the absence of disinfectants. After filtration, a final disinfection (usually chlorine alone or in combination with ammonia to form chloramines) is fed to control bacteria levels in the distribution system. Additional treatment steps can be added to the basic conventional treatment train to deal with specific pollutants or improve water quality. Powdered activated carbon (PAC) can be fed during pretreatment to remove taste and odor compounds as well as micropollutants. A second-stage filtration (postfilter adsorber) may be required when waters contain high levels of organic compounds (nutrients, taste and odor, or synthetic organic compounds).

Organic Carbon Transformation During Water Treatment

Treatment of organic carbon is important because these materials can be responsible for water taste, odor, and color. Organic matter will affect oxidant demand, disinfectant by-product levels, micropollutant removal, residual disinfectant stability, and bacterial regrowth in distribution systems. The reduction of organic matter concentrations and its biodegradable fraction during water treatment is one strategy to control bacterial regrowth in the distribution system. A variety of treatment processes can be used to control BOM levels in drinking water. The degree of organic carbon removal during drinking water production depends on several parameters such as the treatment train design, operational conditions, and the seasonal fluctuations of the source water quality. In general, coagulation, biological filtration, or membrane filtration reduces BOM levels, whereas oxidation with ozone or chlorine forms biodegradable compounds from relatively nondegradable DOC.

Settling. Coagulation, flocculation, and sedimentation are critical steps in surface water clarification. Historically, most coagulation processes were primarily designed for particle and turbidity removal. However, some plants, especially those having to treat highly colored water, were designed to remove organic matter. NOM and BDOC levels can be reduced by coagulation through colloid destabilization, precipitation, coprecipitation, or adsorption onto floc (48,49). Organic matter concentration is generally reduced after settling. The elimination of organic material is impacted by many factors such as the characteristics of the NOM, coagulation conditions (coagulant type and dose, coagulation pH), the nature and concentrations of inorganic compounds, and the design and operation of the sedimentation basin. Consequently, the removal of organic matter by coagulation varies widely, and is generally between 10 and 90%.

Organic Matter Characteristics. In general, higher organic matter removal is observed for samples with high DOC values. For example, a study showed that water samples with DOC concentrations greater than 4 mg/L exhibited DOC and BDOC removals of 55 and 58%, respectively, versus 31 and 18% for waters with DOC levels below 4 mg/L (50). Lind (51) reported NOM removals as high as 90% for high-TOC water samples (>10 mg/L) from the southeastern United States. Coagulation mostly removes the hydrophobic organic fraction (humic substances) and large molecules. Hydrophilic compounds are little affected by coagulation (1,4,52,53). Moreover, the removal of NOM is affected by other physical and chemical properties of NOM, including the solubility of organic compounds, the charge density of molecules, or the functional group composition (1,4,54–58).

Coagulation pH. The pH of coagulation is also a very influential parameter governing organic removal. Typically, the best removals of humic substances have been obtained between pH 4 and 5 with ferric and between pH 5 and 6 with alum (59–61). A series of coagulation tests performed on a bench scale (jar tests) showed that the pH of coagulation for optimized organic matter removal with ferric chloride and alum ranged from 4.4 to 6.7 and from 5.6 to 7.1, respectively. Polyaluminum chloride (PACI), another type of coagulant, can be used at a higher pH (6.0 to 6.8). Lowering the pH of coagulation with sulfuric acid led to additional DOC and BDOC removal (versus coagulation without pH adjustment) of 6 to 17% and 0 to 13%, respectively (50). In comparison, Chowdhury and coworkers (62) reported a TOC removal of 9% under plant conditions, but TOC removals increased to 25% when carbon dioxide was added to lower the pH from 8.0 to between 7.0 and 7.3. Lind (51) also found that TOC removal was improved at lower pH values with alum and ferric chloride, except in cold, low alkalinity, and low TOC water. At lower pH, the dissolved organic matter precipitates and becomes particulate organic matter. Organic particles are then removed by sweeping or adsorption on floc.

Coagulant Type. In addition to pH, the amount of organic material removed is also dependent on the type of coagulant used. Studies reported in the literature are contradictory, suggesting that the performance of a particular coagulant is dependent on the specific characteristics of the organic matrix and the test conditions. Several studies have demonstrated that iron-based coagulants are superior to alum salts (50,52,63). Inorganic coagulants (ferric or alum) also seem superior to synthetic organic polymers for coagulation of organic matter (64). Researchers (57) compared the performances of ferric chloride versus alum or PACI for removal of DOC and BDOC in different surface waters. They showed that iron salts typically resulted in greater removal of DOC and BDOC, as high as 28 and 21%, respectively. PACI resulted in the lowest removal of DOC and BDOC. In other experiments performed on high-TOC water (Hillsborough River, Tampa, Florida), the average TOC removal was 47% with alum and 65% with ferric sulfate (65). Alternatively, a field study involving 46 different plants showed that TOC removal was best with PACI or alum with sulfuric acid (51). The average TOC removal was 39% with low basicity PACI, 32% with alum, and only 13% with ferric salts.

BOM Removal. As seen for DOC, reduction in BDOC levels varies from one water sample to another, and the characteristics of the biodegradable materials govern their removal during coagulation. Limited studies have been performed to assess biodegradable DOC removal by coagulation. Removal of BDOC ranged from 50 to 86% using alum at a full-scale treatment plant using alum and no preoxidation (66). Croué and coworkers (67) reported that removal of BDOC by ferric chloride and alum correlated to removal of DOC, and ranged between 38 and 88%. When coagulation was optimized or enhanced for removal of dissolved organic materials for various surface waters, the removal of DOC could be increased from 25 to 43% (50). Similarly, removal of BDOC could be improved from 30 to 38% through the application of enhanced coagulation. However, when coagulation is optimized, the additional NOM removal preferentially impacts the refractory (nonbiodegradable) fraction of DOC as opposed to the biodegradable DOC fraction (50). Some biodegradable compounds such as proteins are removed very well by precipitation. Hureiki and coworkers (68) reported that coagulation removed 34 to 72% of total amino acids. However, AOC is typically not affected by coagulation, probably because AOC target small molecular weight, nonhumic compounds that are not amenable to coagulation. AOC removal during settling could be attributed to phenomena other than physicochemical reactions. Huck and coworkers (69) found AOC removals ranging from 0 to 85% by clarification; however, the reduction in AOC levels may have been caused by biological activity because no oxidation step was applied before coagulation, and there were long residence times within the sedimentation basin (70).

Filtration. The removal of the biodegradable fraction of organic matter is one of the main goals of biological treatment. When there is no prechlorination stage before filtration, a large amount of biomass can accumulate on filter media in the form of a biofilm. This biofilm can absorb and assimilate biodegradable materials contained in the water. Organic removal during filtration is impacted by the organic matter's quality and quantity, and will vary by season, media type, contact time, and backwashing strategy.

Temperature. Water temperature can limit bacterial activity within biological filters. Moreover, season affects the composition and concentration of the organic matrix and its subsequent biodegradation kinetics. Huck and coworkers (69) suggested that biological contactors should be operated seasonally, depending on seasonal water characteristics and utility criteria. Bacterial density and biomass activity have shown differences between winter and summer periods (71). The removal of DOC, BDOC, and trihalomethanes (THMs) was found to be significantly greater during warm temperatures (71–73). Merlet and coworkers (72) showed that DOC removal ranged from 0 to 15% in winter and 25 to 30% in summer. In a pilot study (73), two filters containing similar bacterial biomass were loaded with the same water at 8 and 20 °C . Bacterial activity led to a 60% removal of BDOC at 20 °C and a 27% removal at 8 °C . Consequently, it was necessary to double the contact time to have similar BDOC removal efficiency.

Filtration Media. Various filtration media can be used alone or in combination; however, the medium type is critical. Filtration using biologically active carbon is more efficient than biological sand filters for the removal of biodegradable organic carbon (74). GAC also showed better removal of DOC, BDOC, oxalate, aldehyde, and glyoxalic acid than anthracite (75,76). This difference can be explained by higher densities of fixed bacteria (four times as much) on carbon filters. Compared to microporous activated carbon, macroporous carbon provides the bacteria with a larger number of attachment sites protected from the abrasive action of backwash. The more abundant biomass allows for stable BDOC removal as well as sustained nitrification, even in cold waters (72). First-stage filters that are designed to remove particles can also achieve significant BOM removal through biological activity. However, the accumulation of floc and particles could act as a diffusion barrier for BOM molecules and affect biomass activity, especially under cold-water conditions (76).

Contact Time. The water-filter media contact time influences the amount of organic compounds removed. The higher the contact time, the better the removal. DOC removal was doubled (from 7 to 15%) when empty bed contact time (EBCT) was increased from 5 to 20 minutes (72). Some organic compounds also require longer contact times to be removed by biological filtration. Biologically active filtration is very effective on aldehyde removal. However, dialdehydes such as glyoxal require a slower filtration rate for their removal than formaldehyde and acetaldehyde (77).

Backwashing. Effective backwashing is essential for long-term successful filter service and for avoiding the formation of mudballs or filter cracks. In the case of biological filtration, the role of backwash is of primary importance for removal of nonbiological and biological particles without removing all the fixed bacteria. Different filter backwash methods are available, using water alone or in combination with air. While using an upflow wash, water is introduced into the bottom of the filter, and the filter medium gradually assumes a fluidized state as the backwash water flow increases and the bed expands. Particles accumulated are washed out of the filter media. Backwash flow is continued with full fluidization until the wastewater is clear. The effect of backwashing on biofilter bacteria varies depending on the type of support media and the backwash strategy. Backwashing with chlorinated water may remove a significant portion of the fixed biomass and decrease the performance of the filter for removal of organic carbon (78,79). In the case of anthracite, backwashing with chlorinated water may remove a significant portion (24%) of the fixed biomass (79). This had a short-term effect on the removal efficiency of certain organic molecules such as aldehydes. Similarly, Characklis (78) showed that chlorinated backwash of pilot sand/anthracite filters decreased TOC removal and microbiological activity in the filter, as evidenced by the number of heterotrophic bacteria fixed to the media. As for GAC filters, chlorinated and nonchlorinated backwashes lead to the same amount of fixed biomass and similar TOC removals (80). Servais and coworkers (71) reported that in the case of activated carbon, the loss of biomass appeared to be negligible, and it was less than 5% in warm water. A combination of water and air can be used to improve backwash efficiency. Pilot studies showed that backwashes with a combination of water-air scour and with water only yielded similar postbackwash AOC and TOC removals (81).

Modeling. Several models were developed to predict the performance of biological filters. Biofiltration processes are based on biofilm process principles. Biofilm kinetics has been well studied in the wastewater field. Ritmann (82) applied steady state biofilm modeling to interpret field data from drinking water biofilters. The principle of steady state biofilm is that the growth of new biofilm caused by substrate utilization is balanced by the biofilm losses caused by decay, detachment, and predation. The application of steady state biofilm kinetics to drinking water filters requires additional considerations. First, under low nutrient conditions, the presence of soluble microbial products might also affect the quality of the filter effluent. Moreover, backwash effects must be included. Biofilm detachment is high during backwash, whereas it is relatively low between backwashes when biofilm growth may accumulate. Finally, biofilms composed of multiple bacterial species are exposed to a wide range of inorganic and organic nutrients (82–85). Huck and coworkers (86) predicted the removal of biodegradable materials such as AOC and BDOC, disinfection by-product precursors, and chlorine demand by first-order models. The removal rate of biodegradable substances is defined as the difference in concentration at the inlet and outlet of the filter divided by the EBCT. The removal rate is proportional to the influent concentration at the inlet of the filter. The slope of the relationship between the removal rate and the BOM level is defined as the average specific removal (r_{as}) expressed in units of inverse minutes. The relationship also allows one to determine a minimum concentration below which the biodegradable materials could not be reduced by biological filtration. This concentration was estimated as 20 to 25 μg/L and 3 to 4 μg/L following first-stage filters and GAC contactors, respectively (86). The CHABROL Model is another tool used to predict BDOC removal during rapid sand or GAC filtration (46,71,87) (Fig. 8). The model includes the following processes occurring during biological filtration:

- *Interaction Between Bacteria and Organic Matter*. Bacteria can directly assimilate monomeric substrates (S fraction) and utilize easily and slowly biodegradable organic compounds (fractions H1 and H2, respectively), after exoenzymatic hydrolysis.
- *Interaction Between Bacteria and the Filter Media*. Bacteria can be biologically fixed (population B1) or adsorbed to the solid support (population B2) and suspended in the liquid phase (B3).
- *Mortality and Grazing of Bacteria*. The model describes bacterial biomass fate and BOM removal during biofiltration. The relationship between experimental results collected in full scale or pilot treatment plants and data predicted by the deterministic model are generally satisfactory. The CHABROL Model can be used to design filters producing biologically stable water.

Ozonation. Ozone has been widely applied at different stages of the treatment trains in Europe and more recently in the United States. The use of ozone in pre- or posttreatment considerably improves the quality of drinking water. Ozone is a powerful disinfectant that effectively oxidizes many chemical pollutants, removes color, tastes, and odors, and enhances coagulation (88). However, ozonation of NOM leads to the production of a large number of biodegradable compounds such as carboxylic acids, keto-acids, and aldehydes. The oxidation of organic matter by ozone leads to an increase in molecular polarity, encourages the formation of low molecular weight compounds at the expense of larger molecules, and reduces the aromaticity (reduction in UV absorbance at 254 nm). Ozone reacts with organic contaminants in water via two major chemical pathways. It reacts directly as molecular ozone (O_3) through highly selective and fast reactions. Ozone acts directly to form carbonyl groups by acting as a dipole agent on C=C double bonds, as an electrophilic agent on aromatic molecules by ring hydroxylation, or as a nucleophilic agent on C=N double bonds. Ozone can also react indirectly as a free radical (hydroxyl radical $OH^{\bullet}$) arising from ozone decomposition to form carbonyl compounds. The radical action of ozone is less selective than the direct action. Many compounds are only partially oxidized by ozone or are refractory to the action of ozone alone. Several processes

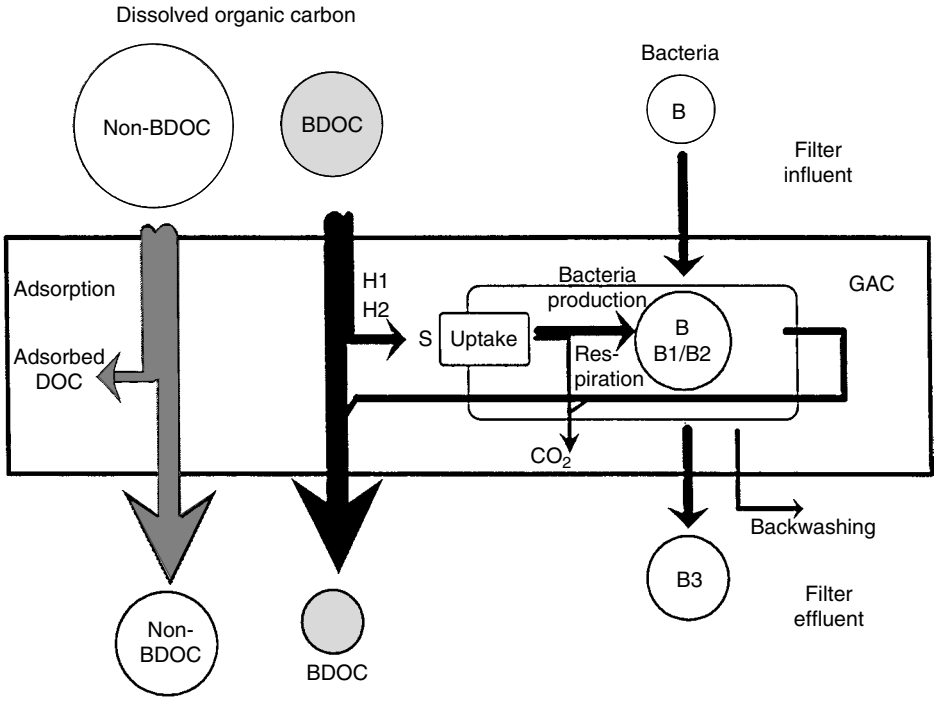

Figure 8. CHABROL Model and functioning of GAC filters (adapted from Servais and coworkers (71)). H1: Rapidly hydrolysable polymeric BDOC; H2: slowly hydrolysable polymeric BDOC; S: direct substrate; B: total filter bacteria; B1: biologically fixed bacteria; B2: adsorbed bacteria; B3: free bacteria.

have been combined with ozone to increase the oxidation level of molecules and to oxidize a larger spectrum of organic compounds (88–91). The ozone-hydrogen peroxide and ozone-UV systems provide nonselective degradation by enhancing free radical oxidation. The ozone-hydrogen peroxide combination leads to the degradation of alcohols, aliphatic acids, aldehydes, and some micropollutants such as atrazine and chlorinated solvents that are refractory to the action of ozone alone. The oxidation of these compounds with free radical action may be accompanied by significant TOC reduction when hydrogen peroxide-ozone is applied at an optimal ratio of 0.35 to 0.45 g/g in waters of neutral pH. Ozone has also been combined with a catalyst such as titanium dioxide in an attempt to mineralize a greater fraction of organic matter to CO_2 and H_2O (92).

Several authors have noted the increase in biodegradability of model substances or dissolved NOM following ozonation (88,91,93,94). BDOC concentrations of the ozonated water are a function of the raw water BDOC and ozone dosage. After ozone application, BDOC is formed within the first minute of treatment. The best ozonation conditions for producing BDOC are generally those that simultaneously provide maximum UV reduction measured as changes in absorbance at 254 nm (maximum changes in aromaticity) and leave traces of ozone residuals (Fig. 9). Ozone treatment increases the biodegradability of organic molecules in two stages: first, the rate of BDOC formation is high at low/intermediate oxidant levels. Then higher doses have little effect on the biodegradability of organic substances because all the molecules likely to be BDOC precursors have been transformed (93) (Fig. 9). Optimum BDOC formation is generally obtained with moderate ozone doses of 0.5 to 1.0 mg O_3 per mg DOC. Within the approximate range of 0 to 1 : 1 ozone to DOC ratio, several studies reported a 0.15 to 0.20 mg BDOC increase for each milligram of ozone added (93,94). At higher ozone doses, BDOC production is low (<0.05 mg BDOC/mg O_3). BDOC levels typically increase from 20 to 90% after ozonation of various river or sand-filtered waters. Applied ozone dose also shows a greater effectiveness than contact time. For equivalent applied ozone dose-contact time, a short contact time and a high ozone dose lead to higher BDOC formation than a long contact time associated with lower ozone dose (93). Figure 9 also compares the influence of ozonation used alone or in combination with hydrogen peroxide or a catalyst (titanium dioxide) on a fulvic acid solution. Maximum BDOC formation was obtained with ozone-hydrogen peroxide and ozone alone. BDOC formation was 30% lower in the presence of a catalyst than with ozone because catalytic ozone induced oxidation of ozone by-products into CO_2 (95).

Ozonation is often combined with biological filtration to remove biodegradable molecules produced after oxidation. When the filter influent water is ozonated, the biological degradability and thus filter biological activity are enhanced. Although ozone increases biodegradability by lowering the RDOC, ozone followed by biological filtration removes an additional DOC and AOC/BDOC fraction, reducing the number of chlorine-reactive sites, which is proportional to the risk of THM formation (71,96–101). By-products formed during ozonation, such as carboxylic acids, aldehydes, and peroxides (some of which are health concerns), can be removed through biological filtration (88,102–104).

Membrane Filtration. Different membrane technologies are available for the production of potable water, including reverse osmosis (removal of ions and organic matter), nanofiltration (NF) (removal of polyvalent ions

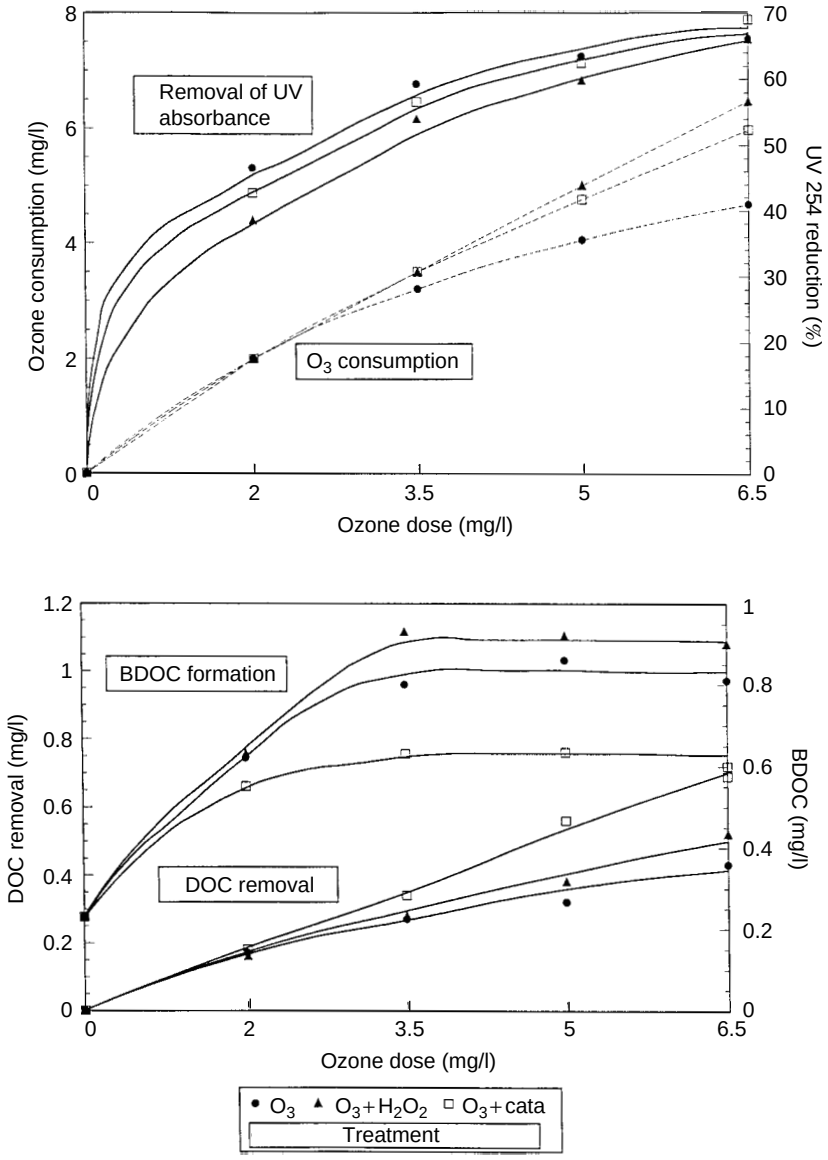

Figure 9. Effects of different oxidation treatments on UV absorbance, oxidant residual, BDOC, and DOC levels for a fulvic acid solution (O_3 + cata: ozone with a titanium dioxide catalyst).

and organic compounds larger than 400 Da), ultrafiltration (UF) (removal of colloids and molecules larger than 10,000 Da), and microfiltration (MF) (removal of particles greater than 0.2 μm, including turbidity, parasites, bacteria, and some viruses). MF and UF may not be suitable for organic matter removal unless pretreatments such as ozone and PAC are applied (105–107). The addition of PAC increased DOC removal efficiencies of ultrafiltration membranes to 40 to 50% (106). Ozonation improved DOC removal by the PAC/UF process up to 80% (108). NF membranes produce high removal efficiencies of DOC (from 50 to 99%), BDOC, precursors of chlorination by-products, pesticides/herbicides, color, and UV absorbance (109–111). However, main organic constituents in the membrane permeate following NF were identified as amino acids and sugars that are highly biodegradable. These data suggest that not all BOM molecules could be retained during membrane filtration treatment (111,112). Full-scale and lab data (112) showed that under high hardness and low pH conditions of feed water, NF allowed the passage of the AOC fraction even though DOC and BDOC rejection was near complete. This also highlights the complementary nature of AOC and BDOC as parameters.

Chlorination. Few studies documented the effects of chlorination on organic matter. It has been reported that biodegradability tends to increase after chlorination (96,100,113). Hambsch and coworkers (113) reported higher biodegradability of humic substances after chlorination.

BOM Changes During Conventional Treatment. BOM levels can be altered (increased or decreased) depending on treatment practices. Figure 10 shows the fate of organic compounds at different points within a typical

conventional treatment, before and after GAC implementation. Removal of biodegradable substrates is typically not favored during conventional treatment with sand/anthracite. While organic matter concentrations can be reduced, those of biodegradable substrates can be increased when using sand or sand/anthracite filters. Overall, after prechlorination and anthracite/sand filtration, the site recorded a DOC removal of 25% and an increase of AOC concentration of 50% through the treatment process (Fig. 10). Removal of DOC occurred during coagulation and settling, but removal was primarily of the refractory part (nonbiodegradable) of the DOC. Average raw water AOC level increased from 122 to 174 μg/L after preoxidation and settling processes, suggesting that chlorine pretreatment resulted in a large production of AOC. DOC, BDOC, and AOC were not removed by mixed media anthracite/sand filtration because a continuous chlorine residue was maintained through the filters. In contrast, GAC implementation modified organic fate during treatment and BOM was removed by biological GAC filtration. Overall, the plant recorded a reduction in AOC and BDOC levels after implementing GAC filtration (Fig. 10). AOC was increased by preoxidation; however, AOC levels were reduced to 58% by GAC filtration. BDOC concentrations also decreased after GAC filtration. Biological activity can take place during conventional treatment when chlorine levels are low on top of the GAC filters. Solutions for conventional treatment plants with high BOM levels could include the conversion of existing sand and sand/anthracite filters to sand/GAC filters and possibly delay the preoxidation step until after filtration, to limit BOM levels entering the distribution system.

BACTERIAL REGROWTH IN DISTRIBUTION SYSTEMS

Biofilm Formation and Bacterial Regrowth

BOM that is not removed during water treatment can result in the growth of biofilm bacteria in the distribution system (Fig. 11). The consequences of this bacterial growth can include: degradation of bacterial water quality, the acceleration of corrosion rates, the development of tastes and odors, customer complaints, and the development of a food chain leading to the presence of invertebrates (114–117). The degradation of bacterial water quality can be observed by growth of heterotrophic bacteria such as *Flavobacterium*, *Acinetobacter*, *Pseudomonas*, *Bacillus*, *Moraxella*, and *Staphylococcus* (118–120) and sometimes by the occurrence of coliforms (*Klebsiella*, *Escherichia coli*, *Enterobacter*, etc.) (121–124). Coliform regrowth can cause a violation of drinking water regulations. Suspended bacteria present in the water column come mostly from biofilms formed on the surface of distribution pipes, suspended particles, or sediments accumulated in storage tanks (124,125). Microbial accumulation in biofilms is governed by the three processes of adhesion, growth, and detachment (125–129) (Fig. 11). Bacteria adhering to the pipe surface have several origins. They may come from the source water through the treatment plant (130), regrowth of biofilm cells existing already within the distribution system, and introduction during main repair or cross connection. Growth of bacteria fixed on pipes is a combination of cell multiplication and mortality. Biofilm levels at steady state in pilot or full-scale distribution systems generally range between 10^5 and 10^7 bacteria/cm^2. The detachment of biofilm bacteria into the water column can be induced by fluid

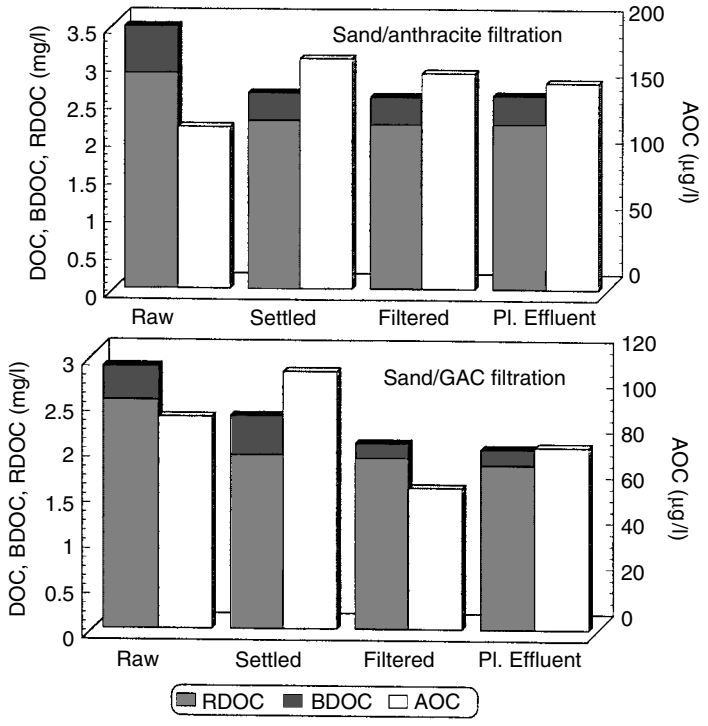

Figure 10. Changes in DOC, BDOC, and AOC concentrations during water treatment using sand/anthracite or GAC filtration. DOC = RDOC + BDOC where RDOC: refractory DOC.

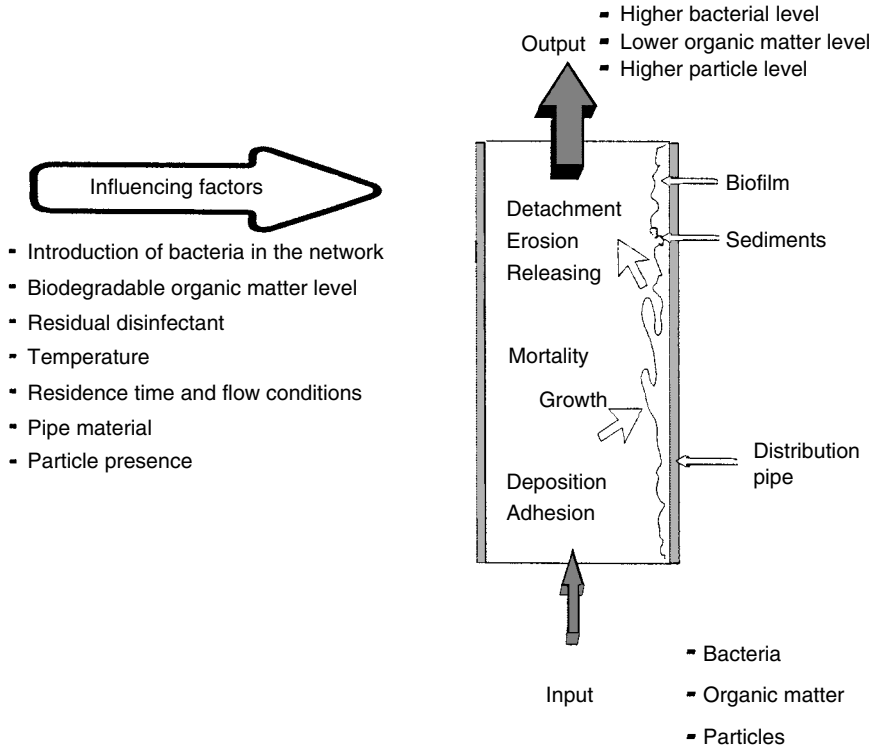

Figure 11. Biofilm in distribution systems.

shear stress at the biofilm surface or other water quality changes, such as increased disinfectant levels. It is possible to correlate the bacterial density in the biofilm to the dynamics of suspended bacteria in the bulk water phase. Servais and coworkers (131) suggested a ratio of approximately 60 between biofilm and suspended bacteria for small diameter pipes in several full-scale distribution systems. Consequently, a biofilm density of 10^7 bacteria/cm^2 could correspond to 5×10^4 bacteria/mL. Mathieu and coworkers (132) reported that a biofilm of 10^6 bacteria/cm^2 resulted in suspended bacterial concentrations of 10^3 to 10^5 bacteria/mL in pilot system studies.

BOM and Bacterial Regrowth

The level of BOM is an important parameter affecting bacterial regrowth because all heterotrophic bacteria use organic carbon for the production of new cell material or for utilization as energy (132–134). BOM is gradually consumed as the water travels through the distribution system. When both BDOC levels and temperatures are high in the water treatment plant effluent, BDOC consumption within the distribution system can be very rapid (36,131). There is generally a trend observed in biofilm detachment and organic loading.

The control of bacterial regrowth can be achieved when the amount of BOM entering the distribution system is limited. The BOM level required for biostability depends on the amount of disinfectant present. Block and coworkers (130) recommended an absence of biodegradable organic material after water treatment to limit bacterial regrowth. Servais and coworkers (131) associated biological stability (corresponding to no BDOC consumption within the distribution system) with a BDOC concentration of 0.16 mg/L or less in finished water in the absence of chlorine residue. Volk and Joret (135) indicated that BDOC levels should be less than 0.15 mg/L at 20 °C (warm temperature) and less than 0.30 mg/L at 15 °C for achieving biological stability in the Paris suburb an distribution systems. Coliform occurrences were related to the consumption of more than 0.10 to 0.15 mg/L of BDOC within the distribution system (135). Van der Kooij (134) showed that heterotrophic bacterial levels in nonchlorinated systems did not increase when AOC levels were lower than 10 μg/L. LeChevallier and coworkers (133) suggested that regrowth of coliform bacteria in chlorinated systems may be limited by AOC levels less than 50 to 100 μg/L. All the above objectives are difficult to consistently achieve and require very high levels of treatment. In addition to the amount of nutrients, the composition of biodegradable organic materials is also an important factor for controlling microbial growth. Amino acids are only a small fraction of the NOM, but they allow a high regrowth potential (high biomass production per unit of substrate) and are highly reactive with chlorine (104,136). Amino acids, carbohydrates, and humic substances were found to support heterotroph growth. However, coliform bacteria were able to persist in water containing amino acids or carbohydrates, but not with humic substances alone (104). The presence of disinfectant modifies the affinity of biofilm bacteria toward various organic substrates. In the absence of any disinfectant, biofilm cells preferentially utilize amino acids, then carbohydrates, and finally humic substances. However, in the presence of chlorine, biofilm affinity switches to amino acids, then humic substances, and finally carbohydrates. Humic substances may adsorb onto the biofilm and protect the microorganisms

from disinfection. In addition, some of the humic substances can be oxidized and converted into more easily degradable compounds after reaction with chlorine. Moreover, the presence of a disinfectant also affects substrate consumption and the regrowth of heterotrophic bacteria in the system. In the presence of chlorine, biofilms show greater carbon removal, higher specific biofilm growth rate, but lower biofilm yield, and lower biofilm densities than unchlorinated biofilms (137,138). The authors suggest that there is a protective mechanism of bacteria cells, which may require more substrate in the presence of a disinfectant. Bacteria may produce larger amounts of extracellular polymeric substances (EPS) to react with and neutralize chlorine (explaining the higher substrate uptake and carbon requirement). Acting as a sacrificial barrier, EPS are critical in limiting chlorine penetration into the biofilm (138).

Biofilm density and bacterial water quality are related to the amount of biodegradable material entering the system. Servais and coworkers (131) observed a relationship between biofilm bacteria and the concentrations of BDOC at the point of entry of several full-scale distribution systems. Another study compared bacterial water quality in two pilot distribution systems supplied with different levels of organic matter (139). The first system was fed with ozonated water, whereas the second was supplied with biologically filtered water. Lowering the nutrient levels with biological filtration led to lower biofilm densities. Biofilm counts were 10^6 to 10^7 CFU/cm^2 for the ozonated system, compared to 10^5 to 10^6 CFU/cm^2 for the system fed with biologically filtered water.

It is critical to produce low nutrient level waters. Several studies evaluated the effects of reducing nutrient levels on bacterial water quality after a treatment change. In two studies (140,141), bacterial water quality changes were monitored after implementation of NF in a pilot or full-scale system that was initially supplied with surface water treated with ozonation and biological filtration. In the pilot study (140), BDOC levels decreased from 0.25 mg/L in the ozonated/filtered water to less than 0.1 mg/L after NF. The authors did not observe drastic changes in the biofilm or suspended bacteria levels after the treatment change. At the beginning of the study, total and culturable counts were 4.9×10^6 cells/cm^2 and 4×10^5 CFU/cm^2 for the biofilm and 2.6×10^5 cells/mL and 10^3 CFU/mL in bulk water, respectively. Bacterial concentrations slightly decreased after 6 weeks of supplying nanofiltered water (suspended bacteria of 1.4×10^5 cells/mL and 259 CFU/mL; biofilm of 2.3×10^6 cells/cm^2 or 1.2×10^5 CFU/cm^2). After one year of supplying nanofiltered water, biofilm levels were 1.9×10^5 CFU/cm^2 and suspended bacterial levels were 50 CFU/mL. Similarly, bacterial water quality changes were not obvious when the same treatment conversion was performed in a full-scale distribution system supplying a suburban community (141) in Paris, France. Biofilm densities were low before the treatment change because of the high chlorine levels (0.85 mg/L) used to combat microbial growth caused by the high BDOC levels (0.75 mg/L). Following the application of NF, biofilm levels remained low, but a low disinfectant residual could be used because of the improved biostability (low BDOC) of the water. Another pilot study using annular reactors to simulate distribution systems evaluated the effect of reducing nutrient levels after biological filtration on bacterial water quality in drinking water (142). A system fed initially by conventionally treated water received biologically treated water. BOM levels were reduced approximately by half after biological treatment. On an average, biofilm densities were reduced by 1 log unit by biological treatment. Interestingly, the effect of the treatment change on bacteria levels was not immediate. It required approximately six months of biological treatment before there was an observable impact on bacterial water quality.

Field experience shows that distribution systems represent complex reactors and that a variety of parameters influence biofilm growth. Factors such as water temperature, disinfectant type and residual, selection of the pipe material, corrosion control, and hydraulic conditions may be more influential than the levels of organic matter for regulating the biological activity of the biofilm. These (and other) parameters probably influence microbial water quality data as much as the amounts of nutrients variable. Pipe characteristics strongly influence the density of fixed biomass. Iron pipe surfaces have been shown to stimulate bacterial growth (117,122,143,144). Camper (143) found that more heterotrophic bacteria grew on mild steel surfaces than on polycarbonate. Although growth rates were higher in the polycarbonate reactors, mild steel surfaces contained 10 times more heterotrophs and 2- to 10-fold more coliform bacteria. Biofilm levels are also governed by the pipe conditions. Corrosion, pitting, and tuberculation are fundamental to the presence of biofilms, their metabolic activity, and the release of bacteria into the water column (144). Pipe conditions also indirectly impact biofilm bacteria by affecting disinfection efficiency, especially with free chlorine. There is a relationship between the corrosion of iron surface and the protection of biofilm bacteria from chlorine disinfection (117,144). Rompre and coworkers (139) reported that free chlorine produced a rapid decrease in biofilm density (>1 log CFU/cm^2) in polycarbonate annular reactors, whereas the chlorine did not affect the biofilm in gray-iron reactors. Moreover, organic matter tends to adsorb to corrosion products on iron pipe surfaces and the elevated concentration of organic molecules can stimulate bacterial regrowth (137,138). A large survey conducted to understand coliform regrowth showed that coliform occurrence rates were higher in systems with a large proportion of unlined cast iron pipes subject to corrosion, suggesting that corrosion control is an important factor for limiting coliform regrowth (145). The use of phosphate-based corrosion inhibitors was associated with lower coliform levels in several systems. Coliform regrowth can also be related to several engineering and operational factors, including water filtration, the use of ozone without biological treatment, a large proportion of storage tanks, the presence of uncovered finished water reservoirs, corrosion control, and distribution system flushing (145). Removal of BOM through effective treatment and filtration is critical for controlling bacterial water quality. Coliforms occurred more

frequently in systems using unfiltered surface waters or using ozone without biological filtration. Finally, the configuration and management of the distribution system also influenced water quality. Increased levels of coliforms were observed in systems having a large proportion of storage tanks. Storage tanks are necessary to meet water demand, and provide adequate pressure and fire protection. However, the disinfectant can dissipate quickly and microbial water quality can deteriorate when water is stagnant in storage tanks. Systems with open finished water reservoirs are prone to animal contamination and algal bloom, and more likely to experience coliform regrowth (145). Annual flushing of the distribution is a maintenance practice performed to remove accumulated sediments, limit red water complaints, and reduce coliform occurrences.

Distribution System Modeling

Several models have been developed to predict water behavior and degradation of bacterial water quality during distribution. Although different factors may be listed and examined individually, in reality, all these factors are interrelated, sometimes with competing effects. For instance, increased water temperature favors microbial growth, but higher temperatures also improve disinfection efficiency (decreasing bacterial regrowth). Warm temperatures lead to higher reaction rates that may result in more rapid dissipation of disinfectant residuals and stimulate pipe corrosion. Higher disinfectant doses can reduce bacterial growth but increase nutrient levels and stimulate iron corrosion. Because of the complexity of the distribution networks and the variety of confounding effects, the existing models are overly simplified or apply only to a single site (146). Several models are available for predicting hydraulic flows and retention times (147). These models can incorporate a reactive component such as chlorine decay or bacterial growth rates. The EPANET Model simulates hydraulic and water quality behavior in distribution systems (148). The water quality modules include chlorine decay, trihalomethane propagation, or fluoride tracer analysis. PICCOLO software is another example of a residence time model that integrates the prediction of free chlorine decay within the Paris suburbs network (149).

Biofilm development on a surface is the result of several chemical, physical, and microbial processes, including an initial colonization phase of the pipe surface (transport and adsorption of organic material and bacteria from the bulk water to the surface and adhesion of bacteria), the growth of bacterial cells leading to a multilayer biofilm embedded in a polymer matrix, and the detachment of bacteria. Although fundamental aspects of these biofilm processes have been investigated (150), models for predicting bacterial water quality are limited. The Biofilm Accumulation Model (BAM) models the processes of nutrient (AOC) transport and consumption, biofilm development, and subsequent growth and decay of bacterial cells, detachment, and transport of microorganisms (148). The validation of the BAM has been performed in a pipe loop pilot system.

The SANCHO Model was adapted from biofilm processes observed during biological filtration (151). It is based on the relationship between bacteria, disinfectant, and BDOC levels in distribution systems (Fig. 12). The components of the model include the attachment of bacteria onto the surface pipe (reversible adsorption followed by biological attachment), the interaction between bacteria and organic matter (direct assimilation or exoenzymatic hydrolysis of organic material, growth of fixed and bulk bacteria, and bacterial mortality), and free chlorine behavior (chemical demand, disinfection of bacteria). The model successfully evaluates the spatial fluctuations of BDOC, chlorine, and suspended and fixed bacteria concentrations in a water mass circulating in a series of pipes with decreasing diameters. The model can be used to determine treatment goals to prevent the degradation of microbial water quality in any network (47,151,152).

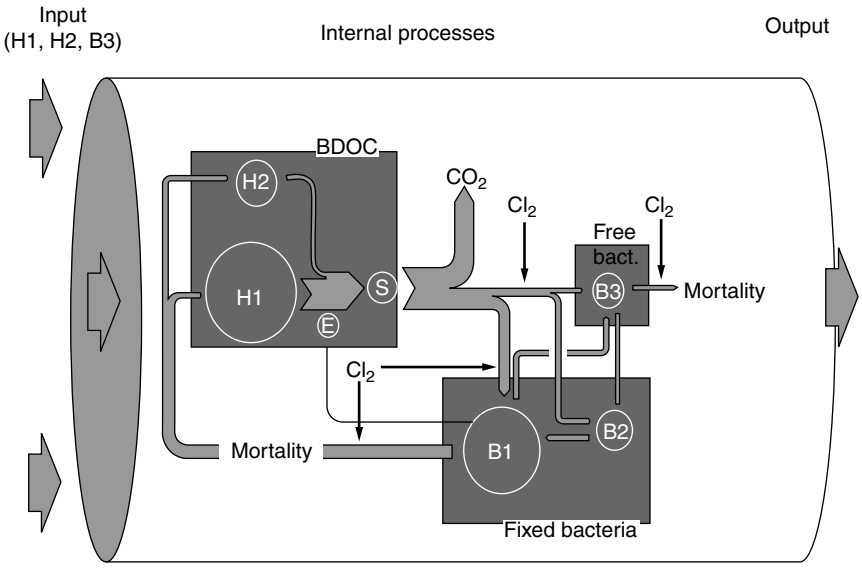

Figure 12. SANCHO Model (from Servais and coworkers (151)) H1: Rapidly hydrolyzable polymeric BDOC; H2: slowly hydrolyzable polymeric BDOC; S: direct substrate; B: total filter bacteria; B1: biologically fixed bacteria; B2: adsorbed bacteria; B3: free bacteria.

Because coliform occurrences are not related to a single variable, it is necessary to simultaneously examine the interaction of multiple parameters to predict the propensity for coliform regrowth events. Tree-based statistical models have been used to define predictor variables for coliform regrowth (146). A tree-based model is a descriptive summary of how a set of predictor variables relate to an outcome variable (e.g., presence or absence of coliforms). Coliforms can be predicted using a large set of variables, including AOC level, turbidity, temperature, disinfectant type, residual, pH, phosphates, TOC, and alkalinity. Although it may be possible to develop extremely sophisticated models using a large number of variables to predict coliform occurrences, such models are too complicated to be applied to most water utilities. Volk and Joret (135) developed the ALCOL Model to evaluate the risk of occurrences of total coliform bacteria in full-scale distribution systems in the suburbs of Paris, France, on the basis of temperature, BDOC consumption, disinfectant residual, and suspended bacteria counts (microscopic counts by epifluorescence) in the distribution network. The analysis of coliform occurrence data has shown no simple linear relationship between coliform-positive samples and these four water quality parameters. However, it is possible to determine a threshold value above which coliforms occur more commonly. The model uses the following four critical thresholds: water temperatures at or above 15 °C, BDOC consumption greater than 0.15 mg/L, a chlorine residual lower than 0.10 mg/L, and a logarithm of bacterial concentration higher than 5.2. The decision tree presented in Figure 13 graphically depicts the combinations of the threshold criteria. The sum of the positive criteria (number of threshold variables simultaneously exceeded) is indicated for each combination. Four positive criteria recorded for a distribution network lead to the most favorable situation for coliform occurrence (high temperature, low disinfectant residual, high nutrient consumption, and elevated bacterial concentration). Alternatively, a ranking of zero combines all the conditions for coliform control (low temperature, high chlorine residual, low nutrient consumption, and low bacteria levels). The probability of experiencing coliform bacteria when various threshold criteria are exceeded is shown in Table 4. The majority of positive coliform samples occurred when the four criteria were exceeded. The probability of coliform occurrence was 64% when the four criteria were positive, but nil when only one or none of the thresholds was exceeded. Such a model for the prediction of coliform episodes may be a useful tool to control bacterial regrowth. When a system is considered to be at high risk, various actions have to be undertaken to control bacterial water quality. Punctual actions such as increased flushing, boosting disinfection residuals, and decreased storage tank residence time can

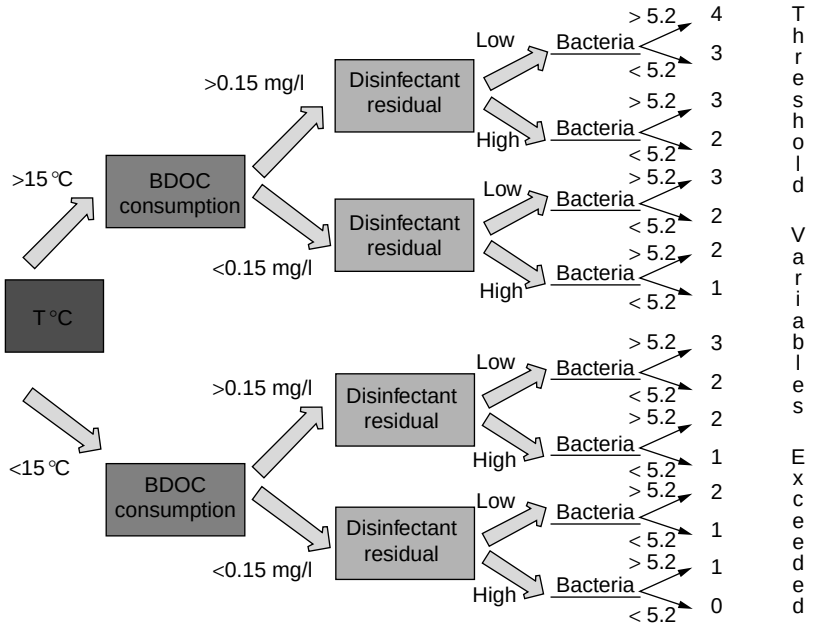

Figure 13. Decision tree for predicting coliform regrowth (ALCOL Model, 135).

Table 4. Risk of Coliform Occurrences in a Distribution System

Risk	Number of Positive Criteria	Total Number of Events	Number of Coliform Episodes	Frequency (%) of Coliform Observations
Exposed	4	14	9	64
Low risk	2 or 3	87	3	3
No risk	0 or 1	22	0	0

be effective in certain areas of the distribution system. Treatment modifications such as increasing plant effluent disinfectant residuals or improving BOM elimination can also be implemented at the production facility. However, the current model is site-specific and situations in which coliform regrowth does not occur while the model predicted coliforms are possible. Further refinement of the models may make these tools more accurate and reliable. Individual models for problem distribution systems may be warranted and could integrate hydraulic models, pipeline configurations, and operational characteristics of the network. Additionally, the weight of each parameter can be defined to refine the risk calculation.

CONCLUSION

Because a high BOM level is one factor related to bacterial regrowth, BOM removal should be emphasized during water treatment to improve water quality. Several bioassays are available to determine the levels of biodegradable organic materials in water. Measured BOM concentrations are often related to the applied methodology and the laboratory conducting the test. Each method has its own advantages and disadvantages. There is a weak correlation between AOC and BDOC concentrations. The BDOC test attempts to identify the entire pool of BOM, including both very labile constituents and slowly biodegradable molecules (requiring the successive steps of cell adsorption, exoenzymatic hydrolysis, and cell consumption), whereas the AOC test detects only easily assimilable organic compounds. Because both tests emphasize different fractions of BOM, both parameters should be monitored when studying nutrient changes during water treatment and distribution. Bacterial regrowth and coliform occurrences increase with temperature, the absence of disinfectant, and elevated levels of BOM. Beyond these three major factors, coliform regrowth is also dependent on other physicochemical, engineering, and operational parameters such as pipe material, hydraulic shear, and corrosion. Therefore, it is difficult to predict the effects of a treatment change at a specific site, depending on the weight of the different factors regulating bacterial growth. As a first step, a water utility can better limit biofilm problems when simultaneously addressing the following three issues: nutrient levels, corrosion, and disinfection. High organic matter removal during water treatment and effective corrosion control during distribution would improve disinfection and limit bacterial regrowth within the distribution system.

INTRODUCTION

Of the enormous number of different halogenated organic compounds that have been chemically synthesized, several have found widespread use, particularly as solvents and biocides. This use has led to their being accidentally or intentionally released into the environment, mainly to groundwater. Although there is good evidence for natural production of chlorinated organic compounds (1), many of these anthropogenic organic halogen compounds appear to be resistant to chemical and biological degradation and therefore persist in the environment. This chapter discusses the roles of anaerobic microorganisms in the biodegradation of these compounds and focuses mainly on chlorinated compounds, which are the most pervasive organohalogen contaminants and have received the greatest attention. Additionally, reactions carried out by microorganisms in pure culture are emphasized.

Chlorinated organic compounds of environmental significance (Fig. 1) include chlorinated methane, ethane, ethene, and benzene solvents; the biocide pentachlorophenol; the herbicide 2.4-dichlorophenoxyacetic acid (2,4-D); polychlorinated biphenyls (PCBs); the insecticide DDT [1,1,1-trichloro-2,2-bis (chlorophenyl) ethane]; and dioxin contaminants such as 2,3,7,8-tetrachlorodibenzodioxin (TCDD). The chlorinated solvents found widespread use because they are nonflammable and were once considered relatively nontoxic; however, many are currently considered to be carcinogens, teratogens, neurotoxins, or estrogen mimics. Moreover, because many chlorinated compounds are lipophilic, they tend to accumulate in fat deposits in members of higher echelons of the food chain including humans.

When chlorinated solvents are released into soil, they form dense nonaqueous phase liquids (DNAPLs) or, in combination with other compounds such as hydrocarbons can form light nonaqueous phase liquids (LNAPLs). The DNAPLs, in particular, tend to accumulate as neat solvent at the bedrock or soil interface and then slowly leach into groundwater forming a plume. Because the maximum

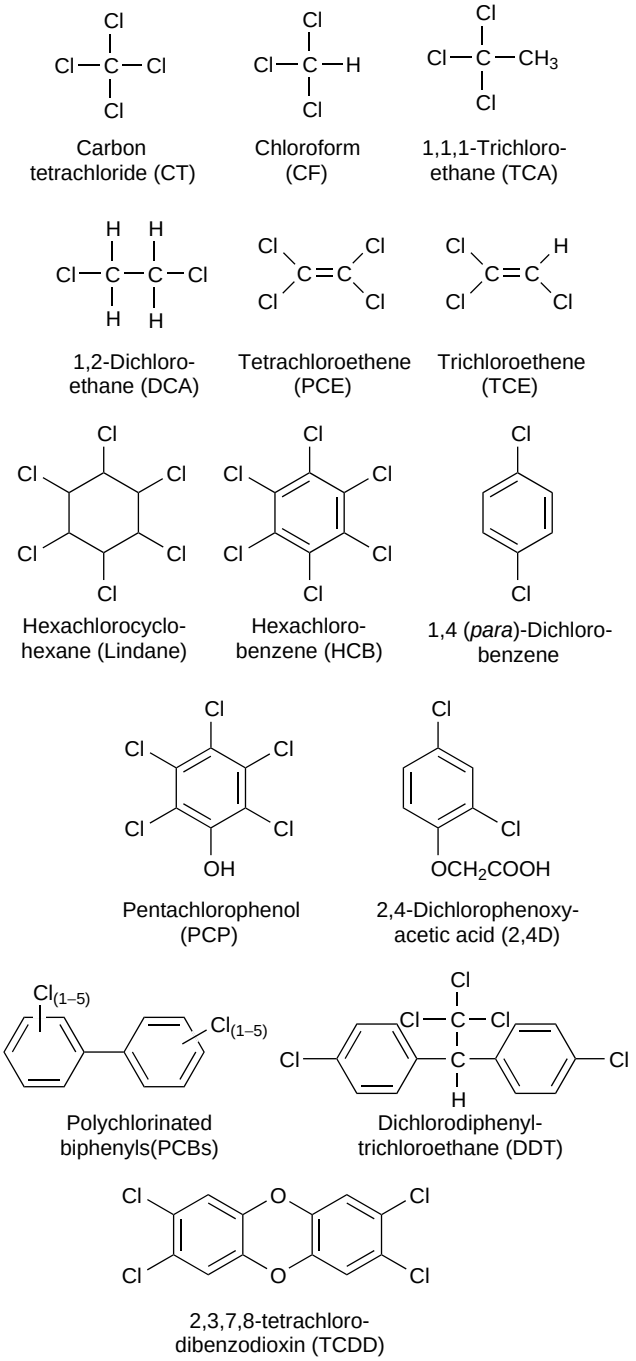

Figure 1. Examples of synthetic organochlorine compounds of environmental significance.

allowable concentrations of many of these solvents in drinking water are one to five parts per billion, a large amount of groundwater can be contaminated by a relatively small amount of these compounds.

Research on biodegradation of chlorinated compounds initially focused on aerobic metabolism, and much exemplary scientific data has been obtained about the organisms, pathways, and genes involved in aerobic degradation processes. However, it became increasingly apparent that many highly chlorinated compounds

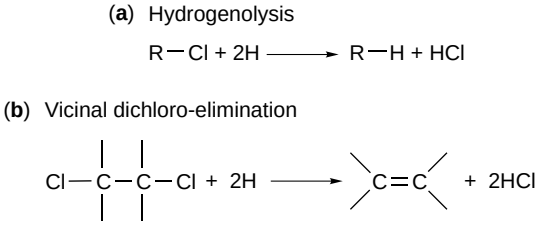

Figure 2. Reductive dechlorination of chlorinated organic compounds. (**a**) Hydrogenolysis. (**b**) Vicinal dichloro-elimination. If the carbon–carbon bond is double in part B, a triple bond is formed.

degrade poorly. Anaerobic processes, on the other hand, were originally considered slow, unreliable, and applicable to only a few compounds. Significant improvements in anaerobic techniques, however, have led to studies showing that there is a much greater metabolic diversity of anaerobes than was originally believed and that anaerobes were capable of utilizing highly chlorinated compounds, often better than more lightly halogenated ones.

Aerobic metabolism of chlorinated organic compounds generally proceeds via destabilization of the carbon–chlorine bond by addition of proximal hydroxyl or epoxy groups by oxygenases, or sometimes by replacing the chlorine with a hydroxyl group by hydrolytic enzymes. Under anaerobic conditions, electrons derived from the oxidation of organic matter are available for reductive reactions, such as reductive dechlorination. The most common type of reductive dechlorination is essentially a hydrogenolytic reaction replacing a Cl with an H, liberating HCl (Fig. 2a). In certain compounds containing chlorines on adjacent carbons, there can also be a vicinal dihalo elimination (Fig. 2b) in which two chlorines are released as 2HCl and another carbon–carbon bond is formed.

COMETABOLIC REDUCTIVE DECHLORINATION

Early studies showed that reduced transition metal complexes including biological tetrapyrroles such as hemes (Fe^{2+}), and vitamin B_{12} and other corrinoids (Co^{1+}) could carry out reductive dechlorination and other dehalogenations (2). Later, reduced cofactor F_{430}(Ni^{1+}) from methanogens (3) was also shown to carry out reductive dehalogenations. Thus it was not surprising that various reductive dehalogenation reactions were demonstrated in organisms rich in these cofactors, such as sulfate-reducers (hemes), acetogens (corrinoids), and methanogens (corrinoids and F_{430}). However, in all these cases, the reactions represented a low fraction of the organisms' overall metabolism and the organisms received no tangible benefit from them. These reactions are therefore considered cometabolic. Cometabolic reductive dechlorination may be quantitatively important in anaerobic habitats in which these organisms are naturally abundant such as in anoxic sediments.

A few examples of this type of dechlorination are given in the following section. Gantzer and Wackett (4) tested several compounds and found that hematin, vitamin B_{12},

and coenzyme F_{430} could dechlorinate tetrachloroethene (PCE), hexachlorobenzene (HCB), and carbon tetrachloride (CT), whereas ferredoxins, which contain iron-sulfur centers, and azurin, which contains copper, could not. Indeed, vitamin B_{12} and F_{430} could reduce PCE completely to ethene. All the dechlorinations followed first-order kinetics, and each subsequent dechlorination was slower by more than an order of magnitude than that preceding it. In another example, the enzyme carbon monoxide dehydrogenase from *Methanosarcina thermophila* could also reduce PCE to ethene (5), and a similar amount of reductive dechlorination was obtained from corrinoids in concentrations equal to that of the enzyme. Similarly, crude extracts of the methanogen *Methanobacterium thermoautotrophicum* were shown to reduce 1,2-dichlorothane(DCA) to ethene (vicinal dihalo-elimination) and to chloroethane (hydrogenolysis) (6). A large fraction of this activity could be attributed to the enzyme methyl-coenzyme M methyl reductase, which contains cofactor F_{430}. Interestingly, this enzyme could also slowly reduce to ethene bromoethane sulfonic acid, a molecule that is often used in ecological studies as a specific inhibitor of methanogenesis because of its inhibition of the methyl reductase.

It has been shown that a variety of obligate and facultative anaerobes can carry out reductive dechlorination of the pesticide Lindane (hexachlorocyclohexane, Fig. 1) (7). A culture of *Clostridium rectum* was shown to conserve more ATP from pyruvate oxidation when it reduced Lindane to 1,2,4 trichlorobenzene or pentachlorocyclohexane to 1,4-dichlorobenzene (8). In this case, the Lindane apparently was serving as an "electron dump," allowing greater oxidation of the pyruvate, rather than as a respiratory electron acceptor. Enhanced growth by *C. rectum* in the presence of Lindane could not be demonstrated, presumably because of toxicity.

REDUCTIVE DECHLORINATION AND DEHALORESPIRATION

A water shed paper in the field of reductive dechlorination was that of Suflita and coworkers (9) in 1982. It described enrichment cultures derived from lake sediments and sewage sludge that carried out the reductive dechlorination at relatively high rates of several chlorinated, brominated, and iodinated benzoates, but not fluorinated benzoates. This was the first description of reductive dechlorination of halogenated aromatic compounds. Perhaps even more significant, however, was their statement that a mixed culture that completely converted 3-chlorobenzoate (3-CB) to methane and carbon dioxide with benzoate as an intermediate had been maintained for two years. This was the first suggestion that reductive dechlorination could promote growth of a microorganism.

Further studies led to a better characterization of the microbiology of the 3-CB–utilizing consortium (Fig. 3) (10). A dechlorinating organism reductively dechlorinated 3-CB to benzoate, which was then converted to H_2, CO_2 by a benzoate oxidizer resembling *Syntrophus buswellii*. One of the moles of H_2 was used for the reductive dechlorination of 3-CB, whereas the other two moles

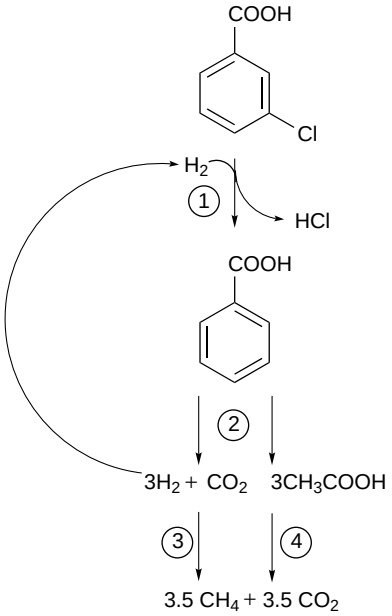

Figure 3. Conversion of 3-chlorobenzoate to CH_4, and CO_2 by a microbial consortium. Predominant microorganisms involved: (*1*) Reductive dechlorinator (*Desulfomonile tiedjei* (DCB-1)); (*2*) Benzoate oxidizer (*Syntrophus buswelii*); (*3*) H_2 consuming methanogens (*Methanobacterium formicicum*, and *Methanospirillum hungatei*); (*4*) Acetotrophic methanogen, (*Methanosaeta* (*Methanothrix* sp.). After Dolfing et al. (10).

were used by hydrogenotrophic methanogens to produce 0.5 moles of CH_4 from CO_2. Another three moles of CH_4 and CO_2 were produced from acetate by a *Methanosaeta*-like methanogen. This consortium must function as a unit because benzoate oxidation is only thermodynamically favorable if H_2 is removed by methanogens and the dechlorinator and acetate is removed by the acetotrophic methanogens (11). Moreover, the dechlorinator is dependent on benzoate oxidation to provide reducing power (H_2) needed for its dechlorination, whereas the benzoate oxidizer is dependent on the dechlorinator for its substrate.

Desulfomonile tiedjei strain DCB-1 was eventually isolated from the consortium (12). It grew only poorly, even in rich medium, until its nutrient requirements were determined to include nicotinic acid, 1,4-naphthoquinone, and thiamine. Once the organism grew well in a defined medium, it was clearly demonstrated to be able to use 3-chlorobenzoate as a respiratory electron acceptor for growth (13). *Desulfomonile tiedjei* also used sulfate, thiosulfate, and several metachlorinated benzoates as electron acceptors (Table 1).

Using reductive dechlorination as a respiratory anaerobic electron-accepting reaction has been called dehalorespiration as well as halorespiration (14), but because the latter term could also apply to reduction of compounds such as perchlorate, the former one is used here. A considerable amount of energy is available for conservation from reductive dechlorination. For example, the oxidation-reduction potential of chloroethene reductions varies from 0.37 to 0.58 v (2) and that for chlorinated aromatics varies

Table 1. Representative Organisms Capable of Respiratory Reductive Dehalogenation

Organism	Representative Dehalogenations	Electron Donors	Other Electron Acceptors	Phylogenetic Position
Desulfomonile tiedjei (12)	3-chlorobenzoate to benzoate	H_2, formate, pyruvate	Sulfate, thiosulfate	Delta *Proteobacteria*
Isolate 2CP-1 (50)	2 chlorophenol to phenol	Acetate	Oxygen	Delta *Proteobacteria*
Desulfitobacterium dehalogenans (27)	2, 4, 6-trichlorophenol to 2,4-dichlorophenol	H_2, butyrate, pyruvate	Sulfite, fumarate, nitrate,	*Firmacutes*
Dehalospirillum multivorans (74)	PCE to *cis*-DCE	H_2, formate, pyruvate	Fumarate, nitrate	Epsilon *Proteobacteria*
Desulfitobacterium frappieri (26)	Pentachlorophenol to 3-chlorophenol, PCE to TCE/*cis*-DCE	Pyruvate,	Sulfite, thiosulfate, nitrate	*Firmacutes*
Dehalobacter restrictus (25)	PCE to *cis*-DCE	H_2	None	*Firmacutes*
Enterobacter strain MS-1 (30)	PCE to *cis*-DCE	Formate, pyruvate, acetate	Oxygen, nitrate	Gamma *Proteobacteria*
Desulfuramonas chloro ethenica (29)	PCE to *cis*-DCE	Acetate, pyruvate	Polysulfide, fumarate, Fe(III)	Delta *Proteobacteria*
Dehalococcoides ethenogenes (31)	PCE to ETH 1,2-DCA to ETH(VC)	H_2	None	*Chloroflexi*
Desulfovibrio strain TBP-1 (53)	2,4,6-tribromophenol to phenol	H_2, formate, lactate	Sulfate, thiosulfate, S°	Delta *Proteobacteria*
Trichlorobacter thiogenes (47)	Trichloroacetate to dichloroacetate	H_2S (acetate)	S°, fumarate	Delta *Proteobacteria*
Dehalococcoides strain CBDB1 (56)	Tetra- and trichlorobenzenes to tri- and dichlorobenzenes	H_2	None	*Chloroflexi*

from 0.27 to 0.48 v (15), close to the nitrate/nitrite couple (0.43 v). Reductive dechlorination is therefore a much more favorable electron-accepting reaction than is sulfate reduction (−0.22 v) or methanogenesis from H_2/CO_2 (−0.24 v).

Desulfomonile tiedjei was officially described in 1991 and had been in pure culture for several years before that, yet it was not until the mid-1990s that several additional dehalorespiring organisms were isolated (Table 1). Nearly all were most closely related to the gram-negative sulfur compound reducers in the delta and epsilon subphyla of the *Proteobacteria* (purple bacteria and relatives) or to the *Desufotomaculum* group in the *Firmacutes* (low %G + C gram-positive bacteria). These groups contain organisms that are versatile at using electron acceptors.

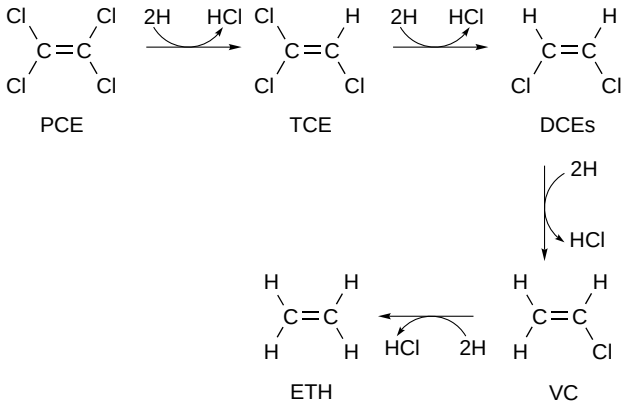

Figure 4. Reduction of tetrachloroethene (PCE) to ethene (ETH). Intermediates include trichloroethene (TCE), dichloroethene isomers (represented by the *cis* isomer), and vinyl chloride (VC).

CHLOROETHENE UTILIZATION

The solvents PCE and trichloroethene (TCE) were used extensively in the second half of the twentieth century, particularly for degreasing metal parts and dry cleaning clothes. They are among the most frequently encountered groundwater pollutants. Aerobically, TCE can be oxidized to an epoxide form by a variety of oxygenase enzymes such as methane monooxygenase or toluene dioxygenase (16), whereas PCE appears resistant to oxidative attack. Several studies showed reductive dechlorination by anaerobic microbial communities to the extent of vinyl chloride (VC) (17), a known human carcinogen. Freedman and Gossett (18), in their studies on an enrichment culture derived from a sewage digestor, first demonstrated complete reductive dechlorination of chloroethenes to ethene (ETH) (Fig. 4), and reduction as far as ethane has also been described (19). In the former system, it was shown that in the anaerobic enrichment culture, when methanol was fed as an electron donor, reductive dechlorination of PCE could occur at unprecedentedly high rates (20). It was subsequently demonstrated that H_2 was the direct electron donor for dechlorination even when methanol was being supplied to the culture (21). The dechlorination of PCE, TCE, and *cis*-DCE all followed zero-order kinetics in the

concentration range assayed, and rates of utilization of these chloroethenes were similar (22), in marked contrast to reductive dechlorination carried out by reduced transition metal cofactors (4). A more defined culture using H_2 as the electron donor was shown to require vitamin B_{12}, a cofactor that presumably was supplied by methanol-utilizing methanogens and acetogens in the methanol-PCE enrichment culture.

Several laboratories isolated organisms that could reduce PCE to TCE (23) or more often to *cis*-DCE. These include *Dehalobacter restrictus* (24,25), a gram-positive organism capable of utilizing only PCE or TCE as electron acceptors and H_2 as the electron donor (Table 1), hence its species epithet. *Dehalospirillum multivorans* is more metabolically versatile than *D. restrictus* and is a member of the epsilon subphylum of the *Proteobacteria*. Several strains of *Desulfitobacterium* are capable of dechlorinating PCE and TCE (23,26–28). *Desulfitobacterium* is a gram-negative endospore former and is phylogenetically related to the sulfate-reducer *Desulfosporosinus (Desulfotomaculum) orientis* and to *D. restrictus*. *Desulfuromonas chloroethenica* (29) is one of the few dechlorinators capable of using acetate as an electron donor and can also reduce polysulfide compounds. *Enterobacter* strain MS-1 (30) is a facultative aerobe and reduces PCE and TCE when utilizing nonfermentable substrates in the absence of another electron donor such as nitrate or oxygen. Interestingly, an *Enterobacter* strain from the American type culture collection that presumably was naive to any exposure to chloroethene solvents was capable of PCE reductive dechlorination. From these and other studies it can be concluded that organisms that reduce PCE as far as DCE are cosmopolitan, and at least some of them are relatively easy to culture.

The enrichment culture has been studied from the Gossett laboratory, eventually describing in 1997 (31) the isolation of an organism, tentatively named *Dehalococcoides ethenogenes* strain 195, capable of reductively dechlorinating PCE to etherene (ETH). *Dehalococcoides ethenogenes* had a very complex nutrition, requiring acetate, vitamin B_{12}, and extracts of mixed cultures containing it for its growth. Of many substrates tested, it used only H_2 as an electron donor and only chloroethenes or 1,2-dichlorothane (DCA), which it reduces primarily to ethene, as electron acceptors. Conversion of VC to ethene is the rate-limiting step, and subsequent results (32) showed that it cannot grow using VC or trans-DCE as electron acceptors. *Dehalococcoides ethenogenes* is a small disc-shaped organism that is resistant to peptidoglycan synthesis inhibitors such as vancomycin and ampicillin and apparently lacks a peptidoglycan cell wall. Initial phylogenetic analysis of its 16S rDNA showed that it was in the bacteria but not closely related to any isolated species. More recent analysis (33) shows that its 16S rDNA resides in a deeply branching subphylum of the *Chloroflexi* (green nonsulfur bacteria), most closely related to sequences that were derived from uncultured organisms in natural habitats (33). Interestingly, one of the most closely related sequences to that from *D. ethenogenes* was derived from an enrichment culture carrying out reductive dechlorination of PCBs (34).

Thus far, *D. ethenogenes* is the only isolate capable of reductive dechlorination of chloroethenes past DCE. Although *D. ethenogenes* cannot grow reducing VC to ethene, there is good evidence that other organisms in enrichment cultures are capable of growth from reductive dechlorination of VC (35,36).

CHLORINATED METHANE AND TRICHLOROACETATE UTILIZATION

Three of the chloromethanes, carbon tetrachloride (CT or tetrachloromethane), chloroform (CF), and dichloromethane (DCM or methylene chloride), are widely utilized solvents and are pervasive groundwater contaminants. Chloromethane is produced biogenically by several fungi and algae (1). Aerobically, CT and CF are barely utilized, whereas DCM can be utilized as the sole source of carbon and energy by several aerobic methylotrophic microorganisms (37). For anaerobic metabolism, one could imagine a reduction series for chloromethanes similar to that for chlorinated ethenes in which CT is sequentially dechlorinated to CF, DCM, CM, and finally CH_4. However, utilization of chloromethanes as respiratory electron acceptors has not been described, although it is thermodynamically feasible. Rather, these CT and CF compounds appear to be cometabolized by a variety of organisms, particularly those with high levels of corrinoids, that can chemically convert them to CO_2, CO, or formate (38–43). *Pseudomonas stutzeri* strain KC secretes a factor that converts CT to CO_2 along with small amounts of CS_2 and COS when grown under nitrate-reducing and iron-limited conditions. This factor has been identified as pyridine-2, 6-bis(thiocarboxylate) (44), a compound previously isolated from a *Pseudomonas* strain and considered to be a metal ion chelator.

Both DCM and CM are used as substrates by anaerobic acetogenic microorganisms. In both cases, the chloromethanes serve as substrates rather than as respiratory electron acceptors. *Dehalobacterium formicoaceticum* (45) converts DCM to acetate by the equation:

$$3CH_2Cl_2 + 2CO_2 \rightarrow 2HCOO^- + CH_3COO^- + 9H^+ + 6Cl^- \quad (1)$$

The DCM is at the same oxidation state as formaldehyde and feeds into the acetogenic pathway in a similar manner. It is to be noted that formate rather than H_2 was produced by this organism, which is unusual. *Dehalobacterium formicoaceticum* grew poorly without a methanogen or sulfate-reducer to remove the formate it produces. The only tested substrate that *D. formicoaceticum* could use was DCM. Dibromomethane was utilized in short-term assays but did not serve as a growth substrate, presumably because of toxicity. The organism's 16S rDNA sequence showed that it is a member of the *Firmacutes*.

Strain MC1 is a gram-positive organism that forms cocci in chains and ferments CM to acetate, CO_2, and HCl by the equation:

$$4CH_3Cl + 2CO_2 + 2H_2O \rightarrow 3CH_3COO^- + 7H^+ + 4Cl^- \quad (2)$$

Strain MC uses the CM as a source of a methyl group to ferment, much like it uses methanol (46). It was quite versatile at substrate utilization, growing on sugars, methanol, methoxylated aromatics, H_2/CO_2, lactate, or pyruvate. However, it did not utilize DCM.

An organism has been isolated that reductively dechlorinates the trichloromethyl group of Trichloroacetate (TCA) (47), which has been used as an herbicide. *Trichlorobacter thiogenes* has an unusual metabolism for its reductive dechlorination of TCA to dichloroacetate in that it uses sulfide as the source of electrons for the reduction, thereby oxidizing it to elemental sulfur, which it stores as intracellular granules. Sulfide was regenerated from the sulfur by electrons derived from oxidation of acetate, a metabolic mode similar to its close relative *Desulfuromonas* in the delta subphylum of the *Proteobacteria*.

CHLOROPHENOL AND BROMOPHENOL UTILIZATION

Chlorophenols have been used as biocides, and there is particularly widespread use and environmental contamination by pentachlorophenol (PCP). 2,4-Dichlorophenol is formed after hydrolysis of the common herbicide 2,4-dichlorophenoxyacetic acid (2,4-D) (Fig. 1). Moreover, chlorophenols and related methoxylated compounds are formed during lignin degradation by fungi (48) and are, therefore, natural compounds found in soil. Aerobic organisms that can degrade lightly chlorinated phenols such as 2,4-dichlorophenol are relatively abundant, and there are aerobes that can degrade PCP (49).

Reductive dechlorination of chlorophenols has been found in anaerobic sediments and enrichment cultures and in at least two genera that are capable of conserving energy from the reductive dechlorination of chlorophenols. One of these, called *Isolate 2CP-1*, dechlorinated 2-chlorophenol to phenol (50). This organism was a facultative aerobe and is phylogenetically related to the fruiting myxobacteria, an unusual affiliation for a reductive dechlorinator, although in the delta subphylum of the *Proteobacteria*. *Desulfomonile tiedjei* could dechlorinate PCP to 2,4,6-trichlorophenol, but the activity needed a chlorobenzoate inducer and concentrations greater than 10 μM inhibited rather than stimulated growth on pyruvate, suggesting that the activity is fortuitous (51).

Several *Desulfitobacterium* strains can use chlorophenols (23,26,27). Most strains only affect *ortho* dechlorination of chlorophenols, whereas *D. frappieri* (26) is capable of converting PCP nearly stoichiometrically to 3-chlorophenol (Fig. 5). It attacks the *ortho* chlorines first, and then after a lag period, during which the organism is presumably inducing a different dehalogenase(s), it attacks the *meta* and *para* chlorines. *Desulfitobacterium frappieri* can dechlorinate many different chlorophenols except monochlorophenol and certain dichlorophenols. It also dechlorinates several chlorocatechols and chloroanilines and both dechlorinates and demethoxylates several methoxylated chlorophenols (52).

Bromophenols are produced by certain marine invertebrates, apparently as a means of controlling microorganisms in their burrows (1). Degradation of bromophenols by marine sediments has been documented, and the sulfate-reducer *Desulfovibrio* strain TBP was isolated from an anaerobic bromophenol-degrading enrichment culture derived from estuarine sediments (53) and was shown to completely debrominate 2,4,6-tribromophenol to phenol as a dehalorespiratory process.

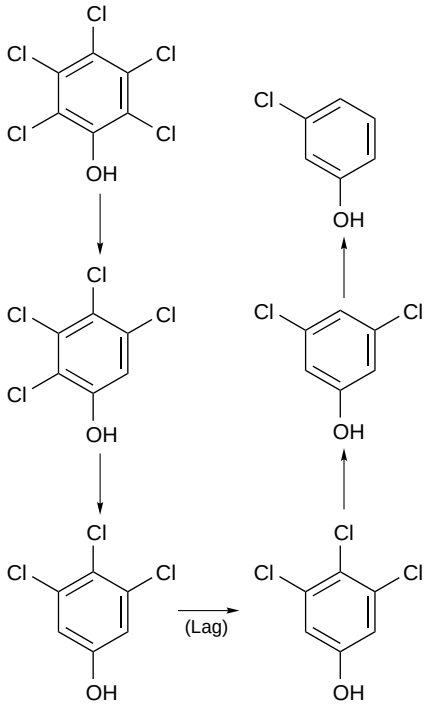

Figure 5. Reductive dechlorination of pentachlorophenol (PCP) to 3-chlorophenol by *Desulfitobacterium frappieri* (26). Addition of H, and removal of HCl as in Figure 3 are not shown for simplicity.

REDUCTIVE DEHALOGENATION OF OTHER ORGANOHALOGEN COMPOUNDS BY MIXED MICROBIAL POPULATIONS

There is good evidence of microbial reductive dechlorination of several other organochlorine compounds by anaerobic microcosms or by mixed microbial cultures. 1,1,1-trichloroethane (methylchloroform, TCA) (Fig. 1) was a commonly used solvent that has been shown to be transformed to 1,1-dichloroethane and chloroethane by mixed anaerobic microbial populations (2). It also underwent a slow abiotic elimination reaction leading to the formation of 1,1-dichloroethene, which was then biologically transformed to VC (2).

1,2-dichloroethane (DCA) (Fig. 1) is commonly used for making plastics and as a solvent and is readily biodegradable under aerobic conditions. *Dehalococcoides ethenogenes* could utilize DCA as an electron acceptor (32), converting it to approximately 99% ethene (dihalo-elimination) and 1% VC. Mixed cultures containing *Dehalococcoides ethenogenes* also carried out a rapid conversion of the fumigant 1,2-dibromoethane to ethene (22), but attempts to grow the pure culture using this compound as a respiratory electron acceptor failed. Another chlorinated ethane, the solvent 1,1,2,2-tetrachloroethane

(PCA), was dechlorinated mainly to *cis* and *trans* isomers of DCE and to VC by freshwater tidal sediments (54). 1,2-dichloropropane, an antinematode fumigant, was metabolized by mixed cultures to propene, with monochlorinated propenes detected only in early stages of enrichment (55), and apparently did not serve as intermediates in propene formation.

Chlorinated benzenes have been shown to be reductively dechlorinated, and reactions leading from hexachlorobenzene (Fig. 1) to monochlorobenzene have been demonstrated (14), although usually not all in the same sample. Often a large amount of 1,3,5-trichlorobenzene accumulates in cultures containing hexachlorobenzene, suggesting that dechlorination occurs most readily when two chlorines are adjacent to each other. *Dehalococcoides* strain CBDB1, which showed 98.3% identity in its 16S rDNA sequence with *D. ethenogenes*, could dechlorinate 1,2,3-trichlorobenzende, 1,2,4-trichlorobenzene, and some of the tetrachlorobenzene isomers (56). The organism did not dechlorinate PCE. Conversion of monochlorobenzene to benzene is slow, if carried out at all, by mixed cultures.

The insecticide DDT (Fig. 1) is no longer used in the United States but is still used elsewhere in the world to protect crops and to eliminate malaria-bearing mosquitoes. Through chemical and biological processes, it has been shown that DDT's trichloromethyl group under anaerobic conditions can be completely dechlorinated (57). The fate of the rest of the molecule under anaerobic conditions is not known. PCBs and dioxins (Fig. 1) are often resistant to aerobic biodegradation because of their high level of chlorination. Evidence for reductive dechlorination of these important environmental contaminants has been obtained using microcosms from contaminated sites (14,58–60), as is discussed in greater depth in another chapter in this volume.

BIOCHEMISTRY AND MOLECULAR BIOLOGY OF REDUCTIVE DECHLORINATION

With isolates in hand that carry out specific reductive dechlorinations, the enzymes that are responsible for the process and the genes encoding them can be studied. These studies are providing information about the molecular mechanisms of reductive dehalogenation and about the evolution of the process and the organisms carrying it out. It is conceivable that some day they may provide material for genetically engineering organisms for reductive dechlorination.

Because transition metal complexes are capable of catalyzing reductive dechlorination, they are good candidates for prosthetic groups of reductive dehalogenase enzymes, which can provide these complexes with a milieu that can accelerate their catalysis. This prediction has held true because the reductive dehalogenases characterized thus far contained either heme or corrinoid prosthetic groups. Moreover, the dehalogenases carry out the terminal reactions of a respiratory electron transport chains to develop a proton motive force, and research is being done on electron transport from the electron donors to the reductive dehalogenases (61).

Ni and coworkers (62) purified the membrane-bound 3-chlorobenzoate reductive dehalogenase (RD) from *Desulfomonile tiedjei*. The dehalogenase that was found only in cells grown in the presence of 3-CB was relatively oxygen tolerant and used reduced methyl viologen as an electron donor (as do all the RDs characterized so far), but not any known physiological electron donors. The protein had two subunits with molecular weights near 64 and 37 kDa. The spectrum of the purified protein indicated the presence of a heme group. In a subsequent study, evidence for an electron transport chain to the reductive dehalogenase involving a novel quinone and a low potential (-0.34 v) cytochrome c was obtained (63).

There have also been studies on the biochemistry of reductive dechlorination in chloroethene dechlorinating organisms. The PCE RD from *Dehalobacter restrictus* was isolated (64) and found to be membrane associated. It consisted of a single subunit with a molecular weight near 60 kDa. Both visible and electron paramagnetic resonance (EPR) spectral evidence showed the presence of iron-sulfur centers and a corrinoid, with oxidation-reduction potentials of 150 mv for Co(II) to Co(III) and -350 mv for Co(I) to Co(II). Incubation of the Co(I) enzyme with PCE yielded the Co(II) form. On the basis of the lack of reductive dehalogenation when whole cells were treated with reduced methyl viologen, which is considered to be unable to permeate the cell membrane, it was concluded that the PCE dehalogenase was on the inside face of the membrane and the hydrogenase was on the outside face (65). Evidence for the involvement of a quinone in the electron transport chain was also obtained.

The biochemistry of reductive dehalogenation in *Dehalospirillum multivorans* has also been intensively studied. The PCE RD from this organism was purified as a soluble cytoplasmic corrinoid-iron/sulfur-protein with a molecular weight near 58 kDa (61). The gene encoding this protein, *pceA*, was isolated and found to have little sequence similarity with previously described genes in the databases, including those for other corrinoid proteins. Cotranscribed with *pceA* was a second gene, *pceB*, that encoded a small (8.3 kDa) hydrophobic protein hypothesized to serve as the membrane anchor for the RD. The *pceA* gene was expressed in *Escherichia coli*, but no enzyme activity could be detected, probably because the expressed protein lacked correctly inserted prosthetic groups. Thus, if one wanted to transfer a reductive dehalogenase to another organism, it would need to be one that assembles the RD properly.

Two RDs were purified from a mixed culture containing *Dehalococcoides ethenogenes* (66). The first enzyme was a PCE RD that reduced PCE to TCE and had a molecular weight near 51 kDa, whereas the second enzyme had a molecular weight near 61 kDa and reduced TCE to DCEs, then to VC, and slowly reduced VC to ethene. Thus, PCE reduction to ethene is at least a two-step process in this organism. Inhibitor studies indicated that both RDs were corrinoid proteins.

An *ortho* chlorophenol RD was isolated from *Desulfitobacterium dehalogenans*. This membrane-associated protein had a molecular weight near 48 kDa. As for the haloalkene RDs, it contained iron/sulfur centers and a

corrinoid group. Its cloned gene, *cprA*, was approximately 30% identical at the amino acid level with *pceA* from *Dehalospirillum multivorans*, much closer than to any other proteins. Moreover, associated with it was a gene *cprB* that encoded a small protein homologous to *pceB*. Also of interest is that the cprA gene product had a signal sequence for secretion as well as a twin-arginine motif that is considered to be a signal for secretion of a cofactor-containing polypeptide into the periplasm. The *pceA* gene product in *D. multivorans* also has these periplasmic localization signals, in conflict with biochemical evidence placing it in the cytoplasm.

Thus, the RDs from *Dehalospirillum multivorans* and *Desulfitobacterium dehalogenans* form a distinct gene family that may have evolved for reductive dechlorination. A perusal of the BLAST microbial genomics site (*http://www.ncbi.nlm.nih.gov/Micro blast/unfinish-edgenome.html*) of the unfinished genome of *Dehalococcoides ethenogenes* indicates that it has several homologues of these corrinoid-containing RDs. A transposon mutagenesis system has been developed for *D. dehalogenans* (67) and should prove useful in defining genes involved in reductive dechlorination.

BIOREMEDIATION STUDIES

Bioremediation, especially in situ bioremediation, is considered a promising technology for treating groundwater sites contaminated with chlorinated organic compounds. There are both oxidative and reductive strategies for the bioremediation of chlorinated organic compounds. Many lightly chlorinated compounds degrade naturally and it is mainly a matter of ensuring that the right physiochemical conditions are present to allow for their biodegradation. Another aerobic approach takes advantage of the nonspecificity of certain oxygenases so that TCE, for example, has been treated in pilot studies by adding methane or toluene plus oxygen to groundwater aquifers to stimulate the appropriate organisms (68).

Approaches to anaerobic bioremediation of chlorinated organics involve both natural attenuation and accelerated bioremediation (69). In the former case, other compounds, such as hydrocarbons or organic solvents or natural organic compounds, are present along with chlorinated organic compounds. Degradation of these nonchlorinated compounds leads to anoxic conditions under which they can then be fermented to products, such as H_2, acetate, lactate, or butyrate, which are then utilized as electron donors by organisms capable of reductive dehalogenation. Lightly chlorinated products may migrate into aerobic zones in which they may be degraded. By careful analysis of a contaminant plume, one can sometimes document that the organohalogens are present at sufficiently low concentrations to meet regulatory guidelines by the time they migrate off site or reach a receiving body.

If natural attenuation is not rapid enough, steps can be taken, such as addition of an electron donor, and sometimes other nutrients, to accelerate the process. It is desirable to have an electron donor that supports reductive dechlorination but does not support a competing process, such as methanogenesis, as well. In the case of PCE and TCE biodegradation, it has been shown that because of the more favorable energetics of reductive dechlorination versus methanogenesis, reductive dechlorinators had a much lower threshold for H_2 than methanogens [Loffler, 1999 #415]. Moreover, electron donors that lead to low H_2 concentrations, such as butyrate or propionate, known to be poor substrates for methanogenic consortia (11), allowed much higher ratios of dechlorination to methanogenesis than other electron donors, such as lactate or ethanol, leading to higher concentrations of H_2 (70). It should be noted that in some cases, however, lactate or ethanol can be converted to propionate or butyrate, so that they may actually be good substrates, and it is always advisable to test dechlorination in microcosms before doing pilot or full-scale tests.

Early in situ studies, such as the one in which benzoate was added to a contaminated aquifer in Texas (71) and allowed complete conversion of PCE to ethene, indicated that stimulation of in situ anaerobic biodegradation was technically feasible. One important question is whether the appropriate dehalogenating organisms are present at the site. For example, it appears that organisms that reduce PCE and TCE to DCE are cosmopolitan, whereas those carrying out further reduction, such as *Dehalococcoides ethenogenes*, are not (72). Both microcosm studies and pilot scale studies for a contaminated site at Dover Air Force Base, Delaware, indicated that conversion of TCE did not proceed past DCE despite the feeding of large quantities of a lactate/yeast extract mixture. An enrichment culture developed from a site in Florida that carried out complete reductive dechlorination of TCE to ethene was added to Dover microcosms and complete dechlorination was effected (72). Several hundred liters of this culture were then added to the site (after pathogen tests and Environmental Protection Agency clearance), after which complete conversion of TCE to ETH was detected (73). This is a successful example of bioaugmentation, the addition of microorganisms to hasten biodegradation. It should be pointed out that often it is inappropriateness of the physiochemical milieu, such as pH or lack of nutrients, rather than lack of an appropriate organism that limits biodegradation of a pollutant.

It should be noted that reductive dehalogenation in contaminated aquifers requires the interactions between dehalogenators and other microorganisms in microbial communities, such as that depicted in Figure 3. The understanding of the diversity of reductive dechlorinators and the other members of the communities is still rudimentary. It will be fruitful to apply both cultural methods and molecular biological tools [Flynn, 2000 #457; Loffler, 2000 #437] to characterize these communities so that it will be possible to understand and manipulate them better.

CONCLUSION

It is now clear that many chlorinated organic molecules are susceptible to reductive dechlorination, including many highly chlorinated molecules that are resistant to aerobic attack. Particularly attractive for development are those

processes in which the chlorinated organic can serve as a respiratory electron acceptor because it then supports growth of the organisms carrying out the dechlorination. A greater understanding of both respiratory and cometabolic reductive processes and the organisms carrying them out will increase that ability to optimize the destruction of chlorinated organic molecules in the environment.

BIODETERIORATION OF MINERAL MATERIALS

CHRISTINE GAYLARDE

Preston, United Kingdom

Mankind uses rocks, stones, and other natural and manufactured products as construction materials. Both in their natural state and when incorporated into a built structure, they are subject to the deteriorative and degradative action of the environment and microorganisms. These processes are normally referred to as *weathering*. It is often difficult to distinguish between nonbiological and biologically mediated weathering of mineral materials. The two processes can occur concurrently, each contributing to the overall deleterious effects. Mineral materials are used extensively in the construction industry and include a range of familiar building materials such as stone, bricks, roofing tiles and shingles, asbestos, mineralized felts, fascias (which are often natural stone or ceramic in nature), cement-based renderings, plasters and mortars, and adhesives and groutings. Concrete is used as reinforced structural elements and as building blocks.

BIOFILMS AND MINERAL MATERIALS

Biofilms are not confined to solid-liquid interfaces. They can also be found at solid-air interfaces (1). Almost all surfaces in nature, including mineral materials, may be colonized by microorganisms; this includes buildings (2) and monuments (3,4). Microorganisms are able to obtain calcium, aluminum, silicon, iron, and potassium from the substratum by biosolubilization, a process that involves the production of various organic and inorganic acids by microorganisms, bacteria, algae, lichens (symbiotic associations between fungi and algae), and fungi. These acids attack and degrade calcareous minerals by the dissolution of calcium ions and lead to the eventual formation of degraded products such as gypsum, calcite, glauconite, dolomite, ettringite, and quartz (5). In addition to liberating nutrients, the production of acids lowers the pH of the surrounding environment.

Microbial colonization of a surface can be associated with the formation of mucilaginous matrices, which may also be involved in degradative processes. Capsules and extracellular polymeric materials are produced by many bacteria and algae, but little attention has been paid to the role of the fungi in the structure or nutrition of biofilms (6). Fungi have been reported as members of natural biofilms (7) and their participation in these structures on mineral materials deserves more attention.

DETERIORATION PROCESSES

The processes involved in nonmicrobiological weathering of rocks are better understood than those that occur in the presence of microorganisms.

NONBIOLOGICAL WEATHERING PROCESSES

Apart from degradation by living organisms, rock, stone, and other constructional materials are weathered, that is, reduced to a more dispersed state, by rain, wind, gravity, ice, temperature change, and reaction with atmospheric gases. There are two general types of weathering: mechanical, involving only physical forces, and chemical, in which the chemical structure of the material is changed. In cold and/or dry climates, mechanical degradation is usually more important, whereas in the humid tropics and semitropics, chemical degradation is predominant.

The products of mechanical weathering include fragments of rock and materials formed by expansion and contraction of the rock, freezing and thawing cycles, and earth movements. Products of chemical weathering include the soil in its many forms; these chemical transformations follow mechanical weathering.

Chemical Weathering

Chemical weathering involves the migration of ions within the rock structure and within the surrounding environment. Ions may be mobilized by solution in water, which is enhanced by the presence of inorganic acids such as carbonic acid, sulfurous acid, sulfuric acid, and nitrous acid, and HNO_3, derived from the gases carbon

dioxide, sulfuric dioxide, nitrogen monoxide, and nitrogen dioxide, respectively. In the cases of iron and manganese, the chemical elements in the structure can be oxidized by atmospheric oxygen or reduced by volcanic H_2S. Silicate rocks are complex salts of silicic acids. Cations such as magnesium and potassium can be leached from the rock, leaving silica as the final product. Clays result from the weathering of aluminosilicates, and other silicon-containing minerals include quartz (SiO_2) and kaolinite ($Al_4Si_4O_{10}(OH)_8$). Iron oxides and bauxite are other resistant products of the weathering of siliceous rocks. Limestones and dolomites are degraded by the dissolution of calcium and magnesium carbonates in the structure, leaving behind the less soluble impurities such as clay and quartz (sand).

BIOLOGICAL WEATHERING — BIODETERIORATION AND BIODEGRADATION

Krumbein and Jens (8) quote the Bible as an early publication on the infectious nature of decay in houses (Leviticus XIV, 33–57), which also indicated the difficulty of treatment. Colonization and biodeterioration of building materials are determined by environmental conditions, the most significant being physical parameters (temperature, moisture, light intensity) and the chemical nature of the surface. It is generally accepted that microorganisms do not directly use the mineral components of building materials, but may solubilize them as a result of their normal metabolic activities, allowing the resultant ions to be absorbed by the cells in some cases. It is axiomatic that the only microorganisms able to colonize clean building surfaces are those that do not require organic materials for growth, namely, the autotrophs. These include the photosynthetic algae and cyanobacteria and lithotrophic bacteria. The literature usually cites photosynthetic organisms as the primary colonizers (9,10,11), but there is little direct experimentation to provide evidence for this.

Most of the information on the biological weathering of minerals comes from the literature on soil formation and describes processes at the soil/rock boundary. Estimates of the rates of weathering of rocks on the continental platforms give half-life values between 30 and 1,800 million years for complete weathering, depending on the site and composition of the rock (12). This is equivalent to 1 mm/y to 1 mm/1,000 y. Such processes may be of importance in the deterioration of structures built below the ground, but the literature in this respect is mostly restricted to the behavior of metal and concrete pipes. Above the ground, biodeterioration is the result of activities of superficial (epilithic) and deeper (endolithic) organisms. Colonizing organisms must be able to withstand dry conditions, the effects of high temperatures and light at the surface. Changes in acidity resulting from anthropogenic and natural inputs are also important. Microorganisms may increase the rate of transformation by their metabolic activities, such as the uptake of ions and the production of acids and chelating agents. They may also alter the water permeability of the minerals by the deposition of polymeric materials and surfactants. Water transport may be increased or decreased, according to the nature of the deposits, leading to localized dissolution or salting (13). Often, the end result of these processes is a catastrophic failure of the surface layer, known as *spalling*. Until such spalling takes place, the structure appears to be in sound condition, although the superficial rind or patina may hide a deep zone of rotten stone beneath the surface. After the initial catastrophic failure, the degraded mineral layer is subject to rapid and sustained erosion. Once this loose, friable surface is exposed, colonization by higher plants, with their extended root systems, may lead to more rapid deterioration.

SILICON AND SILICATES

Silicon is one of the most abundant elements of the earth's crust (about 28%) and is an important part of rock mineral structure, being present in most of the materials that comprise the crust; carbonates, phosphates, sulfates, sulfides, chlorides, and coal are some of the more common examples of rocks in which silicon is not significant. Sandstone, slate, schists, and granitic rocks, together with ceramics, mainly in the form of brick or flooring and roofing tiles, are siliceous materials widely used in buildings.

In view of the prevalence of silicon in the natural world, it is not surprising that there exist microorganisms capable of both degrading silicon minerals and absorbing silicon. Silicon is a structural element in diatoms, the cell walls of which consist of up to 95% hydrated, amorphous silica. They take up the element in the form of orthosilicate (H_4SiO_4) (14). Less well studied has been the uptake of silicon by bacteria, but this has been shown to occur from silica gel, quartz, or sodium silicate (15), whereas some fungi can accumulate silicon from organic silicon complexes (16). All these processes are linked to the biodegradation of silicon minerals.

Bacteria and fungi are able to solubilize silicon and are important agents in the weathering of rock silicates and aluminosilicates, both in nature and when used as building materials. The solubilization mechanisms include:

1. Chelation. Gluconate, for example, produced by various bacteria, can complex the cationic components of silica, solubilizing kaolinite, and quartz at neutral pH levels (17). Organic acids produced during bacterial and fungal metabolism can cause the dissolution of quartz by chelation, which is more rapid in neutral than in acid solutions (18). Silicates, as anions, may form soluble, hexacoordinate siliconate complexes with natural phenolics in soil (19).
2. Acid degradation. Many bacteria and fungi produce inorganic and organic acids that solubilize silicon minerals. Walch and Ullman (20) showed that organic acids are more effective than hydrochloric and nitric acid in solubilizing feldspars, but sulfuric acid produced by sulfur-oxidizing bacteria is extremely active against the aluminosilicates present in concrete (21).
3. Alkaline degradation. Silicates and aluminosilicates are readily mobilized under alkaline conditions because of the lability of the Al-O and Si-O bonds.

A number of bacteria make their surroundings more alkaline by the release of ammonia from proteins or urea and this has been shown, in the case of *Sarcina ureae*, to degrade nepheline, plagioclase, and quartz (22,23). Because silicates are relatively stable in dilute ammonia, it is reasonable to postulate that chelation is also important.

4. Reaction with extracellular polysaccharide. The extracellular polymers released by fungi, and especially bacteria, can react with siloxanes to form the more soluble organic siloxanes (16,24). The reaction seems to be pH-dependent and is favored by acid conditions (25). Extracellular microbial polymers on the surface of a mineral material may also cause increased water residence time, facilitating the chemical reactions that characterize low temperature silicate weathering (26).
5. Depolymerization of polysilicates (siloxanes, metasilicates). Two bacteria (a *Proteus* and a *Bacillus* species) have been shown to be capable of this transformation (27), but in view of the requirement of microorganisms to absorb silicon in its monomeric form, it seems likely that this activity is not restricted to these genera.
6. Where anaerobic conditions exist within the rock, both volatile and soluble alkoxysiloxanes may be formed (28).
7. Under dry conditions, many microorganisms produce osmotic protectants to resist desiccation. These are polyols such as glycerol, mannitol, alpha-glycerylglucose and sucrose, and other low molecular weight organic molecules including proline and betaines (29). Polyols cause the expansion of micaceous minerals by intercalation among the polysiloxane planes of the mica crystals. Such expansion will induce stress in the rocks, leading to physical weathering and spalling, and may increase the access of acids and chelating agents to ions deep in the crystals. Such polyols may also react directly with silanol groups present at the crystal edges to cause solution of silicon.

Chelation and transport of iron and manganese to the surface of rocks, where it is deposited as an oxide film, usually called a *patina*, create a barrier to the evaporation of water. Where this barrier is absent, the excess water evaporates and deposits salts, which can cause severe local spalling. Once this process is initiated, the protective film cannot be reformed, and severe pitting may result. Spalling on the underside of clay roofing tiles is a common problem, which does not become apparent until the entire area needs to be replaced; this is associated with the growth of microorganisms and of mosses and lichens.

LIMESTONE, SHALE, AND SANDSTONE

The three most abundant sedimentary rocks of the earth's crust, accounting for 95% of all sediments, are shale, sandstone, and limestone, formed from silicates, silica, and by the biological deposition of calcium carbonate. These rocks usually consist of a mixture of all three components with varying proportions of other minerals, such as iron oxides. Their properties and classification depend on their chemical constituents and the form of the mineral components. Only limestone and sandstone are commonly used as building materials. Shales are used in their metamorphic form, slate. Limestone is the most abundant of the nonclastic (nondetrital) rocks and is the largest reservoir of carbon at the earth's surface. It is the most important type of crushed stone used in the building industry, constituting about 75% of all the commercial products sold and is the principal raw ingredient used for Portland cement, in addition to being the source of lime used to make plasters and mortars. Sandstone, on the other hand, is a detrital sedimentary rock formed by the cementation of sand grains that are commonly composed of quartz, but which may include many other minerals. The overall stability of the rocks depends on the types of minerals and fragments of other rocks that are present and this will obviously affect their biodegradability.

Rock and stone may be biodegraded by bacterial, fungal, and algal acids (3,10,30) and by mechanical penetration by fungi and phototrophs (31,32). Microorganisms may be classified according to their mode of growth into epi- or endolithic, that is, growing upon or within the stone, respectively. Aesthetic biodeterioration is produced by surface discolorations, which occur on microbial colonization either on or within the stone.

Role of Fungi in the Biodeterioration of Mineral Materials

Fungi have been associated with the mechanical degradation of stone (33,34) and many fungi isolated from stone buildings have been shown to produce acids that could degrade calcareous structures (4,35–38). For instance, a dark-pigmented mitosporic fungus and the bacterium *Bacillus cereus*, both isolated from limestone buildings in Uxmal in the Yucatan peninsula, Mexico, have been shown to reduce an initial pH of 7.0 in a glucose/mineral salts medium to values between 3.0 and 4.0 pH units (39). A range of fungi have been shown to solubilize stone by organic acid production (40–43). Dark-pigmented mitosporic fungi can also actively penetrate limestone, causing "biopitting" (44) and have been shown to be particularly important in arid and semiarid environments of hot and cold deserts because of their ability to resist high temperatures, desiccation, and osmotic stress (45). However, the published literature does not suggest that fungi are present in high numbers on ancient limestone structures. Populations of 10^2 to 10^5 colony-forming units (cfu) g^{-1} in stone are common (38,46,47). It has been suggested that algae can contribute to fungal stone decay by providing organic substrates for the production of acidic metabolites (3,48), and fungal activity rather than numbers may be the more important parameter. Alternatively, the low fungal numbers may be explained by the detection techniques used. Slow growing fungi, which are considered to be important in decay processes, are outgrown in normal culture techniques by less relevant, rapidly growing species, such as *Aspergillus* and *Penicillium* (49), and thus are often not detected.

There is no doubt that fungi are important in the aesthetic biodeterioration of building surfaces. Melanotic fungi and actinomycetes, and cyanobacteria with dark-pigmented cells or capsules, are frequently reported on stone structures (47,50). Such growths cause much of the discoloration seen on stone buildings (Figs. 1–8). Warscheid and Krumbein (51) have discussed this phenomenon with respect to natural stone surfaces.

In the modern world, high levels of particulates in the atmosphere, particularly those contained in fumes from fossil fuels, adsorb to the outer surfaces of buildings and cause a gray-black discoloration (52). This can be mistaken for fungal growth. Winkler (53) discussed the apparent increase in the weathering rate of stone in urban locations after industrialization toward the end of the ninetienth century. It has been suggested that the layers of organic pollutants may act as nutrient sources for the growth of heterotrophic microorganisms (bacteria and fungi), thus accelerating both the aesthetic and physicochemical deterioration processes (30,54,55). The adsorbed pollutants are a diversity of organic materials, including fatty acids and aliphatic and aromatic hydrocarbons (54), and these obviously modify the nature of the stone surface.

Fungi will not grow, even on susceptible substrates, unless there is sufficient moisture. Fungi require water for the diffusion of nutrients into their cells and for the production of enzymes. Water activity (A_w) is numerically equal to RH/100 (e.g., 75% RH = Aw 0.75); on this basis an RH of 70% is near the lowest limit for fungal growth. For most environmental work the term *water potential* is preferred, and it is measured in megapascals (1 mMPa is equivalent to 9.87 atm, or 10 bar).

Fungi require water for the diffusion of nutrients into the cells and for the release of enzymes. However, water can be present in the environment and still be unavailable too because it is bound by external forces:

1. the osmotic potential (solute binding forces ϕ_π)
2. matrix potential (physical binding forces ϕ_m)
3. turgor (ϕ_p)
4. gravimetric potential (ϕ_g).

Their effects are additive, so they are denoted by the general term *water potential* ϕ.

$$\phi = \phi_\pi + \phi_m + \phi_p + \phi_g$$

Role of Cyanobacteria and Algae in the Biodeterioration of Mineral Materials

Cyanobacteria (blue-green bacteria, previously called *Cyanophyceae*, or *blue-green algae*) resemble the oldest fossil organisms on this planet and are found in an enormous variety of habitats. As photosynthetic microorganisms, along with the algae, they do not require organic materials for growth and are common inhabitants of all water bodies and soil. Cyanobacteria survive repeated cycles of drying and rehydration (56), making them particularly important on exposed surfaces and they are probably of greater ecological importance as pioneer organisms on building surfaces than any other class (10). It has also been suggested that they have the most important influence on the weathering of exposed natural stone and rock (31,57), penetrating rock in dry environments at the rate of 5 μm/y (58). In dry, exposed situations, the majority of the organisms are found within the rock.

Many cyanobacteria are able to withstand high levels of UV illumination (59–63), enabling them to exist at upper elevations. Nevertheless, most grow preferentially in shady situations, along with the algae. Chemical and microbiological analyses have shown that superficial growth is heavier on interior walls of ancient limestone buildings (47,64). This is due to the more sheltered conditions, reducing illumination below inhibitory levels and maintaining humidity, and due to the presence of organic nutrients supplied by the droppings of birds, bats, etc. In buildings of the ancient Mayan site of Uxmal, in Mexico, for example, the microbial biomass, expressed as total phospholipid fatty acids (PLFA) per gram of stone, showed that indoor surfaces had an average value of 73.7 nmol g^{-1}, compared with 18.4 nmol.g^{-1} for outdoor sites (47). The PLFA profiles indicated the presence of bacteria, actinomycetes, cyanobacteria, and fungi. Chlorophyll concentrations, showing the presence of phototrophic organisms, were similarly higher on interior rather than outdoor surfaces (1.17 mg.g^{-1}, as compared with 0.22 mg.g^{-1}), suggesting higher algal and cyanobacterial populations on interior walls. This was confirmed by direct examination and culture techniques, when it was found that the biomass was mostly that of cyanobacteria (47). The major genus detected was *Xenococcus*, with *Synechocystis* and *Gloeocapsa* the next most abundant. The latter two cyanobacterial genera have been stated to be capable of limestone boring activity (presumably penetration of the substratum effected by the dissolution of the limestone), along with *Stigonema* and *Schizothrix* (31).

Although there seems little doubt that cyanobacteria are frequently predominant on buildings in Latin America, algae have been cited as the dominant microorganisms in some other countries, with *Trentepohlia* frequently being detected in Singapore (65) and *Chlorella* and *Stichococcus* in Russia (66). It is difficult to know whether these varying results come from the use of different detection techniques in the various locations. However, the recent design of specific primers for the detection of cyanobacteria by molecular methods will assure that such information in the future is reliable and repeatable.

The growth of cyanobacteria and algae on the surfaces of buildings leads directly to aesthetic deterioration of the surface. Photosynthetic biofilms may be gray, black, brown, red, or green, depending on the predominant strain(s) of organisms and the environmental conditions (Figs. 3 and 6). Humidity, temperature, and the degree of exposure to light can all affect growth and pigment production in algal and cyanobacterial cells. Under drier conditions, the biofilms are generally gray in color, whereas more humid areas are more frequently green. The filamentous alga, *Trentepohlia*, found to be the most common colonizer of buildings in Singapore (65), stores orange/red carotenoids within its cells under appropriate

conditions, and this leads to the production of pink or orange biofilms. The presence of other microorganisms also affects the appearance of the biofilm. For example,

a thick fungal growth on top of a cyanobacterial/algal layer will frequently be black (Fig. 8). However, the effects of cyanobacterial growth on building surfaces are not merely aesthetic. Danin and Caneva (57) suggest that cyanobacteria contribute to the decay of calcareous stones as follows:

1. Attachment of cyanobacterial cells in small fissures;
2. Growth within the fissure;
3. Water uptake and expansion of cell mass, exerting pressure within the structure;
4. Precipitation of carbonates and oxalates around the cells;
5. Opening of the fissure because of these internal pressures;
6. Entry of dust, pollen grains, etc.;
7. Partial death of cyanobacterial cells and establishment of heterotrophic bacteria, fungi, and small animals such as mites within the fissure;

8. Increasing internal pressure on the superficial layer of the structure leading eventually to its detachment (spalling) (Fig. 4).

Cyanobacterial cells on limestone buildings are often seen covered by calcareous deposits, suggesting migration of calcium from neighboring sites (47,67,68). The biological immobilization of carbon as carbonates, which can be deposited both intra- and extracellularly, occurs in some bacteria, fungi, algae, and some metazoa, and in cyanobacteria. Phototrophs deposit $CaCO_3$ in the light and solubilize it at night because of changing bicarbonate concentrations. This process has been well studied in

Figure 6. Intense algal growth behind a lamp attached to a building in Sao Joao del Rei, Brazil. Note black growth of mitosporic fungi in the rain runoff area below the lamp. See color insert.

the cyanobacterium *Synechococcus* GL24. These spherical cells possess on their external surface a so-called S-layer, which, in spite of its hydrophobic nature, is able to bind calcium ions at negatively charged sites (67). The bound calcium complexes with carbonate ions when the pH level is more than 8.3, and this high pH is readily produced as follows: bicarbonate ions are taken up by the cells and converted by the enzyme carbonic anhydrase into carbon dioxide and OH^- (69); the carbon dioxide is incorporated into the cell mass and the OH^- ions are released and concentrated around the cells (70), raising the local pH levels. The cells of *Synechococcus* can become encrusted with calcite within eight hours in a suitable environment and must continually shed patches of mineralized S-layer to remain viable (71). The whole procedure is then repeated, allowing the further uptake of calcium. Mobilization of calcium ions by such metabolic activity and ion transport, in addition to the trapping of released particles of calcite, either biotic or abiotic, in the gelatinous cyanobacterial sheath (72,73), is an important mechanism of stone degradation by cyanobacteria. The same processes occur with eukaryotic algae, and electron micrographs showing algal and/or cyanobacterial cells residing in micropits in limestone or mortar have been published (47,74). Siliceous rocks are also more readily degraded at high pH levels, as previously stated, because of the lability of the constituent cations under these

conditions and because the hydrolysis of polysilicates is favored at high pH levels.

The suggestion that algae and cyanobacteria may also dissolve stone by acid production (75) is more debatable. As discussed earlier, photosynthetic organisms actively concentrate carbon dioxide within the cells as bicarbonate, increasing the external pH level to as high as 10.5 within 48- hour laboratory growth in natural lake water (71,76). Nevertheless, Van der Oost and coworkers (77) showed that *Cyanothece* carries out mixed acid fermentation and could, therefore, induce acid degradation of stone. Mao-Che and coworkers (78) demonstrated the release of a carbonate-digesting liquid from the apical cells of one of the *Pleurocapsales* group; although the nature of the substance was not determined, it was suggested that it could have acidic properties. However, there is little evidence that cyanobacteria produce acids in situ, and Waterbury (79) suggests that acid decay of calcareous materials in the presence of cyanobacteria is due to the concurrent presence of heterotrophic bacteria.

Such associations of algal and cyanobacterial cells with heterotrophic bacteria can enhance the weathering of rock minerals through bacterial organic acid production (80). It is also known that fungal microflora can metabolize the organic matter secreted by phototrophic biofilms (81) and contribute to stone decay through the release of acidic metabolites (48). Urzi (46) has challenged the accepted view that phototrophic colonization of stone is followed by the growth of chemoorganotrophs, but Gaylarde and Gaylarde (82) demonstrated that the treatment of external walls with an algicidal substance (a copper-containing compound), used at concentrations too low for bacteriostatic and fungistatic activity, inhibited fungal and bacterial growth. This indicates that the inhibition of algal colonization reduces the growth of fungi and heterotrophic bacteria, and supports the accepted colonization sequence, although on chemically polluted buildings organic materials may act as nutrients for nonphototrophs. Under these conditions, heterotrophic bacteria could, indeed, be the primary colonizers of buildings (83).

Role of Lichens in the Biodeterioration of Mineral Materials

Lichens, symbiotic associations of fungi and algae or cyanobacteria, grow well on sun-exposed stone surfaces and in relatively unpolluted atmospheres (Fig. 7) (84). Ancient mortars are readily colonized by lichens because of their composition and physical structure, through the pores of which the hyphae may pass. Mortars, either ancient or modern, are generally the initial point of lichen colonization for other adjacent building materials, such as marble (85).

Lichens induce the biodegradation of mortar and stone by direct chemical attack of organic acids, principally oxalic acid (5,85–87). Large and small pits are formed on the surface of the material beneath the lichen thallus; hyphae and hyphal bundles produce micropits 5 to 200 μm in diameter, whereas the lichen fruiting bodies lead to pits of 0.5 to 1 mm in size (85). The penetration of the lichen structure into the rock or mortar produces a very strong association between the two and removal of the biological growths may damage the underlying material even further. However, some materials are little penetrated by lichens, the degree of internalization being determined by the mineralogical composition of the substratum (85). A discussion of the effects of lichen growth on various rock-forming minerals is presented in Jones and coworkers (88).

Lichen colonization does not necessarily lead to biodegradation of the structure and, in some cases, may actually protect the surface against the scouring action of wind and weather through the insoluble oxalate layer deposited beneath the thallus (89–91). Lichen growth may also be aesthetically desirable in some cases, covering ugly buildings and providing attractive coloration on otherwise drab constructions (92).

Role of Nonphotosynthetic Bacteria in the Biodeterioration of Mineral Materials

Bacteria have been implicated in the biodegradation of mineral building materials because of the high numbers of these prokaryotic organisms associated with deteriorated built structures (42,93–95). However, Somova and coworkers (66) reported that saprophytic bacteria were more common on undegraded, rather than degraded, masonry and consider that algae are more important.

The two groups of bacteria discussed in the literature are autotrophic and heterotrophic organisms.

Autotrophic Bacteria. Bacteria that oxidize inorganic sulfur and nitrogen compounds are able to degrade stone substrates by the production of inorganic acids (sulfate and nitrate). There is some debate about the overall importance of these microorganisms in the decay of stone, which is well discussed in the article by May and coworkers (30). However, the acceleration of decay by nitrifying bacteria has been demonstrated in the laboratory for limestone (96), ultrabasic rocks (97), and concrete (98). They have also been implicated in the deterioration of plaster (99) and asbestos cement roofs (100) in stables. Weight losses have been detected in concrete blocks incubated with sulfur-oxidizing bacteria (101,102). There is little doubt that these acid-producing bacteria can cause stone decay, but their role in the real world remains to be confirmed.

Chemoorganotrophic (Heterotrophic) Bacteria. The role of heterotrophic bacteria in the formation of soil by rock breakdown is well accepted (103). The rock is degraded by bacterial acids and alkalis and by chelation. There is little work, however, concerning the identity of organisms responsible for built stone decay, although many authors have reported high numbers of heterotrophic bacteria on decaying stone (40,93,104,105). Weight loss experiments have shown the involvement of such bacteria in the degradation of sandstone (95,106,107), and there are a number of publications on the staining of monuments by bacterial pigments (108–110).

Actinomycetes of various genera have been found frequently on ancient wall paintings and monuments (66,111–113). They contribute to biodegradation by the mechanical penetration of the mycelia into the structure. The genus *Geodermatophilus* has recently been considered to be of particular interest (66,113). The other bacterial genus that is frequently isolated from rocks and caves is *Bacillus* (114), although this group may not be important in decay processes (113).

Our knowledge of the bacterial populations present on stone surfaces is currently being modified by the results of molecular biological detection methods, which allow the identification of nonculturable organisms (115,116). Members of the family *Archaea* and many actinomycetes have been detected on degraded wall paintings (117) and the same techniques suggest that the major heterotrophic bacteria colonizing rocks and monuments are actinomycetes, mainly related to the genus *Geodermatophilus* (118,119).

CEMENT AND CONCRETE

It is perhaps inevitable that civilizations in their search for an acceptable substitute for stone as a building material eventually devised a medium with many of the characteristics and properties of natural stone. To the prerequisite properties of durability and strength were added the extra advantages of a material that was relatively inexpensive to manufacture and one that could be easily transported. Furthermore, in the hands of imaginative architects and competent builders, a new era of building was born in which the scale of building was no longer a major problem.

Cement can be described as a material that possesses both adhesive and cohesive properties that enable it to bond various mineral fragments into one complex whole. Since the introduction of Portland cement, concrete has become one of the most widely used synthetic materials within the construction industry (120). Portland cement (Table 1) is the most commonly used cement mixture used in construction. However, other types of cements exist and are widely used. The chemical composition of cement varies according to the role required by that specific batch. It is the unique chemical composition of cement that confers surface properties and tensile strengths peculiar to that specific formulation. In reality however, the silicates found in cement are not pure compounds; they contain minor oxides in solid solution that confer vital effects on the atomic arrangements, crystal form, and hydraulic properties of the silicates (120).

Concrete is composed of cement powder, water, and aggregates of various sizes, such as sand or gravel (121). The main constituents of cement powder are lime, silica, alumina, and iron oxide. The cement paste hydrolyses on curing to form hydrated calcium silicates (C-S-H gels) and Portlandite ($Ca(OH)_2$) (120,122–125), and the arrangement of these crystals allows channels to form within the concrete structure. The formation of these channels within the concrete permits the capillary action of water, which may contain microorganisms. Thus, as water permeates deeper into the concrete, fissures are formed, allowing the deposition of organic material and the further

Table 1. Main Compounds of Portland Cement

Name of Compound	Oxide-Composition	Abbreviation
Tricalcium silicate	$3CaO{\cdot}SiO_2$	C_3S
Dicalcium silicate	$2CaO{\cdot}SiO_2$	C_2S
Tricalcium aluminate	$3CaO{\cdot}Al_2O_3$	C_3A
Tetracalcium aluminoferrite	$3CaO{\cdot}Al_2O_3Fe_2O_3$	C_4AF

A. M. Neville, *Properties of Concrete*, 2nd ed., Pitman Publishing, London, U.K., 1977.

ingress of microorganisms into the concrete (126). In addition to the main compounds of cement, various minor components are present, for example, MgO, TiO_2, Mn_2O_3, K_2O, and Na_2O. These components may serve as important sources of nutrients for colonizing microorganisms.

In 1945, Parker (127) discovered that concrete was being broken down by the metabolic activities of microorganisms. He isolated *Thiobacillus* from areas of badly corroded concrete. This and subsequent studies (127–129) showed that *Thiobacilli* were the causative agents of microbially induced corrosion of concrete structures. This view has been substantiated in recent years by several others working in the same field (130–137).

Biogenic Sulfuric Acid Corrosion of Concrete

The decay of concrete by microorganisms is dependent on the production of corrosive metabolites that can solubilize minerals (138).

Freshly prepared concrete has a pH level between 12 and 13 compared with the highly acidic pH (2.5 to 0.5) of corroded concrete. The original pH must be reduced (by chemical carbonation) before microorganisms can begin to colonize and grow. The major organisms involved in acid concrete decay are the thiobacilli; their incidence and activity are described in Sand and Bock (2) and Milde and coworkers (130).

An example is their involvement in the deterioration of concrete in sewage pipelines. Parker (127) reported that the bacteria use hydrogen sulfide released from the sewage and oxidize it to sulfuric acid. Sand and Bock (2), reporting on the findings of a research project undertaken in Hamburg to establish the mechanism of corrosion found in several pipelines constructed between 1967 and 1971, recorded that thiobacilli were present in high numbers at the corrosion sites. The incidence of *Acidithiobacillus thiooxidans* was found to be high at sites that showed heavy corrosion. The bacterium was not detected at sites where corrosion was not detected. Thus, it was considered appropriate to adopt this microorganism as an indicator of corrosion rather than pH values resulting from bacterial sulfuric acid generation, which are partially buffered by different concrete types. Volatile sulfur compounds that are dissolved in the sewage escape into the atmosphere within the sewer. In this atmosphere, hydrogen sulfide is auto-oxidized to molecular sulfur, which adheres to the concrete walls of the sewage pipes where it is oxidized to sulfuric acid. This acid reacts with the calcitic binding material of the concrete thereby causing its destruction. These workers also detected two other sulfur compounds on the sewer walls, namely, sulfur dioxide and thiosulfate. Thiosulfate is a reaction product of sulfur dioxide with molecular sulfur and forms a good substrate for the growth of thiobacilli.

Biogenic Nitric Acid Corrosion

Although thiobacilli are considered to be responsible for the degradation of concrete above ground, two groups of nitrifying bacteria are considered to play a major role in the degradation processes below ground. They are responsible for the oxidation of ammonia via nitrous acid to nitric acid (2). The first group includes species of *Nitrosomonas* and *Nitrosovibrio*, which oxidize ammonia via hydroxylamine to nitrous acid. The second group that affects the oxidation of nitrous acid to nitric acid includes members of the genera *Nitrobacter* and *Nitrosovibrio* (139). The action of nitric acid upon the calcareous binding material of concrete results in the production of calcium nitrate. This is a soluble salt that is either lost from the concrete, resulting in the formation of corrosion pits, or remains, thus adding salt to the pore water.

Sulfate-Reducing Bacteria

The sulfate-reducing bacteria are usually associated with metal corrosion rather than with the deterioration of concrete, and therefore could be involved in the deterioration of the bars in steel-reinforced concrete. However, sulfate-reducing bacteria are widespread in nature and active in locations made anaerobic by microbial digestion of organic materials. In sewers, the involvement of sulfate-reducing bacteria in concrete decay is mediated by gas, produced as a result of the proteolytic action of sulfate-reducing bacteria living in anaerobic slimes or biofilms formed below the sewage level. (2).

Biogenic Organic Acid Corrosion

Fungi. Fungi isolated from the surfaces of monuments, facades of buildings, and degrading concrete include many genera that are representative of air and soil flora (140–143). Biodeterioration of stone by fungal organic acids has been described (141,144). Di- and trivalent cations are reported to be solubilized by chelate-forming organic acids (145). Krumbein and Schonborn-Krumbein (146) suggest mechanisms involving "siderophores" of fungi in the etching of microfractures, whereas Krumbein and Petersen (145) report on the biotransfer of cations involved in exfoliation induction in sandstone monuments. For concrete, however, this level of research activity is lacking.

Lichens. Oxalic acid has been one of the most studied acids produced by lichens (147). It is produced by the fungal partner of the lichen and is more prevalent in mature, calcium-loving species. (147,148). Lichens known to produce calcium oxalate are highly effective biodeteriogens in a range of rock types with oxalates formed at the thallus/substratum interface. These have closely related chemical compositions to the rocks that they colonize (148). Tiano (147) cites authors who discuss the importance of the pedogenic activity of lichens. The incidence of lichens on cement-based materials, for example, weathered roofing tiles, is common in the United Kingdom and elsewhere, but there is little evidence of biodeterioration problems.

Algae and Cyanobacteria. The hygroscopic sheath covering many algal cells growing on the surface of stones often seals moisture into the material, thus allowing for extended growth periods during dry spells (140). Repeated freezing and thawing of the hydrated algae contributes

further to deterioration. Lithophilous algae and cyanobacteria can be considered as the pioneering inhabitants of stone surfaces (147). The colonizers of such surfaces are closely related to those present in nonflooded soils (32). Controversy exists as to whether these microorganisms have a biodeteriogenic effect on the surfaces that they colonize (10,121). One point of view is that their deteriorative effect is negligible (149,150). However, there are reports of the positive role of these microorganisms on the weathering of stone in nature (151,152) and on monuments and sculptures (151,153,154). Such speculation applies equally to weathered concrete surfaces.

Chemoorganotrophic Bacteria. Chemoorganotrophs excrete organic acids, including acetic and benzoic acid (155), which can affect the structural properties of concrete. The metabolic activity of these microorganisms will depend on nutritional levels that prevail, in addition to a range of environmental conditions (147). However, there is little published work on their role in concrete degradation.

CONCLUSION

The deterioration of stonework, brickwork, and other mineral materials by microorganisms has an immediate impact on the construction and conservation industries because of the financial implications of remedial treatments. The incidence of lichens, cyanobacteria, algae, and fungi on stonework and monuments is often considered merely to be aesthetically undesirable, rather than severely damaging to these structures. However, there is little doubt that physical and chemical attack can also occur through the activities of organisms growing on the surface (epilithic) or in deeper layers (endolithic) of rock and stone structures. The role of bacteria in the breakdown of natural rock and the genesis of soils has long been accepted and the same processes can participate in the biodegradation of stone-built structures. The actinomycetes have recently been highlighted as important bacterial colonizers of rocks and buildings of cultural heritage and future research will certainly focus on the degradative activities of these organisms.

Biofilms, as regions where the metabolic activities of microorganisms are concentrated, have been accepted as of major relevance in the biodeterioration of materials, and this is an area of increasing importance in the study and control of biodeterioration of construction materials. Techniques recently introduced into biofilm research, such as atomic-force microscopy, environmental-scanning electron microscopy, confocal-laser-scanning microscopy, green fluorescent protein, fluorescent in situ hybridization (FISH), denaturing gradient gel electrophoresis (DGGE), and other molecular biology methods, are already being used on artificial and natural mineral materials. Rolleke and coworkers (156) using 16S rDNA analysis, showed the presence of the Archaea genus *Halomonas* on a mural in a German church, confirming the presence of extremophiles (in this case, salt-tolerant bacteria) on buildings. Recently, Saad and coworkers (157) have suggested the use of 17S rDNA analysis by DGGE to identify fungal genera on painted surfaces. Early results suggest that this is a promising technique for probing building surfaces and identifying changes in fungal biodiversity caused, for example, by the use of biocides. The future will see a huge increase in our knowledge of the types of organisms whose activities are really important in the deterioration and degradation of these structures.

BIODIVERSITY IN SOILS: USE OF MOLECULAR METHODS FOR ITS CHARACTERIZATION

WERNER LIESACK
PETER F. DUNFIELD
Max-Planck-Institut für
Terrestrische Mikrobiologie
Marburg, Germany

Soil is a matrix of organic and inorganic particles formed by the combined action of biotic and abiotic processes. Geographic, geologic, hydrologic, climatic, vegetation, faunal, and anthropogenic factors together determine a soil's properties and, in turn, its resident microbial community (1,2). The soil mineral composition, salinity, pH, nutrient availability, organic content, temperature, and water content, among other factors, define which ecological niches are present. High spatial heterogeneity within a soil is a result of the vertical horizon structure and of heterogeneity in such factors as plant cover, microtopology, and perturbations by fauna. Therefore, just as plant communities show local variations in species composition within one vegetation type (3), so does the microbial community vary within one soil type (4). Plants, besides adding organic material to soil and affecting the microclimate, create the unique rhizoplane and rhizosphere habitats. The increased microniche complexity (5) at or near root surfaces selects for different microorganisms than those dominant in the bulk soil (6). Seasonal changes in weather and the concurrent vegetation cycles add a temporal heterogeneity to this complex system, so that no two-soil samples have the same microbial community. As a consequence, soil probably harbors most of the planet's undiscovered microbial biodiversity.

In one study of genotypic diversity in a forest soil, DNA renaturation kinetics were used to estimate that 4×10^3 to 7×10^3 differently sized microbial genomes were present in 1 g of soil (7). This represents as many as 13,000 species (8). Obviously, these species are not present in equal numbers, but vary from a single cell to as many as 10^8 cells per gram of soil. In a similar study employing DNA hybridization techniques, it was shown that the diversity varied with soil type (9).

Two qualities of microbial communities can be addressed in molecular microbial ecology studies: (*1*) diversity, and (*2*) community structure. Although diversity has been defined in a number of ways (3,10,11), it is often used in molecular microbiological studies, albeit incorrectly in a classical ecology framework, as a synonym for species richness (12). This is the number of different species or, more precisely, the number of different sequence types (phylotype richness) detected. Because of the special problems involved in quantitative analysis of molecular biology data, we shall adopt the convention that diversity studies needs to only include information on species presence. In contrast, analysis of community structure includes quantitative information on the abundance of different taxa or physiological groups, and is thus more related to classical definitions of ecosystem diversity such as Shannon's index.

The assessment of the diversity and structural composition of soil microbial communities is extremely dependent on the methodological tools used. Traditionally, characterization of microbial communities was based on cultivation of the respective members. However, this technique identifies only that tiny portion of the community which can grow on the media used, which is often less than 1% of the viable species present (13–15). Cultivation studies may fail to detect abundant or even dominant members of soil microbial communities and thus are strongly biased (16–20). This approach is also time consuming and labor intensive. As a consequence, the past decade has witnessed the development of a variety of molecular methods that bypass cultivation and instead base community analysis on DNA or RNA extracted directly from a given environment. This article will focus on the current state-of-the-art molecular ecology techniques available for cultivation-independent investigation of the phylogenetic and functional diversities of the prokaryotic domains Bacteria and Archaea in soils. It is organized into the following sections:

- Extraction of total nucleic acids (DNA, RNA) from soils
- Fractionation of total DNA based on mol% G + C content

- Phylogenetic diversity assessment by retrieval and comparative sequence analysis of small subunit (SSU) ribosomal DNA (rDNA)
- Retrieval and comparative sequence analysis of genes coding for key enzymes that perform defined functions
- Molecular profiling of soil microbial communities using phylogenetic and functional markers
- Microbial activity at the functional level
- Metagenome analysis

EXTRACTION OF TOTAL NUCLEIC ACIDS FROM SOIL

The extraction and purification of high-quality nucleic acids, either DNA or RNA, is a prerequisite for almost all molecular ecology studies on indigenous microbial communities (fluorescence in situ hybridization [FISH] is an exception). In principle, studies using extracted DNA assess the phylogenetic diversity (rDNA) or genetic potential (functional gene markers) of soil microbial communities. Studies on rRNA preferentially assess the active members of a community, because many species vary their ribosome content in positive correlation with their cellular activity (21). rRNA studies should therefore reveal adaptational shifts in community structure and activity more readily than DNA studies do. In addition, rRNA-based approaches have the advantage of a natural amplification of target numbers, as one cell can contain thousands of ribosomes. Although rRNA is the main component of total RNA extracted from natural environments, messenger RNA (mRNA) can also be extracted. Studies using mRNA are, however, technically far more problematic (see section Analysis of Microbial Activity at the Functional Level).

Extraction of Total DNA

DNA extraction should be carried out as soon as possible after soil samples have been collected from the field, as changes in community structure can occur during storage. In one study, storage of soil samples for three weeks at 4 °C significantly reduced the fraction of high molecular weight DNA retrieved (22). Two different procedures–indirect and direct–can be applied for the extraction of soil DNA. Indirect methods separate intact cells from the soil matrix prior to the lysis step (pioneered by Holben and coworkers (23)), whereas direct methods lyse cells within the soil (pioneered by Ogram and coworkers (24)).

Indirect Methods. Indirect methods use differential centrifugation steps to separate the cell fraction from the soil matrix. The cell fraction is then lysed, and total DNA isolated and purified (25–29). The main drawback of this method is the bias inherent in removing cells from soil particles. Although several physical and chemical dispersion techniques have been employed to efficiently desorb cells from soil or sediment particles (27,30–32), DNA obtained by these extraction procedures might not be representative of the entire microbial community, that is, might exclude DNA from microbes that attach strongly to soil particles (24,33–35). As a consequence, the use of direct DNA extraction techniques is usually preferred for studying soil microbial diversity. One advantage of the indirect approach is that uncultured bacterial cells might still be viable. This was observed to be especially true for a cell purification procedure involving lectin-mediated bead extraction (31). The applicability of cell extracts for parallel study of physiology and ecology has also been demonstrated for uncultured methane-oxidizing bacteria (36).

Direct Methods. In comparative studies, direct in situ cell lysis procedures have produced DNA yields that are higher by 60% (37), one order of magnitude (22) or 20 to 70 times (25), compared with yields obtained by indirect cell extraction procedures. Consequently, DNA extraction protocols reported in the last decade are primarily based on direct cell lysis within the soil or sediment (24,25,38–48).

A critical factor in determining the DNA yield by direct extraction methods is the choice of lysis protocol. Mechanical disruption of the cells should facilitate a quantitative extraction of environmental DNA (24,25) and allow the detection of the overall genetic potential in the sample, including dormant microorganisms. It may also recover DNA from moribund populations and even extracellular DNA from naturally lysed cells. On the other hand, some DNA released during the direct lysis procedure may bind to soil colloids and thereby reduce the overall recovery of soil DNA (49–52). This DNA adsorption is directly dependent on soil composition. A high content of clay minerals has an especially strong negative influence on the recovery of total DNA. Frostegård and coworkers (47) reported that this problem could be overcome by pretreating the soil with RNA to saturate the adsorption sites. RNA pretreatment of soils having a high clay mineral content increased the DNA recovery to levels obtained from soils with less clay content.

Of the lysis treatments available, those using the detergent sodium dodecyl sulfate (SDS) in combination with bead mill homogenization give the highest DNA yields from soil (41,45,48). Moré and coworkers (41) reported that the sequential application of SDS treatment and bead mill homogenization was more efficient than SDS treatment followed by three cycles of freezing and thawing. The improved extraction efficiency was attributed to a higher proportion of cells being lysed. Viable counts of sediment microorganisms revealed that 2 and 8%, respectively, survived the bead mill homogenization and freeze-thaw procedures. *Bacillus* endospores were not lysed by freeze-thawing treatment (94% survival rate), but were almost completely lysed by mechanical disruption (2% survival rate). Similarly, Kuske and coworkers (45) reported that only bead mill homogenization was effective for DNA extraction from *Bacillus* spores. However, the study by Moré and coworkers (41) also showed that small bacterial cells (0.3 to 1.2 μm) were more difficult to lyse than were larger bacteria (2 to 10 μm). After an SDS treatment and 10-minute bead mill homogenization of one sample, the remaining unlysed 6% of the original number of bacterial cells, as determined by direct counting with acridine orange, were all in an approximate size range of 0.3 to

1.2 μm. A major portion of soil bacteria (50 to 70% of the total bacterial numbers in nonrhizosphere soil) are less than 0.5 μm in diameter (53) and thus fall within the size range of unlysed cells in the study of Moré and coworkers (41).

Miller and coworkers (48) evaluated the effectiveness of various DNA extraction procedures on samples of varying organic mater content, including two silt loam soils and a silt loam wetland sediment. Again, bead mill homogenization in a lysis mixture containing chloroform, SDS, NaCl, and phosphate-Tris buffer (pH 8) was found to give the highest DNA yield and the most complete cell lysis. The recovery of high molecular weight DNA was greatest when using brief, low-speed bead mill homogenization. Under optimal physical lysis conditions, the maximum molecular size of the DNA extracted was 16 to 20 kb, which was similar to that obtained in previous studies using bead mill homogenization [e.g., 20 to 25 kb (37,44)]. More intensive use of bead mill homogenization increases the risk of severely shearing environmental DNA (24,33). Highly sheared, low molecular weight DNA might still be useful for polymerase chain reaction (PCR) amplification of SSU rRNA or functional marker genes, but there is an increased risk of chimeric gene fragments being formed during PCR (see section Analysis of SSU rRNA and Its encoding gene).

An alternative to bead mill homogenization is soil grinding (35,43,47,54). Frostegård and coworkers (47) suggested that this method is equally efficient as, or even more efficient than, bead mill homogenization. Using soil grinding only, 16 to 59 μg of DNA per gram of soil was obtained from different dried soils, a yield comparable to that obtained with extraction protocols involving bead mill homogenization (depending on the soil this ranges from 1.5 to 53 μg DNA per gram of dry soil (22,39,41,44,48,55).

Soft lysis techniques without mechanical treatment facilitate the retrieval of environmental DNA of high molecular weight (37,56). For example, a combined lysozyme and SDS treatment extracted soil DNA of size 40 to 80 kb (37). DNA of this size is suitable for metagenome analysis (see section Metagenome Analysis). However, DNA obtained by soft lysis techniques might be biased toward easily lysed microbial populations, especially gram-negative microorganisms (43), and thus might not be representative of the entire microbial community.

Purification of Crude Extracts. The extent to which purification is necessary depends upon the characteristics of the soil under investigation, especially its humic acid content. Watson and Blackwell (57) reported that a brown-tinted organic component of soil inhibits PCR and is tightly associated with the soil microorganism fraction. It was found to be distinctly different from humic and fulvic acids in both its solubility properties and in its Fourier transformed infrared and nuclear magnetic resonance spectra. This soluble inhibitor complexes with proteins, and thus the authors postulated that it inhibits PCR through interaction with *Taq* DNA polymerase.

In general, molecular detection of gene sequences from indigenous microbial populations demands a more intensive purification of extracted DNA than does the detection of artificially introduced bacteria (58). DNA extracted from crude cell fractions might also be more contaminated with humic acids than DNA extracted using in situ cell lysis (37). Procedures that have been applied, individually or in combination, to separate impurities from environmental DNA include: (*1*) adsorption of impurities on polyvinylpolypyrrolidone (PVPP) (23,44,59); (*2*) treatment with lysozyme (37); (*3*) cesium chloride density gradient centrifugation (22,24,25); (*4*) Sephadex G-75 (44), Sephadex G-200 (22,48,60,61), and Sepharose 4B (61,62) gel filtration; (*5*) precipitation of DNA with potassium acetate, cesium chloride, and spermine-HCl (39); (*6*) agarose gel electrophoresis (43,48,58,63); (*7*) reversible binding of DNA on silica-based support material (43,48); (*8*) a magnetic capture-hybridization PCR technique (64); and (*9*) affinity matrix purification (46). This last method is a sequential injection fluid system combining affinity purification with novel renewable-surface microcolumn technology. The affinity matrix used for purification is based on the universal SSU rDNA oligonucleotide 1392r (65), which is covalently attached to 60-μm microbeads by a dT_8 linker. Besides DNA oligonucleotide probes, peptide nucleic acid clamps have been assessed for their use in affinity purification of DNA and RNA from soils and sediments (66).

An evaluation of four different DNA purification methods (silica-based DNA binding, agarose gel electrophoresis, ammonium acetate precipitation, and Sephadex G-200 gel filtration) found that Sephadex G-200 gel filtration was the most effective at removal of PCR inhibitors from crude DNA extracts of a silt loam soil (48). However, CsCl/ethidium bromide density gradient ultracentrifugation was better than Sephadex G-200 gel filtration at removing humic acids from crude soil DNA extracts in a separate study (22).

Commercial kits for extraction of nucleic acids from soils also commonly include purification steps. Purified extracts from two commercial kits, the FastDNA Spin kit (Bio101, La Jolla, California) and the UltraClean Soil DNA kit (MoBio Laboratories, Inc., Solana Beach, California) gave similar PCR product yields (indicating similar coextraction of impurities) as soil DNA extracted with an SDS-bead mill homogenization method and purified on Sepharose 4B spin columns (62). However, there were differences in community fingerprints obtained by amplified rDNA restriction analysis (ARDRA) and ribosomal intergenic spacer analysis (RISA) (see section Microbial Community Fingerprinting) of these PCR products, indicating that different biases were inherent at some stage in the three different extraction/purification methods.

In summary, various protocols are available for cell lysis and for purification of crude extracts of soil DNA. Selection of the most appropriate methods depends on the aim of the study and on the characteristics of the soil being investigated, especially its humic acid, organic matter, and clay mineral content. If complete extraction of the gene pool for studies such as PCR-based assessment of microbial diversity is the main criterion, harsh techniques, which extract DNA fragments of up to 25 kb in size, should be applied. These include bead

mill homogenization and soil grinding. In contrast, if the focus of the study is metagenomic analysis, soft lysis techniques, which allow the extraction of large 40- to 100-kb DNA fragments, are more appropriate. Comprehensive manuals are available, which have detailed descriptions of different protocols for the extraction and purification of DNA from bulk soil (37,47,67,68) and from other habitats, such as aquatic systems, the rhizoplane, rhizosphere, and phyllosphere (67).

Extraction of Total RNA

Because RNA is more labile than DNA, more care has to be taken in both extraction and subsequent molecular analyses. All solutions and glassware have to be rendered ribonuclease (RNase)-free by diethyl pyrocarbonate treatment (69), and only certified RNase- and deoxyribonuclease (DNase)-free plasticware should be used. As a consequence, relatively few protocols have been published for extraction of total RNA from soils (32,70–75) or sediments (76).

Protocols have recently been developed for rapid coextraction of rRNA and DNA (32,75,76). Cell lysis is achieved by bead mill homogenization, either of soil samples directly (75,76) or of crude cell extracts obtained by using sodium pyrophosphate to disrupt cell-soil aggregates followed by several washing steps (32). Removal of humic acids and other contaminants from total nucleic acids is achieved using phenol-based extraction buffers in combination with various treatments already described for extraction/purification of total DNA, for example, inclusion of polyvinylpyrrolidone or hexadecyltrimethylammonium bromide in the extraction buffer, phenol/chloroform extraction, and Sephadex G-75 spin column filtration. Separation of rRNA from DNA is achieved either by treatment with RNase-free DNase (32,75) or by Sephadex G-75 spin column filtration using different concentrations of the elution buffer (76).

A protocol described by Felske and coworkers (74) recovers intact rRNA from soils by isolating ribosomes. After mechanical cell lysis, the glass beads, soil particles, and cell debris are removed by centrifugation at low speed (15,000 to 30,000x g), and then the ribosome fraction is pelleted by ultracentrifugation at 100,000x g for 2 hours at 2 °C. The inclusion of PVPP in the extraction buffer to adsorb humic acids was essential for high efficiency of RNA recovery. The RNA yield obtained by the ribosome isolation technique was 0.2 μg of highly purified RNA per gram (dry weight) of soil. Yields from direct RNA extraction methods are clearly higher, ranging between 0.25 and 5.0 μg RNA per gram (dry weight) of soil, depending on the extraction procedure and the soil type (32,75).

FRACTIONATION OF TOTAL DNA BY MOL% G-C CONTENT

Soil DNA extracts can be used directly for molecular community studies. Alternatively, the DNA can first be separated into fractions of different guanine plus cytosine (G + C) content (77). The rationale behind this fractionation is that the G + C content of prokaryotic DNA varies from approximately 24 to 76%, but that particular taxonomic groups vary in G + C content by no more than 3 to 5% (78,79). The G + C profiling percentage provides a coarse level of resolution in cultivation-independent community analysis, which is not achieved by the other available techniques (80). It allows a comprehensive and quantitative analysis of the structure and dynamics of complex microbial communities in soils (80–82) and other environments (29,83,84). However, the method requires a relatively large amount of DNA (50 to 100 μg) and an ultracentrifuge to separate various G + C fractions.

The separation is achieved through the binding of bis-benzimidazole (Hoechst reagent number 33258) to adenine and thymidine. The bound bis-benzimidazole changes the buoyant density of DNA, and this change is proportional to its A + T (hence, G + C) content (77). A gradient of DNA fragments sorted by G + C content is established by equilibrium density-gradient (CsCl) centrifugation, then DNA fractions with different G + C contents are collected and quantified by spectrophotometry. After purification, individual DNA fractions can be further analyzed using molecular ecology techniques. For example, comparative sequence analysis of SSU rRNA genes retrieved from DNA fractionated based on %G + C content allowed the characterization of dominant and rare members of a young Hawaiian soil bacterial community (81). Other molecular techniques that have been applied to G + C fractionated DNA include functional gene probing (80,85), SSU rDNA-based fingerprinting (81), and amplified rDNA restriction analysis (81,82).

ANALYSIS OF SSU rRNA AND ITS ENCODING GENE (rDNA)

Methodological Aspects

Comparative analysis of SSU rRNA sequences has become the central tool for determining phylogenetic relationships or, to put it otherwise, for reconstructing the history of life (86–91). It led to the proposal of the domains Archaea, Bacteria, and Eucarya as the three main divisions of the universal tree of life (92). Many properties of SSU rRNA make it an ideal marker biomolecule for the inference of phylogenetic relationships: (*1*) it is universal to life, (*2*) it is highly conserved structurally and functionally, (*3*) it is, as the central component of the highly complex translation apparatus, one of the most refractory biomolecules, and has probably never (or very infrequently) been transferred horizontally from one species to another. SSU rRNA–based trees therefore depict evolutionary lineages of organisms and not of the gene only, (*4*) it contains sufficient nucleotides to infer phylogenetic relationships, (*5*) different regions of the gene vary at different rates (93,94), thereby allowing the inference of phylogenetic relationships from the domain to the species level. Highly invariant, slowly evolving positions confer valuable information on widely separated groups or organisms, whereas positions of higher variability are useful for the elucidation of more recent branchings (89,94), and (*6*) highly conserved regions present targets for universal primers that allow PCR amplification of almost–full-length SSU rDNA from most members of either the domain Bacteria (65,95–98)

or the domain Archaea (99,100). Primers for amplification of partial SSU rDNA from most members of Bacteria and Archaea together have also been designed (65,95,97).

The ease with which SSU rDNA sequences can be studied has led to a rapid increase in the number of sequences now available in public-domain databases. For example, the SSU rDNA database of the Ribosomal Database Project (RDP) (101) currently contains more than 16,000 aligned prokaryotic SSU rRNA sequences (~75% are longer than 899 bp). Most of these have been retrieved directly from environmental samples during cultivation-independent studies into microbial diversity.

These cultivation-independent studies generally proceed by retrieval of total community DNA, PCR amplification of SSU rDNA, generation of an SSU rDNA clone library, and analysis of the clone library by comparative sequence analysis. PCR is carried out using the universal primer sets noted above, targeting Bacteria (102–106), Archaea (100,107–109), or both domains (110,111). Nowadays the most-widely used system for generation of SSU rDNA clone libraries is the TA cloning kit (Invitrogen Corp., Carlsbad, California). In this kit the linearized cloning vector carries single 3′ thymidine residues to take advantage of a particular characteristic of the *Taq* polymerase, the addition of a single adenosine overhang at each 3′ terminus of the double-stranded PCR products (112). This system avoids the need for endonuclease restriction of the PCR product prior to the ligation reaction, and results in a high cloning efficiency by avoiding the loss of information, which may occur because of restriction. The current state-of-the-art tool for administration and analysis of SSU rDNA sequence data is the ARB software package developed by O. Strunk and W. Ludwig (Technische Universität München, Germany). It is available online at *http://www.mikro.biologie.tu-muenchen.de/pub/ARB/*. The program includes various tools for phylogenetic analysis, including the phylogeny inference package (PHYLIP version 3.2 113) and maximum likelihood treeing methods (fastDNAml (101)). Details on how to construct phylogenetic trees with SSU rDNA sequence data and the various treeing algorithms available are reviewed elsewhere (94,114,115).

Total RNA, instead of DNA, can be extracted from soils, and the SSU rRNA reverse transcribed (116–119). Especially in soil environments, diversity assessment with rDNA is experimentally less problematic than with rRNA. However, organisms detected by retrieval of SSU rDNA may be ecologically unimportant because DNA persists in moribund and dead cells (120) and can be present as extracellular DNA adsorbed to mineral surfaces (24,121,122). In contrast, RNA is highly labile. Ribosome levels, and therefore rRNA levels, have been correlated with cellular activity (21,123–126). Thus, it can be argued that retrieval and analysis of SSU rRNA provides a more representative view of the metabolically active members of microbial communities (116–119).

Assessment of the SSU rDNA diversity in a clone library is usually carried out by partial or full-length sequence analysis of randomly selected clones, or by techniques which rapidly assign clones to operational taxonomic units (OTUs) (127) (the term phylotype is often used as a synonym to OTU (104)). One such technique is ARDRA. In ARDRA, the SSU rDNA clones are digested by hexameric and/or tetrameric restriction endonucleases and the resulting digests are separated into size fragments by agarose gel electrophoresis. Restriction fragment length polymorphisms (RFLPs) are used to assign SSU rDNAs to particular OTUs (80,82,104,128). Representative clones of individual OTUs can then be selected for sequence analysis (82,104). This approach is rapid, efficient, and thoroughly assesses the species richness in SSU rDNA clone libraries. However, a single OTU defined by ARDRA may consist of several diverse SSU rDNA sequences. Dunbar and coworkers (104) reported that partial SSU rDNA sequences (427 nucleotides analyzed), which had been grouped into the same OTU based on identical *Rsa*I-*Bst*UI RFLP patterns, had an average sequence similarity of only 87%. Thus, the screening of clone libraries by ARDRA provides only a broad, preliminary estimation of microbial diversity. McCaig and coworkers (105) grouped SSU rDNA sequences randomly sampled from clone libraries into OTUs defined by a 97% level of sequence similarity. Sequences exhibiting similarities above 97% may or may not correspond to microbial strains of the same genospecies, but sequence types below this similarity value never correspond to strains of the same genospecies (129). The number of unique OTUs retrieved in relation to the total number of randomly sampled sequences (collector curve), provides information on how well the species richness of clone libraries has been assessed (105).

It should be noted that the relative frequencies of defined OTUs in SSU rDNA clone libraries do not provide any quantitative information on community structure. Although the relative abundance of a single OTU relative to others is frequently compared across samples to show community differences in the relative importance of this OTU (see section Microbial fingerprinting techniques), one OTU cannot be directly compared to another because many biases lead to the preferential recovery of some sequences over others. Bias can occur at all methodological levels from environmental sampling to data analysis (130), but are especially severe during extraction of total soil DNA (47,62), during multitemplate PCR (131–136), and because of possible contaminant sequences (137).

Another problem in interpreting environmental SSU rDNA sequences is the formation of chimeric SSU rDNA (hybrids) during multitemplate PCR (136,138–141). Chimeric SSU rDNA sequences result in artificial lineages during treeing analysis, therefore any conclusion that a new microbial lineage has been detected in an environment must always be made with care. It should be checked by separate analysis of the 5′ and 3′ sequence halves (106,108,142), by use of the chimera check program of RDP (101), and by a careful secondary structure analysis.

Phylogenetic Diversity

The first cultivation-independent phylogenetic surveys of microbial diversity were published in 1990, regarding samples collected from hot springs of the Yellowstone National Park (143) and the Sargasso Sea (144).

The first studies on soil were published shortly thereafter, using samples from subtropical Australia (63,145). Since then, surveys of microbial diversity have been conducted on diverse soil environments including: tropical Hawaiian forest and pasture soil (82), mature forest soil and active pasture in Eastern Amazonia (111), arid pinyon pine-juniper woodland soils in Arizona (102,104), grassland soils in Scotland (105,146) and the Netherlands (119,147,148), agricultural soils in Wisconsin (110) and the Netherlands (149), German moorland soils polluted with zinc (150) or polychlorinated biphenyls (117), Italian rice paddy soil (106,118,142,151), and Siberian tundra soil (152).

These cultivation-independent studies have dramatically changed our view of microbial diversity (88,91,107,153,154). They have contributed to the tripling of identifiable bacterial divisions (also called *main lines of bacterial descent* or *phyla*) during the last 12 years (154–156). Only 23 of the 36 to 40 presently recognized bacterial divisions are currently represented by cultured species (154,155). The total number of divisions may in fact be well over 40, judging by various division-level lineages represented by only single or few known sequence types (142,154,157). Major bacterial groups commonly detected by cultivation-independent phylogenetic surveys of soils are: *Holophaga/Acidobacterium* (103,154,158); *Proteobacteria* (82,102,104,105,110,111,117,119,147,150,152,157); gram-positives with low G + C content (104), including clostridial sublineages (106,110,111) and *Bacillus* (102,106,110,111,119,147,152,157); *Actinobacteria* (102,105,116,117); the *Cytophaga/Flexibacter/Bacteroides* group (102,104–106,110,111,150); *Nitrospira* (104,149); *Planctomycetales* (102,110,111,117,152); and *Verrucomicrobia* (104–106,111,157,159).

The abundance and activity of each bacterial division depends strongly on physicochemical soil properties. For instance, the assessment of bacterial community structure along a vertical oxygen gradient in flooded paddy soil microcosms suggested that α- and β-*Proteobacteria* colonized the oxic soil especially, whereas clostridial subgroups predominated in the anoxic soil zone (118). Buckley and Schmidt (159) determined the relative abundance of rRNA from *Verrucomicrobia* in soil microbial communities by quantitative dot blot hybridization using a *Verrucomicrobia*-specific oligonucleotide probe. A total of 85 soil samples were taken to assess rRNA changes with soil depth and moisture content and in relation to plant community composition and soil management history over a period of 2 years. The authors concluded that *Verrucomicrobia* were significantly affected by environmental characteristics that changed in relation to time, soil history, and soil depth. A statistically significant amount of the variation in verrucomicrobial rRNA abundance could be correlated to changes in soil moisture.

A detailed description of the diversity and environmental range of all major bacterial divisions is beyond the scope of this article, so the *Holophaga/Acidobacterium* division will be used as an example. There are presently only three cultured representatives of this main line of bacterial descent: *Acidobacterium capsulatum* (160), *Holophaga foetida* (161), and *Geothrix fermentans* (162). However, members have been detected both by SSU rDNA (82,102–105,111,149,150,157,158) and by SSU rRNA (117,119,147) retrieval from various soil types and geographic regions (Fig. 1). Based on the three cultured representatives and on the many environmentally retrieved SSU rDNA sequences, up to eight monophyletic subdivision-level lineages within the *Holophaga/Acidobacterium* group have been identified. The three cultured organisms provide clues about the physiological versatility within the group: *A. capsulatum* is a moderately acidophilic aerobic heterotroph, whereas *H. foetida* and *G. fermentans* are strict anaerobes that ferment aromatic compounds and acetate, respectively. *Geothrix fermentans* is also able to grow by dissimilatory iron reduction. These diverse phenotypes, and the widespread occurrence of SSU rDNA sequences belonging to the *Holophaga/Acidobacterium* division in diverse environments, suggests that members of this group are active in many soil ecosystems. Besides terrestrial soil (103,154,158), species have been detected in a peat bog (163), acid mine drainage (164), marine samples (165), activated sludge (103), bioreactors (166), a contaminated aquifer (155), and a hot spring (153), as well as in sediments, water column and lake snow aggregates of freshwater lakes (103,167), and on sediment particles sampled from the permanent ice cover of an Antarctic lake (168).

Cultivation-independent molecular phylogenetic surveys have also helped to shape the present perception of diversity in Archaea. Cultivated members of the kingdom Euryarchaeota are physiologically diverse and include halophiles, thermophiles, and methanogens, whereas cultivated members of the kingdom Crenarchaeota are more homogeneous, consisting only of sulfur-dependent extreme thermophiles, such as *Pyrodiction occultum* and *Thermoproteus tenax* (91). Consequently, it was assumed at one time that Crenarchaeota are restricted to extreme high-temperature habitats (92). However, cultivation-independent retrieval of crenarchaeal SSU rDNA sequences has revealed this assumption to be false. Crenarchaota are widely distributed, inhabiting not only high-temperature habitats but also moderate- and low-temperature environments, such as marine waters, terrestrial soils, marine and freshwater sediments, and also living in association with metazoa (169,170). Pelagic crenarchaeota may even be one of the ocean's most abundant cell types (171). Crenarchaeota sequences from low-temperature habitats form several deeply branching clades clearly distinct from the monophyletic group of cultured thermophilic Crenarchaeota. Representatives of these groups have still not been obtained in pure culture.

Terrestrial soil environments in which SSU rDNA of nonthermophilic crenarchaeota have been detected include boreal forest soil in northern Finland (109,172); agricultural soils in Germany (173), Wisconsin (174,175), and Michigan (176); forest soil in Eastern Amazonia (111); and Italian rice paddy soil (177). Crenarchaeal SSU rDNA retrieved from soils form two distinct clades named the *FFSB cluster* and the *Terrestrial cluster* (176). Quantitative dot blot hybridization with an SSU rRNA–targeted

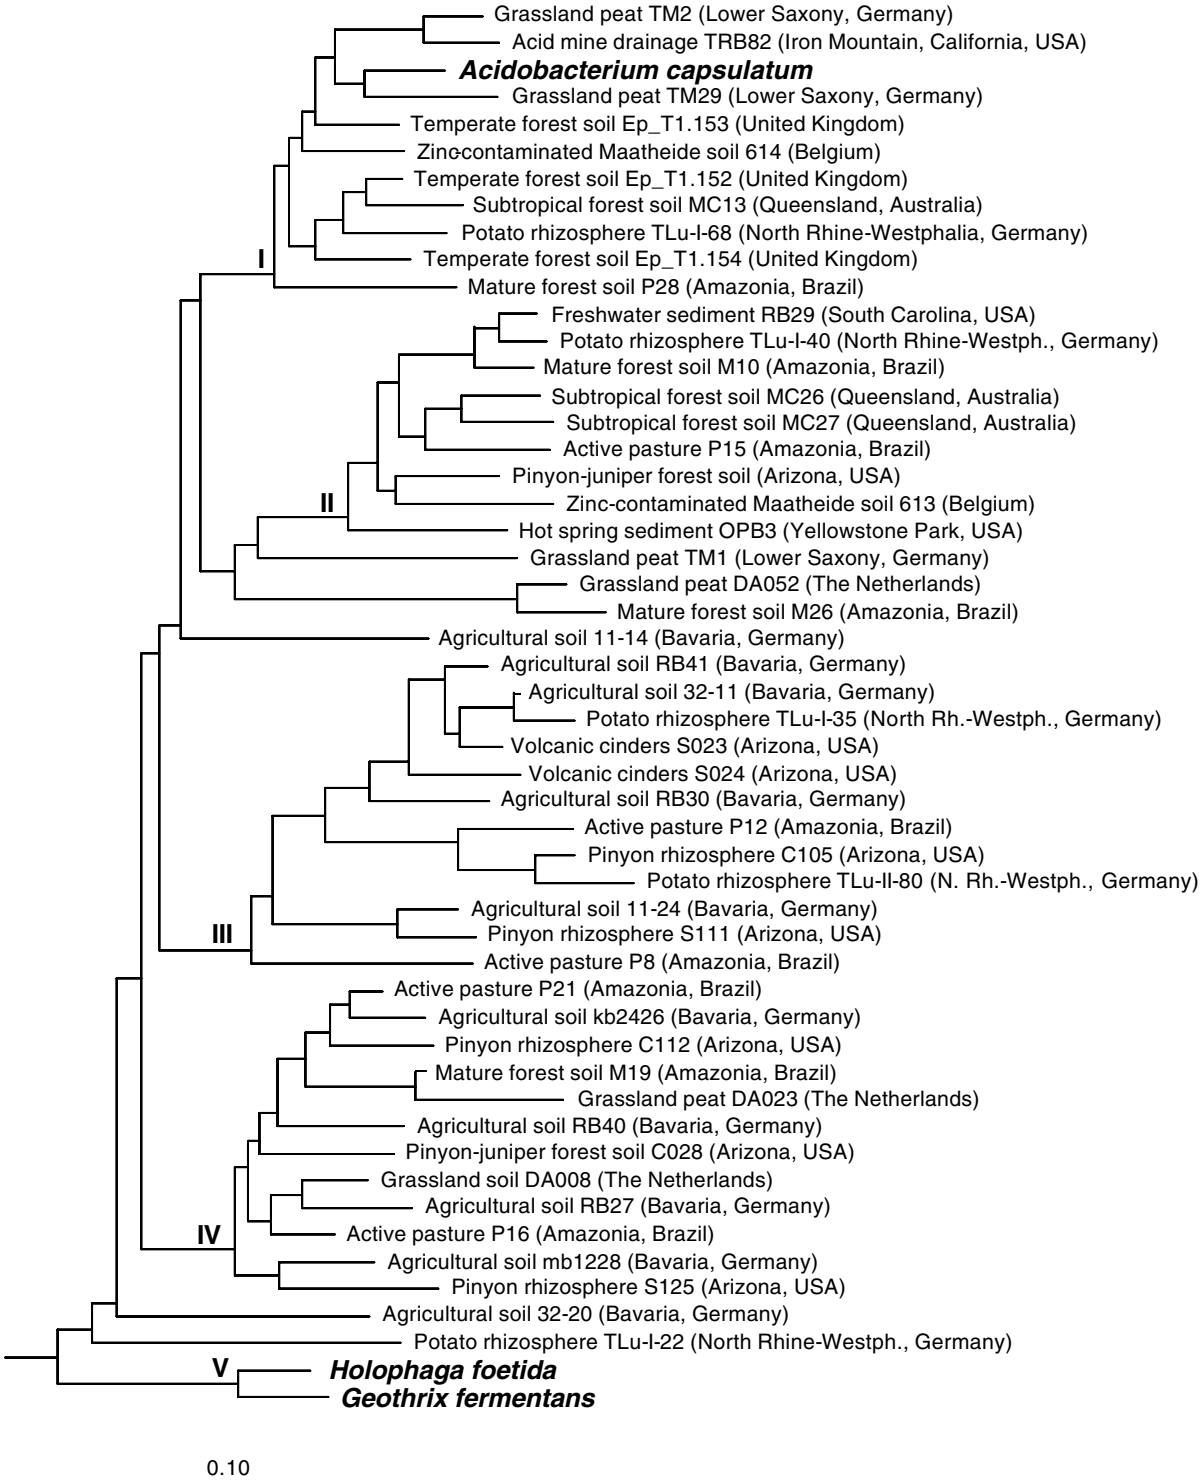

Figure 1. Phylogenetic dendrogram of the *Acidobacterium*/*Holophaga* division. Cultivated organisms are shown in bold. For each environmental sequence the habitat source, clone name, and geographic region from which the sequence was obtained are given. Subdivision-level lineages with bootstrap values of greater than 90% in 1,000 data resamplings are indicated by roman numerals (I to V). The tree was rooted using the SSU rDNA of *Escherichia coli* as the outgroup reference. The scale bar indicates 0.1 change per nucleotide.

oligonucleotide probe specific for all known nonthermophilic crenarchaeotal sequences assigned as much as 1.42±0.42% of the SSU rRNA extracted from agricultural soils to this group (176). FISH analysis with a set of SSU rRNA–targeted oligonucleotide probes specific for Archaea, Crenarchaeota, or nonthermophilic Crenarchaeota showed that Crenarchaeota colonize terrestrial plant roots at an unexpectedly high frequency (175).

Archaeal SSU rDNA directly retrieved from Italian rice paddy soil included, besides sequences from well-known methanogens, various novel lineages of Euryarchaeota (108). One of these lineages, termed *rice cluster I*, formed a distinct clade within the phylogenetic radiation of the orders Methanosarcinales and Methanomicrobiales and thus was considered a novel taxonomic group of methanogens at the family or order level. Members of rice cluster I also occur in close association with rice roots (108,178). A methanogenic phenotype for rice cluster I species was further supported by parallel phylogenies of SSU rDNA and sequences encoding the methanogen-specific gene marker methyl coenzyme M reductase subunit A (179) (see section Analysis of Functional Genes). Kim and coworkers (180) have also detected a novel clade of deeply branched Archaea in total DNA extracted from various Japanese rice paddy soils. This novel group could be assigned neither to the Euryarchaeota nor the Crenarchaeota.

Comparative sequence analysis of environmental SSU rDNA has therefore provided, and will continue to provide, insight into microbial diversity. It does not, however, allow conclusions about the metabolic capacities, phenotypes, or ecological niches of microorganisms. This is especially true for groups from which no representatives have yet been cultured (20,142,169).

ANALYSIS OF FUNCTIONAL GENES

Phenotypes of the organisms from which SSU rDNA sequences are retrieved cannot be known for certain, only inferred from the phenotypes of the closest phylogenetic neighbors that are available for study in pure culture. Consequently, assays have been developed, which target functional genes indicative of biogeochemically important groups. Ideally these genes code for an enzyme that is both universal and specific for the microbial group of interest, so that the presence of the phenotype is inherent from the recovery of the sequence. For example, the *amoA* gene is universal to autotrophic ammonium oxidizers, and possession of an *amoA* gene implies that the organism is an ammonium oxidizer (181,182). The sequence phylogeny of the functional gene also ideally corresponds closely to the SSU rDNA–based phylogeny, that is the selective pressure acting on the gene should be primarily neutral or negative and no interspecies gene transfer should occur.

Some functional genes that have been used as phylogenetic markers are listed in Table 1.

Further promising genes have also been identified, for example the hydroxylamine oxidoreductase gene (*hao*) (226). Many, on the other hand, such as the plasmid genes encoding for 2,4-dichlorophenoxyacetic acid–degrading enzymes (227) and the *nod* genes of rhizobia (228), have been shown through phylogenetic analysis to be very mobile across species, and the retrieval of these sequences from nature would not allow a clear deduction of the bacterial species from which they came. Several of the markers included in Table 1 also suffer to some extent from this drawback, but have nevertheless been applied for general phylogenetic deduction.

Examples of good functional phylogenetic markers are the *pmoA* and *amoA* genes. The phylogenies of these genes are excellent mirrors of SSU rDNA phylogeny, and allow identification to the species level (181–184). The *amoA* gene, originally applied phylogenetically by Rotthauwe and coworkers (181), codes for a subunit of ammonium monooxygenase, the enzyme that essentially defines the group of autotrophic aerobic ammonia oxidizers. Community analysis of *amoA* products amplified from environmental DNA has been performed with a wide

Table 1. Functional Genes Useful as Phylogenetic Markers

Gene	Enzyme	Target Group	Selected References
pmoA	Particulate methane monooxygenase	Methane oxidizers	183–190
mmoX	Soluble methane monooxygenase	Methane oxidizers	191–195
amoA	Ammonia monooxygenase	Ammonia oxidizers	181,182,196–203
mxaF	Methanol dehydrogenase	Methylotrophs	186,204–207
nifH	Dinitrogenase reductase H	Nitrogen-fixers	208–214
mcrA, mcrI	Methyl coenzyme M reductase	Methanogens	179,215,216
rbcL	Form I ribulose bisphosphate carboxylase/oxygenase	Autotrophs (phytoplankton)	217
nirK, nirS	Nitrite reductase	Denitrifiers	218,219
nosZ	Nitrous oxide reductase	Denitrifiers	220–222
narG	Nitrate reductase	Denitrifiers	223
dsrA, dsrB	Dissimilatory sulfite reductase	Sulfate reducers	224,225

combination of methods, including cloning followed by sequencing (181,196–200), denaturing gradient gel electrophoresis (DGGE) separation and hybridization analysis (201), RFLP of cloned sequences (202), and terminal restriction fragment length polymorphism (T-RFLP) (203). The *pmoA* assay targets subunit A of particulate methane monooxygenase, which is functionally and evolutionarily related to the *amoA* gene (183). This assay has been applied to identify methane-oxidizing species in various environments and enrichment cultures (185–188), and the discovery of novel *pmoA* sequences in forest soils has suggested the existence of not-yet cultivated species of methane-oxidizing bacteria (189,190). Unfortunately, there are pitfalls in the use of functional gene markers. The *pmoA* gene, for example, is neither completely universal nor completely specific. Although particulate methane monooxygenase was originally thought to be present in all methane-oxidizing bacteria, a species has recently been isolated, which seems to contain only the alternative, soluble form of the enzyme (229). Furthermore, the *amoA* gene can also be amplified by *pmoA* primers. This is not a problem if the sequences clearly fall within a known group such as the *Nitrosospira*. However, the interpretation of novel or unusual sequences (189,190,200) can be problematic.

MICROBIAL COMMUNITY FINGERPRINTING

Several molecular fingerprinting techniques are available to characterize and compare microbial communities. These analyses begin with a PCR product (either SSU rDNA or a suitable functional gene) obtained from complex community DNA, which is then separated into a pattern of different phylotypes based on some properties of the component DNA sequences. The most commonly used methods are DGGE, temperature gradient gel electrophoresis (TGGE), and T-RFLP.

DGGE is the electrophoretic separation of sequence types in an increasing gradient of chemical denaturant (urea plus formamide). The manner in which double-stranded DNA denatures in the gradient, and hence its electrophoretic mobility, is controlled by the arrangement of strong G–C bonds versus weak A–T bonds. TGGE is a variant in which the denaturation is controlled via a temperature gradient rather than a chemical gradient. The principles and technical aspects of these two methods have been well reviewed (230–232). A similar technique is single-strand conformation polymorphism (SSCP), in which separation is achieved in a polyacrylamide gel based on the different secondary conformations of different single-stranded DNA sequences (233).

Details of the T-RFLP method are covered by recent reviews (234,235). T-RFLP is a simplification of ARDRA, a technique used primarily to identify single DNA phylotypes by their unique patterns of restriction digests in an agarose gel. ARDRA can also give community-specific patterns for mixed PCR products (80,236), but these can be extremely complex for environmental samples and are therefore of limited use in phylogenetic deduction or assessment of species richness. In T-RFLP, one PCR primer is labeled with a fluorescent dye. After restriction digestion of the PCR product followed by gel or capillary electrophoreses, the terminal fluorescent fragments can be detected using a laser (237). In this way T-RFLP analysis detects a single-size fragment (T-RF) for any given sequence type. Typical T-RFLP patterns for SSU rDNA PCR products are shown in Figure 2. The comparison of DNA extracted from BIOLOG plates versus soil again demonstrates the greater complexity obtained with cultivation-independent analysis (238). Other, less-popular, size-based fingerprinting techniques include length heterogeneity PCR (239) and RISA (111,240,241), in which the length variability of SSU rRNAs, or of the intergenic region between the SSU and large subunit

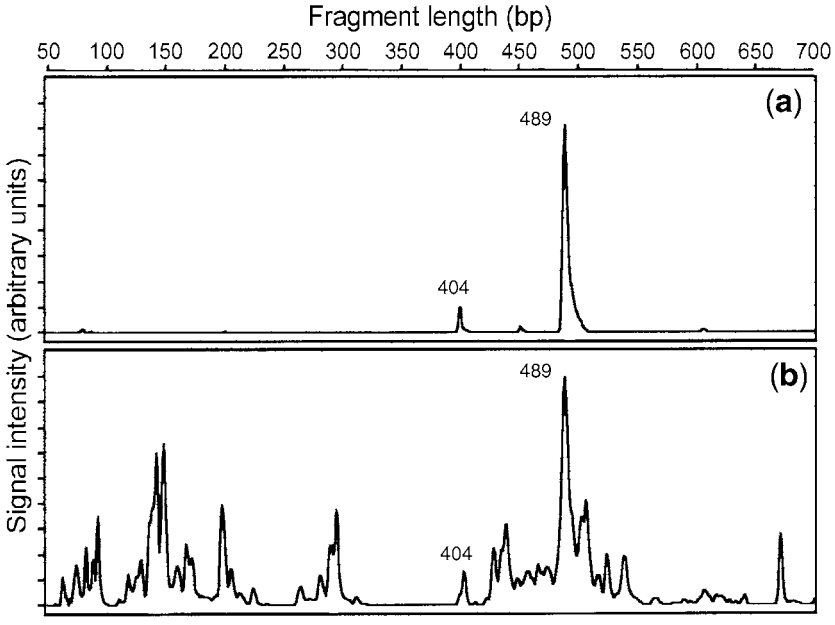

Figure 2. Comparison of SSU rDNA-based T-RFLP community fingerprint patterns obtained from a potato-rhizosphere soil sample after cultivation on a BiOLOG GN microtitre plate (**a**) or obtained by a cultivation-independent approach (**b**). The 404-bp T-RF corresponds to *α-Proteobacteria* and the 489-bp T-RF to *β-* and *γ-Protoebacteria*. The T-RFs indicative of bacterial groups detectable only by the cultivation-independent approach correspond to various major bacterial groups including the *Holophaga/Acidobacterium* cluster, the *Cytophaga/Flexibacter/Bacteroides* division, *Planctomycetales*, and *δ-Proteobacteria*.

rRNA genes, are the respective criteria for the separation of phylotypes.

The simplest analysis of the patterns obtained by community fingerprinting methods is visual: that particular species/phylotypes are detectable or not detectable in a community (190,213,242). This is the primary goal of studies analyzing single samples, and is generally sufficient when comparing few samples (142,202). For example, the disappearance or appearance of species with time has been followed with DGGE (186,243), and changes in bacterial community structure along a vertical oxygen gradient were clearly demonstrated with T-RFLP (118). Presence/absence data can also be used to calculate simple similarity coefficients between community profiles, which can be used in cluster analysis (244). However, better numerical quantification of the patterns facilitates more intensive analysis. Quantification is easiest and most reliable with T-RFLP, where the intensity of the fluorescence signal is used as a measure of the abundance of any product relative to the others, and a threshold signal/noise level can be set to score the presence or absence of a peak (236,245). Quantification in DGGE or TGGE is generally accomplished by image analysis software, and may or may not include a densitometric comparison of band strengths (246–248).

Relative abundances of T-RFs are often compared across communities, to conclude that particular T-RFs comprise a greater or lesser proportion of the total product in one sample compared to another (118,177,219). Of course, caution must be exercised in making conclusions because of well-known PCR biases, as well as the fact that data are relative and therefore all cross-correlated. If sufficient replicate data are available, a multivariate statistical analysis can determine whether the patterns observed significantly differ across samples or treatments (236). This analysis also takes into account the cross-correlation of the various T-RFs and allows the determination of which T-RFs contribute most to the overall variability of the patterns (236).

Phylotype richness–the total number of DGGE bands or T-RFLP peaks–is also often reported (142,235,242,249, 250). Combining this with relative abundance data then allows the calculation of classical ecological diversity indices such as Shannon's index and Simpson's index. This frequently give useful results (251–253), although because gel bands or T-RFs do not represent standard phylogenetic units, the resolution may not be fine enough to distinguish among very similar samples (245). Cluster analysis using matrices of pairwise correlation coefficients or any of a variety of similarity coefficients (244) is a popular and powerful method to determine whether certain classes of communities are distinguishable within a large group of samples (222,235,246–248,250–252,254). Cluster analysis of various marine bacterioplankton communities gave similar results with T-RFLP and DGGE data, although the T-RFLP detected more total phylotypes (255). T-RFLP analysis of a variety of soil samples also gave similar community clustering patterns as those obtained from analysis of SSU rDNA gene clone libraries (245). Different fingerprinting methods therefore seem to give consistent and comparable community profile patterns.

In choosing a fingerprinting method, one must consider the aim of the study. Of the methods described, T-RFLP best lends itself to quantitative analyses, but is least useful for phylogenetic deduction. T-RFs of SSU rDNA can be compared to the RDP to analyze possible phylogenetic affiliation (101). Unfortunately this is often not unequivocal, as many T-RFs are not species- or even genus-specific (256). This problem can be partially solved by comparing T-RFs instead with clone libraries generated from the same sample (142,177), but this procedure may defeat the desired simplicity of T-RFLP analysis. Alternatively, PCR assays specific to particular microbial groups can reduce the total diversity of the T-RFLP profiles. Assays have been developed for the functional genes *nifH* (212), *amoA* (203), *nirS* (250), and *mcrA* (179). Group-specific SSU rDNA primers may also be applied. Nevertheless, a major advantage of DGGE/TGGE and SSCP is still that individual bands can be excised from the gel and sequenced for direct identification. A problem with DGGE/TGGE is that they are often too sensitive for the determination of total community fingerprints, since nearly identical sequences can give separate bands. The situation is especially problematic for SSCP, where a single sequence can have multiple secondary conformations. The nonspecificity of T-RFs might therefore be considered an advantage when dealing with complex communities, since the overall redundancy of the fingerprint is decreased and broader OTUs are detected.

ANALYSIS OF MICROBIAL ACTIVITY AT THE FUNCTIONAL LEVEL

PCR-based retrieval of functional genes gives insight into the species composition of microbial communities, and their potential to carry out certain functions, but it does not provide information on in situ activity. This gap can be bridged by investigating gene expression at the transcription level. The hybridization of poly-A mRNAs to oligo(dT) probes allows direct extraction and purification of eukaryotic mRNA from complex matrices and has been performed for soils (257–259). However, bacterial transcripts lack polyA tails and are not detectable with these methods. In addition to the general methodological problems involved in the extraction of total RNA from soils (as mentioned earlier), the transient character of prokaryotic mRNA transcripts and their low cellular abundance relative to rRNA (260) account for the paucity of papers reporting the detection of prokaryotic mRNA transcripts from soils (72,73,260–264) and aquifer sediment (265).

Because of the present interest in biotechnology, most of these studies have focused on the detection of mRNA transcripts for genes coding biodegradation enzymes. They have included: (*1*) the detection of mRNA transcripts for naphthalene dioxygenase and mercury resistance genes by Northern blot hybridization (73), (*2*) quantification of mRNA transcripts of naphthalene

dioxygenase (261,262) and soluble methane monooxygenase (265) using an RNase protection assay, and (*3*) reverse transcriptase-PCR amplification of mRNA transcripts for β-glucuronidase (264). These methods of mRNA analysis require a priori information about the gene sequences of interest to design specific DNA probes (hybridization assays) or primers for mRNA detection and measurement. In this way they are simply an extension of the previously described techniques for detection and characterization of functional and catabolic DNA sequences (263).

Fleming and coworkers (260) combined the differential display (DD) technique (266,267) and the RNA arbitrarily primed PCR method (268,269) to detect cryptic or unknown RNA sequences transcribed under in situ conditions in soils. An arbitrary primer for the reverse transcriptase step and the same arbitrary primer in conjunction with a Shine-Dalgarno (SD) primer in the PCR step were used to monitor differential bacterial mRNA transcription between control and toluene-contaminated soil microcosms. The SD primer was used to amplify, by PCR, a wide range of prokaryotic mRNA sequences. The use of this arbitrary primer in combination with the SD primer for DD resulted in highly reproducible RNA fingerprints. However, one major shortcoming of the method was a high percentage of false positive bands. Of the putative clones screened, only one in 12 was confirmed to be unique and differentially expressed in the toluene-induced soil microcosms. Another limitation of this technique is the short lifetime of mRNA. Half-lives of mRNA molecules can be as long as 50 minutes, but typically range between 0.5 and 2 minutes. Thus, a large fraction of the prokaryotic mRNA pool may not be accessible for study, even after induction. Nevertheless, the DD technique has great potential for studying gene expression in soil environments, and potentially allows the detection of novel and differentially expressed gene sequences.

A promising alternative to mRNA-based techniques for analysis of microbial communities is the use of biomarkers, such as bromodeoxyuridine (BrdU) (270,271), or substrates labeled with stable isotopes (206), which are incorporated in the genomic DNA of active microbial populations only (206,240,270). Labeled DNA can be isolated from the target group of microorganisms and then characterized taxonomically by gene probing and sequence analysis.

Culture-independent identification of soil microorganisms that grow in response to specific stimuli can be performed using BrdU (270). After incubation of a soil with BrdU, total DNA is extracted and the newly synthesized DNA isolated by immunocapture of the BrdU-labeled DNA. This approach was used to measure bacterial functional redundancy in soils along a reclamation-revegetation gradient (240). Samples were taken on a transect from a mine site to a soil under a new-growth forest, and from an adjacent pristine forest. The diversity of bacterial groups responding to the substrates L-serine, L-threonine, sodium citrate, and α-lactose hydrate were determined by incubating soils with BrdU plus the various substrates, and then performing RISA of the BrdU-labeled DNA fractions. The major conclusion of this study was that bacterial functional redundancy increases with regrowth of plant communities.

Stable isotope probing takes this analysis a step further and directly links genomic DNA with the metabolism of defined microbial groups. With the BrdU method the soil can be manipulated to favor the growth of different bacterial groups (e.g., particular substrates can be added) and the actively growing groups identified, but with the stable isotope method the incorporation of a substrate can be followed directly. This technique is based on the capability of ^{13}C-DNA, produced during growth on a ^{13}C-enriched carbon source, to be resolved from ^{12}C-DNA by density-gradient centrifugation. Using this technique, methanol-utilizing microorganisms were investigated through the addition of $^{13}CH_3OH$ to a forest soil (206). Phylogenetic analysis of SSU rRNA genes recovered from the purified ^{13}C-labeled DNA fraction identified CH_3OH-utilizing bacteria from two distinct lineages, the α-subclass of the *Proteobacteria* and the *Acidobacterium* division. The conclusion that active methylotrophs belong to the α-subclass of *Proteobacteria* was also supported by a parallel analysis of *mxaF* sequences (see Table 1).

The BrdU and stable isotope probing techniques each provide cultivation-independent means of investigating the effect of environmental conditions, such as temperature, water potential, pH, and substrate availability on the identity of active microorganisms, and thereby allow analysis of functionally relevant ecological diversity. However, both techniques have methodological shortcomings that necessitate care in their application and in the interpretation of the data obtained. A major limitation of the BrdU strategy is the range of organisms capable of BrdU uptake and incorporation. In one study, only two of four different bacterial strains tested incorporated BrdU (271). One of these belonged to the α-*Proteobacteria* and the other to the γ-*Proteobacteria*, whereas failing to assimilate BrdU were a flavobacterium and a gram-positive bacterium. Stable isotope probing also has limitations that may render it unsuitable in certain situations. For instance, simultaneous growth of target microorganisms on an unlabeled (^{12}C) substrate will dilute the proportion of ^{13}C that is incorporated into their DNA. This will reduce the proportion of DNA that becomes isotopically labeled, making it more difficult to identify the microorganisms that are the primary users of a labeled substrate (206).

Other innovative cultivation-independent methods have been developed for linking the functional activities of microorganisms with their taxonomic identity. These include the combination of FISH with microautoradiography (272,273) and the coupling of radio- or stable-isotope analyses with characterization of microbial phospholipid ester-linked fatty acids (PLFAs) (189,274,275). For example, bacteria oxidizing atmospheric methane in soil samples from Greenland, Denmark, the United States, and Brazil were characterized by incubation of the soils under $^{14}CH_4$ and subsequent analysis of the radioactively labeled PLFAs (189,275), and in parallel by analysis of methane monooxygenase gene libraries (189). The ^{14}C-PLFA fingerprints of the soil methanotrophs were clearly different

from the PFLA profiles of the type I γ-proteobacterial methanotrophic bacteria, but similar to PLFA profiles of the α-proteobacterial type II methanotrophs. These ^{14}C-PLFA fingerprint results corresponded well to the results of monooxygenase sequence analyses. Phylogenetic treeing analysis identified a novel cluster of *pmoA* sequences possibly belonging to an unknown group of methane-oxidizing bacteria. These sequences were more closely related to those of type II α-*Proteobacteria* methanotrophs than to those of the type I γ-*Proteobacteria*.

METAGENOME ANALYSIS

Cultivation-independent surveys of microbial communities based on single gene phylogenies provide information on the diversity of microorganisms at the phylogenetic or functional level, but allow little inference about the detailed physiology or biochemistry of these organisms. Recent improvements in molecular analytical techniques and bioinformation sciences have provided methods suitable for the analysis of the metagenome–the total gene pool of a complex microbial community (276). Metagenomic analysis begins with the cloning of large fragments of DNA extracted directly from the microbial community. Analysis of these cloned fragments can provide a link between phylogenetic and functional information and allow for the characterization of total gene operons isolated directly from an environment. Pioneered by DeLong and coworkers, this new approach has been applied to characterize genome fragments of uncultivated nonthermophilic marine crenarchaeota (277), including *Cenarchaeum symbiosum* (278,279), a psychrophilic archaeon that lives in specific association with the marine sponge *Axinella mexicana* (280).

More recently, bacterial artificial chromosome libraries (BACs) from soil metagenomes have been constructed (56). BACs are modified plasmids that contain an origin of replication derived from the *E. coli* F factor. The replication of the BAC vector is strictly controlled, keeping the replicon at one or two copies per cell. BAC vectors can stably maintain inserts as large as 600 kb (281). It has also been suggested that BAC vectors display a low level of chimerism as a result of two genes carried on the plasmid (*parA* and *parB*) (282).

A critical step of soil metagenome analysis is the extraction of high molecular weight DNA suitable for the construction of BAC libraries (see section Extraction of Total Nucleic Acids from Soil). The total fragment mixture of DNA extracted from an agricultural soil was cloned into BAC library SL1, which had clone inserts ranging in size from 10 to 60 kb, but mostly between 20 and 30 kb (56). DNA fragments greater than 40 kb were then selected from the same extract by preparative gel electrophoresis prior to construction of BAC library SL2. This SL2 library had clone inserts ranging between 10 and 80 kb in size. The average insert size was 44.5 kb, and more than 60% of the inserts were larger than 40 kb (56).

A phylogenetic survey of BAC library SL1 identified seven genome fragments containing SSU rRNA gene sequences. These belonged to four different bacterial phyla: the *Proteobacteria*, low G + C gram-positives, the *Cytophaga/Flexibacter/Bacteroides* group, and the *Holophaga/Acidobacterium* cluster. Members of these phyla are typical inhabitants of agricultural soil. Complete sequence analysis of one BAC clone insert identified various open reading frames, including a gene cluster similar to the phosphate transport cluster (*pstCAB-phoU*) of *E. coli* (283). This finding demonstrated the potential of metagenomic DNA analysis to characterize complete, intact operons.

Screening the two BAC libraries identified clones expressing DNase, antibacterial compounds, lipase, and amylase of metagenomic DNA. This demonstrated that BAC libraries contain heterologous DNA sequences that can be expressed in *E. coli* at detectable levels. The analysis of metagenomic BAC libraries has the potential not only to provide insight into the genomic potential and ecological role of soil microorganisms–cultivated or not–but also to provide enzymes with biotechnological applications. This was demonstrated by comparative sequence analysis and expression in *E. coli* of biotin biosynthesis operons recovered from various soil enrichment cultures by direct cloning of total DNA (284).

FINAL COMMENTS

This article has attempted to provide an overview of the current cultivation-independent state-of-the-art methodological toolbox used to describe phylogenetic and functional diversity, structural composition and dynamics, and metabolic activities of soil microbial communities. New methods developed during the last few years or currently under development might soon be added to those described here. One candidate is quantitative PCR, which can be used to determine the exact number of functional or phylogenetic target genes in a sample (e.g., the TaqMan technique (285)). However, development of a bias-free application of quantitative PCR to environmental samples is still not complete (286,287). Another technique with great potential is the hybridization of fluorescently labeled total RNA to microarrays of immobilized rRNA-targeted oligonucleotide probes. This technique may soon allow a rapid and detailed assessment of the diversity and activity of microbial communities (288,289).

Various aspects of soil microbial diversity have been covered by other reviews, which we recommend because they nicely complement the present article. These reviews have focused on the exploration of bacterial diversity and functioning in relation to bioindication in agroecosystems (290,291) and on the impact of chemical pollutants on soil microbial diversity (290,292,293). Finally, an argument in favor of adopting a natural species concept for prokaryotes (294), that is, one that takes the ecological niche into consideration, is also recommended for further reading.

BIOFILM DETACHMENT

BRUCE E. RITTMANN
CHRYSI S. LASPIDOU
Northwestern University
Evanston, Illinois

A biofilm consists of microorganisms attached to a solid surface called the substratum (1–7). Usually, the microbial cells are embedded in a matrix of organic polymers produced by the cells. Biofilms are ubiquitous in nature and are increasingly important in engineered processes. Some biofilms are viewed as "good," and we try to promote their accumulation. Examples of good biofilms include those that are exploited in fixed-film processes used to treat contaminated water, wastewater, and air (4,5,8), those that attach to stream beds and aquatic vegetation, leading to self-purification of water bodies (9), and those responsible for engineered or intrinsic bioremediation of contaminated groundwater (5,8,10). Other biofilms are viewed as "bad," and we try to remove or prevent them. Bad biofilms include those that foul ship hulls and pipelines, thereby increasing friction loss and corrosion, those that cause "souring" of oil wells, and those that cause medical problems, such as dental caries and infection related to implants (1,2,6,7).

Biofilms are highly diverse (1,3,4,11). Some are physically very thin, consisting only of small clusters of cells on a substratum. Other biofilms are quite thick, having a depth of as much as a few millimeters. While the physical structure of some biofilms is dense and homogenous, other biofilms are physically heterogeneous and have clusters or streamers of biomass intermingled with open channels (11). While single-species biofilms are useful for research studies, naturally occurring biofilms often show

a high degree of ecological diversity that can exhibit fascinating layering or sub-clustering.

One of the reasons that biofilms are so diverse is that many processes occur together as the biofilm forms (2,12): for example, microbial growth and death, attachment, and detachment. Furthermore, biofilms are characterized by strong gradients (2,5,8). Thus, the processes occur in very different ways at the outer surface of the biofilm, compared to near the substratum.

The subject of this article is biofilm detachment, which is the physical movement of microbial cells from the biofilm matrix. Detachment results in a loss of material from the biofilm, and these materials generally move to the liquid that is in contact with the biofilm. The article begins by describing the ways in which detachment can occur. Then, it discusses why detachment is such an important process for understanding and controlling biofilms. Finally, the article summarizes what is known about how forces acting on the biofilm and physiology of the microorganisms in the biofilm affect detachment rates.

Whether the goal is to encourage or discourage biofilm accumulation, detachment is one of the key determinants for how much biofilm accumulates, as well as its physical and microbiological characteristics. Biofilm detachment is an emerging research field. Although some broad concepts are coming into view, most of what needs to be known about what affects detachment rates will be discovered in the future. This article provides a structure for comprehending how physical forces and physiology interact to control biofilm determinant.

DETACHMENT PATTERNS

Detachment can occur with three broad patterns. The first pattern is erosion, which is a continuous process by which relatively small pieces of biofilm are removed from the biofilm's outer surface (2,8,12,13). Each erosion event has a small impact on the biofilm, but, because the events occur continuously, erosion can be a significant loss mechanism.

The second pattern, sloughing, is an abrupt, intermittent loss of a large segment of the biofilm (2,8,12,13). The sloughed segment extends deep into the biofilm, often all the way to the substratum. One sloughing event can cause a profound change to the physical and microbiological structure of the biofilm. Sloughing is associated with a breakdown of the structural integrity of the biofilm, allowing a "fault" to occur along lines of structural weakness. Figure 1 illustrates the difference between the erosion and sloughing mechanisms of detachment.

The third pattern can be termed scouring, and it involves removal of large segments of biofilm through the action of very strong physical forces, such as abrasion or scraping. Predation (sometimes called grazing) also removes biofilm mass, but we do not include it among the detachment mechanisms reviewed in this article.

IMPORTANCE OF DETACHMENT AND ITS PATTERN

Biofilm Accumulation

The most obvious impact of detachment is to control the total amount of biofilm present. The total mass of biofilm per unit of substratum surface area is called biofilm accumulation, and it can be represented mathematically by $X_f L_f$, in which X_f is the biomass density of the biofilm (mg biomass/cm^3) and L_f is the biofilm thickness (cm) (8,14). The accumulation results from a balance among gain by synthesis from substrate (food) utilization, loss by decay (or death), and loss by detachment. For a steady-state biofilm, that balance leads to (8,14)

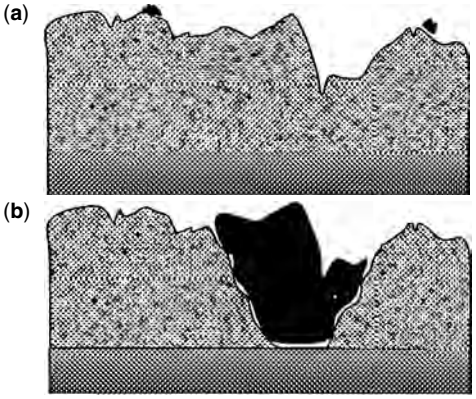

Figure 1. Schematic of two detachment mechanisms: (**a**) erosion and (**b**) sloughing.

$$X_f L_f = \frac{YJ}{b + b_{det}} \tag{1}$$

in which Y = true yield of biomass synthesized per substrate utilized (mg biomass/mg substrate), J = flux of substrate into the biofilm (mg substrate/cm^2 – d), b = specific decay rate (d^{-1}), and b_{det} = specific detachment rate (d^{-1}).

Equation 1 makes it clear that the amount of biofilm present on the surface ($X_f L_f$) increases if more food is available (making J larger) or if the detachment rate (b_{det}) is smaller. For situations in which biofilm accumulation is to be encouraged (say, to treat wastewater), b_{det} may have to be decreased. On the other hand, when biofilm accumulation is to be decreased (say, to minimize fouling or infection), it may be preferred to increase b_{det}.

In principle, biofilms are totally eliminated if the substrate concentration is so low that the positive growth rate from synthesis is always less than the sum of the loss rates from decay and detachment. This threshold concentration is called S_{min}, and it can be computed from (8,14):

$$S_{min} = K \frac{b + b_{det}}{Yq_{max} - (b + b_{det})} \tag{2}$$

in which K = the Monod half-maximum-rate concentration (mg substrate/cm^3), and q_{max} = the maximum specific rate of substrate utilization (mg substrate/mg biomass – d). The major trend is that increasing b_{det} makes S_{min} larger, thereby making it more difficult to sustain a biofilm.

Average Specific Growth Rate and Activity

Communities of slowly growing microorganisms accumulate a significant amount of inactive or inert solids because

low substrate concentration and endogenous decay lead to a residue of "dead" or "dormant" biomass (8). The inert solids also include extracellular polymeric substances (EPS) that hold the biofilm together and tend to accumulate most near the substratum. Therefore, slowly growing communities are less "active" than are fast-growing communities in which less inert biomass accumulates.

For steady-state biofilms, the average specific growth rate (μ_{ave}, d^{-1}) is equal to the specific detachment rate (8), or $\mu_{ave} = b_{det}$. Thus, the metabolic activity of a biofilm is controlled strongly by the detachment rate (8,15–21). Low detachment rates lead to biofilms having a low average specific growth rate and being enriched in inactive biomass.

Ecological Selection

Detachment rates and patterns affect ecological selection in profound ways. In multispecies biofilms, the most slowly growing species tend to accumulate deep inside the biofilm when erosion is the detachment pattern (15–21). Being deep inside the biofilm protects them from detachment losses that occur from the outer surface. Protection effectively lowers b_{det} for these slow growers, which increases their $X_f L_f$ (Eq. 1) and decreases their S_{min} (Eq. 2) (11).

Detachment by erosion leads to a layering of microbial types. The fastest growing species predominate near the outer surface, where they have the advantage of the best access to their substrate. On the other hand, the slowest growers predominate well away from the outer surface, where they have the advantage of protection from erosion. Examples of this sort of layering include heterotrophs protecting nitrifiers in aerobic biofilms (15,9) and sulfate-reducers protecting methanogens in anaerobic biofilms. The slowest growing "species" is the inert biomass produced as part of endogenous decay or dormancy; it predominates at the substratum (22).

In the short term, an increased rate of erosion removes the fastest growing, most active biomass, which resides near the outer surface. However, more erosion of active bacteria from the outer surface allows the substrate to penetrate deeper into the biofilm. This may activate dormant bacteria near the substratum, and it causes the active bacteria near the substratum to grow faster, which gradually pushes the inert biomass to the outer surface, where it erodes (15). Therefore, the long-term effect of erosion is most profound on the slowest growing species. Although it requires some time for the full effects to be realized, an increase to the specific erosion rate lowers the accumulation of slow growers (including the inert of biomass) most dramatically (15).

When detachment is by sloughing or scouring, the layering effects associated with erosion may be reduced or eliminated. Detachment that extends down to the substratum removes all types of biomass. These detachment patterns can be quite devastating to slow-growing species (such as nitrifiers), whose survival in the biofilm depends on protection from detachment.

Suspended Biomass Concentration

When biofilms dominate the biomass accumulation in a system, the concentration of suspended microorganisms is controlled by the rate of detachment from the biofilm. This is expressed mathematically as

$$\Delta X = b_{det} X_f L_f A / Q \tag{3}$$

in which ΔX = the steady state increase in suspended-biomass concentration caused by detachment (mg biomass/cm^3), A = the surface area of the biofilm (cm^2), and Q = the volumetric flow rate (cm^3/d). Equation (3) makes it clear that increasing b_{det} or A/Q makes biofilm detachment a more dominant influence on the concentration of suspended microorganisms.

Substratum Properties

As detachment decreases and $X_f L_f$ becomes larger, the physical and chemical characteristics of the substratum can be altered. Examples of changes to substrata are

- increased diameters and decreased density of substratum particles, such as sand and activated carbon (20,23–25);
- decreased flow-path sizes in pipes and channels;
- increased friction losses in pipes, channels, and porous media (26,27);
- decreased or increased surface roughness (2,27,28);
- changes to surface charge or hydrophobicity; and
- increased heat-transfer resistance (2,7).

FACTORS AFFECTING DETACHMENT RATES

What controls biofilm detachment is far from well understood today. Detachment is an active research area that generates conflicting points of view. Three characteristics of the field lead to today's tumultuous state.

1. Biofilms are incredibly diverse in terms of substrata, hydrodynamics, microbial ecology, and substrate loading. The controlling mechanisms surely differ widely from one system to another. Thus, one common "detachment theory" should not be expected.
2. Experimental methods to measure the biofilm properties relevant to detachment are primitive.
3. Theoretical models for linking observed detachment rates to biofilm properties are crude. So far, these connections rely mostly on statistical correlations, rather than mechanistic principles.

Despite much uncertainty, detachment is not totally mysterious. Certain factors that affect detachment rates are emerging, and they are the subjects of this section. The factors can be grouped into two categories: physical forces acting on the biofilm and the physiology of the microorganisms in the biofilm.

Physical Forces

The first factor recognized to affect the detachment rate is the tangential shear stress (29), τ (dyne/cm^2). Shear stress is proportional to the friction losses for water passing by the substratum, and it acts at the biofilm's outer surface. In general, a greater shear stress increases the detachment rate, although the effect is not necessarily linear. Bakke and coworkers (30) and Peyton and Characklis (31) found an approximately linear relationship between b_{det} and τ, although there was considerable variation. Rittmann (32) found that b_{det} was proportional to $\tau^{0.58}$ for thin biofilms ($L_f \leq 30$ μm), and Chang and Rittmann (28) found that this relationship was quantitatively accurate for biofilms on smooth surfaces. When the biofilm was thicker than 30 μm, the specific detachment rate declined, presumably because the biomass deep in the biofilm was protected from erosion (29). When the biofilm was grown on a highly irregular surface, b_{det} was essentially zero until the biofilm accumulated enough to fill the crevices that protected it from shear stress (28). Once the biofilm fully covered the surface, the detachment rate was similar to that of smooth surface (28).

The several studies that examined shear stress show that it is an important factor for determining b_{det} as long as the biofilm is actually exposed to the shear stress and other factors do not overwhelm it. Protection of all (28) or part (29) of the biofilm from the shear stress can result in substantially reduced detachment rates. Likewise, the effects of shear stress can be "swamped" by other factors. For example, Chang and coworkers (32) saw that b_{det} was inversely correlated to τ for fluidized-bed biofilm reactors. This correlation was the result of other factors (discussed in the following section) controlling b_{det}, $X_f L_f$, and τ.

The second factor that affects the detachment rate is the axial force acting on a biofilm. This force could be realized as tensile or compressive stress, σ (dyne/cm^2), which acts axially on the biofilm. Such stresses can occur through two main mechanisms: abrasion, caused by collisions with other particles, and pressure fluctuations, caused by turbulent eddies (Fig. 2).

Abrasion effects were studied by varying the carrier concentration (C_p, g/l) in a fluidized-bed biofilm reactor (32). Using C_p as a measure of the frequency of particle-to-particle contacts, Chang and coworkers (32) showed that b_{det} was strongly correlated to the abrasion intensity.

Turbulent effects can be gauged by the Reynolds number, $\mathrm{Re} = \upsilon\, L/\nu$, in which υ = the liquid velocity (cm^2/s), L = a characteristic size dimension, such as carrier diameter or pipe diameter (cm), and ν = the liquid's dynamic viscosity (cm^2/s). In the same fluidized-bed studies (32), b_{det} also correlated strongly with Re. Two other studies with fluidized beds confirmed a positive correlation between b_{det} and Re (24,25).

Turbulence effects can be greatly increased by adding energy inputs, such as from mechanical mixing or aeration. When fluidized-bed biofilm reactors were aerated to create a three-phase operation (20,23), the detachment rate increased significantly and was controlled primarily by the gas velocity, although C_p and Re were still significant.

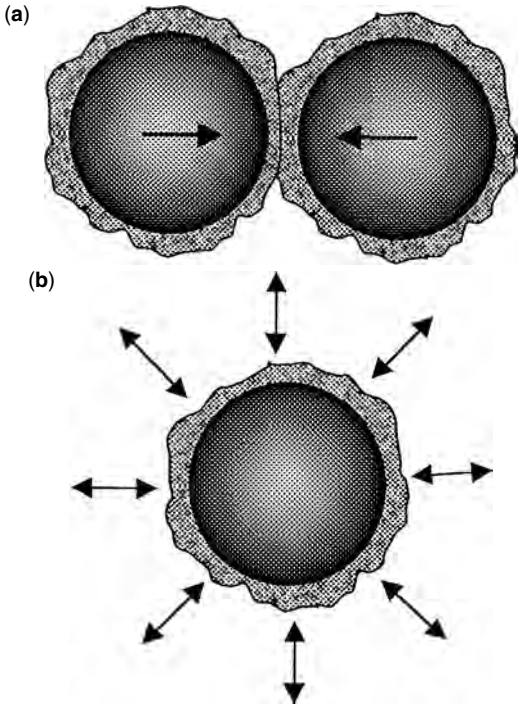

Figure 2. Graphic representation of the two main mechanisms through which axial stresses can occur on biofilm: (**a**) abrasion, shown as compressive forces acting on biofilm caused by the collision of two bioparticles, and (**b**) pressure fluctuations (represented by arrows) on a bioparticle caused by turbulent eddies.

The studies in which abrasion and/or turbulence created strong axial stress show that axial stress can overwhelm shear stress if the axial stress is large enough. For example, the specific detachment rate increased up to 25-fold over what was expected from shear stress alone in the two-phase fluidized bed (8,32). Aeration increased b_{det} by approximately another factor of 2 (8,23). Although the effect of abrasion can be profound, we have a weak basis for quantifying it or its impact on b_{det}.

Detachment is a structural failure of the biofilm matrix, which means that the stress at the point of failure exceeds the yield stress, σ_y. When the actual stress in the biofilm exceeds σ_y, the biofilm breaks. Several groups have measured yield stresses by different methods. Ohashi and Harada (33) applied tensile stress and found σ_y in the range of 0 to 1,750 N/m^2.

Two models have been proposed to explain the way in which the biofilm matrix behaves as the shear stress approaches σ_y. One model (33) views the biofilm matrix as a Bingham fluid (34), a useful concept in polymer science. A Bingham fluid exhibits non-Newtonian behavior. For stresses less than the Bingham yield stress, τ_0, it does not deform. When the stress reaches τ_0, the Bingham fluid flows with a viscosity that depends on τ_0.

The second model (35) views the biofilm matrix as a viscoelastic structure, which can be characterized by an elastic (Young's) modulus (E) and a shear modulus (G). E is the ratio of the applied axial stress to the strain (ε) caused by extension of the material (Fig. 3). G is the ratio of the

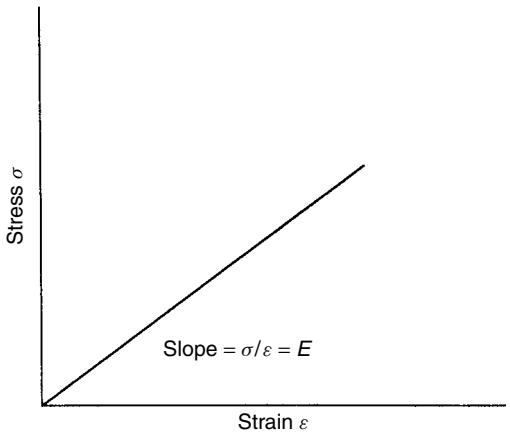

Figure 3. The stess-strain curve of a material, which defines its Young's modulus E.

applied shear stress to the shear strain caused by bending the material. Strain is the ratio of the distortion distance (ΔL) to the total length of the material (L), whereas shear strain is the gradient of deformation under shear. In an ideally elastic solid, strain is directly proportional to stress, and E or G is constant. If the stress is released, the solid returns to its original shape. Stoodley and coworkers (35) performed in situ deformation studies that gave average E and G values of 40 and 27 N/m^2, respectively.

Biofilms can also exhibit plastic behavior, which is a deviation from ideal elastic behavior. Plastic behavior can be viewed as the material "flowing" like a liquid that has a very large dynamic viscosity. Creep, an example of plastic behavior in biofilms (35), refers to the continued deformation of the material over time, although the applied stress is constant. On release of the stress, the plastic material that has undergone creep does not return to its original shape, but remains deformed. Creep probably occurs because intermolecular bonds between polymers in the biofilm matrix "unzip" gradually, allowing the molecules to slip past each other in viscous flow. When the stress is removed, the polymer strands contract and reaggregate with neighboring strands in a new position. Flemming and Wingender (36) have termed this sort of breaking and reforming of bonds "fluctuating adhesion points" and attributed it to the large number and widely ranging type of bonds formed by EPS. The formation of a new EPS may stabilize the new position further.

Physiology

The physiology of the microorganisms in the biofilm appears to affect the strength of the biofilm material and, therefore, detachment rate and pattern. Five physiological factors are reviewed: EPS, density, heterogeneity, specific growth rate, and quorum sensing.

EPS. The cells in a biofilm use EPS to adhere to each other and the substratum (37). The acronym EPS is sometimes used to mean extracellular polysaccharides, but this usage does not accurately represent the composition of the polymers. Although sugars are important in the EPS, proteins and nucleic acids are also key and may be more important in some cases (38,39). EPS formation is important in biofilm detachment because EPS forms the matrix that gives the biofilm structural integrity and its viscoelastic properties. It seems that EPS production depends on the substrate-consumption rate (40,41). Microorganisms seem to produce less EPS when rapidly consuming substrate. As the substrate concentration is higher near the outer surface of the biofilm, the EPS content may be lower there. As EPS is critical for cohesive strength, the outer part of the biofilm may be structurally weaker (e.g., a lower σ_y), and this may help explain how erosion comes about.

Biofilm Density. The density of the biofilm seems to play a crucial role in biofilm strength and detachment rate. In general, denser biofilms are stronger (e.g., a higher σ_y) and have smaller specific detachment rates (b_{det}). Ohashi and coworkers (42) found that the EPS content of the biofilm was directly proportional to the density. Kwok and coworkers (24), Chang and coworkers (32), and Nicolella and coworkers (25) found that thinner, denser biofilms had smaller b_{det} values. Stoodley and coworkers (35) found that E increased for biofilms exposed to increased shear stress.

Differences in biofilm density are often explained by assuming the presence of different types of microorganisms. However, evidence is strong that hydrodynamic conditions have a direct effect on biofilm density. Vieira and coworkers (43) showed that the density of a pure-culture biofilm increased with increasing shear stress on the biofilm. Chang and coworkers (32) and Kwok and coworkers (24) found that biofilms in fluidized-bed biofilm reactors became denser when the particle concentration (C_p), a surrogate for abrasion forces, was larger.

The evidence on the effects of shear stress and abrasion suggests that biofilms exposed to detachment forces adapt to become denser and stronger. How this adaptation occurs is not known. One hypothesis is that strong detachment forces remove low-density new growth from the outer surface (24). The continued removal of this less dense layer enables the substrate to diffuse into the inner biofilm layers, where microcolonies grow within the strong EPS matrix. A second hypothesis is that the microorganisms produce more and/or stronger EPS in response to the detachment force. This could occur by selecting for microorganisms that produce strong EPS (in multispecies biofilms) or by a regulatory response. A third hypothesis is that a denser biofilm is the result of a gradual displacement of loosely bound water out of the matrix.

Another factor that helps explain the differences in density across a biofilm is the buildup of inert solids, such as inactive biomass. Long-term operation with a long solid's retention time (i.e., a small b_{det}) allows inactive biomass solids to accumulate, particularly near the substratum. Mature biofilms, therefore, have a relatively large fraction of inactive volatile solids (20,23,42). Although inactive biomass cannot produce EPS, it may be well embedded in existing EPS, possible allowing a closer packing arrangement if loosely bound water can be squeezed out more easily. In fact, the EPS is probably part of the inert biomass.

Other inert solids that can build up deep in a biofilm are inorganic precipitates, including metal carbonates,

sulfates, sulfides, phosphates, and hydroxides. Often, these are formed because microbial reactions alter the chemistry within the biofilm and cause super-saturation for a solid phase (22,44–48). Precipitation of inorganic solids could create a very dense and strong structure (44), essentially "cementing" the biofilm in place. Alternately, inorganic deposits could make the biofilm brittle, perhaps making the biofilm susceptible to sloughing (35).

One very interesting adaptation finding (35) is on the importance of the shear stress applied during growth of the biofilm (τ_g). When exposed to other shear stresses, biofilms behaved as elastic solids when the applied τ was less than τ_g. However, they behaved like plastic fluids for $\tau > \tau_g$. In other words, τ_g was a good surrogate for the Bingham yield stress, τ_0. For, $\tau > \tau_g$, the elastic modulus (E) increased, indicating that the stiffness of the biofilm was increasing with strain once the biofilm became plastic.

Heterogeneity. Heterogeneity within the biofilm may affect the detachment mode. Ohashi and Harada (49) studied the in situ behavior of biofilm development and detachment using a video camera set up above an open-channel reactor in which they maintained uniform flow. They observed major sloughing events for mature biofilms. After 34 days of biofilm accumulation, massive sloughing events removed about 25% of the observable biofilms. They found that sloughing was associated with the formation of cavities within the biofilm.

Stoodley and coworkers (35,50) also used video imaging to evaluate the behavior of filamentous streamers that oscillate rapidly in the flow. These streamers cause increased head loss. The streamers exhibited hysteresis for high applied shear stress. Hysteresis was more evident near the base of the streamer than the tip. Streamers exposed to prolonged oscillations may experience fatigue, which involves thinning and finally detachment. Fatigue failure requires some time; as a result, it may be possible for the microorganisms to produce EPS that repairs small "cracks" or "thin regions." However, it probably will be unable to repair cracks or thin regions that result from high frequency oscillations.

As a biofilm grows on the substratum, it starts with sparsely distributed cell clusters. If the clusters grow together, they create a relatively planar biofilm. The shear and axial stresses acting on individual cell clusters will vary until the biofilm "fills in." If the clusters are far enough apart, the velocity and stress profiles around the clusters can reestablish between clusters so that each cluster experiences similar stresses. The roughness of the clusters may increase shear stress and turbulence. On the other hand, when the clusters are close together, clusters in the "wake" behind an upstream cluster may experience significantly different stresses than the upstream cluster. Once the biofilm fills in to become more or less planar, the surface may be hydrodynamically smoother, causing the shear stress and turbulence to decline. Therefore, shear and axial stresses depend on the degree of surface coverage by the biofilm and the distribution pattern of clusters in heterogeneous biofilms.

Specific Growth Rate. The specific growth rate (μ) of microorganisms in the biofilm has been implicated as a key factor affecting the detachment rate (31,51,52). This relationship appears reasonable based on the observation that EPS formation is inversely related to the substrate-utilization rate (40,41). However, conclusions about the role of the specific growth rate must be viewed cautiously because the average specific growth rate for a steady-state biofilm equals the specific detachment rate: $\mu_{ave} = b_{det}$. This equality opens up the possibility that observations of a relationship between μ_{ave} and b_{det} are a tautology, not cause and effect.

Some studies suggest that a high μ is not responsible for high detachment rates. Sawyer and Hermanawicz (53) report an inverse relationship between detachment rate and substrate availability. Gjaltema and coworkers (54) found that the effect of C_p on the detachment rate in fluidized beds differed depending on substrate availability. When substrate was available to give high biofilm growth rates, increasing C_p resulted in a slower detachment rate, a finding consistent with others (24,25,32). When substrate was not available for growth, a higher C_p caused a faster detachment rate.

Quorum Sensing. The final physiological factor is quorum sensing, which involves chemical signals by which microorganisms communicate with each other (55,56). Certain bacteria continually produce signal molecules, particularly homoserine lactones. When the density of bacteria is high enough in an aggregate (such as a biofilm), the signal molecule achieves a high enough concentration that it triggers a rapid community response. One known response is to control aggregation or disaggregation of biofilms of *Pseudomonas aeruginosa* (55). Although the range of applicability of quorum sensing is undefined, it could dramatically increase or decrease detachment for situations in which it acts.

CONCLUSION

Detachment is one of the most important phenomena affecting the accumulation, physical properties, and ecology of biofilms. The physical and physiological factors that control detachment are just beginning to come into view, and this article defines a framework for designing and interpreting the research that will illuminate detachment. Understanding detachment is at the core of answering fundamental questions about biofilms: for example, Why do some have an open structure, while others are dense? Why do biofilms sometimes experience massive sloughing events, while others only erode? How do physical forces interact with biochemical reactions to control where different microorganisms reside in a biofilm?

BIOFILMS: BACTERIAL-FUNGAL BIOFILMS

SARA K. ROBERTS
HILARY M. LAPPIN-SCOTT
University of Exeter
Exeter, United Kingdom

Naturally occurring biofilms comprise a variety of different organisms including bacteria, fungi, algae, and protozoa. Costerton and coworkers (1) commented on the ubiquitous nature of bacterial biofilms, and although they are less studied, so too are bacterial-fungal biofilms. There are many definitions of a biofilm; however these definitions generally only refer to bacterial biofilms. Attempts have been made recently to account for the presence of other organisms. For the purpose of this review, a biofilm is defined as microbial cells immobilized at an interface, surrounded by an exopolymeric matrix of microbial origin. The simplest biofilm model to study is the monoculture or pure culture biofilm. This model alone offers numerous avenues for research, so the possibilities in studying mixed organism biofilms are vast. This in part may explain why bacterial-fungal biofilms are so little studied. Fungi play an important role in the biodeterioration of materials: They are implicated in several nosocomial infections and are associated with other health issues, and they are used in many industrial and biotechnological processes. The importance of understanding mixed organism biofilm formation, especially with the emergence of nosocomial infections and problems to industry, is apparent. The aim of this article is to discuss our current understanding of bacterial-fungal biofilms and to examine methods for their study. It is also the aim to highlight areas of bacterial-fungal biofilm dynamics that necessitate further investigation.

DEVELOPMENT OF BACTERIAL-FUNGAL BIOFILMS

In order to discuss bacterial-fungal biofilms, it is important to briefly mention the fundamental differences between bacteria and fungi. Fungi are eukaryotic organisms and can be differentiated from bacteria by the fact that fungal cells are normally larger and contain a nucleus, vacuoles, and mitochondria. Collectively, fungi are a large group of functionally diverse species and can be classified into three groups of major practical importance: moulds, yeasts, and mushrooms.

In spite of the variation in the definitions available to describe biofilms, and the inherent heterogeneity of biofilms, reports of biofilms always describe the following: A biofilm is always associated with a surface-interface at which cells accumulate and biofilm microorganisms produce an exopolymer matrix within which the cells are enclosed. There are a number of factors that will affect bacterial-fungal biofilm formation and development. To date it is assumed that the same factors that affect bacterial biofilm formation will also affect bacterial-fungal biofilm formation. These include biological factors, including competition, chemical factors, including the nature of the surface, and physical factors, including flow conditions. It is not the aim of this article to describe these factors in great detail but to describe the events that lead to bacterial-fungal biofilm formation (Fig. 1).

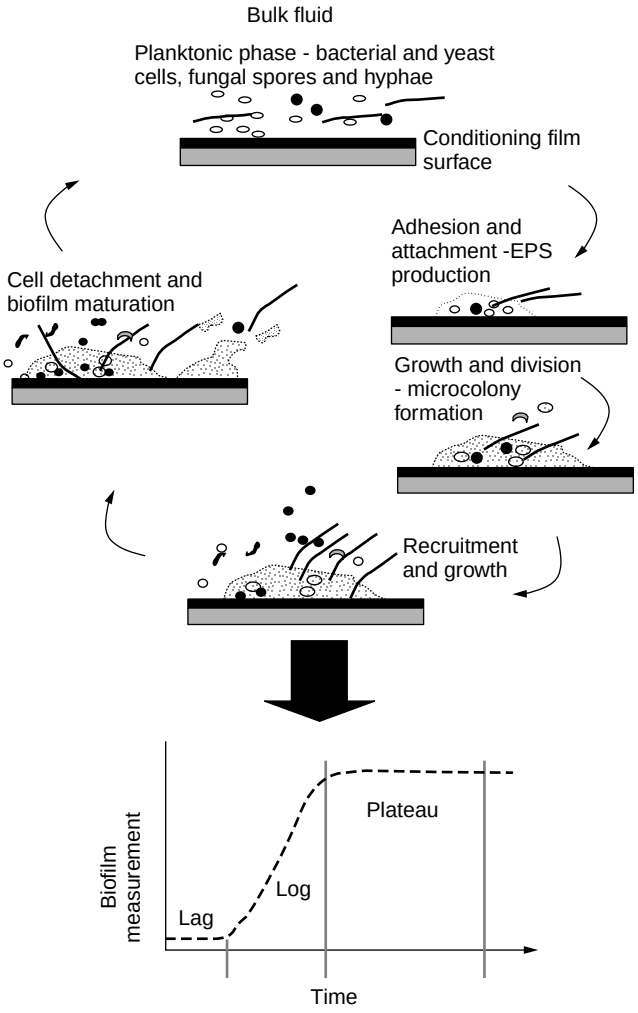

Figure 1. A schematic illustration proposing the life cycle and growth pattern, typically a sigmoidal growth curve, of a mixed organism biofilm.

The conditioning film is a crucial component in the attachment of cells to a surface. When a surface is exposed to the environment, for example, in aqueous systems, a layer of organic deposits, including proteins and humic acids, forms. This is termed the conditioning film. Molecules and small particles ($<0.01-0.1$ μm) rapidly adhere to the surface and can induce changes in the surface properties. These range from the acquisition of a net negative charge to changes in the hydrophobicity of the surface. The composition of the conditioning film will vary with the type of surface and the environment. It is generally assumed, though with no conclusive evidence that the conditioning film across the surface is uniform in both composition and coverage. It has been proposed that the strength of biofilm formation becomes dependent on the cohesiveness of the conditioning film to the surface, rather, than on the direct bacterial contact with the bare substratum surface (2).

Most surfaces and cells have a net negative charge; therefore, when a cell comes into contact with a surface,

a repulsion barrier is established between the cell and the surface. For attachment to take place this must be overcome. There are a number of attractive forces, including van der Waals forces and hydrogen bonding, which play a role in bacterial attachment but are less defined for fungal cells. The three step mechanism proposed by Busscher and Weerkamp (3) takes into account the different forces, which arise at different stages of attachment. This hypothesis is based on the distance between the cell and the surface. At distances greater than 50 nm only van der Waals forces operate; this stage is reversible. At distances between 10 and 20 nm both van der Waals forces and electrostatic repulsion forces are active. Adhesion at this stage is initially reversible but has the potential to become irreversible. In the third stage, where the separation distance is less than 15 nm van der Waals forces, electrostatic forces, and specific interactions, including the production of adhesive exopolysaccharides lead to irreversible bonding of the cell to the conditioning film/surface.

Fungi have been described as excellent colonizers of surfaces (4). Fungal adhesion has a number of stages that appear to be in common with bacterial biofilm formation. Spores, like bacteria, have a negative surface potential. Consequently, the adhesion of fungal cells to a surface is subject to the same electrostatic forces operating with bacteria. The initial contact of fungal spores to a surface may be described as passive, when spores are entrapped or adhere to a surface by appendages, and active when the spore is stimulated to produce adhesive mucilage (5). Spores may become entrapped on jagged surfaces where they are held by physical forces. Passive attachment may be mediated by a number of spore appendages including mucilaginous sheaths, hamate, or caplike appendages, which unfurl to form viscous threads, sticky appendages surrounding the spore, and tufts of fibrillar appendages.

Fungal spores, like bacteria, make repeated contact with surfaces. Fungi are thigmotropic, that is, they have the ability to respond to localized physical contact, and as a result the fungus is able to release spore adhesins on contact with a surface, which then attaches it to the surface. The chemical structure of the adhesins range from only carbohydrate or protein to a mixture of protein and carbohydrate. Once attached to a surface, the fungal spore swells by adsorption of water, and germ-tubes develop and elongate to form young hyphae. Both the germ-tube and hyphae are enveloped in a mucilaginous sheath. This mucilaginous sheath has been likened to the exopolymeric substances produced by bacteria, and is believed to play a similar role including anchorage, protection from desiccation, adhesion sites for other microorganisms and serving as a source of support and nutrition (5). Aquatic hyphomycetes have been shown to be specifically adapted to their habitat by having a high germination rate and the production of tetraradiate, branched, and filiform spores. The yeast *Candida albicans* produces pseudohyphae, which not only provide anchorage for the cells but also produce exoenzymes that aid in the penetration of the cell to tissue lining. It may be that all fungi have specific adaptations to their habitat but as yet many remain undiscovered. These habitat specific appendages may limit the colonization and attachment of the fungi to a specific environment and it may be that the habitat induces the expression of certain phenotypes. The success of biofilm formation, pure culture or otherwise, is therefore dependent on the success of the organism to adapt to its environment.

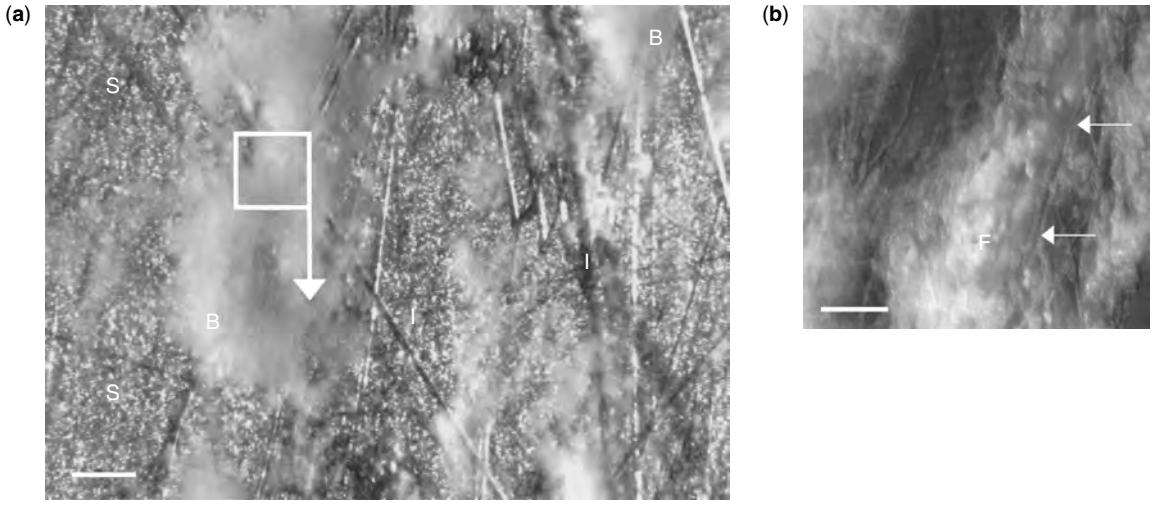

Figure 2. A mixed organism biofilm after 7 h growth on stainless steel using image analysis. The biofilm consisted of seven organisms isolated from an industrial system: *Stenotrophomonas maltophilia*, *Pseudomonas alcaligenes*, *Flavobacterium indologenes*, *Alcaligenes denitrificans*, *Rhodotorula glutinis*, *F. oxysporum*, and *F. solani*. (**a**) **B**, biofilm; **I**, interstitial channels; **M**, microcolony; **S**, stainless steel surface. Bar = 200 μm. (**b**) by varying the plane of focus different section of the biofilm microcolony can be visualised. **F**, fungal biomass; arrows indicate mycelial network. Bar = 50 μm.

Investigations into the development a biofilm has revealed that a typical three-stage sigmoidal growth curve occurs, much the same as a planktonic growth curve. The model proposed by Bryers and Characklis (6) consists of (*1*) initial biofilm formation (lag); (*2*) exponential accumulation (log) and (*3*) steady state (plateau phase) (Fig. 1). It is not known whether a hierarchical order of colonization exists between bacteria and fungi. However, the complexity of naturally occurring biofilms suggests that this would occur. It is recognized that the order in which cells attach to a surface may affect the attachment of other cells; it has been demonstrated that this is a species-specific event and would depend on the nature of the surface (7). However, once the biofilm has reached steady state conditions, the order of colonization may not be of great importance compared with its overall function.

BACTERIAL-FUNGAL BIOFILM ARCHITECTURE

The range of biofilm structures that have been identified vary from a thin layer of attached cells to more complex attached communities containing multiple species interacting with each other. Biofilm structure and architecture is strongly connected to the function required for the survival and maintenance of the microorganisms within and has been shown to be linked strongly to nutrient availability and flow conditions (8) (Fig. 3 and Fig. 4).

As yet, there is no consensus model for the structure of a typical biofilm. Initially a two-dimensional model for biofilm formation was proposed (9). With the increased knowledge of biofilm structure it has become apparent that biofilms are inherently heterogeneous, so three-dimensional models depicting biofilm structure have also been put forward (10). Research has shown that there are many conditions, which contribute to biofilm architecture and structure. The combination of species specificity dictating biofilm architecture and the different variables, which also influence biofilm structure, means that it is virtually impossible to obtain a consensus biofilm model. In practice different models are available for different growth conditions and a **consensus** of variables that influence biofilm architecture.

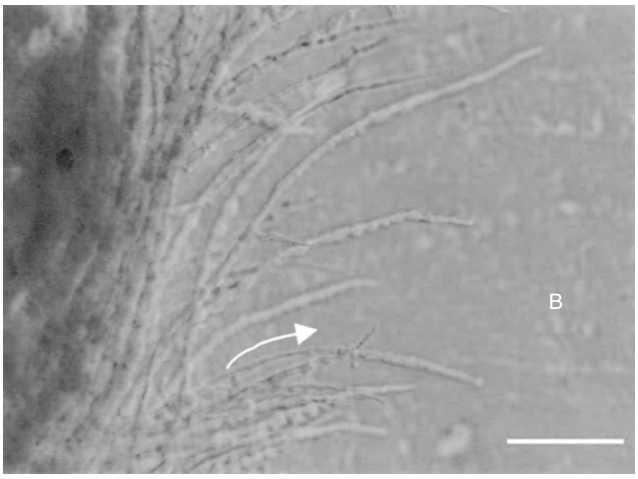

Figure 3. Filamentous fungal attachment (*Fusarium oxysporum* and *Fusarium solani*) to a PVC surface in flowing conditions. The fungal mycelia are positioned in the direction of flow (indicated by arrow). **B**, bulk fluid; **S**, PVC surface. Bar = 50 μm.

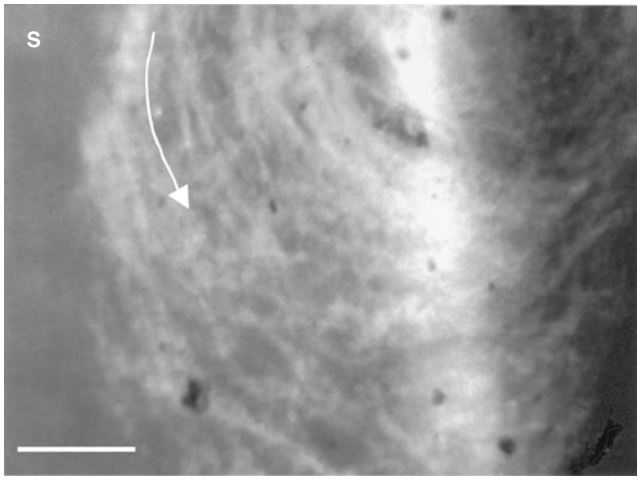

Figure 4. Filamentous fungal attachment (*F. oxysporum* and *F. solani*) to a PVC surface in flowing conditions. The fungal hyphae extend out into the bulk fluid and are positioned in the direction of flow (indicated by arrow). **B**, bulk fluid; **F**, fungal hyphae. Bar = 50 μm.

CHARACTERIZING BACTERIAL-FUNGAL BIOFILMS

Mixed organism biofilms can be described as diverse functioning communities. A community describes an association of interacting populations, usually defined by the nature of their interaction or the place where they live (11). The development of a mixed biofilm leads to a variety of complex relationships involving interspecies and intraspecies interactions. The number of interactions increases when there are more species within the mixed population. The simplest interaction model consists of a two-membered, or binary, population. In this scenario there are only three possible responses that a growing population can make to the presence of a second population, that is, beneficial, detrimental, or neutral (12). The interactions can occur in a reciprocal manner and the outcome consists of a maximum of six types of interaction: neutralism, mutualism, commensalism, amensalism, predator-prey relationships and competition (Table 1). However, another classification can be added to include a direct interaction, if it involves physical contact between individuals, or indirect if the nonliving environment is a necessary intermediary between the two populations (13). The binary system is useful for defining simple interactions; however, in natural communities, interactions will be more complex, and more than one type can occur with one species.

Although biofilms are considered in terms of microbial ecology, the complex nature of mixed organism biofilms necessitates descriptions, which are applied to macroecology. By measuring the diversity of a community, both the variety of species and the relative abundance of each

Table 1. Interaction Terms Used to Describe the Effect That One Population Has on Another

Interaction	Description
Neutralism	Occurs when neither population is affected by the presence of the other
Mutualism	Occurs when both members derive some advantage by the presence of the other population
Commensalism	Occurs when one member of the population benefits and the other member does not
Amensalism	Occurs when the growth of one of the populations is restricted and the second population is unaffected
Predator-prey	Occurs when one member gains directly at the expense of another
Competition	Occurs when both populations are limited in terms of growth or final population size by a common dependence on an external factor required for growth

species is taken into account. It has previously been discussed that many microorganisms exhibit certain traits that are particular to a habitat, and habitat specialization increases in direct relation to diversity. That is, the more diverse a habitat, the more diverse are the organisms. If a habitat is highly specialized, then diversity is decreased but habitat specialization is increased. Diversity indices have been devised to express the diversity of sample by using a single number. The most frequently used is the simple totaling of species numbers to give species richness (14). One of the indices that combine species richness with relative abundance is the Shannon diversity index (15). This method could be used to assess not only the diversity of a sample but to also to monitor the effect of disturbance to a system, for example, an antimicrobial regime or predation.

The reason that certain species grow together in a particular environment will usually be because they have similar requirements for existence in terms of environmental factors such as nutrient availability and temperature. If species do grow in association with each other, many of them should have similar responses and tolerances to environmental pressures. Over a period of time, community composition will often change according to the principles of succession. Succession involves the immigration and extinction of species together with changes in their relative abundances. Primary succession occurs on a bare surface. Organisms that are the first to colonize an area are termed *primary colonizers* and several successive groups of species, termed *secondary* and *tertiary colonizers*, will then establish. The end result of succession is known as a climax community. These stages are in common with the stages involved in microbial colonization of a surface. Populations within a community may cycle quite regularly and population cycles will vary from species to species. The degree of variation in the size of the population depends on both the magnitude of disturbance and on the inherent stability of the population. When a mixed organism biofilm reaches steady state or a climax community it could be said that if all parameters remain constant and there is no disturbance to the system that it is a stable community.

THE OCCURRENCE OF BACTERIAL-FUNGAL BIOFILMS

Most habitats contain a wide structural and functional diversity of microorganisms, which is in part related to the heterogeneity of the habitat and the evolution of species, which exist there. Presently there are limited reports describing bacterial-fungal biofilms, although this is changing rapidly. Bacterial-fungal biofilms have been isolated from a range of diverse locations including photoprocessing tanks (16), automobile air conditioning systems (17) and even the black slime that appears on the base of shower curtains is teeming with bacteria and fungi. There are many other habitats that are currently being investigated with respect to microbial adhesion and biofilms; These include soil particles, plant surfaces, and animal guts. Microbial adhesion and physiology are much more difficult to investigate in these habitats because of their diversity and range of conditions and knowledge of these areas should increase with advancing technology. The reader should also be made aware that in many examples describing bacterial biofilms the surrounding environment will invariably consist of other organisms and these will include fungi. It should also be noted that in the literature, bacteria and especially fungi are discussed without reference to a biofilm mode of growth when it is highly likely that in nature they will exist within a biofilm.

Biofilms play an integral role in the system in which they are present and are considered to either have a beneficial or detrimental effect on that system. The terms fouling and biofouling describe the presence of undesired surface associated microbial growth and are used frequently in the scientific literature. The uncontrolled and undesirable accumulation of biofilms in medical and industrial systems has three primary effects: physical damage, for example, corrosion and tooth decay; decrease in the function of the system, for example, reduced efficiency of heat exchangers, and the establishment of a reservoir for potential pathogens.

Medical Bacterial-Fungal Biofilms

Many recurrent infections are associated with bacterial biofilms and because of the nature of the medical environment, these infections are mainly attributed to a single species. Any medical implant ranging from a catheter to a replacement heart valve has the potential to be colonized by bacteria and fungi. Detachment of the organisms from the biofilm often results in septicaemia, which may be responsive to drug therapy; however the biofilm generally is not so responsive and therefore acts as a continuous source of infection. As a result, implant-associated infections are difficult to treat and in most cases the implant must be removed.

The occurrence of monoculture biofilms in the medical environment is well documented and there are now reports emerging concerning the infectious nature of fungal biofilms. Many fungi that are now increasingly responsible for nosocomial infections were previously thought to be of low virulence. The increase in the number of fungal-associated infections is related to the increase in the use of antibiotics. There are many examples of pathogenic fungi in the literature, for example, *C. albicans* and *C. neoformans*. It is unlikely, however, that in a medical environment the causative agent of infection would be attributed to bacterial-fungal biofilms. Infections are caused separately by bacteria and fungi, and presently it is considered extremely rare if found otherwise, although reports have demonstrated that *C. albicans* is the dominant and causative organism in a bacterial-fungal biofilm isolated from a voice prosthesis. However, with the increase in antibiotic resistance it may not be long before bacterial-fungal biofilms are the combined causative agents of infection.

Biofilm formation by *C. albicans* has generated much interest because it is a major fungal pathogen of humans and can be fatal to immunocompromised patients, for example, those with acquired immunodeficiency syndrome (AIDS). *Candida albicans* is a dimorphic, diploid fungus. The pathogenicity of this fungus is thought to be related to the production of pseudohyphae. The pseudohyphae produce exoenzymes, which penetrate cell tissue and medical implants. Analysis of *C. albicans* biofilms have shown that it consists of a dense network of yeasts, hyphae, and pseudohyphae (18). Another adaptive mechanism exhibited by *C. albicans* is the existence of different strains within the same location. The ability of the organism to achieve this is thought to be governed by its genetic makeup. There is no sexual stage associated with this fungus and it has what are termed as specific repetitive sequences, which contribute to the organism's ability to increase strain variation. It is likely that the biofilm mode of growth enhances the pathogenicity and recalcitrance of *C. albicans* by offering protection from antimicrobial agents and by facilitating the optimum utilization of nutrients.

Dental biofilms are also examples of mixed organism biofilms. Colonization of the oral cavity is a continuous process. The relatively smooth surfaces of the teeth are exposed to frequent mechanical cleaning by the tongue, cheek, saliva, or toothbrush; however, these actions have proved ineffective at preventing tooth decay/biofilm removal alone. The very structure of teeth, a nonshedding surface, favors the retention of food and thus provides numerous sites for harboring dental biofilms and it has been reported that there are between 200 to 500 resident bacterial species in the mouth. Species of *Candida* including *C. albicans* have also been isolated from dental biofilms. It has been found that the initial attachment of bacteria to the conditioning film is relatively species-specific and involves the cooperation and coaggregation of only a few gram-positive streptococci including *Streptococcus sanguis*, *S. sobrinus*, *S. mutans* and *S. mitis* (19,20). The growth of this microbial film encourages the proliferation of other organisms including filamentous gram-negative *Fusobacterium* species (*Fusobacterium nucleatum*) and spirochetes such as *Borrelia* species. Dental biofilms illustrate the complex nature of mixed organism biofilms and highlight some of the aspects covered in the literature.

Environmental and Industrial Bacterial-Fungal Biofilms

Biofilms that accumulate on suspended particles in rivers, lakes, and marine systems are considered beneficial to their environments because they play an essential purification role by removing suspended, settled, and dissolved organic material. Freeman and coworkers (21) described river biofilms as a trophic link between dissolved nutrients in the water column and the higher trophic levels of the ecosystem. These river biofilms possess the ability to trap nutrients by ion exchange processes and thereby increase the nutrient concentration within the biofilm. Natural biofilms are able to biodegrade organic compounds and transform inorganic compounds as part of their natural metabolic pathway. The role of bacterial-fungal biofilms in the degradation of environmental pollutants is not well understood. The ability of fungi to degrade environmental pollutants has been well documented but these studies rarely include a biofilm model. It is assumed that in a natural environment such as the soil habitat, bacteria, and fungi do form biofilms (22) and therefore the degradation of environmental pollutants occurs in a biofilm state where it is also assumed that there is a higher level of enzyme activity. The degradative capabilities of biofilms have been exploited in wastewater treatment systems including trickling filters and fixed or fluidized bed reactors. Such systems are based on particles that provide a large surface area for biofilm formation. The mixed biofilms that develop on these surfaces break down a wide range of chemical substances found in wastewater.

Bacterial-fungal biofilms have been recognized to play a role in the accelerated deterioration of buildings, including the well known and dreaded dry rot fungus. The degree of colonization and subsequent deterioration is dependent on the moisture content of the construction materials. The formation of bacterial-fungal biofilms in buildings has many serious health implications including the harboring of allergenic fungal and actinomycete spores. *Stachybotrys atra* grows on damp wallpaper and other domestic surfaces. It produces potent macrocyclic trichothecene toxins and is associated with chronic health problems. The building can also act as a reservoir for diseases including Legionnaire's disease. It is important therefore that the potential to form bacterial-fungal biofilms is assessed in the architectural design and that plans should include minimizing the ingress of water into the building construct.

In industrial systems, biofilms are particularly deleterious because of their ability to corrode the surface with which they are associated, a phenomenon known as microbial induced corrosion (MIC). The corrosion of metal ships, pipelines, and oil rigs is an extremely costly problem. Marine biofilms that form on ship hulls increase drag and frictional forces, which results in an increase in fuel consumption and a decrease in engine efficiency. In water distribution pipelines the formation of biofilms reduces

the pipe diameter, which affects flow and in cooling systems an estimated £500 million annually is lost due to an inefficient operating system.

CONTROL OF BACTERIAL-FUNGAL BIOFILMS

The control of biofilms has generated a huge commercial market in designing and developing new antimicrobial regimes. A wide variety of biofilm control strategies have been tested with varying degrees of success. There are two main approaches to the control of biofilms: the prevention of initial colonization and subsequent biofouling, and the development of removal/control strategies against an existing biofilm. Biocides and antibiotics have been incorporated into different surfaces in an attempt to prevent microbial colonization. However, to date these types of control strategies tend only to prevent biofilm formation for a limited period and subsequent biofouling occurs as if there was no antimicrobial agent in place. Present day control strategies of industrial biofilms are aimed at maintaining partial control and a minimum contamination level. In many cases, infection by antibiotic-resistant organisms, for example, methycilin resistant *Staphylococcus aureus* and vancomycin resistant *Enterococcus faecium*, biofilm eradication is not achieved and infection is fatal. Fatalities in these incidences are higher in immunocompromised patients. The ultimate aim is obviously to design an antimicrobial regime that will permanently prevent biofouling. This control strategy would be one that was entirely specific for the target organisms and would have no other detrimental effect. This is currently a problem that needs to be addressed. For example, infections caused by *C. albicans* can be treated with antifungal antibiotics including amphotericin B, however, the effect of the antibiotic on the patient often has more serious side effects than the original infection. Paints that have been used to protect ship hulls have been shown to have an irreversibly detrimental effect on marine life, namely, in generations of dog whelks, which have lost the ability to reproduce.

Antimicrobial agents may exert what are termed static or cidal effects although the mechanism of action of each may differ (23). The term static is used to describe the prevention or inhibition of growth by an antimicrobial agent measured under conditions in which growth would normally occur. The effect is reversible as removal or neutralization of the agent will allow the cell to reestablish growth. Cidal effects are the result of damage to cellular structures and function and cidal effects are irreparable and irreversible. In order for the antimicrobial compound to have its desired effect, the compound must be taken up by the cell, move to the target sites and then react with the target site. Different antimicrobial agents have different modes of action and it would be impossible to cover them all within this chapter. It is common practice to use a combination of antimicrobial agents to achieve a synergistic effect, for example, to use a combination of antibiotics, which will have a complimentary and enhanced effect without disrupting the mode of action of either of the antibiotic. This is referred to as combination therapy.

Once any type of biofilm is established in a system, complete eradication is very difficult and in some instances irremediable. The biggest problem associated with the control of biofilms is that biofilm cells are less susceptible to antimicrobial agents than their planktonic counterparts. The mechanisms for this increased resistance remains to be elucidated. The production of exopolymeric substances by biofilm cells are believed to play an important role in the protection of the cells from antimicrobial agents and was thought to be the basis of biofilm resistance (24). It is now believed by many research groups that the reduced penetration of antimicrobial agents through the extracellular polymers are insufficient to account for much of the observed resistance (24,25). There is no doubt that the exopolymeric matrix can function as an ion exchange column and excludes large, highly charged molecules; however, most solutes will equilibrate across it and access the resident population (24). The extent of penetration and concentration of the antimicrobial agent that reaches the population is dependent on the thickness of the biofilm. This is a transport limitation phenomenon common to control strategies, which aim to remove an established biofilm.

In addition to the physical barriers that a biofilm presents, individual cells possess structures, which prevent the biocide reaching its target(s). In the case of gram-negative bacteria the presence of the lipopolysaccharide cell envelope wall offers a supplementary barrier. This structure has a significant moderating influence on the penetration of both hydrophilic and hydrophobic molecules, establishing a molecular weight cutoff for the passage of molecules through water filled pores (porins) and requiring optimum lipophilic properties for the progress of hydrophobic biocides (23,26,27). The walls of fungal hyphae and spores also contain a variety of components, which help protect them from chemical treatment. Melanin components are chemically very stable and are frequently found in many surface moulds. The production of melanin in the cell wall in response to an antimicrobial regime has been shown to contribute to the resistance of fungal hyphae to lytic enzymes (28), oxidizing agents such as hypochlorite (29), and radiation (30). Regardless of cell wall structure, all cellular components offer opportunities for nonspecific binding of the antimicrobial agent, thereby depleting the chemical challenge (23).

Another problem that is of primary concern for the control of fungal biofilms is their location. Many types of fungi, such as the moulds, are found to grow on the interior and exterior of most buildings and the success of colonization by these fungi is related to the moisture content of the building construct. If a building is poorly insulated there will be an increase in the amount of condensation produced, which in turn will increase the diversity of the biofilm. Introducing equipment such as dehumidifiers into the home environment is not always a practical solution. Fungi are able to penetrate deeply into the building construct and emerge on wallpaper and wood, and it is not always possible because of safety reasons to provide a chemical solution for domestic purposes. The

areas of contamination may also be located in places that are not suitable for disinfection on a daily basis.

There are many other proposed mechanisms, which are thought to play a crucial role in the protection of biofilm cells from an antimicrobial regime. It is thought that because of the structure of the biofilm, nutrient gradients will exist where cells located in the upper sections of the biofilm will be exposed to higher levels of nutrients compared to those cells located at the surface, which are assumed to be exposed to less nutrient rich conditions. This will affect a number of physiological actions including enzyme activity. As a result, the growth rate of the biofilm is believed to be slower than planktonic cells, which have the high doubling-time capacity. Other defensive mechanisms activated by bacteria and fungi in response to stressful conditions include the viable but nonculturable state (bacterial) and the production of spores.

It is widely recognized that bacteria exposed to stressful conditions experience what is termed as sub lethal injury. This is when a cell maintains minimal metabolic activity but viability is still retained. The genes that are thought to regulate these responses are expressed on entry to stationary growth phase where a slow growth rate would allow the cell an adaptation period to many stressful conditions including antimicrobial regimes and heat shock. In order to monitor the success of an antimicrobial regime, an accurate recovery protocol must be established to take into account cells that are stressed. Quantification of cells in a stressed state by conventional methods, including plate counts, may lead to the underestimation of the level of contamination.

METHODS TO STUDY BACTERIAL-FUNGAL BIOFILMS

It has been common practice in the past to directly compare laboratory planktonic data directly to biofilm conditions based on the assumption that there was no difference between planktonic and biofilm cultures. It is now widely accepted that this is not the case. If the level of contamination in industrial systems was assessed by monitoring the number of planktonic cells, a serious underestimate of the level of contamination would ensue as it has been reported that typically for every one planktonic bacterium there are between 1,000 and 10,000 cells attached to the surface (31).

The ultimate aim in designing any experimental apparatus is to include the major components of the system under investigation so as to provide the most accurate model possible. Table 2 highlights some of the measurements that can be evaluated from experimental model biofilms. The results obtained would then be more reflective of in vivo conditions. In practice, most experimental biofilm models only represent certain aspects of a system under investigation and tend to fall into in to two main categories: replicative, which encompass a wide range of complex environmental variables, and investigative, which are usually simpler and enable the control of a variety of influencing factors (32,33). The techniques used to study biofilms can either be destructive, which involves the disruption and destruction of the biofilm, or they are nondestructive, which permits the monitoring of the biofilm in its natural state. There are currently a wide range of experimental models available to study biofilms and it is not our aim to discuss them all, but rather to discuss those that would be significant in increasing our understanding of bacterial-fungal biofilms.

The Modified Robbins Device (MRD, Fig. 5) was initially developed to study biofouling in industrial pipelines (34). Since then it has been used to study biofilms from a number of different systems. The MRD consists of an enclosed lumen with 25 replaceable sampling studs. Different surfaces can be attached to the studs and removed for analysis by a number of different techniques. The MRD can

Table 2. Examples of Some of the Measurements That Can Be Assessed from Experimental Model Biofilms

Measurement		Method
Microbial activity	Viable cell counts Metabolic activity	Culture techniques ATP levels Fluorescent staining Molecular techniques
Biofilm constituents	Exopolysaccharide	Protein content Total carbohydrate Fluorescent staining
Biofilm growth	Thickness Biomass Quantification Surface area	Image analysis Culture techniques Fluorescent staining
Biofilm formation	Structure Development	Microscopy — Image analysis — Scanning electron microscopy — Transmission electron microscopy — Confocal scanning laser microscopy — Environmental scanning electron microscopy — Fluorescent microscopy

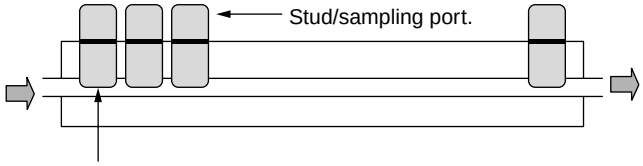

Figure 5. Diagrammatic representation of an MRD showing direction of flow (block arrows) and position of studs.

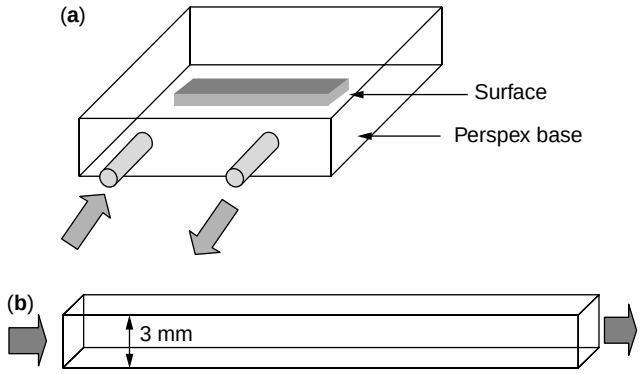

Figure 6. Diagrammatic representation of (**a**) a flat plate reactor and (**b**) a square glass tube reactor. Block arrows indicate direction of flow. The required reactor would be place on a microscope stage and images captured via a camera and analysed using the appropriate software.

be incorporated into a variety of experimental models such as a batch recirculating and flow through culture systems. It can be connected to a chemostat as a recirculating or flow through culture system, which would allow the control of growth conditions and thereby permit the assessment of growth rate as a function of biofilm resistance.

The main drawback with the MRD system is that it is a destructive technique and involves scraping of the biofilm for analysis of biofilm accumulation and metabolic counts. Other drawbacks with the MRD system are the inability to visualize the biofilm in situ, and possible nutrient gradients along the length of the lumen from the inlet to the outlet. Hydrodynamics around the sampling stud may also be compromised (35). Nevertheless, the information obtained from the MRD model is valuable and allows comparisons to be drawn with other techniques.

Although valuable information can be obtained from models that involve the disruption of the biofilm, the continuous and nondestructive analysis of biofilms is essential in understanding biofilm processes (36). In situ monitoring techniques have advanced with recent developments in image analysis technology. The advantages of this technique include the monitoring of the biofilm in a hydrated state, and real-time analysis. Using digital image capture, accumulation rates can be calculated by comparing captured images with those at the outset of the experiment, allowing quantification of the growth kinetics of the biofilm; qualitative information regarding surface colonization is also possible (35). The flat plate reactor (Fig. 6) was developed at the Center for Biofilm Engineering, Bozeman, Montana. In this apparatus, different surfaces can be examined and compared (35). The surface can also be removed for other types of analyses. The disadvantage of the flat plate reactor is that it is constrained by the channel thickness. This model of flow cell is limited by the nature of the working distances of the microscope objectives, resulting in a compromise between magnification and hydrodynamics (37). Use of the square glass tube reactor can overcome this problem and facilitates higher magnification of the biofilm, allowing the flow cell to be viewed from above (35). The square glass tube reactor flow cell (Fig. 6) was initially designed to replicate biofilm fouling in industrial pipelines. Stoodley and coworkers (38) have characterized the flow hydrodynamics of this system using the relationship between the friction factor and the Reynolds number, and found that they fit established equations describing laminar and turbulent flow through a smooth pipe. This system also permits visualization of biofilm formation under both laminar and turbulent flow concurrently (38).

Another technique that has also been instrumental in increasing our understanding of biofilm formation and structure is confocal scanning laser microscopy (CLSM). CLSM operates using a krypton/argon laser, which excites fluorophore dyes present within the sample. The resulting fluorescence is detected by photomultiplier tubes and a digital image is obtained. Alteration of the focal depth (z plane) and the subsequent acquisition of the x-y plane images (parallel to the surface) enables a series of optical sections to be collected that are then processed by a computer using image analysis software to create a three-dimensional image. CLSM is an effective tool to study a wide range of biofilm features, which include physiological profiles and structural heterogeneity that would be particularly pertinent to mixed organism biofilms. CLSM permits the visualization of biofilm formation in situ and therefore allows the study of the biofilm in its natural hydrated state. A number of other techniques could also be used in combination, including microelectrodes to monitor pH, and oxygen and nutrient gradients, resulting in a comprehensive profile of the biofilm. Biofilms that have been examined using CLSM are shown to be heterogeneous and consist of microcolonies or cell clusters separated by interstitial voids and channels (8). These channels have been shown to act as transport channels (39) and therefore the use of CLSM would allow the study of transport phenomenon within the biofilm, which would be relevant in assessing the delivery of an antimicrobial agent to the biofilm.

It has been previously discussed that microorganisms are not culturable by traditional culture methods. Recent advances in molecular biology have circumvented this problem. These methods include gene probing, DNA hybridization, polymerase chain reaction (PCR) and reporter gene technology. In 1994, a novel marker system, the green fluorescent protein (GFP) became available (40). The GFP is a 27-kDa polypeptide, which converts the blue

chemiluminescence of the Ca^{2+}-sensitive photoprotein, aequorin, into green light (40). This fluorescence was first observed in the jellyfish *Aequorea victoria*. GFP has been successfully used in eukaryotic systems and there are an increasing number of reports of the success that GFP has to prokaryotic systems. GFP is stable in the presence of many denaturants, high temperatures (65 °C) and a range of pH (6–12). It is therefore an attractive marker system to monitor individual cells within a biofilm. GFP is now commercially available in two other colors, red and yellow, and has also been applied to fungal cultures.

CONCLUSION

There still remains many aspects of bacterial-fungal biofilms to investigate. This paper has provided areas for discussion and has given insights into the complex nature of studying mixed organism biofilms. Characterizing bacterial-fungal biofilms in terms of macroecology may aid our understanding of such heterogeneous communities. Fungal colonization of a surface has many stages in common with bacteria, including the production of exopolymeric substances. Bacterial-fungal biofilms cause considerable problems in many systems, particularly within industry. They may act as a source of pathogens and because of their inherent resistance to many antimicrobial regimes are a serious health hazard. The treatment of bacterial-fungal biofilms is additionally problematic because the biofilm cells have an altered physiology and morphology, which promotes their success in a particular habitat. The advances in technology are aiding in our understanding of biofilms with the ultimate aim to control biofilm formation in the first instance.

The concept of bacterial behavior and growth has long been influenced by studies of bacteria grown in liquid culture in the laboratory. In natural and engineered aquatic systems, however, microorganisms tend to grow preferentially in organized communities at almost all available interfaces. These organized structures, which are best defined as "cells immobilized at a substratum and frequently embedded in an organic polymer matrix of microbial origin" (1), are commonly referred to as biofilms. Costerton and coworkers (2) later broadened the definition to include microbial aggregates in the free-water phase ("matrix-enclosed bacterial populations adherent to each other and/or to surfaces or interfaces"), however, the widespread occurrence and importance of eukaryotic microorganisms in biofilms is neglected in this definition. Biofilms are ubiquitous in all aquatic habitats, ranging from thick cyanobacterial mats, biofilms covering stones and pebbles in rivers and lakes, immobilized cells in wastewater treatment reactors, surface-associated growth in drinking water distribution systems, to biofilms of medical relevance, such as dental plaque, bacterial growth on gut endothelial cells or on artificial implants.

Unlike bacteria multiplying as single cells in the planktonic phase, biofilm bacteria grow in a highly structured microenvironment, where diffusion of substances is affected by the properties of the biofilm and where metabolic interactions, cellular communication, and genetic exchange are facilitated by the close and ordered spatial arrangement of the cells (3,4). Biofilm bacteria are, to a certain extent, sheltered from harmful substances such as disinfectants, antibiotics, antibodies, toxins, and also from viruses. Bacterial growth rates are often enhanced within biofilms because of the accumulation of nutrients at interfaces and the cooperative mobilization of nutrients by different organisms of the microbial community. Thus, microbiologists have to study biofilm communities (1–4) to catch a glimpse of the true nature of microbial communities in the environment.

BIOFILM COMPONENTS

The structure and composition of biofilms can vary widely, depending on the environmental conditions and the population structure of the microbial community. The extracellular polymeric substances (EPS) excreted by the attached bacterial population, forming a slimy, highly hydrated matrix that acts as glue for all biofilm components, should certainly be regarded as a key constituent of biofilms. EPS generally consist of polysaccharides, proteins, nucleic acids, and heterogeneous polymeric compounds (5). The volume of the EPS matrix, in which the microorganisms are embedded, normally clearly exceeds the volume of the cells. Because of the reduced diffusion of substances, the EPS matrix acts as a protective barrier against harmful chemical compounds and viruses, retains extracellular enzymes, and leads to the establishment of gradients across the biofilm (6).

Bacteria generally form the dominant population, but eukaryotic organisms are also present in most biofilms, although they have been less extensively studied than the prokaryotic community. These protozoa have an important function as predators, influencing not only biofilm thickness and structure but also the species composition of the bacterial population (7). Apart from protozoa, fungi can occur in biofilms, as can algae in phototrophic biofilms. Although the EPS matrix was thought to prevent viruses from infecting biofilm bacteria, bacteriophages were recently found to be able to infect cells and multiply in single-species laboratory biofilms (8,9). Most biofilms are dominated by organic matter, namely microbial cells and their excretions, and usually to a minor extent by depositions of inorganic material like quartz grains and iron particles. In some cases, however, biofilms can also be largely dominated by inorganic compounds. In drinking water biofilms, for example, certain types of bacteria can be responsible for massive deposits of iron and manganese particles (7).

FORMATION AND STRUCTURE OF BIOFILMS

Colonization of Surfaces and Biofilm Development

The physicochemical properties of a surface submersed in an aquatic system not only influence the adsorption of organic molecules and ions to the surface, the so-called "antenna-effect," but also affect bacterial adhesion (10,11).

Bacteria in aquatic systems can reach a surface either by random Brownian displacement, by fluid dynamic forces transporting small particles to the viscous boundary layer at a surface, by random flagellar- or pili-based motility, or by active chemotactic movement toward the nutrient-enriched layer at the surface. The initial contact is followed by reversible or irreversible adhesion of the cell to the surface. To describe this process, the Derjaguin-Landau and Verwey-Overbeek (DLVO) theory, which was developed for colloid chemistry and describes changes in Gibbs energy of interaction as a function of the distance between two objects, has been invoked. In contrast to colloid particles, bacteria might play a more active role in adhesion because of cellular appendages such as fimbriae, flagella, pili, cell surface adhesins, and because of their motility. At small distances of separation, short-range forces such as hydrogen bonding and ion forces become effective. The physiological status of a cell can have a significant influence on its attachment behavior, although the effect may differ from species to species. Starved cells often show reduced motility, changes in cell surface hydrophobicity, and a reduction in cell size. For starved cells, both increased and decreased ability for adhesion has been reported (12,13), and these differences might be due to species-specific behavior and to differing starvation conditions generated in the experiments. Bos and coworkers (14) have discussed the initial interactions of microorganisms with surfaces and the various methods for studying adhesion, aggregation, and coadhesion.

Exopolymers produced by the adherent cells accumulate and act as glue between cells and the surface and lead to an irreversible attachment of the bacteria (6,15). Colonization of the surface may then proceed in a number of ways, depending on surface characteristics and on the colonization behavior of the attached species (16). For example, in streams, a range of colonization behaviors have been described, including formation of tightly packed, spreading, or branching colonies (17). In the marine environment, a *Psychrobacter* sp. initially formed microcolonies, followed by the development of compact, multilayered biofilms at hydrophobic surfaces but developed only long, multicellular chains at hydrophilic surfaces (18). Time-lapse microscopy was used and *Pseudomonas aeruginosa* was found to initially form a monolayer of cells on the surface, followed by formation of microcolonies through aggregation of cells from the monolayer, which led to a biofilm structure of dispersed microcolonies in the monolayer of cells (19). In highly oligotrophic systems, like drinking water or seawater, biofilms can be restricted to a monolayer of cells (20,21).

Structure of Mature Biofilms

The structure of mature biofilms in natural or engineered systems is as diverse as the habitats themselves, ranging from thin monolayers of dispersed cells in extremely oligotrophic habitats such as drinking water distribution systems, patchy arrangements of matrix-embedded cell clusters interspersed with water-filled channels observed in many natural ecosystems, and in laboratory model biofilms, to the layered, densely packed biofilms, forming cyanobacterial mats or dental plaque. The architecture of biofilms is controlled by many parameters. The kind and concentration of nutrients present in a habitat certainly has a tremendous impact on biofilm thickness and overall structure (22), as well as on the species composition of the microbial community. Mass transfer of nutrients, metabolites or inhibitors, diffusion of oxygen, salts, and ions create gradients across the biofilm and induce the formation of microniches, influencing microbial growth rates, production of extrapolymeric substances, and interactions between the microorganisms. Hydrodynamic forces can become important in shaping the biofilm architecture. When grown under turbulent flow conditions, where high-shear forces act on the biofilm, structural changes from loose cell aggregates toward streamlined filaments and ripples can be observed. It has also been shown that structural rearrangements occur within biofilms in response to environmental conditions, that is, turbulent flow (23). Moreover, the microorganisms themselves shape their environment. Eukaryotic predators, including amoebae and other protozoa, and bacterial parasites such as *Bdellovibrio* spp. may control the biomass and species composition of biofilms. Bacterial shape, motility, production of extracellular polymers, and cell signaling between bacteria, all play a crucial part for the architecture of mature biofilms. Substratum properties such as hydrophobicity, roughness, and electrostatic forces, on the other hand, play a substantial role in the initial stages of biofilm formation but appear to be less significant in established, steady state biofilms.

Detachment and Dispersal

(see Biofilm Detachment, this Encyclopedia)

Hydrodynamic forces, which influence the biofilm structure, are mainly responsible for the detachment and sloughing off of clumps of cells or small parts of the biofilm. These large particles will be transported by the flow and sediment or attach to a substratum when flow conditions permit it, thus contributing to the colonization of new surfaces. Biofilms, however, are not only subjected to passive detachment processes. Several studies have demonstrated that individual cells might actively leave biofilms. Cell division can cause the active detachment of cells, involving different dispersal strategies, with daughter cells leaving the biofilm, whereas the parental cell remains firmly attached (17,24) or detachment taking place during cell division, followed by dispersal or reattachment (25).

Genetics of Biofilm Formation

Attachment of bacteria is thought to induce an alteration of bacterial gene expression and metabolic activity. A positive effect of surfaces on bacterial growth had already been observed in the 1930s (26). Cells grown on solid surfaces or on agar show physiological properties and behaviors that are quite different from cells growing in the liquid phase; a striking example is the coordinated multicellular

behavior displayed in swarmer cell formation of bacteria such as *Serratia liquefaciens* (27), or induction of lateral flagella in *Vibrio parahaemolyticus* (28). Molecular tools applied in pure culture studies have helped to identify a number of genes required for biofilm formation and genes with altered levels of expression between sessile and planktonic growth. Genes whose expression is altered in biofilms can be identified by using gene reporter technology (29), whereas genes with an essential function in biofilm formation can be detected by random transposon mutagenesis, followed by screening for biofilm formation defective mutants and determination of the genes involved (30).

Altered gene expression has been reported for *Escherichia coli* by analysis with reporter genes. Expression of 38% of the genes was found to be affected by growth within biofilms. Some genes such as a gene involved in flagellin synthesis, were downregulated in sessile bacteria. Other cellular components showed enhanced expression; examples are the OmpC porin, the high-affinity transport system of glycine betaine, the colanic acid exopolysaccharide, tripeptidase T, and the nickel high-affinity transport system (31). These changes in gene expression show that bacteria rapidly adapt to the environmental conditions encountered in a biofilm, where osmolarity and cell density are increased, and oxygen less available.

Genes with an essential function for biofilm formation have been discovered by isolation of mutant bacteria and analysis of the affected genes. Biofilm formation can be triggered by external environmental cues and by bacterial cell-cell signaling, which is also important in the establishment of the complex three-dimensional structure of biofilms. For the initial stages of biofilm formation, motility mediated by flagella or pili is essential, whereas adhesins and EPS play a crucial role for interactions between cells and between cells and the surface (32).

The significance of cell signaling has been recently demonstrated for a *Pseudomonas aeruginosa* mutant, which had a mutation in the *lasI* gene. LasI directs the synthesis of an acylated homoserine lactone (AHL), which acts as a signaling molecule between cells and activates the transcriptional activator LasR. The mutant *P. aeruginosa* could only form flat, undifferentiated biofilms, which showed an increased sensitivity toward a biocide. When a synthetic signal molecule was added, biofilm growth appeared to be normal (33). In *Serratia liquefaciens*, swarming motility has been found to be controlled by two separate regulons, the *fhlDC* operon, a flagellar master regulator, and the *swrI* gene, a putative homoserine lactone synthase. It appears that the AHL cell-signaling system controls the production of an extracellular biosurfactant, which enables swarm cells to travel on top of surfaces and facilitates the movement of differentiated swarm cells, whereas swarm cell differentiation itself (i.e., cell elongation and hyperflagellation) is controlled by the *flhDC* operon (27). As mentioned in the preceding section, environmental cues such as nutrient availability, not only affect the metabolic status of cells but also biofilm formation. In *P. aeruginosa*, a mutation in the catabolite repression control (Crc) protein causes an inability to build biofilms: the mutant strain forms only a dispersed monolayer of cells and does not develop the dense monolayer punctuated by microcolonies typical of the wild-type strain. This phenotype had so far been observed in type-IV pilus mutants, which were defective for twitching motility. Apparently, the Crc protein acts as part of a signal transduction pathway that regulates, among other traits, pilus expression and thereby biofilm development (34).

Flagellar-mediated motility has been demonstrated as an important factor in biofilm development for a number of gram-negative bacteria including *E. coli*, *P. aeruginosa*, *P. fluorescens*, and *Vibrio cholerae*. For each of these organisms, mutations in genes involved in flagellar-mediated motility hindered biofilm formation. Apart from motility based on flagella action, twitching motility has been found to be essential for *P. aeruginosa* biofilm formation. Twitching motility is based on type-IV pili and seems to be widespread among gram-negative bacteria. Twitching plays a role in the establishment of biofilm structure, especially in the formation of microcolonies, whereas flagellar action apparently is necessary to generate cell surface contacts. Motility-defective mutants might, however, regain their biofilm formation capacity by mutations in other genes such as the *ompR* gene discussed in the following section, or they can be restored by addition of specific nutrients (32).

The ability to adhere to a surface or to another cell is crucial for the formation of biofilms. For example, cell-cell (intra or interspecific or multigeneric) coaggregation among biofilm bacteria has been shown to be significant in a number of systems including aquatic habitats (35). Mutant strains of *Staphylococcus epidermidis* have been isolated, which were affected in their primary attachment to polystyrene, but remained able to form multilayered cell clusters. These mutants lacked four cell surface proteins, which are postulated to function as adhesins. Other mutants were defective for intercellular adhesion and thus unable to form cell clusters and biofilms as a result of a failure to produce a specific polysaccharide (36). A mutant strain of *E. coli* has been isolated, which showed an increased biofilm-forming ability compared to classical laboratory strains. The mutant *E. coli* displayed a single point mutation in the regulatory protein OmpR, resulting in an increased expression of the particular fimbriae type Curli. Apparently, Curli acts as a cell surface adhesin and is under the control of the EnvZ-OmpR two-component regulatory system (37). Other examples are genes coding for the mannose-sensitive type I pilus and the pilus adhesin FimH, which are essential for *E. coli* biofilm formation or the mannose-sensitive hemagglutinin pilus in a *V. cholerae* strain (32). For *P. aeruginosa*, genes of the alginate synthesis pathway were found to be upregulated on attachment and biofilm formation, and expression of a putative alternative sigma factor required for expression of the critical alginate biosynthetic gene *algD* has been reported (38,39). Alginate is produced in large quantities by mucoid *P. aeruginosa* strains, which is a critical pathogenic determinant during chronic infections in cystic fibrosis patients. In a *V. cholerae* strain, production of an exopolysaccharide encoded by the

vps locus confers biofilm-forming capacity and chlorine resistance. Mutations within this locus result in an inability to form biofilms (40).

IDENTIFICATION OF BIOFILM BACTERIA

(see BIOFILMS: BACTERIAL-FUNGAL BIOFILMS, this Encyclopedia)

rRNA-Based Phylogeny and In Situ Hybridization

The most remarkable recent advance in microbiology was undoubtedly the development of molecular tools for the identification and in situ detection of bacteria based on their evolutionary history. Sequencing of ribosomal RNA (rRNA) genes from diverse organisms, which revealed the tripartite organization of life according to the domains Bacteria, Archaea, and Eucarya, eventually led to the design of short, labeled oligonucleotide probes complementary to specific target sites on 16S or 23S prokaryotic rRNA. Ribosomal RNAs contain highly conserved and variable sequence regions, which together with the natural amplification effect due to their high copy number in the cell, makes them ideally suited for in situ hybridizations with oligonucleotide probes, targeting phylogenetic groups ranging from domains to species (41,42).

For a first analysis of the phylogenetic diversity of a microbial biofilm community, in situ hybridizations with already existing probes are performed in a top-to-bottom approach, where oligonucleotides with increasing phylogenetic narrowness will be applied. If a complete analysis of the microbial community is attempted, bulk DNA is extracted from the habitat, rRNA amplified by PCR with universal primers, subcloned, subjected to DNA-sequencing, and finally compared to existing sequences in published databases. However, the data thus obtained have to be interpreted with caution because of the possibility of amplification and cloning biases, resulting in misjudgments of species abundances or the formation of chimeric artifacts (43). The sequencing data can subsequently serve for the design of new hybridization probes and their application in the microbial community, thus obtaining quantitative information on the population composition. Hybridization probes also allow the monitoring of enrichment cultures and enable the isolation of specific species of interest.

Fingerprinting Techniques: DGGE and RFLP

DNA strands of the same length but different sequences can be separated by exploiting differences in their migration behavior in denaturing gradient gel electrophoresis (DGGE). Genes coding for 16S rRNAs obtained by PCR amplification procedures from microbial communities can be subjected to this technique. The banding patterns or "fingerprints" thus obtained offer the possibility to rapidly detect changes in population structures of microbial communities. Apart from the visualization of such profiles, specific DNA bands of interest can be excised and further analyzed by DNA sequencing (44). DGGE has been successfully applied to investigate principles of microbial community ecology in a hot spring microbial mat (45), which is presented in more detail in the following section on examples of natural biofilms.

As an alternative to the DGGE technique, restriction fragment length polymorphism (RFLP) analysis of rRNA genes amplified from microbial communities can be applied to obtain specific fingerprints. After amplification and subcloning of the PCR products, RFLP patterns for the rRNA clones are determined with restriction endonucleases (46). Alternatively, RFLP patterns can be obtained for total 16S rRNA from a microbial community (47). A modification to the RFLP technique, termed *terminal-RFLP* (T-RFLP), consists of labeling one of the PCR primers, followed by restriction digestion and fragment detection by capillary electrophoresis, where only the end-labeled fragment of each PCR product is detected. DGGE and T-RFLP have been compared in a recent study, revealing that although both techniques show similar results, T-RFLP was more sensitive than DGGE (47). Because both techniques rely on PCR-procedures, they are subject to the same problems as cloning procedures with regard to chimeric sequences and quantification of species abundance.

Detection of Known Bacterial Strains

For the detection of known cultivated bacteria in microbial biofilm communities, the application of labeled antibodies or species-directed PCR procedures might be useful. Both methods, which depend on the prior cultivation of the species of interest, are mainly used for the detection of pathogenic bacterial species. Thus, *Legionella pneumophila* could be visualized by immunogold- or fluorescein-labeled monoclonal antibodies in drinking water biofilms (48). Problems with the use of antibodies in natural biofilms are posed by hindrance of antibody penetration into the biofilm and possible cross-reactivity with antigens presented by other species.

PCR procedures are helpful if the bacteria of interest are suspected to be present in such low numbers that detection by antibodies, in situ probing, or fingerprinting is impossible. Examples of this include detection of *Helicobacter* spp. or *Mycobacterium* spp. by rRNA amplification from microbial communities in drinking water systems. Specific PCR can be coupled with dot-blot hybridizations, reducing the possibility of false-positive detection of pathogens (49,50). For the differentiation of a known pathogen from other closely related bacterial species, PCR amplification of specific genes, differentiating these strains from others can be a very useful tool. In a recent study, a multiplex PCR approach was developed for the simultaneous identification of *Listeria monocytogenes* and five other species of this genus, based on species-specific amplification of the *iap* gene (51).

Cultivation Strategies

Cultivation of bacteria from natural microbial communities usually yields less than 1% of the bacterial population, even though the proportion of metabolically active bacteria in situ far exceeds this percentage,

a phenomenon described as the "great plate-count anomaly" (52). Comparison between cultivation and in situ detection methods in different habitats revealed drastic cultivation-induced population shifts; the composition of the isolates obtained did not reflect the in situ population composition (45,53,54). In one case, however, bacteria able to form colonies on solid media were reported to account for a large fraction of the community (55). Although PCR-based studies hold the potential to describe microbial diversity without cultivation-dependent biases, it has to be kept in mind that this technique is subjected to its own limitations (43,45). Furthermore, cultivation is indispensable to correlate phylogenetic information with physiological properties of the respective organisms. Cultivation of in situ relevant bacterial species can be feasible if it is combined with and monitored by molecular identification techniques. In young drinking water biofilms, isolation of the dominant species was successful, based on findings gained by in situ probing and activity measurements, which had revealed that most of the bacteria were affiliated to the β-subclass of Proteobacteria and that most cells could utilize the medium used for cultivation in modified direct viable count assays (54). Kane and coworkers applied a probe designed for an environmentally derived rRNA sequence for the enrichment and isolation of a sulfate-reducing bacterium (56). In cyanobacterial mats, an organism with little numerical relevance was found to competitively exclude other species that were more dominant in situ, when in laboratory culture. Only by dilution of the inocula to extinction before enrichment, could these specific cyanobacteria that were highly relevant in situ, be recovered. Enrichments from highly diluted inocula also allowed the isolation of in situ abundant chemoorganotrophic bacteria from this environment (45). Ward and coworkers stress the point that the incongruity between culture and molecular methods should not lead to the conclusion that many or most bacteria in natural environments are "uncultivable" (45). They should rather be regarded as "uncultivated" because the most likely explanation for cultivation failures might be our inability to understand and reproduce the real environmental niches of bacterial species.

Different methods of bacterial identification in biofilms are summarized in Table 1.

Table 1. Methods of Bacterial Identification in Biofilms

Method	Parameter Measured	Level of Measurement
Light microscopy	Transmission of light	Individual cell
Epifluorescence microscopy	Emission of light	
Confocal laser scanning microscopy (CLSM)	Transmission, emission, and reflection of light	
Scanning electron microscopy (SEM)	Transmission and reflection of short-wavelength light and electron beams	
Environmental scanning electron microscopy (ESEM)		
Total cell count determination:	Fluorescence emission after binding of nucleic acid–specific fluorochromes	Individual cell
DAPI (4',6-diamidino-2-phenylindole)		
AO acridine orange		
Hoechst 33258		
Hoechst 33342		
SYTO stains		
SYTOX stains		
SYBR Green		
PicoGreen		
Propidium Iodide		
FISH (fluorescence in situ hybridization)	Fluorescence emission after hybridization of DNA-probes to ribosomal RNA	Individual cell
GFP (green fluorescent protein)	Fluorescence emission after expression of the GFP	Individual cell
Microcalorimetry	Heat originated from microbial metabolism	Community
FTIR spectroscopy	Absorption spectra (amide I and II bands of proteins) obtained by their attenuated total reflection	Individual cell
RFLP (restriction fragment length polymorphism)	Fragment lengths after restriction of specifically amplified genes	Community and individual cell
DGGE (denaturing gradient gel electrophoresis)	Migration of specifically amplified genes of similar length along a denaturing gradient	Community and individual cell
Immunostaining	Fluorescence emission after binding of antibodies to their antigens	Individual cell

ASSESSMENT OF METABOLIC ACTIVITIES

Direct Viable Counts

Among microbiologists, it is widely accepted that "a single, viable microorganism is represented by a cell capable of dividing and forming at least one live daughter cell when it is placed in a favorable environment" (57). According to the definition given by Oliver (58), bacteria that show metabolic activity but are incapable of undergoing the sustained cellular division required for growth on a favorable artificial medium are termed *viable but nonculturable cells* (VBNC, see VIABLE BUT NOT CULTURABLE (VBNC) MICROORGANISMS, this Encyclopedia). To determine the metabolic potential for bacteria to undergo cell division, Kogure and coworkers (59) developed the direct viable count (DVC) method, where bacterial samples are incubated with appropriate nutrients in the presence of an antibiotic, which prevents DNA synthesis. Because other cellular functions are not affected, bacteria will elongate and can subsequently be enumerated by microscopy.

The difference between heterotrophic plate counts and elongated cells is commonly considered the portion of a given bacterial population in a VBNC state and according to this, DVC has become the most widespread method to determine the number of cells in a VBNC state. A major recent modification to this technique involves the application of a cocktail of five antibiotics, which greatly reduces the probability of cell growth due to the presence of bacteria with antibiotic resistance and allows longer incubation times (60). Another modification complements enumeration of elongated cells with in situ hybridizations, enabling one to monitor the metabolic potential of specific species or groups of organisms of interest (54).

Additional methods for determination of viable and nonviable cells include a commercial live-dead stain (Molecular Probes, Eugene, Ore.), and some measures of respiratory activity (see the following section) may also be used to assess activity. Because of the complexity of determining the status of bacterial cells, a combination of techniques may be required, particularly, in complex communities.

Respiratory Activity

Bacterial respiratory activity can be assessed on the basis of the reduction of tetrazolium salts to formazan crystals by the activity of cellular dehydrogenases. The tetrazolium salt (CTC) has replaced salts used in earlier studies because of the easy detection of its fluorescent-reduced form (61). CTC can be applied to biofilm samples, with or without addition of nutrients, yielding either the number of actively respiring bacteria under in situ conditions or the number of cells with the potential for respiratory activity when nutrient limitation is lifted. Some authors, however, reported that they could find no difference between incubation with or without nutrients (62). CTC has recently been shown to have a toxic effect on several bacterial metabolic processes. Samples subjected to a CTC-assay yielded lower heterotrophic plate counts, displayed lower bacterial production, and lower respiratory activity as measured by glucose incorporation and respiration, suggesting that the number of metabolically active cells in a microbial community might be underestimated by this method (63).

Microautoradiography

The uptake of specific substrates by microorganisms under in situ conditions can be studied by using radiolabeled substrates in combination with microautoradiography (64). This method has become widely used in ecological studies and allows conclusions about the metabolic activity of microbial populations. A correlation between active substrate uptake and identity of the organisms, however, is not possible based on microautoradiography alone. A combination with immunofluorescent-labeling of specific organisms was developed (65) but suffers from the drawbacks of antibody application in natural microbial communities mentioned in the preceding section. Recently, microautoradiography was successfully combined with rRNA hybridizations and applied for the characterization of seawater picoplankton (66) and activated sludge communities (67). For single-cell resolution in sludge samples, flocs were cryosectioned and examined by confocal laser scanning microscopy. Uptake of specific substrates could thereby be combined with the analysis of the phylogenetic identity of the organisms.

Other Methods

In recent years, a number of techniques have been developed for the assessment of the general metabolic potential of bacteria. Most of them can be grouped into methods detecting activities of enzymes, synthesis of macromolecules, or membrane potentials. They include detection of esterase activity (68), alkaline phosphatase (69), microcolony formation (70), membrane potential (71,72), membrane integrity (73), or DNA- and RNA-degradation (74).

Specific activities of bacteria can be visualized in situ by the detection of target mRNA sequences. The mRNA of interest is amplified by in situ PCR and subsequently visualized by labeled probes complementary to the amplified DNA (75,76). Reporter genes might be very useful to determine specific metabolic activities of genetically modified organisms in model biofilms. The reporter gene has to be fused to a gene or promoter of interest in a specific bacterial strain; the most commonly used reporter genes are the green fluorescent protein (*GFP*) gene, the *E. coli lacZ* gene, the *lux* gene coding for bacterial bioluminescence, or the firefly *luciferase* gene (77,78, see GREEN FLUORESCENT PROTEIN (GFP), this Encyclopedia).

At the level of activities of microbial communities, determination of the ATP content is one of the most frequently used methods, allowing, for example, study of the influence of water distribution pipe materials on bacterial activity and growth (79). For some applications, a combination of in situ probing and microelectrode measurements can be very useful. In trickling filters, the distribution of sulfate-reducing bacteria was correlated to gradients of oxygen and sulfide (80), and biofilms in a nitrifying bioreactor were examined for distribution patterns and activities of nitrifying bacteria and gradients of oxygen, ammonium, nitrate, and nitrite (81).

Table 2. Methods for Assessing Bacterial Metabolic Activities in Biofilms

Method	Metabolic Parameter Measured	Level of Measurement
RH-795 staining Rhodamine 123 staining Live/Dead Bacteria Light™ (Propidium Iodide/SYTO 9)	Integrity of cell membrane	Individual cell
ATP measurement	Overall adenylate content	Community
Microelectrodes	Redox potential, microbial activity	Community
Microautoradiography	Substrate utilization	Community and individual cell
FISH (fluorescence *in situ* hybridization)	Cellular ribosome content	Individual cell
FISH-MAR (fluorescence *in situ* hybridization microautoradiography)	Cellular ribosome content and substrate utilization	Individual cell
DVC (direct viable count)	Substrate utilization and elongation	Individual cell
PAC (probe active count)	Substrate utilization and cellular ribosome content	Individual cell
SFDA (sulfofluorescein diacetate) CFDA (carboxyfluorescein diacetate)	Hydrolytic enzymatic activity (esterases)	Individual cell
TTC (triphenyl tetrazolium chloride)	Cellular dehydrogenase activity (respiratory activity)	Individual cell
INT (2-*p*-(iodophenyl)-3-(*p*-nitrophenyl)-5-tetrazolium chloride) CTC (5-cyano-2,3-ditolyl tetrazolium chloride)		
gfp gene (Green fluorescent protein) *lacZ* gene (β-Galactosidase) *lux* gene (Bacterial luciferase)	Gene expression	Individual cell

Different methods for assessing bacterial metabolic activities in biofilms are summarized in Table 2.

COMMUNITY INTERACTIONS

Metabolic Interactions

In nature, many degradative processes cannot be performed by pure cultures of bacterial species, but require the metabolic interactions of different bacterial species. Biofilms, where bacteria are in close proximity, are ideally suited for interactions of their community members. Bacterial interactions in biofilms are not limited to competition for available substrates, but often involve a more cooperative behavior such as cometabolism or symbiosis. Well-known examples are the anaerobic degradation of organic matter, where at the end of the food-chain, H_2-producing acetogens and H_2-consuming methanogens interact as symbiotic partners; the nitrification process that requires the combined action of ammonia- and nitrite-oxidizing bacteria; or the degradation of many xenobiotic compounds. In a defined biofilm system in which a drinking water isolate was fed with benzoate as sole carbon source, growth of an added *E. coli* strain could be demonstrated within the biofilm, although the strain was unable to grow on benzoate in pure culture. Apparently, metabolites excreted by the drinking water bacterium allowed not only survival but also growth of *E. coli* (82). Another well-studied example for interspecies exchange of metabolites is the coexistence of *Legionella pneumophila* and *Flavobacterium breve*, caused by the release of cysteine by the *Flavobacterium* cells. Cysteine serves as a nutrient for *Legionella* and as a mild reducing agent (83).

Using GFP as a reporter system, metabolic interaction could also be demonstrated for degradation of benzyl alcohol in mixed culture biofilms. Gene fusions of *gfp* with either the upper-pathway promoter or the meta-pathway promoter of the toluene degradation pathway were generated and introduced into *P. putida*. GFP expression from the upper-pathway promoter could be induced in *P. putida* pure-culture biofilms and in mixed-culture biofilms by addition of benzyl alcohol. Expression from the meta-pathway promoter, however, was only induced when an *Acinetobacter* sp. was added to the biofilm community. Apparently, the *Acinetobacter* sp. degraded benzyl alcohol to benzoate, which leaked from the cells into the surrounding medium and could serve as substrate and inducer of GFP expression from the meta-pathway promoter in *P. putida* (84). In a flow cell-grown model system the effect of a commensal interaction on the spatial structure of the biofilm community consisting of two organisms was investigated using fluorescent in situ hybridization, confocal laser scanning microscopy, and a GFP reporter system (85). Depending on the nature of substrate given in the model system, different colonization patterns could be visualized. When the consortium was fed with chlorobiphenyl, which could only be utilized by one model organism, microcolonies consisting of that bacterium and the associated second organism occurred. In contrast to this, the two species formed separate microcolonies when fed with citrate, which could be metabolized by both organisms.

Cell Signaling

In recent years, it has become clear that to react to changes in the environment, bacteria must possess a form of intercellular communication. One of the important environmental factors for bacteria is the cellular density of their own population. Among many gram-negative bacteria, a "quorum-sensing" system has evolved, based on diffusible, membrane-permeant acylated homoserine lactone (AHL) pheromones that act as cell density cues or "autoinducers" and cause changes in gene expression. AHLs are constitutively expressed at a low basal level but expression is upregulated when the cell density, and hence AHL concentration, reaches a certain level. Quorum sensing has been discovered in *Vibrio fischeri*, where luminescence is controlled by two proteins, LuxI and LuxR. LuxI is an AHL-synthetase and LuxR is a transcriptional activator, which promotes transcription of *luciferase* genes when bound to the AHL-autoinducer. In *P. aeruginosa*, two analogous quorum-sensing systems *las* and *rhl*, have so far been discovered. LasI and RhlI direct the synthesis of specific AHLs, which induce the transcriptional activators LasR and RhlR, respectively. Genes regulated by quorum sensing include, among others, genes coding for an endotoxin, secretion proteins, a protease, and the stationary-phase sigma factor. Thus, production of virulence factors appears to be under the regulation of quorum-sensing systems in *P. aeruginosa*. Similar quorum-sensing systems have been found in numerous gram-negative bacteria, whereas in gram-positive bacteria, quorum sensing is based on peptide signal molecules, which are recognized by sensor kinases that interact with cytoplasmic response regulator proteins (86). AHLs not only serve as quorum sensors but some AHLs also stimulate their own production and can establish positive autoinducer feedback loops.

Apart from the obvious importance of quorum sensing for gene expression in biofilms, where cell densities are very high, defects in quorum sensing seem to have a crucial impact on the biofilm formation potential of bacteria. As already mentioned earlier, a *P. aeruginosa lasI* mutant formed only undifferentiated, flat biofilms, which were more sensitive to biocide action than the corresponding wild-type biofilm (33).

Recently, a marine red alga has been found to produce antagonists of AHLs. These halogenated furanones apparently inhibit AHL-mediated gene expression by displacing AHL from its receptor protein, the transcriptional activator LuxR in *E. coli*. By producing furanones, the alga controls bacterial colonization of its surfaces. Again, these findings demonstrate the importance of cell signaling for colonization and biofilm formation (87). Evidence has also been found for the role of AHLs in the formation of natural and urethral catheter biofilms (88,89).

Gene Transfer

(see GENE EXCHANGE IN BIOFILMS, this Encyclopedia)

Genes can be horizontally transferred between bacteria by conjugation, transduction, and transformation. Gene transfer by conjugation is thought to be one of the major mechanisms for the establishment of new genetic traits in microbial communities, and is also thought to play a considerable role in biofilms. Even though the probability of random encounters of cells is lower in biofilms than in the planktonic phase, the high cell density and stable spatial localization might facilitate intra and interspecies gene transfer. The frequency of gene transfer can be affected by a number of factors, such as cell densities (90), growth phase (91), temperature, pH, concentrations of nutrients, ions, and oxygen (57,92,93), as well as contact time (93) and spatial arrangement (90). Gene transfer methods are described in detail by Christensen and coworkers (78). The frequency of gene transfer is usually determined by plating on selective media, where only transconjugants can grow, raising the question whether the number of culturable transconjugants reflects the number of in situ occurring gene transfer events. In a recent study on interspecies gene transfer between *E. coli* and *Ralstonia eutropha* in biofilms, detection of transconjugants was achieved in situ by a combination of in situ probing and GFP expression. Interestingly, the rate of gene transfer was found to be thousandfold higher than the rate determined by classical plating techniques (93). However, if interspecies plasmid transfer was studied on floating filters, no difference between conjugations was found between in situ detection and traditional plating techniques (94). This discrepancy might be explained by different experimental setups or they could possibly hint at physiological differences between planktonic- and biofilm-associated cells (93). It must also be kept in mind that in situ detection of gene transfer does not allow any conclusions with regard to plasmid stability in the recipient. Because in situ monitoring of plasmid transfer is based on GFP expression from the transferred plasmid, it would be expected that only bacteria that keep the plasmid maintain green fluorescence. The method can be further refined by using unstable variants of the GFP.

Interactions Between Eukaryotes and Bacteria

Grazing of bacteria by various eukaryotic microorganisms is widespread in microbial communities. Moreover, predation was found to have a significant impact on bacterial morphologies and on the taxonomic composition of bacterial populations. In planktonic populations, protozoan grazing could be shown to trigger a population shift from small, fast-growing bacteria affiliated to the β-subclass of Proteobacteria and the Flavobacteria-Cytophaga phylum toward more grazing-resistant, larger cells affiliated the α- and γ-subclasses of Proteobacteria and filamentous bacteria of other phylogenetic groups (95). Grazing by protists may also influence the nature of the exopolymer matrix of biofilms as shown by Möller and coworkers (96).

Comparisons between grazing of planktonic versus attached bacteria showed protozoan preference for attached bacteria in some cases, in other studies, a protective effect of adhesion was reported (97). A recent study attempted to directly quantify protozoan feeding rates on biofilm bacteria by using unstained, viable prey. In this model system, the grazing rate of a small ciliate on *P. putida* cells was determined to be higher for suspended than for attached bacteria (97). Analysis of the

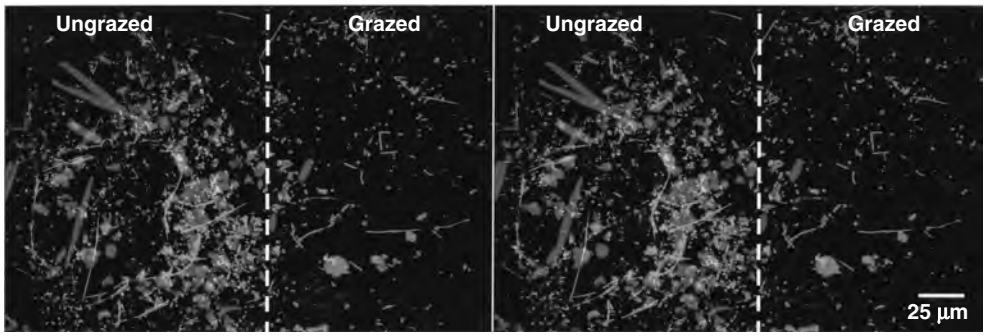

Figure 1. Stereo pair of false color confocal laser scanning micrographs, showing the effects of snail grazing on the distribution of bacteria (stained with Syto 9, green), algae (autofluorescence, red), and extracellular polymeric substance (stained with fluorescent *Triticum vulgaris* lectin, blue) in a river biofilm. See color insert.

bacterial community composition during a diatom bloom suggested that protozoan grazing, together with increased viral abundance, not only leads to a phylotype-shift of the bacterial community but also to a pronounced bacterial colonization of larger suspended particles (98). The study of Hahn and coworkers (99) showed that grazing by *Ochromonas* spp., resulted in the development of a floc-forming subpopulation in *Pseudomonas* sp. MWH1 that was interpreted as a successful grazing defense.

Interactions between eukaryotes and bacteria, however, are not restricted to grazing. A well-studied example for parasitic growth of a prokaryote within a eukaryotic host is represented by members of the family Legionellaceae. *Legionella pneumophila*, the causative agent of Legionnaires' disease, grows intracellularly in a number of amoeba species and in other protozoa-like ciliates. These hosts not only provide nutrients for *Legionella* organisms but also protect them from adverse environmental conditions. *Legionella* spp. present in drinking water systems may be enclosed in cysts of amoebae and thereby be protected from chlorination, ozone, and other adverse conditions (7). Recently, *Mycobacterium avium*, an opportunistic human pathogen that can survive and multiply within drinking water biofilms, has been shown to grow on metabolites excreted by *Acanthamoeba polyphaga*. *Mycobacterium avium* was even able to multiply within the outer walls of the double-walled cysts of the amoeba (100). Interactions between plants and bacteria also occur, as described above for a marine alga, which produces furanones to inhibit colonization by bacteria.

Interactions with micro and macroinvertebrates also influences development of microbial biofilms, through disturbance, sloughing, and active grazing of bacterial and exopolymer components of biofilms. For example, the impact of snail, grazing on the biofilm architecture, and abundance of bacteria, algae, and extracellular polymeric substance is shown in Figure 1.

EXAMPLES OF NATURAL BIOFILMS

Cyanobacterial Mats

Cyanobacterial mats are typical microbial biofilm communities in extreme environments such as hot springs or salt marshes. They are characterized by their layered structure, where production of organic matter through photosynthetic microorganisms is located in the uppermost layer, and aerobic and anaerobic decomposition of the organic substances takes place in deeper layers of the mat. The top layer of a microbial mat typically contains cyanobacteria and sometimes also diatoms and small algae, whereas anoxigenic photosynthesis takes place in the deeper levels. Here, purple phototrophs and filamentous green phototrophs can be found, together with aerobic and anaerobic chemoorganotrophs as well as sulfate-reducing and methanogenic bacteria. Many parameters vary vertically across the mats, including light intensity, oxygen, carbon dioxide, nitrogen, phosphate, sulfur, and organic nutrients (101). One of the most extensively studied systems are hot spring cyanobacterial mat communities, which have recently been covered in a review by Ward and coworkers (45). At the outset of investigations on the microbial ecology of these mats, studies based on microscopical observation and cultivation identified two main bacterial species, a unicellular cyanobacterium and a filamentous green nonsulfur bacterium. Other bacterial species cultivated from the mats were aerobic chemoorganotrophs, gram-positive fermentative bacteria, sulfate-reducing bacteria, and methanogens. Data gained by analysis of pigment and lipid biomarker abundances suggested that cyanobacteria and green nonsulfur bacteria predominated over chemoorganotrophic bacteria, and even fewer terminal members of the anaerobic food chain, such as methanogens or sulfate-reducers, were present. Direct retrieval of 16S rRNA sequences, using different molecular methods, however, did not yield sequences that could be ascribed to previously isolated organisms but only sequences that were 93% or less similar to their closest cultivated or uncultivated relatives. This divergence is thought to be because of competitive exclusion of species that are numerically dominant by bacteria, which perform well in laboratory culture but are not abundant in situ. As mentioned earlier, a solution for recovery of dominant strains may be dilution-to-extinction enrichment. DGGE analysis proved to be a very useful tool for the investigation of the spatial distribution of populations in the mat. Vertical distribution could be demonstrated for cyanobacterial populations and for green sulfur and green

nonsulfur bacteria. Although one cyanobacterial population (termed *type B*) could be detected throughout the top 0 to 0.5 μm layers, the other population (termed *type A*) was found to be restricted to a well-defined layer about 600 μm from the surface, suggesting a vertical stratification and adaptation to different light intensities of cyanobacterial populations. Mechanical disturbance of the mat, caused by removal of the top green cyanobacterial layer, allowed the investigation of recolonization behavior. DGGE analysis revealed that a new cyanobacterial population colonized the disturbed mat, rather than the previously dominant species that remained in adjacent undisturbed sites, indicating that as in macroecology, bacterial species might exist, which are effective at rapid growth rates (so-called r-strategists) and colonization. DGGE surveys also revealed cyanobacterial population changes along the thermal gradient that occurs in the effluent channel of the Octopus Spring location (45). The detected sequences appeared to be from dominant members of the population because they could also be recovered from cyanobacterial isolates obtained from highly diluted inocula. The detected sequences showed a high level of 16S rRNA sequence relatedness, suggesting that the species might have formed through adaptive radiation from a common ancestor (45).

Riverine Biofilms

In the global hydrological cycle from atmosphere to land and oceans, running freshwater systems (lotic systems) are the major linkages between terrestrial and aquatic habitats including surface and groundwater. The common feature of river ecosystems is the continuous movement of the bulk water phase. Microbiological investigations of lotic systems revealed the important role of the complex microbial river communities in global nutrient cycles. It has become apparent that microbial transformations (the so-called microbial loop, 102) have a serious impact on the flux of organic carbon in running waters (103). Consequently, attention is now focusing on the role of bacterial production and the microbial food web as well as their impact on the self-purification capacity of lotic systems.

In a recent study, the planktonic bacteria in the bulk water phase of the Japanese rivers Minoh and Neya were investigated as one distinct compartment of the lotic community, using rRNA-targeted fluorescent in situ hybridization (104). However, biofilm bacteria can comprise the majority of bacterial numbers (105) and most bacterial production and transformation in running waters occurs in biofilms or communities associated with suspended particulate matter (106,107), whereas relatively little production occurs in the free water column. The balance of planktonic, suspended floc, and biofilm communities in rivers is dependent on interactions between the nutrient status, flow regime, and order of the specific river under investigation.

Epilithic biofilms that grow on the surface of rocks or stones cover most substratum in the littoral zone (i.e., those parts of the water body that occur in shallower waters of unspecified depth) and the streambed. These complex mixed assemblages of bacteria, fungi, and algae even occur in the hyporheic zone (108,109), which means the interstitial layer of the river bottom that may be in contact with both the river water and the groundwater flow underneath. The continuously changing riverine ecosystem biofilms contribute significantly to the distribution and recycling of nutrients and inorganic substances (110), and heterotrophic activity is considered to be almost exclusively associated with sediments (111–113). Marxsen (114) discussed the significance of sediment biofilms for the carbon balance of streams. Dissolved organic matter (DOM) is converted by microorganisms in both hyporheic and epilithic biofilms (115–117). Naegli and Uehlinger (118) showed for a prealpine river that the epilithic and hyporheic biofilm community contributed 4 to 19% and 76 to 96% of the total respiratory activity as determined by oxygen consumption, respectively. Although most studies focused on the upper layers of the sediment microhabitat, even deeper sediment zones can be populated by metabolically active bacteria (106,108,113).

From a macroecological point of view, riverine biofilms play an important role as a trophic resource for macroinvertebrates in lotic systems (119,120). Biofilm bacteria and particle-associated microorganisms themselves are subjected to a top-to-bottom control by grazing protists (121,122), which have repeatedly been shown on surfaces in rivers (123).

The biofilm organisms are typically embedded in or associated with a complex heterogenous matrix of extracellular polymeric substances (EPS) secreted by the organisms themselves (124–127). The EPS matrix enhances the immobilization of dissolved organic carbon (DOC), and even particulate organic carbon, and allows the exchange of matter within syntrophic associations of microorganisms. Indeed, Freeman and Lock (128) demonstrated that river biofilms were remarkably resilient to a loss of available carbon in the overlying waters, indicating that river biofilms store energy that is subsequently available during starvation intervals.

Bacteria that can attach and multiply under the high-shear forces normally present in rivers are obviously adapted to live in this environment but only little is known about the physiological plasticity and the ecological impact of planktonic and attached bacteria within these ecosystems. It is generally accepted, however, that the activity of attached microbes dominates in small streams, whereas planktonic bacteria are of greater importance in large rivers because of the different ratios of the surface (of sediments or suspended particulate matter) to the volume of the floating water (110). However, the microbial components of lotic ecosystems have rarely been studied and it is not known to date whether there are specific bacteria in rivers that can be distinguished from those organisms that are passively transported downstream. The overall structure and bacterial composition of specific lotic biofilm communities was described by Lock (110). Nutritional relationships among bacteria and algae in river biofilms were studied by Haack and McFeters (129), suggesting a coupling of photosynthetic and heterotrophic populations. Leff and coworkers investigated the seasonal changes in planktonic bacterial assemblages of two Ohio streams by measuring the abundance of total

bacteria, colony forming units, and the population of *Pseudomonas cepacia* by hybridization with a species-specific probe (130).

Because of the obvious difficulties involved with biofilm investigations in situ within lotic systems, there is a strong need for suitable laboratory models that particularly mimic the development of attached communities under turbulent flow regimes and constant shear forces. Lawrence and Caldwell (17) used continuous flow cells to visualize the rapid colonization of the substratum by a diversity of lotic bacteria. Mohamed and coworkers (131) used flow cells to investigate the impact of nutrients that may control the growth of biofilm bacteria obtained from the Fraser River, Canada. As an important result of the study, the phosphorus limitation of heterotrophic river biofilm bacteria could be shown for the first time.

Rotating annular bioreactors (RAB) were applied for different studies including structural features and metabolism (132,133). Neu and Lawrence (134) used RAB for cultivation and structural examination of stream biofilms by confocal laser scanning microscopy (CLSM). The biofilms were generated in the reactor by feeding with natural river water from the South Saskatchewan River system as inoculum and sole source of nutrients and carbon. The reactor contained removable polycarbonate strips that allowed sampling of biofilm material at desired intervals. The architecture of the biofilms was in contrast to previous views of a homogeneous biofilm structure and more recent biofilm models with channels and inverted biomass distribution. There was a development of ridges, oriented to the flow direction, that were colonized by individual bacterial cells and microcolonies, as shown in Figure 2. As suggested by the authors, the differences may be attributed to the presence and coadsorption of humic and detrital material in natural lotic systems. After an initial phase of biofilm development, both the highest biomass and the numbers of putatively living cells were generally distributed within the outer regions of the biofilm. The heterogeneity of the biofilms was also visualized by the application of a panel of fluorescein isothiocyanate (FITC) and tetramethylrhodamine isothiocyanate (TRITC)-conjugated lectins, indicating the presence of different carbohydrates within the EPS-matrix.

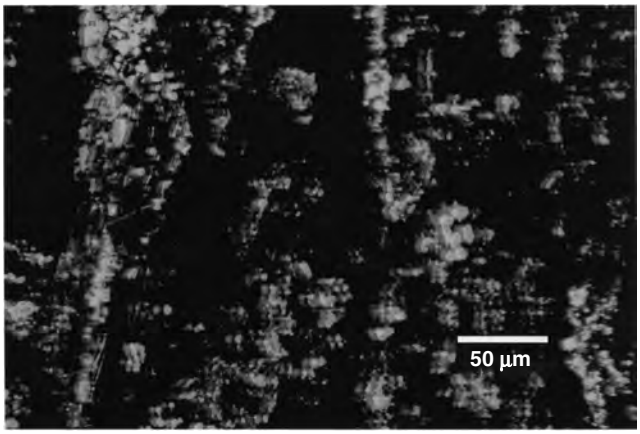

Figure 2. A red-green anaglyph stereo projection of a series of confocal laser scanning micrographs of a river biofilm stained with Syto 9, and TRITC-labeled *T. vulgaris* lectin. See color insert.

The same experimental setup was used in another study investigating algal, bacterial, and exopolymeric components of fully hydrated natural biofilm communities by Lawrence and coworkers (135). Multispectral imaging in conjunction with nucleic acid stains, fluor-conjugated lectins, and autofluorescence was performed in this study to evaluate biofilm community composition. Biofilms were treated with the nucleic acid stain SYTO 9 to quantify the bacterial biomass and fluor-conjugated lectins (i.e., *Triticum vulgaris* lectin) to identify and allow quantification of exopolymeric substances. Digital image analysis of confocal laser scanning sections in each of the channels was used to determine parameters such as biofilm depth, bacterial cell area (biomass), exopolymeric area, and algal biomass at various depths and locations. The results of multichannel imaging, showing an example of a rotating annular bioreactor generated river biofilm stained with fluor-conjugated lectins, a nucleic acid stain, and autofluorescence imaging of algae are shown in Figure 3.

In a further study, the phylogenetic composition, three-dimensional structure, and dynamics of the bacterial communities in river biofilms, generated in the RAB system were studied by a combination of fluorescent in situ hybridization (FISH) and confocal laser scanning microscopy. Digital image analysis was performed to measure specific cell numbers and specific cell area after in situ probing (136). During the different stages of biofilm development, individual cells within the α-, β-, and γ-Proteobacteria as well as the Cytophaga-Flavobacterium group could be visualized, demonstrating that they formed major parts of the attached community. During initial biofilm development, β-Proteobacteria accounted for the greatest part of the bacterial population. This was followed by a rapid increase of α-Proteobacteria and bacteria affiliated to the Cytophaga-Flavobacterium group. In mature biofilms, α-Proteobacteria and Cytophaga-Flavobacteria continued to be the prevalent bacterial groups. β-Proteobacteria constituted the morphologically most diverse group within the biofilm communities and more narrow phylogenetic staining revealed the importance of distinct β1-Proteobacteria for the composition of the microbial community. The importance of members of the β-Proteobacteria is also reported for sessile microbial communities that grew on glass plates exposed in a highly polluted river in Germany (137). In addition, Brümmer and coworkers showed the seasonal dynamics of Planctomycetes and Cytophaga-Flavobacteria that both showed maximum levels of relative abundance in July, and, in case of Cytophaga-Flavobacteria, a second peak in winter (137).

Besides the attached biofilm communities located at virtually all surfaces and interfaces in the rivers, bacteria, algae, and freshwater fungi also constitute a major part of the macroscopic mixed assemblages (suspended particulate matter) present in the bulk water phase. In accordance with microbial aggregates described in oceans and estuaries (107,138–140), in the pelagic zone of lakes (141–143) and rivers (144–146), the suspended particulate aggregates found in rivers have been recently termed *river*

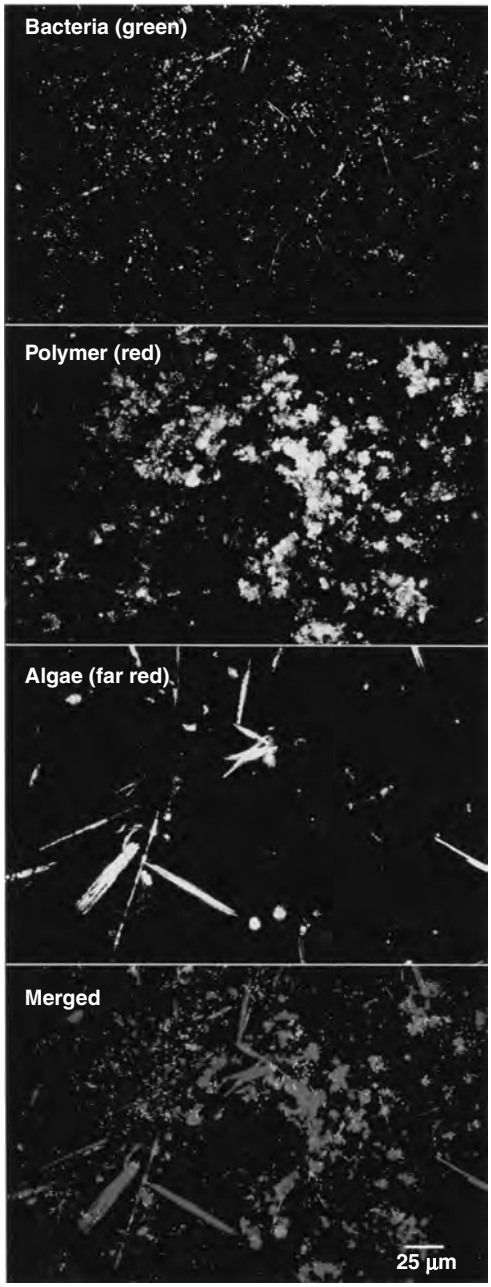

Figure 3. A series of confocal laser scanning micrographs, showing multichannel imaging of a single location in a river biofilm, visualizing Syto 9 stained bacteria recorded with the green channel (top image), *T. vulgaris* labeled extracellular polymeric substance recorded with the red channel (second micrograph), and the algae imaged by autofluorescence recorded with the far-red channel of the microscope (third micrograph). The bottom image shows the false color presentation of merging all three images, visualizing bacteria (green), algae (red), and extracellular polymeric substance (blue). See color insert.

snow (147,148). Like other biofilms, these river snow aggregates, which may be considered as mobile biofilms, consist of inorganic and organic compounds, extracellular polymeric substances (EPS), and the attached microbial populations. In comparison to the bulk water phase, river snow aggregates possess a higher nutrient concentration (149) and the associated bacteria show a higher rate of biological activity (150–152). Within suspended particulate matter, the formation of chemical gradients and anoxic microhabitats has been described (153). The river snow microhabitats are characterized by the occurrence of photosynthetic organisms (algae, cyanobacteria) and a broad range of different heterotrophic organisms including aquatic freshwater fungi (154,155). In the microbial aggregates, there is a pronounced patchiness of nutrients and consequently, these "hot spots" of high nutrient concentrations (156) and microbial life (157) show a high rate of heterotrophic metabolism and accelerate the mineralization process (158).

With regard to heterotrophic bacteria, the phycosphere of algae in which photosynthetic products are released is a particular hot spot of nutrients on a subcellular scale (159).

Because of the physiological plasticity of the mobile biofilm organisms, the river snow aggregates can also be regarded as miniaturized wastewater treatment plants and fulfill an important function within the self-purification processes in lotic systems. The high sorption capacity of the extracellular polymeric substances within the mobile river snow aggregates significantly contribute to the horizontal and vertical shift of inorganic and organic substances and link the pelagic and benthic compartments. Neu (147) examined the fully hydrated architecture of living river snow aggregates from the river Elbe, Germany, by multichannel confocal laser scanning microscopy. Simultaneous application of different fluorescently labeled lectins as carbohydrate-specific probes and general nucleic acid stains, visualized the heterogeneity of the EPS matrix in between the cellular constituents of the river snow community. CLSM performed in the reflection mode and in the far red channel gave additional information about the mineral content in the aggregates and the presence and spatial distribution of chlorophyll-containing organisms.

The phylogenetic diversity and physiological versatility of the Elbe river snow aggregates were investigated at the cellular level, using aerobic and anaerobic cultivation techniques, 16S rDNA based phylogeny, and fluorescent in situ hybridization (FISH) by Böckelmann and coworkers (148). FISH analysis of the river snow community revealed population dynamics to be governed by seasonal factors and more than 70% of the total bacterial cell count could be hybridized with a bacteria-specific probe, indicating the high physiological potential of the river snow community. During all seasons, β-Proteobacteria constituted the numerically most important bacterial group, forming up to 54% of the total cell counts. In contrast to this, the relative abundance of other major bacterial lineages ranged from 2% for the order Planctomycetales to 36% for Cytophaga-Flavobacteria. Cultivation of river snow bacteria under aerobic and anaerobic conditions with a variety of different media resulted in the isolation of 40 new bacterial strains. Phenotypic and phylogenetic analysis revealed them as mostly unknown organisms affiliated to different bacterial phyla. Some Elbe river snow isolates were affiliated to distinct freshwater phylogenetic clusters similar to organisms and environmental clones isolated from other

freshwater systems (160,161). The isolation of river snow bacteria with the potential for degradation of xenobiotics routinely monitored in the Elbe river water indicated the great physiological versatility of the river snow associated microorganisms.

Microbial community analysis by cloning and sequencing of 16S *rRNA* genes was conducted by Crump and coworkers to study the microbial ecology of free-living and particle-attached bacteria in the Columbia River and its estuary (162,163). Both studies showed the great diversity of bacterial sequences and the presence of putatively ubiquitous clades of bacteria within the aggregates. Interestingly, not only eubacterial sequences but also new clusters of archaeal 16S rRNA sequences could be identified, reflecting the great genetic diversity within the riverine microbial aggregates.

Drinking Water Biofilms

Drinking water distribution systems belong to the most oligotrophic aquatic habitats, and bacterial growth is severely limited by low contents of assimilable organic carbon (164) or by phosphorus availability (165). Nevertheless, basically all existing interfaces are partially covered by biofilms, from the waterworks through the distribution system to house installations. The existence of these biofilms was reported and documented several decades ago, based mostly on microscopic or electron microscopic examinations of pipe materials and encrustations from pipe surfaces (164,166).

In drinking water, biofilms are usually very thin and patchy, often consisting of a monolayer of cells. Thick biofilms can only develop if the colonized pipe material releases biodegradable dissolved organic carbon (BDOC), which is the substrate, allowing bacterial development in the drinking water. Apart from the availability of nutrients, the treatment of the raw water, use of disinfectants, temperature, type of surface material, and hydraulics of the system may affect the densities of biofilm bacteria (167–169). Bacteria growing in drinking water biofilms deteriorate the quality of the bulk water, and detachment of bacteria from the biofilms can additionally, negatively affect the water quality. Consequently, pipe and fitting materials used in drinking water systems have to be subjected to extensive testing. The unwanted growth of bacteria within drinking water distribution systems can be limited by distributing biostable drinking water that contains no easily degradable substrates and by applying biostable materials in contact with drinking water (170). The most often used methods for the assessment of the biostability of the materials are based on measurement of respiration activity in the presence and absence of test materials, on the detection of cell numbers by means of ATP content, and on scraping of the biofilm from the substratum and measuring its volume (7).

Drinking water biofilms can also contain high proportions of inorganic compounds, mostly consisting of iron and manganese. The deposits are caused, at least partly, by microorganisms (e.g., the genera *Hyphomicrobium*, *Siderocapsa*, *Gallionella*, *Leptothrix*, *Pedomicrobium*). These inorganic depositions and encrustations (e.g., flocs and tubercles) represent new habitats, where gradients for oxygen, redox potential, temperature, nutrients and toxins develop, thus offering growth conditions completely different from the free-water phase. Some bacteria can also promote corrosion by creating areas with different gradients in oxygen, minerals, and metals and also catalyze reactions associated with corrosion processes such as conversion of divalent iron to trivalent forms (171). In these new microhabitats, bacteria including pathogens may survive and even grow better, although the conditions in the flowing water are inhospitable (7,166,172).

Bacterial species isolated using conventional techniques from drinking water biofilms were typically identified as members of fast-growing genera such as *Pseudomonas*, *Acinetobacter*, *Alcaligenes*, *Flavobacterium*, *Moraxella*, *Arthrobacter* (164,166) mostly affiliated to the γ-subclass of Proteobacteria. In contrast to this, examinations with oligonucleotide probes in biofilms from different drinking water systems revealed the predominance of members of the β-subclass of Proteobacteria (20,173–175).

Recently, biofilm formation has been extensively studied in a house installation system in Berlin, Germany, with regard to population dynamics, species composition, and metabolic potential of the microbial community of young biofilms. Surfaces were found to be rapidly colonized, and a monolayer of rod-shaped β-Proteobacteria developed on the substrata. This young biofilm was grazed by amoebae, leading to a more diverse biofilm structure and population composition. The metabolic potential of the population, assessed by CTC-reduction and a modified DVC-assay (176), decreased with biofilm development. The in situ dominant species could be successfully isolated from the early biofilm formation stage and described as members of the new genus *Aquabacterium* within the β-subclass of Proteobacteria. The occurrence of the genus *Aquabacterium* could also be shown for other drinking water distribution systems (167), regardless of the raw water source used for the drinking water supply. The species composition in established biofilms, however, is expected to be far more complex (20,54,167).

CONCLUSION

- Biofilms are complex microbial communities and highly heterogenous in their structure, composition, and function.
- Biofilms are formed by bacteria, algae, fungi, protozoa, as well as organic compounds and inorganic materials.
- Biofilms are colonizing virtually each known interface of natural and engineered systems.
- The individual biofilm-associated cells within the biofilm communities are linked by extracellular polymeric substances (EPS).
- There is an complex exchange of genetic material between the individual members of the biofilm communities.
- The individual cells in the biofilm communities are communicating to each other by chemical transmitters

that regulate properties of the individual members (e.g., individual cell shape, motility) and of the whole bacterial population (e.g., colony shape, cell density).

- In nature, biofilm communities often form complex stratified microhabitats and foodwebs (e.g., photosynthetic cyanobacterial communities and heterotrophic sulfate-reducers).
- Biofilms in riverine systems play an important role in nutrient and energy metabolisms, can be regarded as hot spots of microbial activity, and are responsible for the self-purification ability of rivers.
- In drinking water distribution systems, biofilms are hygienically and technically important in terms of affecting both the quality of the drinking water and the materials used for pipes, reservoirs, and fittings in the distribution system.

BIOFILMS IN THE FOOD INDUSTRY

GUN WIRTANEN
TIINA MATTILA-SANDHOLM
VTT Biotechnology
Espoo, Finland

This entry deals with biofilm formation, detection, and elimination on surfaces in the food processing environment. Biofilms have been used in research on sanitation, that is, cleaning and disinfection, in the food industry since late 1980s. Microbes in microcolonies have a tendency to form protective extracellular matrices, which are called *biofilms*. The microcolony formation is the start-up in the biofilm formation. The biofilm formation occurs under suitable conditions on any — both inert and living — surface. Besides a surface, the microbes need only water to start-up this formation. The mechanisms of the microbial attachment and biofilm buildup can be divided into the following steps: (*1*) preconditioning of the surface by macromolecules, (*2*) transport of cells to the surface, (*3*) reversible and irreversible adsorption to the surface, (*4*) cell replication, (*5*) transport of nutrients and metabolism, (*6*) production of extracellular polymers, and finally, (*7*) detachment. The food hygiene legislation, the hygienic design of machinery together with increasing public awareness of product quality, make testing of process surfaces and equipment cleanliness important. Microbiological, physical, chemical, and microscopy methods can be used in studying the biofilm buildup and its elimination. Advanced molecular biology methods can also be used in the detection and enumeration of specific organisms on surfaces. Determination of disinfectant efficacy is, however, still performed in suspensions, which do not mimic the conditions on surfaces where the agents are expected to inactivate microbes within biofilms as well. The elimination of biofilm is a very difficult and demanding task because many factors such as temperature, time, mechanical, and chemical forces affect the detachment.

FORMATION OF BIOFILMS IN THE FOOD INDUSTRY

Biofilm formation causes problems in areas such as industrial water systems (1–3), medicine (4–6), and in the food-processing industry (7–12). Biofilm formation has both positive and negative implications in food related processes (13). It has been used effectively in the food industry in the production of vinegar (12) and beer (14).

Biofilms can generally be produced by any microbes under suitable conditions, although some microbes naturally have a higher tendency to produce biofilm than others. The most common food-borne biofilm producers belong to the genera *Alcaligenes*, *Bacillus*, *Enterobacter*, *Flavobacterium*, *Pseudomonas*, and *Staphylococcus* (10). It is somewhat alarming that bacteria such as *Listeria monocytogenes*, *Escherichia coli*, *Salmonella typhimurium*, and *Yersinia enterocolitica* produce biofilms readily, causing severe sanitation problems on surfaces in the food industry (15–21). Experiments have been carried out with *L. monocytogenes*, *Pseudomonas fluorescens*, and *Y. enterocolitica*, which cause contamination of materials used in gaskets (22). *Pseudomonas* spp. have also been found to attach easily to surfaces of hydrophobic materials (e.g., polystyrene. rubber- and teflon-based materials) used in gaskets. Some microbes are also able to decompose rubber and use it as a source of energy (23–24). Biofilm-bound bacteria can accelerate corrosion and material deterioration, for example, in sensors and detectors (25–28). Microbial corrosion has been observed in processing equipment, appearing either in combination with or without biofilm formation. Corrosion leads to huge losses in different industrial areas, for example, piping and cooling water systems (26,28).

In the food industry, equipment design plays the most important role in combating biofilm formation (29,30). The choice of surface materials is of great importance in designing and building equipment and processing lines for industrial use (31). Dead ends, corners, cracks, crevices, gaskets, valves, and joints are vulnerable points for biofilm accumulation (29,32–33). The process equipment is easy to clean if the surface materials are smooth and in good condition (Fig. 1). It should be cleaned frequently to avoid the accumulation of biofilm. The choice

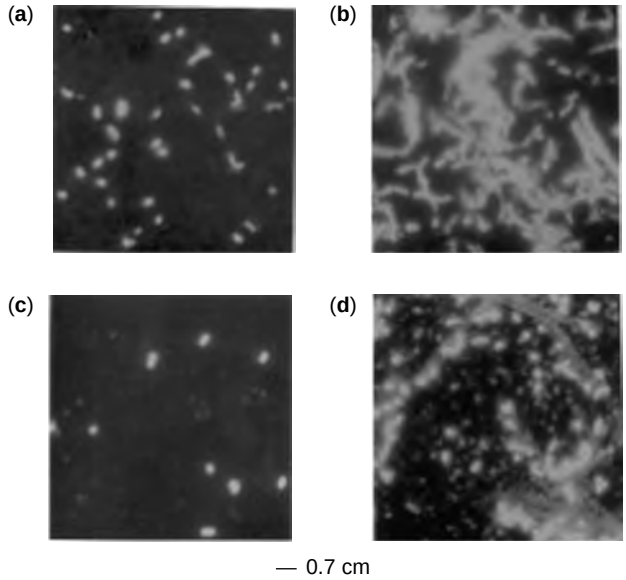

Figure 1. Epifluorescent microscopy photographs of 2 and 10 days old *L. monocytogenes* biofilms stained with acridine orange. The biofilms had been grown on standard as well as electrochemically polished 2B stainless steel surfaces (AISI 304): (**a**) 2-day-old and (**b**) 10-day-old *L. monocytogenes* biofilm on standard 2B, (**c**) 2-day-old and (**d**) 10-day-old *L. monocytogenes* biofilm on electrochemically polished 2B surfaces. The scale marker is equivalent to 0.7 cm. See color insert.

of materials and their surface treatments, for example, grinding and polishing, are important factors in inhibiting the formation of biofilm and in promoting the cleanability of surfaces (34). Treatments of surface materials to reject biofilms can be performed actively to remove or passively retard biofilm reoccurrence. The cleanliness of surfaces, training of personnel, and good manufacturing and design practices are the most important tools in combating biofilm problems in the food industry (30).

Besides causing problems in cleaning and hygiene (35), biofilm can cause energy losses and blockages in condenser tubes, cooling fill materials, water, and wastewater circuits and heat exchangers (36). Biofilms can also cause health risks by releasing pathogens in drinking water distribution systems. Biofilms may enter a food processing system by causing reduced effectiveness in ion exchange and membrane processes (37–38). In the food processing water supply systems, biofilms cause problems in granular activated carbon columns, reverse osmosis membranes, ion exchange systems, degasifiers, water storage tanks, and microporous membrane filters. The bacterial level of the purified water used and the defects found in microelectronic devices correlate directly. Conductance, electromigration, and corrosion in the oxide layers have been observed in devices manufactured with insufficiently pure water (2). Accumulation of mixed population biofilms containing sulfate-reducing bacteria causes corrosion in industrial water systems. A summary of biofilm effects in various processes follows:

- Reduced product quality in food production and processes producing goods for food handling, for example, package material
- Reduced water quality (e.g., pathogenic organisms) in cooling systems and in water distribution systems
- Contamination of immobilized systems, for example, loss of specific chemical transformations
- Material deterioration in metal condenser tubes, pipelines, and cooling systems
- Energy losses in heating of the process equipment
- Reduction in the effectiveness on remote sensors, sight glasses, etc.

Disinfection after removal of biofilms using suitable cleaning procedures is required in food plants where wet surfaces provide favorable conditions for the growth of microbes (22). In practice, a biofilm left on improperly cleaned surfaces is a barrier between microbes and the disinfectants, antibiotics, or biocides used against them (39–42). The permeability barrier of the biofilm considerably affects the efficiency of these agents. The effect of many antibiotics is based on inhibition of active growth. It has been said that most of the bacteria in biofilms are no longer growing actively and their resistance is therefore altered. The resistance of microbes in a biofilm cannot be proved without controlling their growth rate (43).

The food industries in which research on biofilms has been carried out are those producing canned products, meat and poultry products, pastries, biscuits, pizza, fish cakes, cheese, milk products, beer, spices, vegetable and salad products (20,42,44–49). Biofilms cause problems at various sites: air-handling systems (46,50–51), blancher extractors (46), conveyors (12,46), cooling systems (46,50), floors (12,52), floor drains (12,46), food contact surfaces of stainless steel (35,42,46), gaskets (45,48–49), heat exchangers (47,53), manufacture line for paper-based packaging material (28,54), milk-transfer lines (45,47), poultry-processing equipment (55), rubber-fingered pluckers (44), mixers, slicers, packaging machines (46), pasteurizers (47), ultrafiltration and reverse osmosis membranes (38,47), vegetable lines (46). We can see from the list that problems from biofilm can occur anywhere in the food process if the design and maintenance is improper.

Open Process Lines in Food Processing

Although there is a long history of biofilm impacting the food industry, actual biofilm research in this industrial area began in the late 1980s (8,56). The occurrence of slime-forming microbes is a major problem in the sanitation and disinfection of process equipment. Good surfaces, instruments, and equipment hygiene in the food industry promotes the quality of the products processed (55,57). Commonly found microbes on food contact surfaces are enterobacteria, lactic acid bacteria, micrococci, streptococci pseudmonads, and bacilli. Problems with the accumulation of particulates and cells will occur whenever cleaning is for any reason inappropriate (52). The most useful material in processing equipment is steel, which can be treated with, for example, mechanical grinding, brushing, lapping, and electrolytic or mechanical polishing. In electrolytic polishing, a preground surface is treated in an electrolyte bath to obtain an even surface. The surface structure of stainless steel is very important in avoiding biofilm formation (Fig. 2). It has been reported that although the grain boundaries of AISI (American Iron and Steel Institute) 316L acid-resistant stainless steel constitute 3 to 20% of the total surface area, over 90% of the adherent bacteria were found attached to the grain boundaries (58).

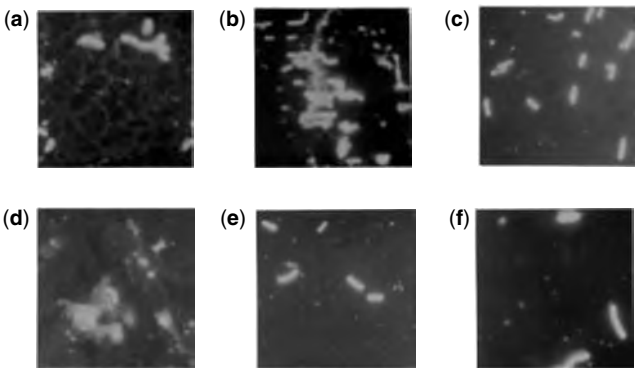

Figure 2. Epifluorescent microscopy photographs of 2-day-old *Bacillus subtilis* biofilms stained with acridine orange. The biofilms had been grown on various stainless steel surfaces (AISI 304): (**a**) standard 2B, (**b**) standard 4N, (**c**) standard BA, (**d**) glass blasted 2B, (**e**) brushed 2B and (**f**) electrochemically polished 2B surfaces. The scale marker is equivalent to 0.5 cm. See color insert.

Inadequate cleaning and sanitation of surfaces coated with biofilm cause contamination because the biofilm protects the microbes against sanitizers and disinfectants (22,59). Many equipment faults can be avoided by using good design practice guidelines, which are summarized in Table 1 (10).

The lubricants used in conveyors can function as a contamination source, especially in dairies and breweries. Oil-based lubricants containing water are very sensitive to microbial growth. *Acinetobacter* spp., *Alcaligenes* spp., *Pseudomonas* spp., and sulfate-reducing bacteria have been isolated from lubricants, and the biofilm formed in the lubricant can indirectly promote corrosion (60). *Listeria monocytogenes*, an opportunistic pathogen, has been isolated from lubricants in dairies (61). Problems with biofilms are also met in engineering works in which lubricants based on vegetable oils are used. Synthetic lubricants containing biocides have been developed, and the problems associated with contamination of lubricants has been decreasing (62).

Closed Equipment in Food and Drink Production

Poorly designed sampling valves can destroy an entire process or give rise to incorrect information because of biofilm effects at measuring points. Owing to their construction, valves are vulnerable to microbial growth and thus constitute a hygiene risk (29,63). Hoses, tubes, filters, etc. containing polyvinylchloride increase the risk of contamination (64). Biofilm is easily formed on measuring probes and the inner parts of equipment because these are usually difficult to clean (45,47). Microbial accumulation is known to be a problem on reverse osmosis membranes (65). When crust has fouled the probe no probe for measuring properties in biofilms can provide an accurate description of the process (29). The penetration of disinfectants and heat are hampered by the porous matrix on the surface, which diminishes the effect of sanitation and sterilization procedures. The bacterial slime of *Bacillus* sp. improved the heat resistance of the bacterium, extending the autoclaving time required for successful sterilization to several hours. Biofilm components can also alter the resistance to steam and formalin (10).

Table 1. Factors in Good Design Practice (10)

Design Area with Relevant Factors
• Organization and personnel responsibility functions, tasks, education, and courses
• Production and production control production: process parameters, installations, and maintenance of hygiene production control: working plan, material flow, and disturbance reports
• Equipment, pipelines, and equipment layout equipment: materials, surface finishing, accessories and joints, checking and cleanability, clearing and cleaning and insulation pipelines: accessories, materials, surface finishing, clearing and cleaning, consoles and insulation equipment layout: cleanability and cleaning of equipment, servicing of equipment, rationalization of operations and systematic layout
• Buildings and structures, electrification, and automation buildings and structures: materials, painting, sewerage, tipping, joints, cleanability of surfaces, layout of the connections of different production units and air-conditioning electrification: shielding of equipment and lighting automation: control of production and process reliability

Cooling Systems

Biofilm formation in process water systems has been known for a long time (3,66–68) and the adhesion of microbial cells to the surfaces in water distribution systems is also well known (1,69–71). The formation of biofilm takes several days at least, or weeks, in low-nutrient water systems. Biofilms formed in slow-flowing systems are structurally different from those formed in systems with high flow rates (72–73). The number of free planktonic cells in water does not necessarily correlate with the amount of biofilm on the pipe surfaces. The numbers of microbial cells adsorbed to surfaces may be as much as 500 to 50,000 times the numbers of planktonic cells in water (74). Biofilm formation appears in sinks, faucets, valves, and in different joint areas through the piping systems (3,75). It has been found that temperatures below 50 °C promote biofilm formation (72). The average temperature in cooling water systems is 35 °C, which is close to the optimum temperature for most microbial growth. From a hygienic point of view, biofilm can include organisms that cause infections and diseases. Problems with *Legionella pneumophila*, a pathogenic organism that is able to form biofilm, can occur in hot water systems (76–78). Biofilm formation can be decreased by more than 50% if the oxygen level in the water system is minimized, and by more than 80% when the amounts of both oxygen and nutrients are minimized (72). Anaerobic conditions favor biofilm formation by anaerobic organisms, which can increase corrosion (73,79).

Ventilation and Air-Handling Systems

Air quality in food production facilities is very important for the final product quality. The microbial population in the air channels depend on the environment, filtration membranes, and the sitings of airholes (51,80,81). Formation of biofilm in air-conditioning systems does not occur without a water reservoir of some kind. Normally, there is no water in the air-conditioning systems, but it can accumulate unintentionally through condensation. The pathogen *L. pneumophila* has been isolated from water systems that were connected to an air conditioner (82). When the air-conditioning system is to be cleaned and disinfected, it is very important that the disinfection medium penetrates the biofilm and does not simply flow through the system with the air (10).

A study carried out in various industrial ventilation ducts has shown that biofilms can accumulate

within the ducts. The occurrence of bacterial and fungal biofilms takes place within a few weeks. Biofilms form very easily in humid surroundings where oil has been left on the surfaces. Biofilm growth was prevented in clean room ducts by using effective filters and appropriate maintenance procedures (50). It is therefore very important to monitor clean room behavior, as the majority of particles in clean rooms originate from the personnel (81,83). The air filtration equipment must be chosen carefully to suit the processing environment (83,84). The membranes in the air-conditioning system and the walls in the air-conditioning channels are places where biofilms start to grow (80,85).

Production of Paper and Packaging Material

Biofilm formation causes major problems in paper machines and it affects the production of good quality paper-based packaging material for the food industry (28,54). The paper machines are connected to water-circulation systems, which are prone to rapid biofilm growth (86). The microbes, mostly bacteria and fungi, enter the process with the nutrients and from the air (87). The use of recycled fibers and changes in the acidity of the process to neutral or alkaline have increased the total amount of bacteria in the paper-making processes (88). It should be remembered that each paper-making machine has its own microbial flora, which depends on processing parameters such as pH and temperature, the season, and the additives used. The slime forming microbial flora can be divided into primary slime formers, for example, bacteria of the *Bacillus*, *Pseudomonas*, and *Enterobacter* genera and fungi of the *Aspergillus*, *Mucor*, and *Penicillium* genera, and secondary slime-formers, for example, bacteria of the *Alcaligenes, Flavobacterium, Klebsiella, Micrococcus*, and *Staphylococcus* strains, and fungi of the *Paecilomyces, Trichoderma*, and *Trichosporum* strains (89). Practical experiments show that biofilm in pulp- and paper-processing equipment detaches easily from the surface and the loose slime causes holes in the paper (90). Bacterial spores withstand the heat treatment during the production and therefore the *Bacillus* genera, which are spore formers, are the main source of contaminants in final paper and cardboard products (91). The slime in paper-machine biofilms contains 10^{11} to 10^{12} cfu/g dry mass. The microbial growth causes problems in corrosion, process flow, contamination, and paper quality (92). It also causes odor problems, which can destroy both the air quality in the process facilities and the quality of the end products (88). Bacterial biofilms of anaerobic sulfate-reducing bacteria, thermophilic bacteria, and bacteria producing acids and reducing compounds (5) cause corrosion of surfaces in the paper machines. Microbial corrosion causes more than 50% of all corrosion problems in pipelines in paper-processing machines. Efforts to combat microbial growth and biofilm formation in paper machines are important because the costs of maintenance of equipments are high (28,92).

DETECTION AND ELIMINATION OF BIOFILMS

Detection of Biofilm

Many reviews have been published on the formation and detection of biofilms in the laboratory (34,42,93,94). Methods of studying biofilm formation include microbiological, physical, chemical, and microscopical methods, and, methods commonly used in molecular biology (Table 2; 34,42,94–97). The biofilm consists of 85 to 96% water, which means that only 2 to 5% of the total biofilm volume is detectable on dry surfaces (4). Monitoring practices based on sampling of the liquid phase does not reflect the location or extent of microbes growing on surfaces. The counts of planktonic cell in the processing fluids should not be used in detecting biofilms because they do not represent the sessile organisms (98).

Inadequate cleaning and sanitation of surfaces coated with biofilms represents a source of contamination within the process (42). Practical methods for assessing microbes and organic soil on processing surfaces are needed to establish the optimum cleaning frequency of the equipment. These systems should, preferably, provide information online, nondestructively and in real time, about microbial growth required within the process. Online monitoring techniques transferred from various industrial fields, for example, glass fiber optics, infrared techniques, ion-mobility techniques, bioluminescence, microelectrodes, and heat transfer, could be used for assessing the quality of raw material and products and for control of microbial and chemical contaminants on processing surfaces. Advanced molecular biology methods can be used in the detection and enumeration of specific organisms on surfaces (34,99–101).

Both open and closed process equipment should be easily cleanable, and therefore, cleanability testing methods are needed. Development of practical detection methods for research on biofilm buildup is needed in order to use the knowledge of biofilm accumulation in the maintenance of process equipment. The natural luminescence of marine bacteria has been used to assess biofilms in marine systems and for on-line evaluation of biofilm formation and antifouling coatings (102,103). The transformation of luminescence-encoding *lux*-genes to food-spoiling bacteria or opportunistic pathogens makes it possible to use bioluminescence in cleanability studies (104). Further efforts are needed to optimize the microbial cleanability assay, using, for example, the *Photobacterium leiognathi* procedure (42), and to adapt the assay to both open and closed systems.

Chemical Agents Used in the Elimination of Biofilms

Efficacy of disinfectants and antimicrobial agents are usually determined in free-cell suspensions, which do not mimic the growth conditions on surfaces where the agents are required to inactivate the microbes (105–108). The agent must reduce the microbial population by 5 log units in suspensions in order to be considered effective. The goal for reduction of surface-attached bacteria with disinfectants is 3 log units (22). The standard suspension tests have proved sufficiently reliable because the

Table 2. Summary of Main Methods Used in Process Hygiene (34)

Detection Method	The Application Assesses
Conventional cultivation based on swabbing and contact agar techniques	Living bacteria on various types of growth media Limitation: sensitivity, time consuming
Impedance measurement	Activity of viable and injured bacteria directly and indirectly after reactivation in liquid growth media Limitation: sensitivity
ATP measurement	Total hygiene; large scatter in analysing biofilms because of different metabolic status of cells Limitation: sensitivity
Measurement of protein residues	amount of protein-based soil Limitation: sensitivity
Microscopical techniques using various staining procedures:	Limitation: not for routine use on-site
• epifluorescence microscopy	Area coverage; microbial distribution; cell type and cell viability; identification of microbes
• electron microscopy	Morphology of microbes; cell distribution; identification of microbes
• scanning confocal laser microscopy	Biofilm structures; ecology of biofilms; identification of microbes
• interference reflection microscopy	Adhesive interactions between surfaces and microbes
• differential interference contrast microscopy	Individual microbial cells (not for quantitative analysis)
Flow cytometry	Microbial cell densities Limitation: detachment of cells
Polymerase chain reaction (PCR)-based methods	Unculturable microorganisms; identification of bacteria in complex ecosystems Limitation: information on presence, but not on numbers and Viability of target organisms

variations of results are within acceptable limits when replication is adequate. There can, however, be problems with the repeatability and reproducibility of suspension tests if the organic load in the suspension varies. It is obvious that the surface tests are even more difficult to perform than suspension tests because of the carrier material used and the viability of dried cells on the surfaces (109,110).

Various disinfectants have been developed to destroy microbes (111). Microbes have, nevertheless, been found in disinfectant solutions, which means that microbial contaminants can be spread on the surface with the solution. Findings as early as 1967 reported that chlorhexidine mixtures were contaminated with *Pseudomonas* spp., which also have been found in concentrated iodine solutions (112). *Serratia marcescens* was found to be viable even after 27 months in a disinfectant containing 2% chlorhexidine. A concentration of 0.1% chlorhexidine is sufficient to kill the cells of *S. marcescens* if they are freely suspended in liquid (74). Microbial contamination has also been found in solutions of aldehydes and quaternary ammonium compounds (82). Other microbes that have been isolated from disinfectants include *Alcaligenes faecalis*, *Enterobacter cloacae*, *E. coli*, *Flavobacterium meningosepticum*, and *Pantoea agglomerans*.

Cleaning Agents. Cleaning agents are applied to remove soil, microbes, and biofilms from surfaces. The effects of the cleaning agents on biofilms have been thoroughly investigated (22,57,59,106). Removal of biofilm is important for the maintenance of the equipment, because the debris left on surfaces can act as nutrients for the buildup of new biofilm (36), or may corrode the equipment material. To minimize biofouling, it is best to clean the equipment at frequent and regular intervals, using suitable efficient cleaning procedures for the process before the biofilm has the opportunity to develop (113,114).

Efficient cleaning of surfaces depends on surface tension, viscosity, chemical reactivity, size of biofilm particles, solubility, and living microorganisms (115,116). The cleaning agents should be surface-active, soluble, easy-to-rinse, noncorrosive, and easy-to-use. They should also emulsify fats and oils, suspend insoluble particulates, and dissolve mineral deposits. Soaps and synthetic detergents clean surfaces in a similar manner, the surfactant molecule having hydrophilic and hydrophobic ends. The hydrophobic end dissolves oily soils (116). The alkaline and acidic detergents are mixtures of several classes of compounds: alkalis, acids, tensides, and surface-active agents (116). Currently used cleaning agents contain chelators, for example, EDTA, surfactants, detergent builders, antideposition agents, enzymes, and disinfectants (1,116,117).

The chelators, however, are not biocides and should therefore be combined with other antibacterial compounds (82). Chelators bind magnesium and calcium ions, thereby destabilizing the outer membranes of microbial cells and extracellular matrices. Chelators have been used in the breakage of the biofilm layers (118,119). Tensides

are large molecules with polar and nonpolar groups forming hydrophobic and hydrophilic parts, depending on the group. The tensides are divided into four types: anionic, cationic, nonionic and amphoteric tensides. Tensides are normally used in cleaning agents to achieve suitable cleaning and foaming effects. The amphoteric tensides contain both anionic and cationic parts and can therefore function both in acidic and alkaline environments or as double ions in the boundary region (120).

Disinfectants. Disinfection is required in food plant operations in which wet surfaces provide favorable conditions for the growth of microorganisms (57,121). The aim of disinfection is to reduce the surface population of viable microorganisms after cleaning, by destruction or removal, and to prevent microbial growth on surfaces during the interproduction period (122). Disinfectants do not penetrate the polysaccharide and glycoprotein matrix left on the surfaces after an ineffective cleaning procedure, and thus do not destroy all the living cells in biofilms (7,11). Disinfectants are most effective in the absence of organic material, for example, fat-, sugar- and protein-based materials (59). Microbes are less likely to survive disinfection after an effective cleaning. The efficiency of disinfectants is generally controlled by interfering organic substances, pH, temperature, concentration, and contact time (22,123). The desired characteristics of disinfectants are the same as for cleaning agents. They must be effective, safe, and easy-to-use, and easily rinsed off surfaces, leaving no toxic residues or residues that affect the sensory values of the product (116).

The use of disinfectants in food plants depends on the material used and the adhering microbes (116). It is therefore recommended that disinfectants used in the sanitation of food-processing equipment should be tested on surfaces in circulating systems. Disinfectant testing in a circulating system provides many replicates, which makes the evaluation easier and more rapid to perform. The variety in soil types, cleaners, and cleaning conditions makes it impossible to give an exact, overall statement on required temperatures and concentrations (124). Disinfectants approved for use in the food industry contain chlorine-based compounds, iodine compounds, alcohols, quaternary ammonium compounds or surfactants (1,116,125,126). The concentration of the disinfectant can be altered to provide shock treatments. It has also been suggested that the disinfectants should be changed continuously. In the maintenance of process hygiene, disinfectants should be chosen according to the process (127).

Chlorine or chlorine-based compounds that are approved for use in food plants, for example, gaseous chlorine, sodium hypochlorite, calcium hypochlorite, chloramine-T, and chlorine dioxide. The antibacterial active moiety is formed when chlorine gas or a hypochlorite compound is added to water and produces hypochlorous acid. Stabilized hypochlorites are used when disinfection of long duration is required (116). The range of microorganisms killed or inhibited by chlorine-based compounds is probably broader than that killed by any other approved sanitizer. Stressing factors such as chlorination can also induce biofilm buildup, for example, of *Pseudomonas* sp. (70). *Pseudomonas* spp. are relatively resistant to chlorine treatments and can even multiply when chlorine has been used. Free chlorine (1.0 mg/L) showed no effect on coliforms growing in biofilms, and even increased concentrations (2.0 mg/L) did not kill *E. coli* grown in biofilms. The material on which microbes form biofilm has a major influence on the effect of the disinfectants used. Capsulated *Klebsiella pneumoniae* grown on glass surfaces has been shown to have a 150-fold resistance to chlorine compound to those grown in suspensions. When a low-nutrient liquid is used, the resistance factor is increased to about 600. On metal and carbon surfaces, the corresponding resistance ratios were about 2,400 and 3,000 times the value in suspension, respectively (70). The effect of surfactant sanitizers against *L. monocytogenes* grown in biofilms was decreased (107,128); however, sodium hypochlorite and quaternary ammonium compounds have proved effective against 24-hour old biofilms (129).

Iodophors are used extensively in the food industry. Iodine oxidizes essential parts of the microbial cells. Like chlorine-containing products, iodophors are active against gram-positive and gram-negative bacteria, yeasts, and molds (116,122,125). Bacterial spores, however, are highly resistant to iodophors. Iodophors cannot be used in food plants in which starch-containing products are produced because iodine forms a purple complex with starch (116). Quaternary ammonium compounds are used as sanitizers in dairies and in the food industry because they have good wetting properties and are nonspecifically described as cationic surface-active agents in which the cationic part is hydrophobic. The greatest effect of quaternary ammonium compounds is observed against gram-positive bacteria, whereas gram-negative organisms, many of them significant in the contamination of food, may not be affected (116).

Hydrogen peroxide has been found to be effective in removing biofilms from equipment used in hospitals. The effect of hydrogen peroxide is based on the production of free radicals, which affect the polysaccharides and glycoproteins in the biofilm (130). The biocidal effect of peracetic acid on microbes in biofilms was shown to vary (131–133). Aldehydes did not disrupt the biofilm, but rather seemed to improve its stability. The biofilm must be disrupted in some way before chemical agents such as peracetic acid and aldehydes can be used effectively (131). The effect of ozone treatment has been found to vary depending on the processing circumstances and the microbes tested; for example, ozonation proved very effective in the treatment of cooling water systems (134,135). Physical disinfection can also be performed using ultraviolet irradiation, pulsed laser beams, or steam disinfection (116).

Elimination of Biofilms in Industrial Systems

General Aspects of Cleaning. Physical, chemical, and microbiological cleanliness are essential in food plants. Factors governing the selection of detergents and disinfectants in the food industry are that the agent should be efficient, safe, not damage or corrode equipment, be easy-to-rinse, and not affect the sensory values of

the product (59,113). Physical cleanliness means no visible waste, foreign matter, or slime on the equipment surfaces. Chemically clean surfaces are surfaces from which undesirable chemical residues have been removed, whereas microbiologically clean surfaces imply freedom from microbes (124). Attached bacteria or bacteria in biofilms can be a problem in food processing and grow and multiply after insufficient cleaning and contaminate the product (35). Once a biofilm is firmly established, cleaning, and disinfection becomes much more difficult (22,136). Caution should be exercised in selecting appropriate disinfectants for contaminated surfaces.

The key to the effective cleaning of a food plant is the understanding of the type and nature of the soil (e.g., sugar, fat, protein, and mineral salts) and of the microbial growth on the surfaces to be removed. The accessibility and type of equipment and accessories to be cleaned and the availability of suitable cleaning agents are also important (116). Intelligent integration and coordination between cleaning programs and manufacturing operations are essential to achieve both successful cleaning and business profit (116). An efficient cleaning procedure consists of a sequence of rinses and detergent and disinfectant applications in various combinations of temperature and concentration (113,131). This controls the development of biofilms on equipment surfaces without corroding the surfaces (113,114). An independent quality-control system to monitor the cleaning results for a food plant can be integrated in the program based on Hazard Analysis of Critical Control Points (HACCP). The goal to achieve a clean food plant must be desired by the plant management, which has to invest the necessary time and money to accomplish it. The personnel must be properly trained and responsible enough to maintain a good level of plant hygiene. The tools and materials must be properly designed for the plant equipment and the methods used must suit the process (122,124).

Factors affecting the cleaning process are based on mechanical and chemical impact, holding time, and temperature (22,59,116). The basic task of detergents is to reduce the interfacial tensions of soils so that the soil becomes miscible in water (116). The effect of the surfactants is increased by the mechanical effect of turbulent flow or water pressure, or of abrasives, for example, salt crystals. A prolonged exposure of the surfaces to the detergent makes the removal efficient. Detergents to be used in the cleaning of open systems are formulated to be effective at room temperature or at slightly elevated temperatures in the range 35 to 50°C (116). In closed systems, the detergents are formulated to be used at temperatures in the range of 55 to 80°C. Fats are easily removed at temperatures slightly above their melting point. Sugars and other carbohydrates are water-soluble at elevated temperatures, but temperatures causing caramelization should be avoided. Proteins are denatured at elevated temperatures and may adhere strongly to surfaces at high-temperatures. Cleaning and disinfection procedures can be optimized with pilot-scale equipment for both closed and open processes.

Elimination of Biofilm in Open Systems. Gross soil should be removed by dry methods, for example, brushing, scraping, or vacuuming, and visible soil rinsed off with low-pressure water. The cleaning effect is increased by using water of sufficient volume and temperature. However, a pure-water washing system is not practical because of its ineffectiveness and cost limitations. Pressure cleaning is used to remove the remainder of the soil and most of the microorganisms present on open surfaces (122). The elimination of biofilm from open systems, for example, surfaces in food-processing equipment, has not been widely reported. Biofilms were used in cleaning and disinfection studies for the food industry (8,56). After a production run, the equipment should be dismantled and the cleaned utensils should be stored on racks and tables, but not on the floor. The cleaning of open-process surfaces is carried out using either foam or gel cleaning. Foams are most effective in situations in which contact with the soil for an extended period of time is necessary. The foam-units are constructed to form foam of varying wetness and durability depending on the cleaning to be performed. The application of gels extends the contact time with a soiled surface and can be used with low-pressure systems (116). The cleaning is mostly carried out in combination with a final disinfection because there are likely to be viable microorganisms on the surfaces that could harm continued production (57,122,131).

Elimination of Biofilm in Closed Systems. In the cleaning regime applicable to closed systems, prerinsing with cold water is carried out to remove loose soil. The cleaning-in-place (CIP) treatment is normally performed using hot cleaning solutions (29), but cold solutions can also be used in the processing of fat-free products. The warm alkaline cleaning solution, normally of 1% sodium hydroxide (NaOH), is heated to 75 to 80°C and the cleaning time is 15 to 20 minutes. The equipment is rinsed with cold water before the acid treatment is performed at approximately 60°C for five minutes. The effect of chlorine-based agents can be divided into three phases: loosening of the biofilm from the surface, breakage of the biofilm, and the disinfecting effect of the active chlorine (137). The cleaning solutions should not be reused in processes aiming at total sterility because the reused cleaning solution can contaminate the equipment (29).

Studies on CIP cleaning showed that the "cleaning effect "decreased markedly when the washing time and the flow rate were reduced, indicating that the cleaning as a whole was affected by mechanical effects, time, temperature, and chemical parameters (57,59). Turbulent flow is therefore a decisive factor in combination with chemical compounds in the elimination of biofilms from closed systems. To ensure the removal of soil and to avoid biofilm formation and soil sedimentation, the minimum flow velocity in the CIP treatment must be at least 1.5 m/s, but 2.0 m/s is recommended. The flow should be turbulent with a Reynold's number from at least 10,000 to preferably 30,000, to ensure good radial mixing and heat, mass, and momentum transfer (138). Chelating agents in the cleaning solution enhance the removal of biofilms from processing surfaces. The CIP-systems

used today are based on a combination of alkaline-acid treatments and time-temperature treatments. Problems caused by equipment constructions, valves, and surface materials cannot be eliminated with CIP because the CIP treatment was not designed to eliminate biofilms. In normal operation, it is impossible to clean pipelines completely by mechanical treatment because there are always bends, corners, pockets, and cracks where biofilm remains (70). The depth of dead zones in the system should be less than two pipe diameters if the dead zone cannot be avoided, to ensure adequate cleaning throughout the system using CIP procedures. The maintenance programs should guarantee that excessive biofilm accumulation does not occur. Tanks should be cleaned by applying the cleaning solution through properly installed, removable spray balls or nozzles. The design should ensure that the part of the tank directly above the spray ball is also cleaned (29). Drainage, minimization of internal probes, crevices and stagnant areas, arrangement of valves, couplings, and instrument ports and instrumentation should be planned carefully so that the equipment is easily cleanable (29).

Legislation on food hygiene and the hygienic design of food machinery, together with the public awareness of product quality and manufacturers' desires to improve product safety, makes reliable cleanability testing an important issue. In this type of testing, it must be possible to assess the relative cleanability of various equipment components to facilitate the design, testing, and maintenance of hygienic food processing equipment. The assessment must use standardized test procedures with a sound scientific basis (139). The aim of the European Hygienic Equipment Design Group (EHEDG), which is an independent consortium of representatives from research institutes, the food industry, equipment manufacturers, and government organizations is to develop hygienic equipment on a scientifically and technologically sound basis.

CONCLUSION

Cleaning in the food industry should be on the basis of systematic planning. Biofilm formation in these systems is a symptom of disturbance in the process because biofilms can be produced under suitable growth conditions by any microbe. Biofilms are less likely to accumulate in well-designed systems, which are effectively cleaned. Detection of buildup on equipment surfaces at an early stage enables effective countermeasures and thus results in an improvement of the process hygiene. Methods used for monitoring the microbial load are based on conventional cultivation techniques using various types of growth media and for the total hygiene ATP (adenosine triphosphate). Careful thoughts must be given to the cleaning procedures, including the program, cleaning agents, disinfectants, and cleaning equipment. Results indicate that low-pressure cleaning is not sufficiently effective to remove biofilms, unless, the cleaning agent is effective. The efficiency of cleaning agents is assessed by their ability to remove biofilm from process surfaces together with their ability to kill the bacteria present in the biofilm. The cleaning effect in open systems can be enhanced using either increased chemical effect through double foaming or added mechanical forces through scrubbing. In closed processes, the removal of biofilms from surfaces can be performed using efficient flowing condition in combination with effective cleaning agents. Strong agents are used to combat microbial deposits on equipment surfaces in problem areas. Satisfactory elimination of biofilms using only disinfectant treatment cannot be achieved. The effects of cleaning procedures used in the food industry can be evaluated using life cycle assessment (LCA). All environmental aspects, including the process and energy consumption in producing the cleaning chemicals, transportation, properties of chemicals before and after cleaning, amount of water used, effects of organic and inorganic loads on the wastewater and on the recipient (e.g., nutrient load, pH, temperature).

BIOFILTRATION

HINRICH BOHN
University of Arizona
Tucson, Arizona

Biofiltration is the removal and destruction of gaseous contaminants in air as the air flows through porous solids containing degradative microorganisms (1,2). In engineering nomenclature, it can accurately be called *ambient temperature catalytic oxidation*. Microbial enzymatic catalysis at ambient temperatures in biofilters achieves the same results as precious metal catalysts at high temperatures. Biofiltration can effectively and economically destroy most gaseous air contaminants. A rule of thumb is that if a molecule can burn in air, it can degrade in a biofilter.

Figure 1 shows a schematic biofilter. Moist-contaminated air flows slowly through a porous biofilter medium; microbes in the medium oxidize the contaminants to carbon dioxide, water, and calcium salts. The biofilter medium can be soil, compost mixed with bulking agents, composted wood chips or wood bark, peat, or synthetic media (activated carbon, porous ceramic, and plastic packing). Because the gaseous contaminants are molecularly subdivided and intimately mixed with oxygen, the oxidation rates are many-fold faster than the same compounds in liquid or solid state.

Biofiltration is the most common application of this air treatment process, which is also used by biotrickling filters and bioscrubbers. In biofiltration, the microbial medium and water are stationary, and air is the moving phase. In biotrickling filters, both air and water move over a stationary microbial support. In bioscrubbers, microbial slurry is sprayed into the air stream.

In contrast to other air pollution control techniques, biofiltration creates or emits no secondary pollutants (NO_x, CO, Cl_2, O_3, wastewater, or waste solids), consumes no fuel or chemicals, and minimizes carbon dioxide loading of the atmosphere.

The microbial population adapts to the input gas composition; the adaptation time depends on the gas composition and, secondarily, to gas concentration (3). For rapidly biodegradable gases (Table 1), the initial destruction/removal efficiency (DRE) is 80 to 95% of the final, steady state DRE. The final DRE is reached after one to three weeks as the microbial population adapts and the medium material settles. The DRE for more slowly biodegradable gases tends to be low initially, and the

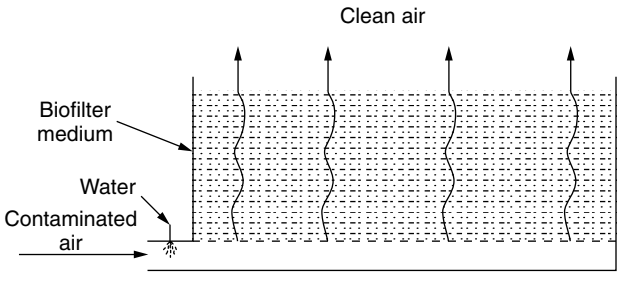

Figure 1. A schematic biofilter.

Table 1. Destruction/Removal (DRE) Rates of Air Contaminant Gases by Biofiltration

Rapid:
H_2S, HCl, SO_2, NO_x, Cl_2, O_3, silanes, alcohols, aldehydes, ketones, organic acids, ethers, esters, amines, mercaptans
Slow: (in approximate order of decreasing degradation rates): CO > terpenes > aromatic hydrocarbons > aliphatic hydrocarbons > CH_4 > monohalogenated and dihalogenated hydrocarbons
Unfeasibly Slow:
Siloxanes, tri-halogenated and higher-halogenated hydrocarbons

adaptation period may be as long as one month. The DRE, thereafter, is not affected by downtimes up to a week or two. Longer downtimes may require a short readaptation period.

The primary function of biofiltration is to destroy gases, but biofilters also filter out particles from air streams, even less than 2.5 μm particles. Particulates generally should be avoided in the input air, however, because they can plug the small pores of the biofilter. Mists are acceptable if the droplets are water or biodegradable liquids.

Although similar in appearance to sorption beds, biofilters function by oxidizing rather than by just adsorbing airborne contaminants. Biofilter media have little adsorption capacity for gases. The lack of any sorption capacity is an advantage in that, the media do not accumulate air contaminants in significant amounts and any adsorbate is quickly oxidized. Spent biofilter media is not a hazardous waste.

The potential benefits of biofiltration over other air pollution control techniques are

1. low to moderate capital costs,
2. low operating cost — no supplemental fuel or energy is needed, and the oxidant is atmospheric oxygen so no chemical oxidant (chlorine, ozone, and permanganate) is needed,
3. no secondary pollutants (CO, NO_x, Cl_2, O_3, dioxins, wastewater, and solid wastes) are created or released,
4. the catalysts (microbial enzymes) are free and continuously regenerate themselves,
5. low maintenance, and
6. inherent safety (low temperature and no combustibles nor hazardous chemicals).

In some cases, poor design and too high expectations have led to a lower than desired degree of pollution control, higher than expected maintenance requirements, and too frequent changeout of the biofilter medium. Biofilters, unfortunately, almost invite naive design because they are mechanically simple and because the air distribution system is not difficult. The difficulties of (*1*) maintaining an active microbial population, (*2*) maintaining low backpressure and uniform air distribution over the long term, and (*3*) moisture management are not apparent in Figure 1.

Some biofilter designs emphasize high effectiveness per unit volume or per unit weight of the biofilter, with penalties of higher initial cost, complexity, and maintenance. Other designs emphasize low initial and operating cost, ruggedness, long life, and low maintenance. Their penalty is larger size and mass.

In addition to the design problems, biofiltration has the inherent disadvantages:

1. Biofilters require longer reaction time than other techniques. Reaction rates at room temperature are slower than those at the temperatures of catalytic and thermal oxidizers and those with strong oxidants in chemical scrubbers.
2. Oxidation rates are compound-specific. Microbes generally oxidize gases containing oxygen, nitrogen and sulfur functional groups faster than hydrocarbon gases. Highly halogenated gases (tri-, tetra-, and higher) do not oxidize in biofilters. Monohalogenated and dihalogenated compounds oxidize slowly.

The air residence time in biofilters is seconds to minutes, depending on the biodegradability of the gas, the kind of medium, and the desired DRE. The residence time is usually expressed as the empty bed residence time (EBRT). The residence time in high-temperature oxidizers and adsorbent (activated carbon and zeolite) beds is fractions of seconds. Biofilters are, therefore, larger in size and area than other air pollution control devices.

Applications

The range of applications for biofilter treatment of contaminated air is potentially very broad (1,2,4). Biofiltration is most advantageous when the contaminant concentrations are low (<1,000 ppmv), at air temperatures of 10 to 55 °C, the air is humid and particulate-free, the contaminants are rapidly biodegradable, space constraints are absent, and recovering the contaminant is not economic, and when low maintenance is needed. The input air can often be made humid and particulate-free and brought to optimum temperature simply by water injection into the air stream. Biofilters are also advantageous where low maintenance, inherent safety, low visibility, and a green technology are important.

Wastewater treatment, food processing, and pharmaceutical, and some chemical manufactures have shown interest in biofiltration to date. This is largely because large airflow rates must be treated and the pollutant concentrations are low, and because their personnel recognize that microbes can influence the chemistry of their products.

In other industries, the responsibility for air pollution control is often given to mechanical and chemical engineers who may be unaware of the possibilities of microbial degradation. The trend toward size minimization also works to the disadvantage of biofiltration.

Potential industrial applications for biofiltration include treatment of ventilation air, process gases, storage tank vents, petroleum refining and handling, printing, solvents of all kinds, and relief valves. Because no start-up procedures are necessary and flow capacity is large, a

biofilter provides simple and useful treatment for storage tank and relief valve emissions. The Bhopal, India, accident reminds us that even simple treatment of accidental releases or safe containment in a biofilter is better than direct release into the atmosphere.

Because of the low cost of biofiltration and the large number of treatable pollutant gases, and because the moisture in the air is a benefit rather than a detriment, the extent of potential industrial applications is as wide or wider than the physicochemical alternatives — thermal oxidation, chemical scrubbing, or activated carbon or zeolite adsorption.

In an ideal world, air pollutants would be recovered for reuse rather than emitted. Recovery by adsorption or condensation is expensive, energy-intensive, incomplete, and sometimes hazardous. Hence, release is inevitable. Released gases are destroyed by oxidation. The choice of oxidative treatment — thermal, chemical, or biofiltration — is determined by economical and environmental constraints.

Economics

Figure 2 shows the applicability, based primarily on cost, of various air pollution control technologies. Over a wide range of airflow rates and pollutant concentrations — indeed the range of most air pollutant emissions — biofiltration has a strong economic advantage (the conversion factors are 1 cfm = 1.7 m^3 and mg m^{-3} = ppmv × molecular weight/24.06). The cost estimates are probably for the rapidly biodegradable gases as shown in Table 1. For hydrocarbons and other slowly degradable gases, the economic advantage of biofiltration is slightly less because the longer residence time requires larger biofilters.

Of the air pollution technologies, the installed cost of biofilters may be the most site-specific because of their size and weight. Urban locations may have too little available space to take advantage of biofiltration. In addition, biofiltration may require more ducting because the biofilter must be farther from the source. Biofiltration could find more applications if the constraints of biofilter weight and size were included in the initial plant design. Biofilter design has shown little imagination in adapting to the available space and configuration. Parking lot areas and rooftops are open invitations to innovative biofilters. In compiling Figure 2, the authors avoided some site-specific cost problems by using data for modular contained biofilters. Built-in-place, open biofilters tend to be less expensive.

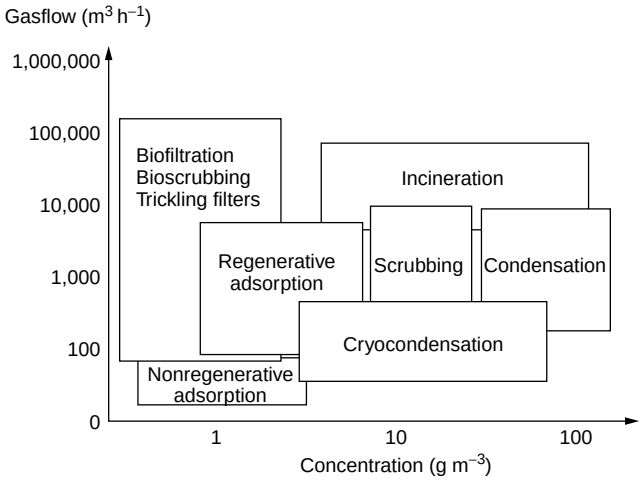

Figure 2. Applicability of various air pollution control technologies based on airflow rates and concentrations to be treated. (From Kosteltz, A. M. et al., in Proceedings of the 89th Annual Meeting and Exhibition of the Air and Waste Management Association, Pittsburgh, PA, 1996. With permission of KPMG Management Consultants, Ottawa, Ontario, Canada.)

Compound Specificity

The oxidation rate varies for each gas. Table 1 shows common gases grouped according to their relative biodegradation rate. If the molecule contains oxygen, nitrogen, or sulfur functional groups, it generally will biodegrade rapidly. A corollary is that if a molecule is water-soluble, it will biodegrade rapidly. Oxygen, nitrogen, and sulfur functional groups tend to increase both the water solubility and the biodegradation rate of organic gases.

Chlorine and bromine functional groups in organic molecules reduce biodegradation rates. Monohalogenated and dihalogenated molecules oxidize slowly under the highly aerobic conditions of biofilters. Biofilter control of these gases may be feasible under some conditions. More highly halogenated compounds need anaerobic conditions for the first stage of their biodegradation, reduction by substituting hydrogen atoms for halogens in the molecule. The reaction products are less halogenated and may be oxidizable in a biofilter. The reduction step is very slow, and a successful two-stage anaerobic–aerobic biofilter has yet to be devised.

Inorganic gases such as H_2S, NH_3, SO_2, and HCl react rapidly in biofilters, whereas NO_x (NO and NO_2–N_2 O_4) reacts more slowly. Nitrous oxide (N_2O) reacts even more slowly. The first step, the removal of the compound from the gas phase, is often chemical rather than biological and is very fast. The sulfur and the nitrogen gases are later oxidized microbially to their oxyacids, H_2SO_4 and HNO_3. The biofilter must neutralize this acidity or the microbes cease to function. The lower limit of acidity is conservatively about pH 2.5 for the sulfur gases and pH 4 for the nitrogen gases.

Table 1 gives no absolute numbers for oxidation rates or EBRT because the oxidation rates vary with the medium, temperature, water content; in some cases with nutrient conditions; and with the degree of DRE required. Laboratory measurements of degradation rates tend to be optimistic when compared with the field conditions, but the relative degradation rates obtained in the laboratory apply.

Mechanism

Under most conditions, where the contaminant gas concentration is less than 1,000 ppmv (ppmv is the volume fraction or mole fraction of the gas × 10^6), the kinetics of

biofilter oxidation are approximately first-order (5):

$$-dA/dt = kC_A \quad (1)$$

where A is a pollutant gas, k is a reaction coefficient related to the biodegradation rate of A, and C_A is its concentration. The oxidation rate increases with gas concentration, and the fraction of pollutant removed and destroyed increases logarithmically with reaction time t.

The DRE is

$$\mathrm{DRE}(\%) = \frac{C_{\mathrm{input}} - C_{\mathrm{output}}}{C_{\mathrm{input}}} \times 100 \quad (2)$$

Under first-order conditions, the DRE is independent of gas concentration, depends on reaction time (EBRT), and, therefore, depends on biofilter volume.

As gas concentrations increase above 1,000 ppmv, the reaction order gradually decreases to zero order:

$$-dA/dt = k \quad (3)$$

Then, the oxidation rate is constant and independent of gas concentration. Hence, the DRE decreases as the gas concentration increases at these high concentrations.

The first step of biofilter removal of air contaminants is chromatographic. The pore walls of the media are in equilibrium with clean air. The major components of air — dinitrogen, dioxygen, argon, and carbon dioxide — have already saturated the pore walls and, therefore, flow unimpeded through the biofilter. The contaminant gases, on the other hand, partition out on the moist pore walls in rough accordance with Henry's law and lag behind the major components of the air. The partitioning of a gas from air to the stationary phase increases with its polarity, water solubility, and molecular weight. The more tightly the gas is adsorbed, the longer the gas remains on the pore walls, the slower it flows through the biofilter, and the more likely it will be absorbed by a microbe and degraded or oxidized.

The chromatographic efficiency of biofilter media has not been measured under moist operating, conditions. In an air-dry sandy soil with low organic matter content, the retention volume (an index ratio of chromatographic efficiency and the reciprocal of the ratio of flow rate of contaminant gas relative to flow rate of air) ranged from one for methane to 10^5 for octane (6). The retention volume increased with increasing clay content in the soil. The retention volumes of the more polar gases methanol, dimethylketone, and diethyl ether were $>10^6$, too large to measure under the same experimental conditions.

The dryness was necessary to prevent appreciable biodegradation of the gases and to prevent large-scale changes of moisture content during the measurements. Biofilters, however, operate under moist conditions in which the water film on soil particles and microbes probably inhibits the partitioning of water-insoluble gases such as hydrocarbons onto the stationary phase and increases their relative flow rates. The presence of water increases the partitioning of water-soluble gases.

The chromatographic partitioning of gases has not been measured in organic, compost-based biofilter media. The greater organic matter content of these media might suggest greater chromatographic efficiency and greater retention of organic gases than in inorganic media. Because operating biofilters are very moist, however, the gases actually contact the moisture film on the particle surfaces rather than on the surfaces themselves. The water film greatly decreases the chromatographic differences between inorganic-based and organic-based biofilter media.

The sorption capacity of activated carbon mixed into biofilter media slightly increases chromatographic efficiency and buffers the effects of rapid changes of gas concentration in the input air (1). The benefit of activated carbon is lessened by its being saturated with water, which decreases its gas sorptivity. Microbes on the pore walls increase gas partitioning by degrading the gases and thereby reducing gas concentration in the water film.

The second and limiting step of contaminant removal and destruction is the rates of microbial oxidation, of chemical reactions, or of the gases on the pore walls. These rates are compound-specific (Table 1).

Biofilter modeling of degradation rates has emphasized the first step: dissolution of the gases into the water film and transport across that film. The shortcoming of this approach is shown by biofilter response to moisture content. Biofilter performance does indeed decrease when the moisture content increases beyond the optimum range. Biofilter performance, however, also decreases sharply when the water content is below this range (7). Although mass transfer across a thin water film is much faster, the important step is the microbial metabolic rate which has a maximum over a narrow range of moisture content.

The water films in biofilters are very thin. In an active biofilter, the water potential or hydraulic head is about -0.2 bar or -20 kPa (equivalent to a water activity of about 0.99 and equivalent to about 50–60% wet weight of water in compost and other organic media). At this water potential, pores with a diameter larger than about 10-μm in diameter are empty of water except for a water film <0.1-μm thick. "Pores" in biofilters are actually the network of interconnected cavities between the particles of the medium. The pores, which transmit the gas by convective flow, are tortuous and have nominal pore "diameters" ranging from perhaps 50 μm to several millimeters. Smaller pores may be dead ends or may have severely restricted openings so that diffusion is an important gas transfer mode in them.

Where the medium's particles contact each other at a water potential of -20 kPa, the water meniscus has a diameter of 10 μm. Between the contact points and on the surfaces of microbes, the water film is less than 0.1-μm thick. Because bacteria are on the order of 1 to 10 μm in diameter, this thin water film is a minor factor in gas uptake. The major function of water is to support microbial metabolism rather than to determine microbe-gas contact.

Gas adsorption and absorption are minor components of biofiltration. Like most solids, biofilter media adsorb only

minute amounts of gases. Porous solids can retain large amounts of liquids by capillarity, but this mechanism is absent in biofiltration. At biofilter temperatures and conditions, the gas concentrations are far below those that allow gases to condense to liquids.

Activated carbon is unique as a solid because its high surface area and nonpolar character help adsorb organic gases. Although compost and its mixtures also are organic, composts have a much lower sorption capacity than carbon because of higher polarity related to cellulose content and because of lower surface area. Silicates in soils are quite polar, a disadvantage for adsorbing nonpolar organic gases but an advantage for adsorbing inorganic gases. The organic coating on inorganic soil particles gives soils an appreciable nonpolar character.

Overloading of biofilters is evidenced by only partial oxidation of the input gases. Alcohols, for example, partially oxidize to aldehydes and organic acids rather than to carbon dioxide. A second indication of overloading is the buildup of microbial biomass that leads to plugging of the biofilter pores. This problem has been seen in laboratory experiments at gas input concentrations of more than 5,000 ppmv and more than 5 g/m^3.

Toxicity and Antagonism

Chemical toxicity to biofilter microbes is extremely unlikely. Microbes are so much more tolerant of biological toxins than higher organisms are that complete inhibition of microorganisms does not occur, although pulses of high concentrations of some pesticides might temporarily reduce degradation rates. Gas concentrations at even 10,000 ppmv are low in terms of mass per unit volume of biofilter media. Adding large amounts of toxic agents via the gas phase, therefore, is physically difficult. Biofilter slowdown usually is because of high or low moisture content or low temperature, rather than because of chemical toxicity. Herbicides for weed control on the surface of open biofilters are in too low a concentration to affect biofilter performance.

Antagonism, a decrease of gas removal or destruction related to the presence of other gases, is rarely seen in biofilters. Gas mixtures even at more than 1,000 ppmv concentrations show little evidence of antagonism; the presence of one gas does not inhibit the oxidation rate of other gases. Instead, the microbes degrade the more rapidly biodegradable gases first. More slowly biodegradable components are oxidized further along in the biofilter column.

Conditions at higher concentrations are more complicated, but antagonism is still small at 5,000 ppmv for some gas mixtures. These high concentrations are in the range where oxidation by synthetic catalysts may be more economical.

Some process gases may be low in oxygen so that, as in other oxidation techniques, dilution air is necessary. Microbes are efficient in their oxygen utilization, so only a little more than the stoichiometric amount of oxygen in air need be added. If the exhaust air contains some oxygen, the microbes in the biofilter are not oxygen-starved.

Biofilter Media

The essential criteria for biofilter media are that they support microbial growth and permit gas flow. Microbes can grow on many materials and some materials, such as soil, compost (alone and in mixtures), and peat, are natural supports for microbial growth. Other porous, synthetic media, including plastic packing, activated carbon, and porous ceramic, can be seeded to provide the initial microbial population.

Since many porous materials can serve in biofilters, the choice hinges on other features of the media, including cost, stability, hydrophobicity or hydrophilicity, density, nutrient supply, pH buffering, and maintenance requirements. The cost differences are large. Synthetic media cost dollars per kilogram, soil mixtures cost up to \$50/m^3, and compost mixtures cost from \$50 to \$500/m^3.

The stability of the medium affects the long-term flow uniformity through the biofilter bed and the frequency of bed replacement (changeout). Organic media are inherently unstable, heterotrophs feed on the media and on the input gases. As the medium is consumed, it shrinks, forms cracks, and pulls away from its container walls. In addition, the media particles become smaller and more mobile. Water flow tends to deposit them in the pores at the interface of the medium and the distribution layer so that this layer becomes impermeable.

Under careful management and in enclosures, some compost mixtures have a 10-year lifetime. Open compost beds can start developing cracks within several months; two years might be a maximum before backpressure builds up and the DRE is no longer satisfactory.

Inorganic media, such as siliceous soil, plastics, and ceramics, are not attacked by microbes, and impermeable layers are less likely to occur. Soils and distribution layers rich in $CaCO_3$, however, can clog severely within months.

Soil and other inorganic media are permanent, that is, no replacement is required and DRE and backpressure are stable. Native soils, however, usually are far too impermeable for industrial-scale biofiltration, and airflow is spatially nonuniform. An appropriate soil mixture is a mixture of several components to provide an acceptable trade-off between DRE, air permeability, and uniform flow.

Hydrophobicity and/or hydrophilicity affect moisture management in biofilters. The most common cause of biofilter failure is inadvertent drying of the medium. Organic substances tend to be hydrophobic when dry; inorganic substances tend to be hydrophilic. Rewetting a dry organic-based medium means taking out the medium and physically mixing in the water, which is a tedious, dirty, time-consuming, and often impossible task. Simply pouring water on the surface is ineffective because the water flows down through cracks and along wall boundaries rather than thoroughly and uniformly wetting the medium.

Hydrophilic substances, on the other hand, rewet easily and water flows to all parts of the biofilter bed.

Simple surface irrigation restores biofilter activity. Soils, ceramics, and pearlite materials are hydrophilic.

Synthetic media provide little or no mineral nutrients (nitrogen, phosphate, calcium, and so on) and hence require periodic supplementation. Microbes attach weakly to plastic media. Compost and the synthetic media are supplemented with a $CaCO_3$ source such as crushed seashells to maintain acidity at pH 6 to 8. Soil media have greater pH buffering capacity, but may require additional lime.

Media density is important when lightweight is important, and when biofilters are portable or placed on structures. Organic media have densities of about 400 kg/m^3 when wet and soil and ceramic media have densities of about 1,400 kg/m^3.

A lower maintenance requirement generally means a more successful and effective biofilter, and lower operating and maintenance (O/M) costs. Included in O/M costs are bed replacement, backpressure, moisture monitoring, and in some biofilters the cost of preheating the air. Since replacement is a high and recurring cost, good biofilter designs make replacement of nonpermanent media as easy as possible. Modular biofilters require replacement of the entire unit. Backpressure is lower initially in compost biofilters than in soil biofilters but increases with time. The backpressure remains stable in inorganic and plastic media. The initial backpressure of a large biofilter bed usually is 2 to 8-cm water head or 200 to 800 Pa. Small modular biofilters may have backpressures of 40 cm-water head, or 4,500 Pa.

Synthetic media are more homogeneous (thereby providing more uniform distribution of airflow through the medium), their DRE per unit mass is greater than that of natural media, and their density is low. As yet, these benefits rarely outweigh their much higher cost.

Moisture

Biofiltration is a microbial process, and the microbes function best over a rather narrow range of moisture content. Moisture content is usually expressed as percentage of wet weight of the bed medium. For organically based media, the range is 50 to 60%. At greater moisture contents, pores become saturated with water, whereas at lower moisture contents, microbial activity decreases. At less than 40%, the degradative capacity is severely limited (7). Rewetting the bed to 50 to 60% may not restore performance. The lack of recovery probably is due to the difficulty of thoroughly rewetting hydrophobic media.

Wet weight is convenient for measurement, but it depends on the density of the medium and the particle size distribution. For organic media, density and particle size distribution are similar enough that 50 to 60% suffices. The range for inorganic media (soil or ceramic), however, is 10 to 25%, depending on particle size.

Worse yet, mass units such as wet weight do not express the actual criterion — moisture availability — that affects microbial activity. Much of the water in biofilter media is too difficult for microbes to extract without slowing their metabolic (degradation) rate.

Availability of water can be expressed either as chemical potential (also called *chemical activity*, which is numerically equal to the relative humidity (RH) of the air at equilibrium) or as physical potential (also called *hydraulic head, water tension*, or *suction*) (8). The 50 to 60% wet weight moisture content in organic biofilters is a water potential or water activity around 0.99, with 0.95 being a lower limit for good performance. The same range of water availability expressed as physical potential is about -0.2 bars, with perhaps -3 bars as a lower limit. The equivalent SI units are -20 and -300 kPa. Measurement of water availability is, however, difficult and slow. Instruments that measure moisture content or availability that can be linked to irrigation devices are being developed.

Because drying out is the most common cause of biofilter breakdown and because the effluent air is at 99 to 100% RH, biofilters should ensure that the input air is at 100% RH. Fogger nozzles in the input air stream are common, indeed almost a necessity. Oxidation of the contaminants raises the biofilter temperature slightly. This decreases the RH of the air and increases evaporation in the medium. Surface irrigation is needed to overcome this internal evaporation and evaporation from the surface. This irrigation usually is triggered by a timer rather than by need.

Because water availability is in effect an index of the thickness of the water film on the medium's particles, water availability can be estimated visually. At water availability at the optimium moisture level, expressed as 0.99 activity, -0.2 bar, -20 kPa water potential, or 50 to 60% wet weight in organic media, the medium appears dark and moist. A visible sheen indicates that the water film is too thick and the moisture content is too high. If the medium is light-colored and darkens when water is added, the medium is too dry. Also, the water film at optimum moisture availability has sufficient surface tension to hold the medium's particles in a cast when the particles are squeezed lightly in the hand. These moisture properties should all be tested at greater than and equal to 15 cm below the surface of open biofilters. Moisture content at the surface reflects recent climate effects rather than biofilter moisture content.

Irrigation and rainfall are sometimes in excess of biofilter needs. Drainage must be provided to prevent water accumulation. Irrigation should be scheduled so that the amount of drainage water is kept to a minimum. The water phase may contain soluble gases, but these concentrations are low. Drainage water from compost biofilters contains brown-colored organic compounds similar to natural humic acids, and the water may be cloudy. The water is nonhazardous but unsightly. Drainage water from inorganic media is clear and colorless. The drainage water can be recycled to the biofilter, or the drainage water can flow slowly into the aerobic soil beneath the bed, where natural processes treat the water further. The risk of groundwater contamination is exceedingly small.

Impermeable liners under biofilter beds can complicate water management by inducing water buildup. Liners can be an additional liability because, despite careful

installation, they leak sooner or later, and all the drainage is concentrated at the leaks rather than spreading out the water for more effective treatment. Concentrating the flow makes natural water treatment much more difficult.

Temperature

The temperature operating range for biofilters is approximately 10 to 55 °C. The optimum is generally considered 37 °C, but some biofilters successfully utilize thermophilic bacteria at around 45 °C. Below 10 °C biodegradation still occurs at slower rates; biofilters can function successfully at very close to freezing temperatures. Input gases beyond the range of 10 to 55 °C can be warmed by steam injection or can be heated and cooled by water injection or mechanical cooling. Water and steam injection have the benefit of maintaining high RH. Water injection has the additional benefit of washing out airborne particulates that otherwise could plug biofilter pores.

The oxidation rates are less temperature-dependent than the typical $Q_{10} = 2$ (the reaction rate doubles with each 10 °C increase of temperature) of microbial reactions would indicate. At low temperatures, gas partitioning improves because gases are less volatile and are more soluble in the water film. Heterotrophs are adapted to function in natural soils in which the average annual temperature is 0 to 15 °C, except in very warm climates where soil temperatures may reach 25 °C.

CONCLUSION

Biofiltration is an effective means of removing and destroying air contaminants from many waste airstreams. Biofiltration is a low-cost technique over most of the range of industrial emissions because it requires no fuel or chemical and relatively little maintenance. In addition, biofiltration creates little or no secondary emissions or wastes, is inherently safe, and is environment friendly. Limitations of biofiltration are its compound specificity and relatively low oxidation rates, requiring relatively large reactor volumes. Good biofilter designs maintain high microbial activity over a wide range of moisture conditions and utilize the most appropriate biofilter medium.

BIOFILTRATION AND BIOODORS

JOSEPH S. DEVINNY
University of Southern California
Los Angeles, California

DEREK E. CHITWOOD
University of California
Riverside, California

With continuing population growth, it has become ever more common that residential developments are situated near industrial and utility facilities. At the same time, the public has become less tolerant of foul odors and is more likely to demand that release of odorous vapors into their neighborhoods be prevented.

Biological processes are commonly used for treatment of odorous wastes such as wastewater, sludge, compost, or garbage. Treatment systems may become sources of odors because vapors escape in their original form from the waste or because odorous compounds are created in the collection or treatment system.

Odors typically consist of low concentrations of contaminants in large volumes of air. This type of discharge is expensive to treat by thermal methods because of the large amount of fuel needed to heat the air. Adsorption often is also inefficient because the low concentrations mean only small amounts of material are adsorbed on a given mass of adsorbent. Biofiltration, in contrast, is well suited for treating odors.

There is a substantial body of literature on the generation and control of bioodors in wastewater and composting systems (1–4), and several summary treatments of sulfide generation in wastewater systems (5–7). There is a modest but rapidly growing body of literature on biofiltration for air contaminants (8) and its application to wastewater odors (9,10).

ODORS IN BIOLOGICAL TREATMENT SYSTEMS

Biological treatment systems are designed to transform waste materials to benign products. Organic compounds are converted to carbon dioxide and water, sulfides are oxidized to sulfate, amines are oxidized to nitrates, wastewater organics are converted to stabilized sludge, and yard waste becomes useful compost (11). However, the variable nature of the waste, the complexity of the waste collection and treatment systems, and the great diversity of microorganisms lead to the creation of transformation products that are offensive odorous compounds.

It is useful to classify odors as those that are released from aerobic environments and those that come from anaerobic environments. The odors from aerobic environments generally are less offensive, and often are described as “musty.” Odors from anaerobic environments are often extremely offensive. Humans undoubtedly evolved to perceive odors from anaerobic biological systems as disgusting because it causes them to avoid spoiled food and human waste that may be sources of diseases. The

Table 1. Odor Compounds in Wastewater Treatment

Reduced Sulfur Compounds	Reduced Nitrogen Compounds	Others
Hydrogen sulfide	Ammonia	Acetaldehyde
Allyl mercaptan	Dibutyl amine	Chlorine
Amyl mercaptan	Diisopropyl amine	Ozone
Benzyl mercaptan	Dimethyl amine	Sulfur dioxide
Dimethyl sulfide	Ethyl amine	
Diphenyl sulfide	Indole	
Ethyl mercaptan	Methyl amine	
Methyl mercaptan	n-Butyl amine	
Phenyl mercaptan	Pyridine	
Propyl mercaptan	Skatole	
Thiocresol	Trimethyl amine

Schafer, Chair, Joint Task Force of the Water Environment Federation and the American Society of Civil Engineers, *Odor Control in Wastewater Treatment Plants* (ASCE Manuals and Reports on Engineering Practice No. 82 and Water Environment Federation Manual of Practice No. 22), American Society of Civil Engineers, New York, 1995.

dominant compounds in waste treatment odor problems are sulfides and amines (Table 1).

The distinction between aerobic environments and anaerobic environments is also useful because it is a key to some control methods. An adequate supply of oxygen can stop generation of the odors that arise from anaerobic systems. On the other hand, conditions that promote vigorous transfer of oxygen from the atmosphere to the microbial ecosystem also promote release of volatile compounds from the liquid. In some cases, it is best to suppress gas transfer until treatment of the odor compounds is complete.

Disposal of Odorous Compounds to Treatment Systems

Some of the compounds that cause odor problems in wastewater or composting systems are those that have been disposed of to the system. Human waste, of course, has odors at the time it is discharged, and manures smell bad when they are added to compost. Industrial wastes may also include odorous compounds, particularly volatile solvents.

Biological Odor Generation

Microorganisms transform chemicals for two purposes: to synthesize compounds that they use to make growing cells and to provide energy. The reactions that produce energy generally process far more material than the synthetic reactions do. Microorganisms need the energy to move and drive their metabolism and often to drive synthetic reactions. Because larger amounts of products are generated, catabolic reactions are more likely to produce odor problems. Further, the products of synthetic reactions are rarely gases, and only gases can become odors.

By definition, energy production requires reactions that are thermodynamically favored under the conditions the cell is experiencing: the products must contain less energy than the reactants. Under oxidizing conditions, the usable reactions are usually redox reactions in which oxygen acts as the electron acceptor and is added to the reactants. Hydrocarbons are converted to aldehydes, alcohols, or carboxylic acids. These compounds are further oxidized to carbon dioxide and water that are compounds with lowest energy under aerobic conditions. Although there is a multitude of metabolic pathways, depending on the starting compound and the microorganism, the ultimate products usually are carbon dioxide and water, which are odorless.

Microorganisms that oxidize organic compounds tend to dominate aerobic ecosystems because the energy available per mole of material processed is far greater than that for reactions possible without oxygen. However, other reactions are possible. Organic nitrogen or nitrite can be oxidized to nitrate by the nitrifying bacteria. Organic sulfide and hydrogen sulfide are oxidized by bacteria such as those in the genus *Thiobacillus*. Nitrate and sulfate have essentially zero vapor pressures, and so do not contribute to odor problems.

Ultimately, oxidative processes tend to convert odorous compounds to end products that are inoffensive (Fig. 1). Although some intermediate compounds such as short-chain fatty acids and amines may be troublesome, they tend to be rapidly biodegraded, so the general tendency is for wastewater, compost, or biosolids to become less odorous as aerobic treatment proceeds. Primary sedimentation basins and fresh solid waste must be covered, but secondary aeration basins and treated compost are far less offensive.

Oxidative processes will dominate as long as oxygen is plentiful. If the amount of oxygen-consuming material is small or if there is a mechanism by which oxygen is continuously supplied, the organic matter will be degraded and the sulfides and amines will be oxidized. However, oxygen is not highly soluble in water. Water in equilibrium with the atmosphere carries perhaps 7 to 9 mg/L of dissolved oxygen, depending on its temperature. A liter of wastewater typically contains material that will consume over 100 mg of oxygen, so the oxygen will soon be depleted in wastewater that is not vigorously

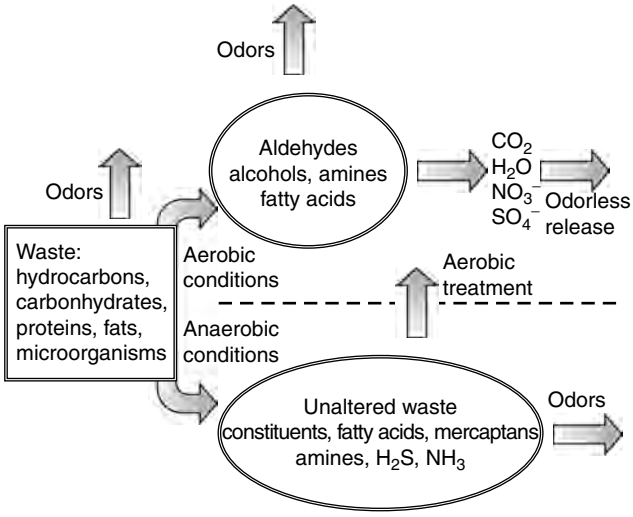

Figure 1. Pathways for odor production and release in biological treatment systems.

aerated. When this occurs, microorganisms that are capable of using other compounds as electron acceptors will proliferate. Denitrifying organisms will use nitrate as the electron acceptor to produce nitrogen gas or nitrous oxide. As nitrate becomes less plentiful, bacteria such as *Desulfovibrio* will oxidize organic matter using sulfate as the electron acceptor, thereby producing sulfides.

Hydrogen sulfide (H_2S) is produced in wastewater collection systems by anaerobic sulfate-reducing bacteria. Organic material contains approximately 1% sulfur (dry weight, 12). Sulfur as sulfate in wastewater ranges in concentrations from a few parts per million (ppm) to hundreds of ppm, depending on the source (5). Sulfate-reducing bacteria can grow only in the absence of oxygen, when the conversion is thermodynamically favored. The reduction rate of sulfate to sulfide depends on the wastewater BOD or COD, sulfate concentration, dissolved oxygen concentration, and a number of other growth factors (5).

Without the energy benefits of oxygen as an electron acceptor, degradation of waste organic matter by microorganisms is much slower and less complete. Under anaerobic conditions, odorous organic compounds that are present in the original waste are less likely to be degraded. Odorous intermediates such as fatty acids, mercaptans, and amines will accumulate.

Transfer of Odor Compounds to Air

The general strategies for control of biologically generated odors follow from Figure 1. The objective is to convert the waste to odorless carbon dioxide, water, nitrate, and sulfate, without releasing odorous intermediate compounds along the way. The best approach is to keep the waste aerobic and contained until it is converted to the odorless product. However, in complex collection and treatment systems, anaerobic zones will develop where force mains are required, where flow is unexpectedly slow, or where sediment or slime layers build up (2,5). Garbage left too long in the truck or compost at the bottom of a storage pile may consume all of a limited supply of oxygen. Some treatment processes intentionally are kept anaerobic. If anaerobic conditions do occur, the waste flow should be contained until aerobic treatment can complete the transformation to oxidized products. For air, this may be done in a downstream biofilter.

An odorous compound becomes a nuisance only after it is transferred to the air. It becomes a problem for the surrounding community only if it is released in sufficient amounts to overcome the dilution that occurs between the point of release and the neighbors and to arrive there in concentrations above the odor threshold.

Quigley and Corsi noted that three factors contribute to the release of volatile compounds from wastewater (13):

1. The amount of compound present in the wastewater. High concentrations of the odorous substance increase the rate of transfer of the compound from water to air.
2. The presence of conditions that create turbulence. Drops in collection system piping and treatment plant equipment such as weirs and flumes mix the water, promoting volatilization. For sulfide and many other compounds in wastewater flow, concentrations in the air above the water typically are far below equilibrium. The mixing constantly brings high concentrations of odor compounds near the surface where volatilization can occur.
3. Rates of ventilation of the headspace above the water. If the wastewater is within a pipe or some other enclosed structure, the rate of release of odor from the structure will depend on the rate at which the air in the structure is discharged. In some cases, it is possible to minimize this discharge by making the structures as airtight as possible. However, in any space that will be entered by workers, 20 to 30 changes per hour are required for safety (5).

Although Quigley and Corsi (12) described release of volatile organic pollutants that had been dumped in sewers, the same principles apply to any volatile compound in a wastewater handling structure. They emphasized that not all these factors may be present at the point where the compounds are discharged or created, and releases are highly variable along the path from wastewater discharge through treatment to treated effluent discharge. It is quite common that odorous compounds generated in one part of the collection or treatment system can be released from another part of the system.

Van Durme (1) made the same point with respect to odor releases at various points within a treatment plant, emphasizing that a compound may be produced in one part of the plant but dominantly released at some downstream point where there is turbulence and exposure to the atmosphere. She noted, for example, that wastewater flowing over weirs is commonly a major source of odor.

ODOR TREATMENT BY BIOFILTRATION

Principles of Biofiltration

Biofiltration removes air pollutants by passing the contaminated air through a damp, porous medium on which a mixed culture of microorganisms is immobilized. The contaminants are absorbed from the air phase into the water phase, which includes water and a biofilm, surrounding the medium (Fig. 2). The transfer rate between the air phase and water phase is dependent on the compound characteristics, the concentration of the chemical in the air and water phase, the concentration of other chemicals in the water phase, the type of medium, the surface area of the water/air interface, and other factors (8).

Biofilters may be characterized as completing the aerobic treatment pathway (Fig. 1). Heterotrophic bacteria in the water and biofilm that use organic compounds for their energy source are chiefly responsible for the oxidation of volatile organic compounds (VOCs). Hydrogen sulfide and ammonia are transformed by chemoautotrophs.

Under ideal conditions, carbon dioxide and water are the ultimate products of contaminant degradation. Treatment of certain VOCs or compounds containing nitrogen, chlorine, or sulfur may produce acids (14–19).

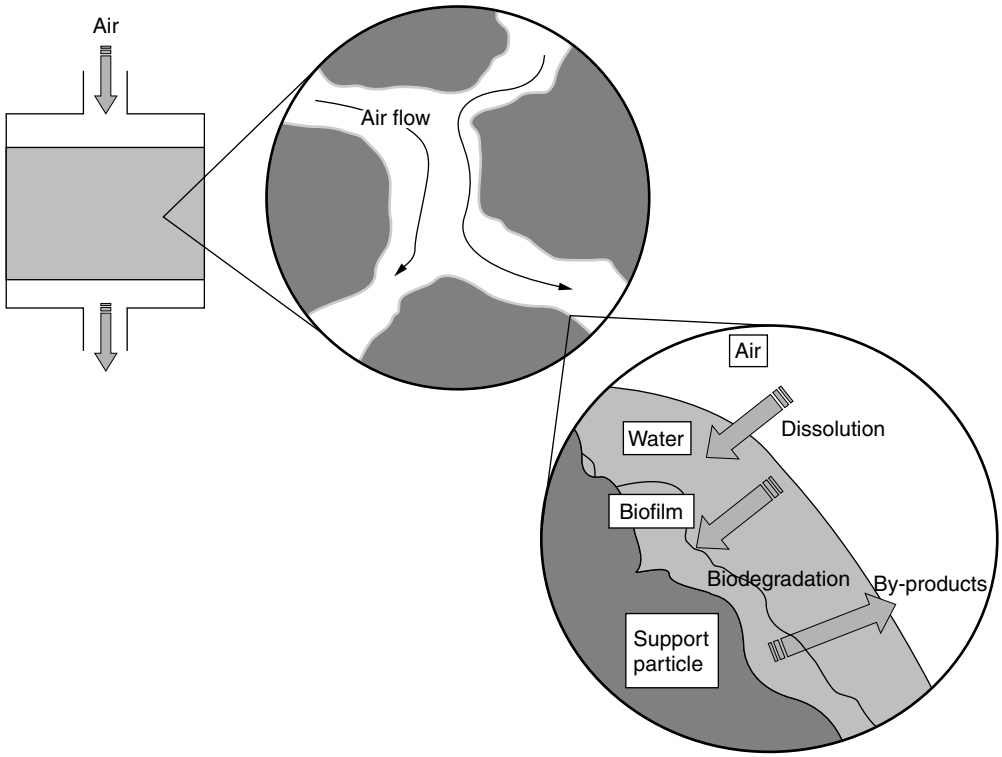

Figure 2. Detail of biofilter mechanisms.

Acid production is a common problem in Publicly Owned Treatment Works (POTW) biofilters because hydrogen sulfide usually is the dominant odor-causing compound, with typical concentrations ranging from the low ppm to the hundreds of ppm. The production of acid causes difficulties for POTW biofilters because most known heterotrophic bacteria capable of consuming VOCs prefer neutral pH (20). Researchers have assumed that removal efficiencies decrease with decreasing pH, and early data supported this (14,15) assumption. A second problem of acid production is that acid degrades organic packing such as compost, opening channels in some areas and compacting others.

Buffers, such as oyster shells (14) or dolomite (21,22), have been added to the packing to avoid pH decrease. However, the rates of acid production commonly seen in wastewater treatment plants consume packing buffer relatively rapidly. The spent minerals and acid-degraded compost often form small particles and contribute to biofilter clogging. Head loss rises, increasing operation costs, and efficiency declines. Elemental sulfur also may accumulate and may be inhibitory. This commonly limits compost to a lifetime of three or four years (15). The packing also may be washed with water to help control the pH (15). However, it is difficult to ensure uniform treatment because the water flows down through the packing in irregular patterns. In practical applications, it is difficult and expensive to control the pH, and the medium is usually replaced when its alkalinity is completely exhausted (20,23) and the pH falls below 6.

However, several recent studies have shown that biofilters are effective at lower pH where only a small amount of wash water is needed to stabilize the pH. The amount of acid discharged in biofilter leachate increases as pH falls because the concentration of protons in solution increases. Thus, the pH falls until acid production is equaled by the discharge of acid in biofilter drainage. Uncontrolled systems typically stabilize at a pH between 1 and 3, where treatment can continue indefinitely. Shinabe and coworkers (24) studied the removal of H_2S by *Thiobacillus thiooxidans*. They found that greater than 99% removal of H_2S was possible in their two-stage full-scale biofilter using a ceramic medium. The removal efficiency was not pH-dependent. Webster and coworkers (25) conducted a bench- and pilot-scale study at a POTW for 18 months. They used a variety of packing materials and compared pH-controlled and uncontrolled conditions. They found that their biofilters were effective at simultaneously removing hydrogen sulfide and VOCs at both bench scale and pilot scale irrespective of pH control. Chitwood and coworkers (26) operated a pilot-scale biofilter with a 1-cm diameter lava rock as the medium. The system was operated with an average hydrogen sulfide inlet concentration of 5 ppm and the bed at pH 4. They observed greater than 90% removal of hydrogen sulfide and 75% removal of total VOC at an empty bed residence time (EBRT) of 13 seconds. Each of these studies used inorganic medium that did not deteriorate at low pH conditions.

A practical limitation of biofilters is the required footprint. Traditionally, biofilters have been designed with an EBRT (calculated as the volume of packing divided by airflow) of 60 seconds. A loading rate of $15–25 \times 10^{-4}$ $m^3/s\text{-}m^2$ is typical. However, biofilters designed for removal

of H_2S from air can accept higher loads. Greater than 90% removal of H_2S has been achieved in several biofilters operated with an EBRT of 15 seconds or less (24,26,27). Under practical conditions for POTWs, transfer of hydrogen sulfide from the air phase to the liquid phase and maintenance of uniform airflow may be more important limitations than contaminant degradation rates.

Biofilter Designs

Conventional biofilters are single-stage, up-flow, and open-bed systems with an organic medium (Fig. 3). These biofilters require periodic watering with sprinklers but no nutrient addition, and require little maintenance. They are often constructed by excavating a pit, lining it with a plastic sheet, placing a perforated pipe, and adding gravel and compost. They are attractive because of their simplicity and low cost. However, closed systems (Fig. 4) that allow better system control and performance are largely replacing open systems in industrial applications (28).

A biofilter system generally consists of eight components. Ductwork collects the gases from the source. An air blower is provided to move the air through the system. The blower is usually located upstream of the biofilter vessel, but it may be placed after the biofilter if a closed bed is used. (With this arrangement, the biofilter operates under pressure slightly less than that of the surrounding atmosphere, so that any leaks will draw ambient air into the system rather than allow contaminated air to escape. This is especially beneficial when the biofilter is located inside a building or when the contaminants are strongly odorous or toxic. It also means that the blower will not be in contact with untreated air that may be corrosive.) A humidification chamber is used to increase the relative humidity of the air to approximately 100% before it enters the biofilter. This is necessary to prevent drying of the bed. Air distribution and ventilation piping provides homogeneous distribution of the air and then collects the treated air to be released. The biofilter bed can be single or multiple layers, depending on the treatment requirements and available space. An irrigation system is used to maintain proper water content in the bed. It can also be used to add nutrients and pH buffers. Although biofilters produce only a small amount of leachate, a leachate collection system is also required. Leachate is often recycled to the inlet of the irrigation system so that the nutrients in it can be reused. Periodic wasting of leachate is necessary to prevent buildup of salts or toxins in the system.

Application to Treatment Plant Odor Control

Application of biofiltration to odor-emitting facilities such as POTWs and compost plants is appropriate because biofilters are most suited for treating large volumes of air with low concentrations of contaminants characteristic of these facilities. Application of biofiltration may be more complicated at facilities that have a tendency to emit lower volumes with higher concentration, such as bakeries and rendering facilities. This problem can be solved in part by simple dilution of the inlet air.

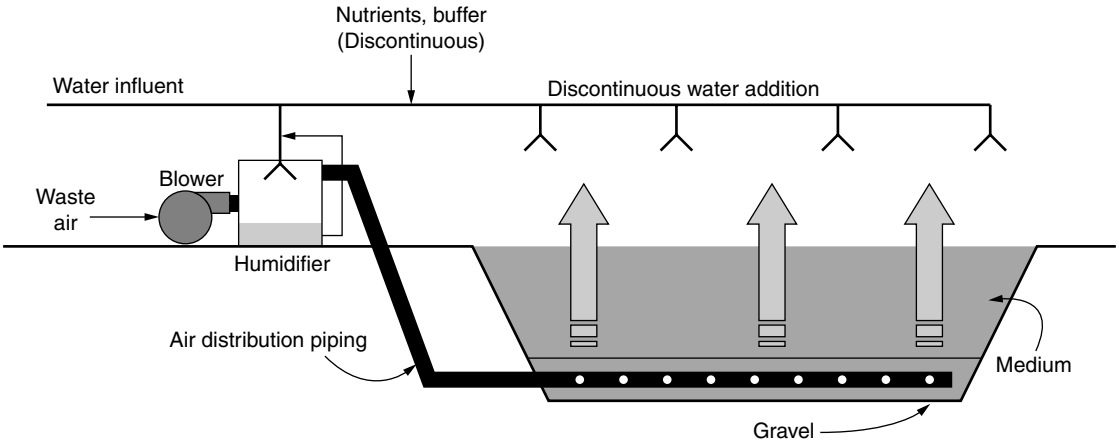

Figure 3. Conventional open bed biofilter design.

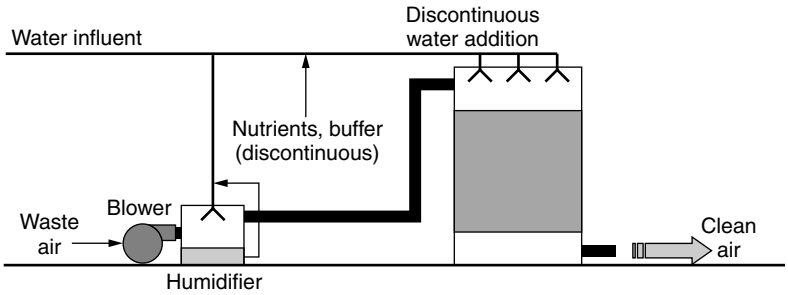

Figure 4. Closed bed system with downward flow.

Emissions from POTWs are characterized by high airflow rates with high moisture content. They are corrosive and may contain aerosols. Emission points include plant headworks (bar screens and grit chambers), primary clarifiers, aeration basins, and solids-handling processes (anaerobic digestion, biosolids dewatering, and composting facilities) (29). Emissions consist of various odor and organic compounds. Concentrations are low and vary greatly with time (30).

Treatment of Hydrogen Sulfide in Biofilters. The effectiveness of biofilters for removing hydrogen sulfide was investigated in numerous studies (15,19,23,31–46). Yang and Allen (15) conducted a comprehensive laboratory study of compost biofilters treating hydrogen sulfide. The relationship between H_2S removal efficiency and temperature, medium pH, water content, air retention time, sulfur loading rate, and sulfate concentration in the medium were experimentally determined. More than 99% removal efficiencies under a wide range of conditions were achieved with a maximum elimination capacity of 150 $g/m^3/hr$. However, lower pH, tested by the addition of hydrochloric acid, negatively affected removal efficiency, and the optimum pH was above 3.2. In long-term experiments, water was periodically added to the system for pH control. Addition of 0.57 liters of deionized water per liter of medium caused an increase in 0.2 to 0.5 pH units.

Treatment of Ammonia in Biofilters. Research has been conducted to determine the effectiveness of biofilters for removing ammonia from waste gas streams (47–50). Ammonia is a common odor problem from composting facilities at POTWs. The studies demonstrated that biofilters with an established nitrifying bacteria population could effectively oxidize ammonia to nitrite, nitrate, and organic nitrogen compounds. However, the major (68%) end product was nitrite (48). The optimum medium pH was approximately 8. Hartikainen and coworkers (47) demonstrated adequate removal of ammonia at pH 6. However, no removal occurred in their test at pH 4.

Treatment of VOCs in Biofilters. A wide range of studies has been conducted to determine the applicability of biofiltration to the removal of organic compounds from waste air. Applications have included bakeries (16), soil vapor extraction emissions (51,52), the print industry (53,54), pulp mills (55), plastics manufacturing (56), and various other industrial applications (8). In general, it was shown that chlorinated alkanes display the poorest removal efficiencies, followed by aldehydes and ketones, with the best removal for aromatics (25). Actual removal is compound-specific. A summary of elimination capacities of various compounds in past biofilter studies has been compiled (8).

POTW Biofiltration Research. Biofilters are an effective means of controlling odors and low concentrations of mixed VOCs from POTWs (14,23,24,31,37,57–59). The first biofilters constructed were used at POTWs to control odors (31). Ergas and coworkers (14) conducted a 10-month pilot-scale compost biofilter study at a POTW. They found that H_2S removal was greater than 99%, whereas aromatic VOC removal was consistently greater than 90%. However, they also controlled the pH at neutrality. Shinabe and coworkers (24) found greater than 99% removal of H_2S by *Thiobacillus thiooxidans* in their two-stage full-scale biofilter using a ceramic medium. The removal efficiency was not pH-dependent. They did not study simultaneous removal of VOCs. Webster and coworkers (25) conducted a 1.5-year bench- and pilot-scale study at a POTW. They used a variety of media and compared pH-controlled and uncontrolled media. They found that their biofilters were effective at simultaneously removing hydrogen sulfide and VOCs at both bench scale and pilot scale, irrespective of pH control. Recent work has confirmed that cotreatment of H_2S and aromatics at low pH is possible (60).

MICROBIOLOGICAL ASPECTS OF BIOFILTRATION

Microbial Ecology of Biofilters

Microorganisms in biofilters grow on the surface of the packing material. They first form colonies that spread to become patches, and the patches finally merge to create a continuous biofilm over the packing. To be active in the removal of contaminants, they must have adequate supplies of water, oxygen, and nutrients, as well as adequate contact with the contaminant.

Biofilter start-up requires an inoculum of microorganisms that are capable of growing under the conditions in the biofilter and obtaining their energy from the degradation of the contaminant. Many biofilters use partially composted materials, such as yard waste, as the packing material. These have the advantage that they carry a diverse and active ecosystem of microorganisms with a broad capability for degradation of organic compounds. It is very likely that microorganisms capable of degrading the contaminant will be present and ready to serve as the seed for rapid development of a dense culture for treatment. Biofilters that use inorganic media such as plastic shapes or stones must be provided with an appropriate inoculum. Biofilter operators commonly choose notably diverse inocula such as sewage sludge or extracts from previously active biofilters. In a few cases, pure cultures of chosen species known to degrade the contaminant have been used.

In any case, the microbial ecosystem will undergo sharp change and rapid development when it is exposed to the contaminant. The species that are capable of utilizing it will grow vigorously. Because of the large flow of air through the biofilter, new species are continually being introduced. In time, predators (e.g., protozoa) and parasites of the successful species will proliferate and then predators of the predators (e.g., nematodes) will grow, creating elaborate food chains. Insect larvae may grow. In one case, the headspace above a compost biofilter was colonized by thousands of spiders that were eating the insects. This process of ecosystem development may proceed for some time. Although a biofilter typically reaches a steady state with respect to treatment success in weeks, there have been reports of continuing ecosystem change after more than a year of operation (61,62). That

is, new species are still being introduced and the relative abundances of the species present are changing.

Factors Affecting Biological Activity

Water content is a key environmental variable for the microbial ecosystem in a biofilter. Drying is commonly the cause of declines in biofilter performance (63). The microorganisms do best when the packing is covered with a film of water. Indeed the microbial community helps hold this water by creating a biofilm composed of polysaccharides that has a significant water-holding capacity. Chitwood (26) showed, for example, that the water-holding capacity of an experimental biofilter using inorganic packing increased by 35% during the first three months of its operation.

Maintaining an ideal water content in the biofilter, however, is difficult. The porous medium water content at equilibrium with the atmosphere is a very sharp function of the RH of the air. Relative humidity values just a percent or two below saturation will cause the biofilter to gradually dry (8). Such slight declines in RH can in turn be caused by an increase in temperature by a few degrees, resulting from compression in the blower or heat gain through duct walls. For this reason, biofilters are often equipped with humidifiers on the incoming air and irrigation systems that spray the packing directly. Desiccation-resistant degraders, particularly fungi, have been investigated for use in biofilters (64), and may have valuable applications. However, even these systems require that the air be near 100% humidity.

An adequate oxygen supply is necessary for the great majority of biofilters that rely on oxygen as the electron acceptor in the degradation process. Unlike water treatment systems, biofilters for air are rarely short of oxygen. The gas being treated is air, and the contaminants are present at concentrations reaching at most a few thousand ppm, so the oxygen concentration is far above stoichiometric requirements. Oxygen availability within the biofilm is far less certain. Oxygen must diffuse from the surface of the biofilm to its depths. Oxygen concentrations and diffusion rates are far lower in water, especially if it contains a thick gel of cells and exudates. Biodegradation within the biofilm is constantly consuming oxygen, and in the deeper portions oxygen depletion is common. This is probable in biofilters treating high concentrations of contaminants that will cause development of a thick biofilm and rapid consumption of oxygen. The development of anaerobic regions at the base of the biofilm, or in the smaller and more remote pores of the packing are not desirable. First, the biomass in the anaerobic regions will not be active, reducing the effectiveness of the biofilter. Second, anaerobic activity may generate odorous compounds, contributing to the very problem the biofilter is intended to solve. Problems of inadequate distribution of oxygen will be more prevalent in deteriorating packing, where the airflow becomes less uniform and local volumes of packing are cut off from the oxygen supply.

Biofilter success requires that the contaminant be brought into close contact with the microorganisms. Like oxygen, it must dissolve in the water phase and diffuse into the biofilm. Degradation within the biofilm serves as a sink, so that the concentration of the contaminant declines with depth. If degradation kinetics are first order, degradation rates will decline where the concentration is low, and regions where concentration of contaminant is zero will contribute nothing to treatment success. In many ways, the challenge of providing contaminants to the microorganisms is much like that for oxygen. The major difference is that oxygen is present in high concentrations and has moderate solubility, whereas contaminants are present in relatively low concentration, and some are only slightly soluble. This means that it is much more likely that degradation rates will be limited by contaminant concentrations in the biofilm. Because contaminant concentrations fall as the air passes through the biofilter, this is especially true near the outlet.

Nutrients such as nitrate and phosphate must be supplied to the microorganisms. Biofilters that use compost or other organic packing may not require further addition of nutrients because the slow decomposition of the organic matter releases the necessary compounds to the biofilm.

Inorganic packing such as stones or plastic shapes does not provide nutrients, and these must be added from an external source. It is particularly important to add these with the inoculum, to ensure that an initial biofilm is rapidly established.

Although the general concepts of nutrient requirements are well established, the detailed dynamics in biofilters are not. The composition of biofilter biomass is probably much like other organic material, so that the mass of nutrient required for growth of a given amount of biomass can be calculated. However, the amount of biomass in biofilters, particularly compost biofilters, is poorly known. Furthermore, significant amounts of nutrients are presumably recycled. As cells die or are consumed by predators, these nutrients are released for reuse by other cells. Some nutrient is probably sequestered in dead or inactive biomass. Some will be lost in irrigation water that drains from the bottom of the bed. In compost biofilters, the rate at which nutrients are released by decomposition of the packing is not known and it is not certain that it is always sufficient to avoid nutrient limitation.

Given these uncertainties, it is not surprising that recommendations for nutrient addition vary widely in the literature. Although the observation that poorly performing biofilters can be improved by nutrient addition is common, the amounts necessary are not certain. Because nutrient addition is inexpensive, the common solution is to add them in excess.

Microbial Ecology of Sulfide Biofilters

Biofilters are quite effective for the control of hydrogen sulfide or organic sulfide odors, but special problems arise because the ultimate product of microbiological sulfide oxidation is sulfuric acid. As treatment proceeds, the pH of the biofilter packing declines. Rapid decline may inhibit the activity of sulfide-oxidizing microorganisms, and a sufficiently low pH will hasten the deterioration of compost packing (17).

One approach is to neutralize the acid and maintain the pH at 7. This can be done by adding buffer material to

the packing or adding base to the irrigation water. While this approach encounters some operational problems, as previously described, sulfide oxidation will proceed well. In addition, a neutral pH is ideal for a wide variety of heterotrophs, so that VOCs in the gas stream are also likely to be degraded.

A second approach is to allow the pH to decline. As pH falls, a successional change in ecosystem composition occurs, utilizing the sulfide and producing additional acid. This succession is better known than most in microbiology because it has been studied extensively in efforts to control sulfide corrosion in sewers (5,59). Ultimately, sulfide-oxidizing organisms tolerant of low pH dominate the ecosystem. These are presumed to be of the genus *Thiobacillus*, and the species *Thiobacillus thiooxidans* is probably common, but the species is rarely identified in practice. *Thiobacillus* produces short-chain fatty acids as metabolic by-products and these are self-inhibitory. Acidophilic heterotrophs that live in a symbiotic relationship with the *Thiobacillus* consume these acids. Some experiments have shown that many organic compounds can also be degraded in low-pH biofilters (60) and that some of the same acidophiles may be involved.

Most sulfide oxidizers are autotrophic and so obtain their carbon from carbon dioxide, which is a costly process in terms of energy. This may be the reason these microorganisms tend to release little polysaccharide and thick biofilms generally are not seen in sulfide biofilters.

Overall, biofilters are an excellent technology for removal of hydrogen sulfide from airstreams. Systems have removed up to 99% of sulfide in the tens of parts per million with an EBRT as low as 15 seconds (65).

CONCLUSION

An ideal biological treatment system uses microorganisms to convert waste materials to benign products. In most cases, the most efficient approach is to use dominantly aerobic systems to produce carbon dioxide, water, sulfate, and nitrate. Odors arise if waste materials or partially transformed intermediates escape to the atmosphere before oxidation is complete. Odorous compounds are generated profusely in anaerobic conditions that may arise from inadvertent stagnation in the waste stream or from anaerobic treatment processes.

Passing discharged air through a biofilter that completes the transformation to oxidized products can prevent the release of odors. Operation of biofilters requires attention to the needs of the microbial ecosystem, but well-operated units can be effective and economical solutions to the odor problems at treatment facilities.

BIOFOULING: CHEMICAL CONTROL OF BIOFOULING IN WATER SYSTEMS

T. Eugene Cloete
Volker S. Brözel
University of Pretoria
Pretoria, South Africa

Microbial biofilms are problematic in a range of industrial environments in which large areas of submerged surfaces are exposed to relatively high nutrient fluxes, providing niches for the formation of copious surface-associated growth (1,2). Bacterial colonization of surfaces in an aqueous environment is a basic strategy for survival in nature as nutrients are more available at the solid–liquid interface (3,4). The resulting aggregates form microcolonies that develop into biofilms (5). Biofilms increase fluid frictional resistance (5) and decrease the rate of heat energy transfer, collectively termed

biofouling. These biofilms also promote corrosion of ferrous and other metals by the concerted metabolic activity of a number of biofilm-associated bacterial types (6–8), a process collectively termed microbially-influenced corrosion (MIC). MIC encompasses a number of specific mechanisms relating either directly or indirectly to the metabolic activity of a variety of microorganisms, notably the action of sulfidogenic bacteria (9,10). As the costs attributable to MIC and biofouling are high, effective control of bacterial numbers in industrial aqueous environments is essential.

A range of bactericidal substances, commonly termed biocides or microbicides, are available, all of which are claimed by their producers to kill bacteria occurring in aqueous systems quantitatively. Biocides target a range of cellular loci, from the cytoplasmic membrane to respiratory functions, enzymes, and genetic material (11). However, different bacteria react differently to bactericides, either owing to inherent differences such as unique cell envelope composition and nonsusceptible proteins (12) or to the development of resistance, either by adaptation or by genetic exchange (13). Bactericides should therefore be evaluated against the organisms that they are chosen to control, that is, the dominant ones in the system to be treated. The composition of microbial populations in systems varies with the type of water used, and changes considerably following treatment with various biocides by selection for resistant strains (14). Bacteria growing as biofilms are also significantly more resistant to most antimicrobial agents known currently, so that methods for their control pose an ongoing challenge (2,15).

Successful biofouling control depends on rationally developed treatment strategies that are based on information about the specific system. The primary target should always be the biofilm-associated flora as it is the catalyst for MIC and impacts negatively on system operation.

Five approaches are currently available and may be used in combination:

1. Bacteria are chemically killed by application of biocides;
2. Cells are dislodged from surfaces by dispersants;
3. The biofilm structure is weakened by enzymes or chelating agents of divalent cations;
4. Biofilms are removed physically by a variety of processes; and
5. Biocide efficacy is enhanced by applying an alternating current or ultrasonic sound across the biofilm.

This entry focuses on the application of biocides to biofouling control.

BIOCIDES

Bactericides are antimicrobial agents employed in various spheres of human activity to prevent, inhibit, or eliminate microbial growth. They can be divided into two groups — those derived from naturally occurring antimicrobial agents (termed antibiotics) and those not occurring readily in nature (termed antiseptics, disinfectants, biocides, bactericides, sanitizers, and preservatives). Members of the second group are classified depending on their chemical nature, but more often on their specific field of application.

The use of biocides to control biofouling in water systems is still an accepted practice, although higher levels of environmental awareness and tighter legislation have placed increased pressure on the water treatment industry to seek alternative means of control (16,17). Nevertheless, biocides are still indispensable components for effective control of biofouling as they remain the core technology for decimating viable numbers whereas all other techniques merely aid in their efficacy.

The modes of action of a plethora of antibiotics have been investigated in detail. Much less is known about the mechanisms of action of the many biocides available for biofouling control. Biocides for water treatment target a range of specific cellular components and functions, from membrane permeability and electron transport to enzyme function.

Bactericides attack functional cell components, placing the bacterium under stress (18). At low concentrations, bactericides often act bacteristatically, and are only bactericidal at higher concentrations (19). Targets of bactericide action are components of the cytoplasmic membrane or of the cytoplasm (11). For bactericides to be effective, they must attain a sufficiently high concentration at the target site in order to exert their antibacterial action. In order to reach their target site(s), they must traverse the outer membrane of the gram-negative bacteria. Therefore, different bacteria react differently to bactericides owing to differing permeabilities of their respective cell walls (20). Bacteria with effective penetration barriers to biocides generally display a higher inherent resistance than those bacteria that are readily penetrated. The rate of penetration is linked to concentration so that a sufficiently high biocide concentration will kill bacteria with enhanced penetration barriers (11).

Water treatment bactericides fall into two categories, oxidizing (e.g., chlorine and hydrogen peroxide) and nonoxidizing. Nonoxidizing bactericides can be divided into five groups based on their chemical nature or mode of action, and these are discussed later.

Oxidizing Biocides

Oxidizing biocides are general chemical oxidants. They are not selective for living organisms, but react with any oxidizable matter. However, they are bactericidal because certain bacterial cell components can react readily with them, having a higher oxidation potential than most other chemicals present in water. Three classes of oxidizing biocides are available for bactericidal applications; oxidizing halogens, peroxides, and ozone.

Peroxides. Peroxides are unstable oxygen compounds that decompose to form free hydroxyl radicals. These react oxidatively with organic matter. The peroxides include hydrogen peroxide, peracetic acid, aromatic peroxyacids, persulfates, and calcium peroxide.

Hydrogen Peroxide. Peroxide has good antimicrobial properties and decomposes to water and oxygen, leaving no toxic waste. Hydrogen peroxide penetrates cells causing site-directed damage on account of metal-dependent OH formation (21). It causes DNA strand breaks and base hydroxylation. Guanine and thymine are the two main targets of peroxide-generated free radical attack. The resulting 7,8-dihydro-8-oxoguanine mispairs with adenine whereas thymine oxidation products stop DNA polymerase, halting replication (21). Most bacterial mutants cannot survive because of incoherent metabolism, so that peroxide treatment at low concentration leads to slow death. Hydrogen peroxide also inhibits mitochondrial ADP-phosphorylation.

The development of resistance to oxidizing bactericides has not been reported in the biofouling control literature. However, a variety of bacteria, mostly fermentative, exhibit oxidizing stress response by producing oxidant-degrading and repair enzymes. Stress response means that cells become more resistant to a deleterious factor within minutes of exposure to subinhibitory quantities of the factor. A variety of defense genes have been characterized in *Escherichia coli*, encoding various superoxide dismutases, catalases, alkyl hydroperoxide reductases and glutathione reductases, as well as DNA repair enzymes (22). In addition, various regulatory genes have been characterized, including *oxyR* and *soxR*. These regulators determine intracellular redox potential and activate stress response when cells are exposed to oxidizing agents.

Organic Peroxides. Peracetic acid is the best known of the organic peroxides. Like hydrogen peroxide, it forms free hydroxyl radicals, which react with various protein structures and DNA. In addition, the dissociation of peracetic acid leads to formation of acetic acid, which is mildly antibacterial. Application of peracetic acid to systems does not leave any toxic waste behind. The antibacterial activity of peracetic acid is not affected by water hardness or organic contamination.

Oxidizing Halogens. Hypochloric and hypobromic acids pose excellent antibacterial activity, although within a defined pH range.

Chlorine Compounds. Chlorine, chlorine dioxide, and hypochlorous acid (HOCl) are the most widely used biocides worldwide. Hypochlorite was first employed as a wound disinfectant by Hüter in 1831, and its bactericidal activity was confirmed by Koch in 1881 (23). Hypochlorite is used in industrial water systems to control biofouling.

The antibacterial mechanism of action of hypochlorite is not clear to date although much work has been done on the mechanism of action in eukaryotic cells (8). HOCl is a powerful oxidizing agent, oxidizing thiol groups and halogenating amino groups in proteins (24), as well as oxidizing lipids and proteins (25). Specific bacterial targets are cytochromes, nucleotides, and iron-sulfur proteins (26). Protein synthesis is impaired (data not published) and the uptake of nutrients is also affected (27). The stability and antimicrobial activity of hypochloric acid is dependent on pH. It dissociates at pH greater than 7, and the undissociated moiety is the antibacterial one (23). Above pH 7.5 it loses its antibacterial activity. It is excellent for biofouling control as it weakens the extracellular polysaccharide structure, leading to sloughing and removal of sections of the biofilm.

Bromine Compounds. Hypobromous acid works similarly to hypochloric acid. It is, however, stable at a pH up to 8.5. This makes it more suitable for application in cooling waters, which are often maintained at a slightly alkaline pH. Certain organic compounds release hypobromic and hypochloric acid slowly when in solution. An example is 3-bromo-1-chloro-5,5–dimethylhydantoin (28). Such compounds maintain a longer antibacterial level of hypohalous acid in the system treated.

Ozone. Ozone is a strong oxidizing material capable of killing bacteria and algae and of inactivating viruses. It is an unstable gas with a pungent odor. It further degrades the extracellular polysaccharide, holding biofilms together, so that treatment results in loosening of the biofilm. This leads to loosening of scale from the surface. Ozone has a very short half-life and therefore has to be generated on-site. In distilled water, the half-life of ozone at 20 °C is 25 minutes. Its solubility in water is 13 times that of oxygen. Upon reaction with organic material it decomposes to oxygen. It does, however, react with several cations and anions such as $Fe^{2}+$, $Mn^{2}+$, $MnO_4{}^{2-}$, $N0^{2-}$, and CN^{-}. Ozone is toxic to humans, and detectors should be installed together with ozone generators. Furthermore, ozone is very costly to produce when compared with chlorine. However, treated water is perfectly safe as ozone degenerates to oxygen whereas chlorine may react with humic substances in water to yield toxic trihalomethanes.

Electrochemically Activated Water

Principles of Electrochemically Activated Water Technology. Electrochemically activated water has recently become available, and has been found effective in biofouling control (29). Water of varying mineralization is passed through an electrochemical cell, the specific design of which permits the harnessing of two distinct and electrically opposite streams of activated water.

Aside from its distinctive attributes, the negatively charged antioxidant solution (catholyte) can also be channeled back into the anode chamber, thereby modulating the quality of the positively charged oxidant solution (anolyte) that is produced. Depending on the specifications of the required application, variations in the design of the hydraulic systems can be effected to meet the requisite objectives.

The design of the cell is such as to ensure a uniformly high voltage electrical field through which each microvolume of water must pass. This unipolar electrochemical activation created by potential gradients of millions of volts per cm^2 between the anode and cathode terminals results in the creation of solutions whose pH, oxidation reduction potentials (ORP) and other

physicochemical properties lie outside of the range, which can be achieved by conventional chemical means.

Properties of Activated Water. The properties of the activated solutions are dependent on a number of factors. These comprise the solution flow rate through the reactor cell, the current being applied, temperature, the degree of feedback of catholyte into the anolyte chamber and the degree of mineralization of the water.

During electrochemical activation, three categories of products within the solution are generated. They comprise:

1. Stable products that include acids and bases that influence the pH of the solutions,
2. Highly active, unstable products including free radicals and electrolytic gases in the form of microbubbles that influence the ORP of the solutions, and
3. Quasi-stable products comprising complexes of hydrated membranes that form clusters of water molecules, which impart the catalytic activity of the solutions.

Without maintenance of the activated state, these diverse products degrade to the relaxed state of benign water and the anomalous attributes of the activated solutions such as altered conductivity and surface tension similarly revert to preactivation status.

It is important to note that the level of mineralization of input water required to generate optimally metastable solutions is not significantly different from the composition of benign potable water. However, the heightened electrical activity and altered physicochemical attributes of the solutions differ significantly from the benign state, yet remain nontoxic to mammalian tissue and the environment.

Biocidal Properties of Anolyte. Earlier technologies that have employed electrochemical activation to generate biocidal solutions have not been capable of separating the output of the anolyte and catholyte solutions. In these cases the two opposing solutions have neutralized each other with regard to potential electrical activity.

The advantages of the current ECA technology has been confirmed, wherein the biocidal activity of hypochlorous acid generated by the current ECA technology is 300 times more active than the sodium hypochlorite generated by earlier systems. Additionally, a comparison of neutral anolyte (pH = 7), with alkaline glutaraldehyde (pH = 8.5), showed that the latter required a concentration of 2% versus 0.05% of the former, in order to achieve the same biocidal efficacy. Similarly, it has been shown that a 5% solution of sodium hypochlorite can only be used for purposes of disinfection whilst a 0.03% solution of neutral anolyte has both disinfectant and sterilizing properties. In general, the biocidal activity of nonactivated neutral anolyte (only stable products and no electrical charge) is 80 times the potential activity of the hypochlorite solution, but still exhibits only one-third of the full biocidal potential of the optimally activated ECA solution.

Thus, activated solutions have been conclusively shown to exceed chemically derived equivalents both in low-dosage effectiveness as well as physicochemical purity. This heightened biocidal capacity relative to traditional chemical solutions permits the incorporation of ECA solutions at substantially lower dose rates, therein obviating the risk of intoxication, adverse environmental impact, while providing cost-effective resolutions.

Nonoxidizing Biocides

Nonoxidizing biocides include a variety of organic chemical compounds that have antimicrobial activity. Their modes of action differ vastly, and their only common denominator is that they are nonoxidizing organic molecules. Most currently used biocides fall into five distinct categories, although a number of miscellaneous compounds are also useful.

Detergent-Type Biocides. Three groups of surface-active antimicrobial agents have been documented to date; anionic, cationic, and amphoteric (23). Anionic antimicrobials are only effective at pH < 3.0 and include the aliphatic acids such as sodium dodecyl sulfate. The cationic antimicrobial agents are the generally organic ammonium salts, commonly termed quaternary ammonium compounds (QAC). The best known is benzalkonium chloride (N-alkyl-N,N-dimethyl benzylammonium chloride) (23). Recently, a number of novel organic ammonium salts of general structure alkyl trimethyl and dialkyl dimethyl ammonium bromide were synthesized and evaluated (30). The authors reported extremely low minimum inhibitory concentrations to *Pseudomonas aeruginosa* of 12.5μg/ml where the second alkyl group was C_6 or longer.

Benzalkonium chloride adsorbs to the cell surface of negatively charged cells (pH > 7.0) in an irreversible way (11,31). The pH minimum for antimicrobial activity is 3.0. It is membrane active and induces leakage of cytoplasmic constituents (23). Upon exposure to benzalkonium chloride, membranes of *Pseudomonas cepacia* appeared irregular, indicating membrane damage (32). At 37 °C it is twice as active as at 20 °C. It is active against gram-positive as well as against gram-negative cells, but not against spores. Cations such as $Ca^{2}+$ and $Fe^{3}+$ decrease its activity, as does NaCl (23).

Biguanides. Biguanides are polymer derivatives of a general guanidine structure. Two biguanides are currently used as industrial bactericides. These are polyhexamethylene biguanide (PHMB) and 1,6-di-(4-chlorophenyldiguanido)-hexane, better known as chlorhexidine (23). Both are not corrosive and all are well-suited for application in cooling water (19).

Biguanides are bacteriostatic at low concentrations and bactericidal at higher concentrations, and have a wide spectrum of activity, especially against gram-negative bacteria (23). They are membrane active agents and attach rapidly to negatively charged cell surfaces (pH neutral or alkaline). By making use of ^{14}C-radiolabeled polyhexamethylene biguanide, it has been shown that polyhexamethylene biguanide absorbed into cells of *E. coli* within 20 seconds after exposure (33). Bactericidal action, however, requires a few minutes. Biguanides compete with divalent cations for negative sites at LPS, displacing these. PHMB then interacts by electrostatic interactions

with the charged headgroups of phosphatidyl glycerol and diphosphatidyl glycerol (negative), but not with the neutral phosphatidyl ethanolamine (34). By binding to phospholipids of the inner leaflet of the outer membrane and of the outer leaflet of the inner membrane, the two membranes attain net positive charges and are repelled from each other, causing membrane damage by distortion. This is supported by TEM studies on *P. cepacia* in which both membranes acquired a distinct irregular appearance after treatment with chlorhexidine (32). Cytoplasmic constituents start leaking out of the cell because of the rupture of the membranes, and the cell loses its viability.

Aldehyde-Based Biocides. Two aldehydes are commonly used as antimicrobial agents, that is, formaldehyde and glutaraldehyde. Further, there is a range of bactericides such as the hydroxyethyl- and ethyltriazine-bactericides available, all of which release formaldehyde (35). Formaldehyde has a high polarity and high nucleophilic reactivity, so that it reacts primarily with free primary amino groups, but also reacts with amines, amides, sulfides, purines, and pyrimidines (35). In water it hydrates to methylene glycol. Reaction with primary amino groups leads to the formation of methyloamines that react further with cellular components. Formaldehyde damages the transport properties of membrane porins, decreasing the rate of proline uptake and of enzyme synthesis. It is active over a wide pH spectrum (3.0–10.0) and is sporicidal (23).

Glutaraldehyde also reacts with amino and sulfhydryl groups (11). It is stable in acid solution but is only active at pH 7.5 to 8.5, so it must be alkalinified before application (23). A 2% solution at the correct pH is 10 times more bactericidal than a 4% solution of formaldehyde (23). Its reactivity is related to temperature; a 2% solution kills spores of *Bacillus anthracis* in 15 minutes at 20 °C, whereas it requires only 2 min at 40 °C. In gram-positive bacteria it reacts with, and binds to, peptidoglycan and teichoic acid and is also sporicidal (11). In gram-negative bacteria it reacts primarily with lipoproteins of the outer membrane, preventing the release of membrane-bound enzymes.

Phenol Derivatives. Phenol was the antimicrobial agent that revolutionized invasive surgery, and was pioneered by Lister in 1870 (36). It enters the cell by dissolving in the membrane, and upon entry into the cytoplasm, precipitates proteins. It is, however, harmful to humans, and its antibacterial activity is not very high (23). A range of halogenated phenols, cresols, diphenyls, and bisphenols have been developed from phenol, and have excellent antimicrobial activity, many being applied in the preservation of pharmaceutical products. Halogenation increases the antimicrobial activity of phenol, as does the addition of aliphatic and aromatic groups (23). Bisphenols have the highest antimicrobial activity of the phenol derivatives, especially the halogen substituted ones. Hexachlorophen and 2,2′-methylenebis(4-chlorophenol) (dichlorophen) fall into this group (13).

Phenol derivatives are membrane-active agents. They penetrate into the lipid phase of the cytoplasmic membrane, inducing the leakage of cytoplasmic constituents (11). 3- and 4-chlorophenol uncouple oxidative phosphorylation from respiration by increasing the permeability of the cytoplasmic membrane to protons (37).

Thiol-Oxidizing Biocides. Thiols on amino acids such as cysteine are important groups that influence the tertiary structure of proteins by forming disulfide bridges. Three groups of antimicrobial agents, isothiazolones, bronopol (2-bromo-2-nitropropane-1,3-diol), and mercury, and other heavy-metal compounds, react with accessible thiols, altering the three-dimensional structure of enzymes and structural proteins (38). Mercury interacts with sulfhydryl groups by complexing with sulfur (23). Bronopol oxidizes thiols to disulfides, reacting especially with the active center of hydrogenase enzymes (23).

Four water-soluble isothiazolones possess antibacterial activity; 5-chloro-2-methyl-3-(2H)-isothiazolinone (CMIT), 2-methyl-3-(2H)-isothiazolinone (MIT), 1,2-benzisothiazolin-3-one (BIT) and 2 methyl 4,5-trimethylene-4-isothiazolin-3-one (MTI) (23). MIT and CMIT are often supplied in a 3 : 1 ratio. Isothiazolones react oxidatively with accessible thiols such as cysteine and glutathione (39). These thiols are oxidized to their disulfide adjuncts, which, in the case of cysteine, leads to an alteration of protein conformation and functionality. Isothiazolone is thus reduced to mercaptoacrylamide, which in the case of CMIT tautomerizes to thioacyl chloride, the latter reacting with amines such as histidine and valine (38). Isothiazolones are primarily bacteriostatic and are only bactericidal at high concentrations.

Miscellaneous Biocides. The mechanisms of action of various antimicrobial agents, employed to control bacterial growth in cooling water systems, have not been formally published to date. These include tetra-alkyl phosphonium chloride, sodium diethyldithiocarbamate, methylene bisthiocyanate (MBT), 2-thiocyanomethylthiobenzothiazole, 2-thiocyanomethylthiobenzothiazole, hexachlorodimethylsulfone, tetrakishydroxymethylphosphonium sulfate (THPS) and a range of 2-arylthio-N-alkylmaleimides (6).

Phosphonium chloride probably has surfactant properties, damaging the bacterial cell envelope. It is active over an extremely wide pH range (2–12) and can be used in conjunction with oxidizing biocides. MBT is readily miscible with dispersants to aid the penetration into and the dispersion of biofilms. The mode of action of this nonmetallic organosulfur compound is as yet unknown. Thiocarbamates are used as agents for the extraction of trace metals such as Fe, Cd, Co, Cu, Mn, Ni, Pb, and Zn (40). This would imply that they chelate iron, a vital trace element of most bacteria. The nucleophilic sulfur atom indicates potential reactivity with accessible thiols. Thiocarbamates do react with accessible thiols and amines. Therefore, their antibacterial mechanism of action would rest partially on denaturation of surface proteins. We have found that the antibacterial mechanism of action depends on the alkyl chain length of the thiocarbamate. Sodium diethyldithiocarbamate is inactivated by free ferrous iron, indicating that it removes iron (a

growth factor) from the cell. Sodium dimethyl dithiocarbamate is not inactivated to the same degree, showing that its antibacterial activity does not rest as much on iron removal. 2-Thiocyanomethylthiobenzothiazole is also stable over a wide pH range and can be used synergistically with surfactants to aid in dispersion of and/or penetration into biofilms. Hexachlorodimethylsulfone is stable at high temperature and is an effective slimicide over a wide pH range, although it is not water-soluble and must be dosed as an emulsion. THPS is an amphoteric surfactant miscible with various other surfactants to improve action against biofilms. It is active in both acidic and alkaline conditions and at high temperatures, and remains water-soluble in oil-water mixtures.

The 2-arylthio-N-alkylmaleimides are extremely bacteriostatic, and many derivatives demonstrate an MIC against various bacteria except *P. aeruginosa* of 6.25 μg/ml (6).

Alternative Approaches of Chemical Control

Surface-Embedded Biocides and Catalysts. Various tertiary amines have been covalently linked to polystyrene (41), and quaternary amine compounds have been complexed into polyvinyl chloride and ethylene vinyl acetate latex (42). The broad-spectrum antimicrobial Triclosan (2,4,4′-trichloro-2′-hydroxy-diphenylether-5-chloro-2-(2,4-dichlorophenoxy)-phenol) has been impregnated into various polymers and shown to suppress surface-associated growth. It is active against most bacteria, excepting *P. aeruginosa*.

Recently, Wood and coworkers (43) reported a strategy for circumventing the resistance of bacteria in biofilms by generating biocidal species at the biofilm-substratum interface from less active agents using surface-embedded catalysts. They embedded the catalysts cobalt- and copper-sulfonated phthalocyanine in surface-associated resin. Both hydrogen peroxide and potassium monopersulfate are broken down into highly reactive oxygen species and significantly enhanced the killing of *P. aeruginosa* biofilms (44).

Enhancement of Biocidal Activity by an Electrical Field. Bacteria in biofilms are well known to be more resistant to biocides than are their planktonic counterparts. A select number of studies have reported that application of low-intensity electric fields in the range 15 $\mu A/cm^2$ to 2.1 mA/cm^2 and with a field strength of 1.5 to 20 V/cm can override the biofilm-associated resistance (45,46). All areas within the electric field are affected as the antimicrobial agent is moved by an electrophoretic effect.

Saccharolytic Enzymes. The biofilm is stabilized by an extracellular polysaccharide matrix, often interspersed by other extracellular polymers such as proteins. The extracellular polysaccharides are composed of homo- and heteropolysaccharides of mannose, glucose, fucose, galactose, mannuronic acid, guluronic acid, and pyruvate, giving rise to a complex array of polymeric structures (47). Saccharolytic enzymes have been used to degrade the polysaccharide matrix, thereby destabilizing the biofilm structure, but the heterogeneity of polymers dictates that mixtures be applied (47,48). Recently, Johansen and coworkers (49) demonstrated that the addition of lactoperoxidase to saccharolytic cocktails contributed not only to biofilm removal, but also to a decrease in the culturable count.

Dispersants (Surface-Active Compounds). More recently, surface-active compounds (surfactants) have been employed to prevent bacterial adhesion to surfaces. It is unlikely that surfactants will have any mutagenic effects on bacteria or that microorganisms would be able to become resistant to the action of surfactants, as can be the case with biocides (11,14). Unfortunately little published information is available on the efficacy of different biodispersants (surfactants) against bacterial attachment (50). According to Paul and Jeffrey (51), dilute surfactants completely inhibited the attachment of estuarine and marine bacteria. Surfactants result in both uniform wetting of the surface to be treated and have an additional cleaning effect (14,50). Whitekettle (52) found a correlation between the ability of a surface-active compound to lower surface tension and its ability to prevent microbial adhesion. White and Russel (53) classified surfactants according to the ionic nature of the hydrophilic group, viz. anionic, cationic, nonionic, and zwitterionic.

FACTORS AFFECTING EFFICACY OF TREATMENT PROGRAMS

The antibacterial activity of bactericides is determined by their chemical reactivity with certain organic groups. Bactericides do not select between free and cell-bound groups. Therefore, oxidizing bactericides react with any readily oxidizable organic compound, and not only with live cells. Bactericide activity is influenced by the chemistry of the environment it is used in (23). Factors affecting bactericide effectivity are the following:

- pH
- Water hardness
- Organic compounds such as proteins or saccharides
- Additives such as antiscaling agents or corrosion inhibitors

These factors affect different bactericides to different degrees. Some bactericides are not very stable in concentrated form and undergo changes. Formaldehyde polymerizes when exposed to polar compounds (acids or alkalis) or high temperature and oxidizes to formic acid when exposed to air (23). Isothiazolones are unstable at temperatures above 40 °C and chlorhexidine is unstable above 70 °C (23). A decrease in the efficacy of a bactericide treatment program can be due to a decrease in bactericide activity or due to inactivation by adverse conditions and does not always indicate bacterial resistance (1).

Chemistry of the Water

Chemicals that inhibit scaling and corrosion are also added to industrial water systems, and some of these chemicals interact with certain biocides. Chromates are used to

inhibit corrosion and also suppress microbial growth, acting synergistically with the biocide used. Glycolic acid secreted by algae can, however, reduce chromate, rendering it inactive. Dithiocarbamates reduce chromate, so the two substances are incompatible (40). QACs form insoluble chromate precipitates at high concentrations, so the two should not be added simultaneously to water. The careless application of chloride can lower the pH to a point at which the protective chromate film is solubilized. Na-2-mercaptobenzothiazole is a corrosion inhibitor that is oxidized by chlorine dioxide. Methylene bis-thiocyanate is hydrolyzed under slightly alkaline conditions (pH 7.5).

Where the chlorine demand of water is high, the large quantity of chlorine added leads to a high chloride level that increases the corrosion potential of the water. Chlorine and quaternary ammonium compounds increase the corrosion rate of copper alloys.

Bacterial Resistance

Bactericide treatment regimes for cooling water systems often fail, posing the question of bacterial resistance to the bactericide. Some authors have argued that the failure of treatment programs was on account of selection for resistant strains. We have, however, shown that susceptible bacterial isolates do acquire increased tolerance to bactericides following serial transfer in subinhibitory concentrations. Resistance has been defined as the temporary or permanent ability of an organism and its progeny to remain viable and/or multiply under conditions that would destroy or inhibit other members of the strain (31,54). Bacteria may be defined as resistant when they are not susceptible to a concentration of antibacterial agent used in practice. Traditionally, resistance refers to instances in which the basis of increased tolerance is a genetic change and in which the biochemical basis is known. Whereas the basis of bacterial resistance to antibiotics is well known, that of resistance to antiseptics, disinfectants, and food preservatives is less well understood. The basis of bacterial development of resistance to water treatment bactericides is little known.

As biocides are selective in their action, application of any one could result in selection for resistant bacteria. As cells in biofilms and planktonic communities are in continuous exchange, death of cells in the planktonic phase would influence the equilibrium and shifts would occur in both the planktonic and the sessile populations. Biocides attack targets of cell function, placing the bacterium under stress. It is well recognized that communities under stress have a lower species diversity and select for fitter species. Therefore, a more resistant community could develop. The concentration of a biocide is not related linearly to its activity; a concentration exponent is involved in the relationship. In many cases a small decrease in concentration will result in a notable decrease in activity.

In an in situ biocide evaluation study we found that the dominant planktonic survivor after 48 hours was a species most effectively killed by the relevant biocide under laboratory pure culture conditions. An example is dichlorophen, which killed 99.94% of *Pseudomonas stutzeri* at 50 ppm and yet left this species the dominant isolate after 48 hours (43%) in the cooling system. Also, thiocarbamate killed 99.87% of *P. stutzeri* at l74 ppm and left it the dominant planktonic survivor (62.5%) in the treated system. QAC-tin killed 100% of *Acinetobacter calcoaceticus* and left *Acinetobacter* spp. dominant (40%) in the system. Although the surviving strains could be different, the correlation is striking.

Two reasons explain why the efficacy of bactericide treatment programs can decrease at times. One is a decrease in the activity of the bactericide and the other is a decrease in the bacterial susceptibility toward the bactericide. Three mechanisms of resistance have been reported in the field of antibiotic study:

- Inaccessibility of the antimicrobial agent to its site of action,
- Absence of the susceptible site, or alteration to an insusceptible form, and
- Inactivation of the antibacterial agent.

Whereas antibiotics used in the medical field are rather specific in their modes of action, targeting specific cellular components or processes, biocides are far less specific so that the alteration of a reactive site or the substitution of an amino acid in a protein will not render bacterial cells resistant. Therefore, inaccessibility and inactivation are the two classes of possible mechanisms of resistance. Additionally, active removal of biocide is a third class of resistance.

Decreased Permeability. The initial stage of bactericide action is binding to the bacterial cell surface. It must then traverse the cell wall (gram-positive) or outer membrane (gram-negative) to reach its site of action at the cytoplasmic membrane or cytoplasm. In gram-positive bacteria there are no specific receptor molecules or permeases to assist or block bactericide penetration. The cell wall of *Bacillus megaterium* is permeable to molecules up to 30 kDa. Intrinsic resistance of gram-positive bacteria to bactericides is therefore low. The gram-negative cell envelope has, however, evolved to regulate the passage of substances into and out of the cell to a remarkable degree of specificity. All the components of the cell envelope, except peptidoglycan, play a role in the barrier mechanisms because peptidoglycan is spongy and therefore permeable. *Pseudomonas aeruginosa* is the most resistant nonsporeforming bacteria to most bactericides, as a result of the superior barrier properties of its outer membrane. In a recent study, the antimicrobial activity of a series of new 2-arylthio-N-alkylmaleimides were compared and many were found active against *Staphylococcus aureus*, *Bacillus subtilis*, and *E. coli*. Only one of the 51 derivatives tested was marginally active against *P. aeruginosa*.

The physiological state of cells and the nature of the habitat can lead to considerable variation in the susceptibility of bacteria to bactericides. The composition of the bacterial cell envelope does change as a response to available or limiting nutrients, so that the barrier properties of the envelope are affected. Exposure to subinhibitory concentrations of bactericides can lead to phenotypic adaptation, resulting in a resistant cell

population. In *E. coli*, certain proteins induced by heat or starvation stress also confer resistance to H_2O_2 and to UV light. Most bactericide-resistance is due to adaptation, and the resistant phenotype is mostly lost upon removal of the bactericide.

Efflux Systems. Bacteria can actively pump compounds out of the cell via membrane efflux systems. Only one type of bactericide-efflux system has been described to date, the QAC efflux system of *S. aureus*. This efflux system is coded by two gene systems. The genes *qacA* and *qacB* encode for a high level of resistance, and *qacC* and *qacD* encode for a low level of resistance. *qacC* and *qacD* are further identical to the *ebr* gene encoding for resistance to ethidium bromide in *S. aureus*, explaining why resistance to QAC is often concurrent with resistance to ethidium bromide. The *qacA* gene codes for a 50-kDa protein, which mediates energy-dependent efflux of both benzalkonium chloride and ethidium bromide. The *qacC* gene also mediates energy-dependent efflux of benzalkonium chloride and ethidium bromide. Two different but isofunctional gene systems appear to have evolved in *S. aureus*.

Enzymatic Degradation of Biocides. Resistance to antimicrobial agents can be caused by enzymes transforming the bactericide to nontoxic form. The phenomenon is usually investigated from the biodegradation point of view, that is, the biodegradation of toxic pollutants. A host of aromatic, phenolic, and other compounds toxic to many bacteria (some of which are employed as bactericides) can be degraded by certain bacteria. The topic has been reviewed by various authors and the current literature reports extensively on biodegradative pathways (55).

Two types of enzyme-mediated resistance mechanisms have been documented, that is, heavy-metal resistance and formaldehyde resistance. Resistance to heavy metals includes resistance to the following: mercury, antimony, nickel, cadmium, arsenate, cobalt, zinc, lead, tellurite, copper, chromate, and silver. Detoxification is usually by enzymatic reduction of the cation to the metal. Whereas some heavy-metal resistance genes are carried on plasmids, others are chromosomal. The resistant phenotype is usually inducible by the presence of the heavy metal. Some heavy metals induce resistance to a broader spectrum of heavy metals. Arsenate, arsenite, and antimony, for example, induce resistance to one another in *E. coli*.

The detoxification of formaldehyde by *P. aeruginosa* and *P. putida* has been studied extensively. Formaldehyde is reduced by an NAD+gluthathione-dependant dehydrogenase, giving formaldehyde NAD+ oxidoreductase. This enzyme is probably plasmid-encoded, and appears to be constitutively expressed. Resistance to most formaldehyde-releasing condensates of formaldehyde is therefore also caused by formaldehyde dehydrogenase activity.

Biofilm-Associated Resistance

Bacteria in biofilms are much more protected from bactericidal action than are planktonic bacteria. In a recent study, biofilm bacteria were found to be 150- to 3,000-fold more resistant to hypochlorous acid and 2 to 100 times more to monochloramine than were unattached cells. *Pseudomonas aeruginosa* growing as a biofilm has been found 20 times as resistant to tobramycin as are planktonic cells. A number of reasons for the increased biocide resistance of biofilm bacteria have been put forward, but none adequately explains the phenomenon. The current arguments are addressed adequately by Stewart (56) and Lewis (10).

CONCLUSION

Biofilms are problematic in a range of industrial environments in which large areas of submerged surfaces are exposed to relatively high nutrient fluxes, providing niches for the formation of biofilms. These biofilms also promote corrosion of ferrous metals by the concerted metabolic activity of a number of biofilm-associated bacterial types, a process collectively termed microbial influenced corrosion (MIC). The use of biocides to control biofouling in industrial water systems is still an accepted practice, although higher levels of environmental awareness and tighter legislation have placed increased pressure on the water treatment industry to seek alternative means of control. As the costs attributable to MIC and biofouling are high, effective control of bacterial activity and numbers in industrial aqueous environments is essential.

The primary target of a biofouling control strategy should always be the biofilm-associated microorganisms as these are the catalysts of MIC and impact negatively on system operation. The most common approaches currently available to control biofouling include the use of:

- Biocide to kill biofilm-associated microorganisms;
- Alternating currents to enhance the efficacy of biocides against biofilms;
- Dispersants to dislodge cells from the surface;
- Enzymes to hydrolyze biofilm-associated polymers;
- Physical processes for biofilm removal; and
- Ultrasonic sound to dislodge and kill microorganisms.

It is clear that an integrated biofouling management strategy is required to control biofilms and associated problems in industrial water systems.

BIOFOULING IN THE MARINE ENVIRONMENT

JAMES S. MAKI

Harvard University
Cambridge, Massachusetts

Biofouling has been defined as the modification of an immersed, artificial structure by organisms, which results in a deterioration in its performance (1). Its occurrence is a complex mixture of physical, inorganic, and organic chemical and biological phenomena (1). Basically, biofouling means that organisms (both microorganisms and macroorganisms) are acting out their normal life cycles, which include a sessile/attached phase, and doing it where humans do not want them to do so. Importantly, it has been observed that biofouling communities on artificial structures can be quite different from communities on natural surfaces (2). The consequences of biofouling are ultimately realized financially. In practical terms, they can be measured as increased fuel consumption by a fouled ship or submarine, deterioration of navigational buoys, blockage of pipes transferring seawater, length of downtime it takes to clean a fouled surface, or some other loss of performance. In addition, because fouling and corrosion are intimately related, the consequences of the former go beyond the simple accumulation of organisms on a surface to include the deterioration of the surface itself. Microorganisms play a variety of important roles in biofouling. They are both a component of a fouling community and may stimulate, inhibit, or have no effect on the subsequent attachment of other organisms. Both their ability to attach to surfaces and their interactions with other organisms are examined.

THE BIOFOULING "SEQUENCE"

Fouling has been traditionally separated into three types: molecular, microbial, and macrofouling (3). The classical and often reported view of biofouling has been described as a successional process (Fig. 1a; 4,5): first, involving a rapid (instantaneous) adsorption of organic and inorganic molecules to form a conditioning film (molecular fouling); second, a rapid formation of a biofilm (microbial fouling) involving formation of a bacterial film followed by algal and protozoan attachment; and third, invertebrate and macroalgal fouling (macrofouling). The idea of a succession in biofouling implies some sort of causality between the levels of fouling. On the one hand, unless causality can be demonstrated, it cannot be assumed (6), and on the other hand, it should not be assumed that causality between stages does not exist (7).

The aforementioned sequence of events in biofouling has been observed and reported many times largely due to the numbers of the components in the different levels and thus, their availability to attach to a surface (1,7). Thus, as an alternative to causal succession, biofouling can be considered to be seasonal or probabilistic (3). Probabilistic fouling (Fig. 1b) depends on the number of molecules and organisms that could attach to or colonize a surface. There are billions of organic and inorganic molecules per milliliter, around a million bacteria per milliliter, thousands of algae per milliliter, and possibly only a few larvae or spores per liter. For the most part, the number of molecules and bacteria per milliliter are "relatively" constant over time and so are readily available to attach to any new surface or one cleaned by a disturbance at

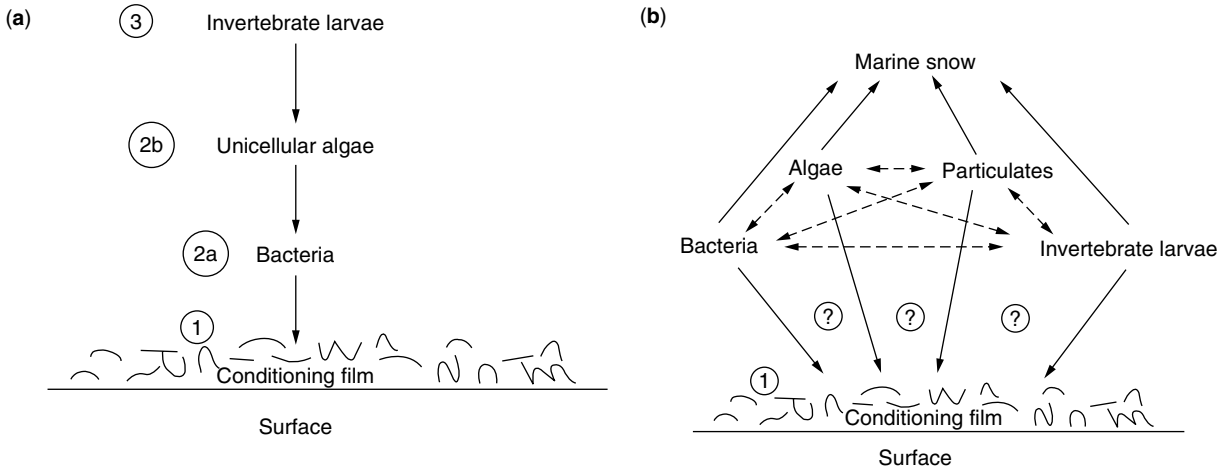

Figure 1. Diagrams of two models for biofouling. (**a**) The classical view of successional fouling on a substratum. Each fouling stage is a step that precedes the following stage and causality between levels is implied. (**b**) A diagrammatic representation of substratum fouling based on the probability that a particular fouling component will encounter the substratum. After formation of the conditioning film, further colonization will depend on which type of organism encounters the substratum. In the absence of a substratum, molecules and organisms may attach to each other and participate in the formation of marine snow. Adapted from A. S. Clare, D. Rittschof, D. J. Gerhart, and J. S. Maki, *Invertebr. Reprod. Dev*. 22, 67–76 (1992).

any time of the year. Although there should also be unicellular algae present throughout the year they will probably undergo seasonal quantitative and qualitative fluctuations. On the macrofouling level, some organisms reproduce throughout the year, but many reproduce seasonally (8). Thus, their arrival late in the fouling "sequence" may be more due to seasonal reproduction, and therefore a probabilistic relationship, than to any causal succession.

MOLECULAR FOULING

Molecular fouling forms what is called a conditioning film on a surface exposed to an aquatic environment (See CONDITIONING FILMS IN AQUATIC ENVIRONMENTS, this Encyclopedia). Macromolecules that adsorb to the surface include proteins, glycoproteins, proteoglycans, and polysaccharides (9,10). Specificity between the nature of the substratum and the chemical identity and quantity of adsorbed materials in the early stages of macromolecular adsorption also appears to occur (11–13). The surface free energy of the substratum can also affect the molecules. On high-energy surfaces the organic molecules are flattened and bind strongly, while on low energy surfaces the molecules are more weakly bound, but may have greater thickness (9). As pointed out in the preceding text, there are billions of organic and inorganic molecules in a milliliter of water. In the formation of the conditioning film on a surface exposed to the bulk phase water, not all organic species present in the water column initially adsorb (11). However, after a certain period, differences disappear. Because the air/water interface already contains a layer of surface-active organic molecules (14), molecular fouling that occurs on surfaces exposed to wave action is different and more complex (3).

The presence of a conditioning film can change both the charge and the free energy characteristics of the substratum (15,16). After the adsorption of the conditioning film, the substratum will assume the net surface charge and the surface fee energy characteristics of the outermost molecular groups of the film. However, the surface energy may not change much because the outermost molecules of the conditioning film reflect the nature of the underlying substratum (17).

The presence of a conditioning film can have two potential effects on attaching microorganisms. First, facilitation between adsorbed molecules and attaching microorganisms has been reported (18–20). However, adsorbed molecules have also been reported to inhibit attachment by microorganisms (12,21). Second, adsorbed molecules may provide attaching microorganisms (e.g., bacteria) with a carbon source for growth. Even molecules that are toxic in solution may become nontoxic when they are immobilized at a surface and provide a suitable substrate for bacteria (22). Attached bacteria on a surface may be able to metabolize adsorbing organic molecules very rapidly (23). In summary, the possibility exists that the nature of the substratum will influence the initial adsorption of components of the conditioning film, and these in turn may influence the types of microorganisms that initially attach.

MICROBIAL FOULING-BIOFILM FORMATION

Bacterial biofilms have been defined as matrix-enclosed bacterial populations adherent to each other and/or surfaces or interfaces (24). In the marine environment, biofilm communities contain a variety of other populations of microorganisms, which also colonize solid substrata including unicellular algae, fungi, and protozoa. Thus, the definition of a marine biofilm will be modified in this report to be matrix-enclosed *populations of microorganisms* adherent to each other and/or surfaces or interfaces. A biofilm should be considered to be more than a layer of cells and slime coating a solid substratum. It possesses dynamic structure and function. It is the nature of the various structures and functions and their changes, which may be involved in the attachment of other microorganisms and macrofoulers. Examples of some of the microorganisms found in marine biofilms follows.

Bacterial Colonization

Bacteria will be among the initial colonizers of a new surface for reasons stated earlier (Fig. 2a). Arrival at the vicinity of a surface will usually be by hydrodynamic means. Once within the viscous boundary layer of still water near the surface, positive and negative

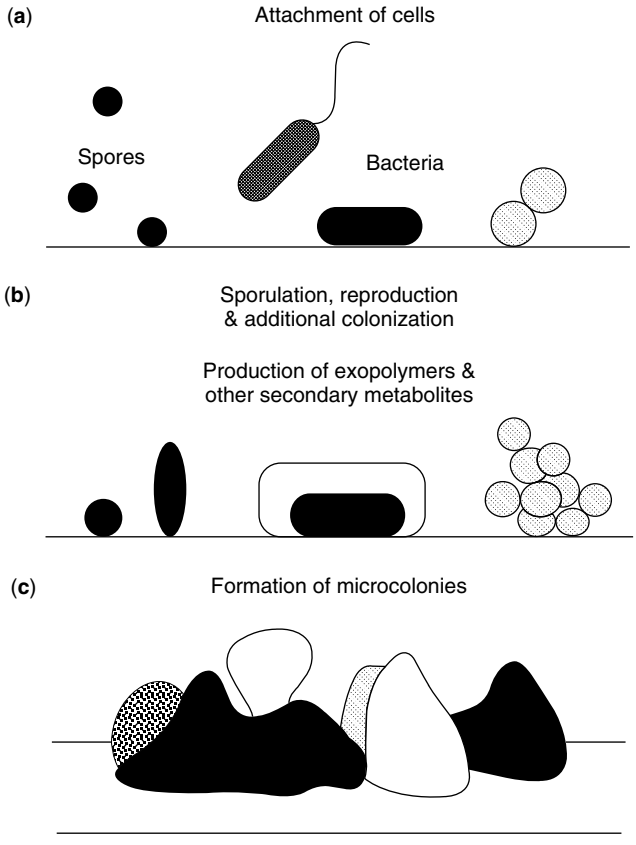

Figure 2. Steps involved in the formation of microbial biofilms in the marine environment. (**a**) Attachment of cells. (**b**) Sporulation, reproduction, and additional colonization. (**c**) Formation of microcolonies. See text for details.

chemotaxis may be important to motile bacteria for their transport to the surface. For nonmotile bacteria, transport through the boundary layer may involve Brownian motion or the hydrophobicity of the cell surface. As described by Zobell (25) and later defined by Marshall and coworkers (26), bacteria approaching a solid substratum have two phases of adhesion — reversible and irreversible or firm. Reversibly attached bacteria do not come in direct contact with the substratum because of electrostatic repulsion, but are capable of scavenging nutrients from the surface (27). The bacteria must overcome the repulsion to be firmly attached. Firm adhesion of a bacterium to a solid substratum is mediated by cell surface and extracellular polymers (28), including polysaccharides (29,30), proteins (31,32), and lipopolysaccharides (33,34). It is also likely that bacteria can utilize more than one mechanism to attach to different surfaces (31,32).

When a planktonic bacterium arrives in the vicinity of a solid substratum it is faced with a microenvironment that has different conditions. These conditions can act to stimulate changes in morphology (35), and turn on previously unexpressed genes (36–38). A bacterium may respond to more than one type of signal when near a surface (39). This may induce the production of new proteins (40) and stimulate the synthesis of exopolysaccharides (Fig. 2b; 41). Conditions that are associated with a surface and may be responsible for inducing genetic responses by an attaching bacterium, either individually or in concert, include changes in gas diffusion, pH, cell density, metabolite accumulation, nutrients, surfactants, viscosity, osmolarity, water activity, and inorganic ions (42).

The formation of a bacterial biofilm is a complex process and can be influenced by a number of factors (43). Once on the surface, factors including motility mediated by flagella and twitching, outer membrane proteins, and exopolysaccharides have been demonstrated to be important in establishing cell-cell interactions for biofilm formation by several bacteria in laboratory studies (44). Microscopic evidence has indicated that the three-dimensional structure of a bacterial biofilm can be quite complex (Fig. 2c; 24,43). In addition, bacteria may communicate between their own species and perhaps others through the use of N-acyl-L-homoserine lactones (AHL, 45–48). These small molecules act as extracellular signals that, when accumulated in the presence of increased cell density, activate transcription and modulate physiological processes. They have been demonstrated to influence the three-dimensional structure of a bacterial biofilm (49). A number of bacteria have been demonstrated to use this type of cell-to-cell communication, which raises the possibility of one bacterium receiving analogous signals produced by another species. These signals may actually be directed toward a different physiological response. AHL activity has been demonstrated to occur in natural biofilms (50). Thus, some biofilm physiology and phenotypic expression may be the result of intercellular communication between bacteria of same and/or different species. However, it is also apparent that some marine algae produce compounds, which interfere with AHL regulatory systems (51). Thus, in the natural environment, these regulatory systems may not function with the same efficacy in all habitats as they do in the laboratory.

Marine bacteria have been shown to produce a wide range of organic molecules that have antibacterial, antialgal, antifungal, antiviral, and anti-inflammatory activity, as well as enzymes, enzyme inhibitors, toxins, and polymers (52–54). Understanding how marine bacteria are adapted to life in the various habitats of the sea (including biofilms), and how these may affect the production of secondary metabolites, may help understand their biosynthetic potential (55). These secondary metabolites may have a wide range of effects on other potential fouling micro and macroorganisms.

Diatoms and Other Unicellular Algae

Of the unicellular algae that may be involved in biofilm communities, diatoms are usually among the primary algal colonizers of new surfaces (56–59). Because of their size and mass, diatoms (and many other unicellular algae) in aquatic systems are transported to surfaces through hydrodynamic means, except under completely calm conditions. Among the diatoms are a number of different attachment systems (Table 1), but all have one thing in common — the presence of mucilaginous material (56,60). The polymers have a high molecular weight, and are largely acidic, with lesser amounts of neutral polysaccharides and small amounts of protein in certain species (57,60). The extracellular polymers are involved in both gliding of diatoms and their adhesion (61,62).

Once it has arrived at a surface, a motile diatom (e.g., *Amphora coffeaeformis*) can move across the surface by means of its raphe and can respond chemotactically to nutrient gradients (58,59,63). Ca^{+2} plays a role in both the initial adhesion and the motility of diatoms (59,64,65). The role of Ca^{+2} is probably dual as it is involved intracellularly in transport and secretion of the adhesive and extracellularly by cross-linking the adhesive (63).

Adhesion of *A. coffeaeformis* can occur under either light or dark conditions and is not inhibited by the

Table 1. Characterization of Adhesion Mechanisms Used by Diatoms[a]

Adhesive Type	Description	Examples
Extracellular pads	Pads peripherally located or distinct pads at polar end or at corners of cells	*Synedra affinis*
Extracellular stalks	Adhesive secreted through slits in valve region	*Achnanthes* sp. *Licmophora* sp.
Extracellular encapsulation/Raphe secretions	Mucilage secreted through raphe fissures and large punctae	*Amphora* sp.
Extracellular sheaths	Sheath mucilage released all over cell through small punctae	*Navicula* sp.

[a] Adapted from Chamberlain (56) and Jones and coworkers (57).

photosystem II inhibitor, DCMU, but does require energy and protein synthesis (63). Once attached, the strength of the adhesion of diatoms to a surface is species-dependent and will increase over time (66). Stalked diatoms appear to stay attached to substrata at higher shear stress while diatoms attached by means of an adhesive pad do not (66).

The adhesion of the unicellular alga *Chlorella* has been reported to be stimulated by polymers recovered from *Chlorella* exudate, bacterial cultures, and seawater that were adsorbed to glass surfaces (18). This interaction appeared to be mediated by lectins or lectin-like activity (67). The growth of a number of diatoms and other unicellular algae was demonstrated to be inhibited by marine bacteria in laboratory studies (68,69). Thus, both positive and negative interactions between bacteria and algae may occur in biofilms.

Fungal Colonization

Fungi are widely distributed in the marine environment and include saprophytic and parasitic types (70,71). Marine fungi can also be members of biofilm communities. Colonization of surfaces by fungi usually takes place through attachment of their spores. Many marine fungal spores have appendages (72,73). The presence of appendages assists the ability of the spores to remain in the water column for longer periods of time than those without appendages (74). Because the spores are nonmotile, they are transported to surfaces through hydrodynamic forces. Once in the vicinity of a surface, spores may initially become entrapped (which may be assisted by the presence of appendages) or attach to the surface (75). Attachment is mediated by several methods (Table 2), all of which employ some mucilaginous adhesive (75,76). The strength of the initial adhesion is variable between species and can (*1*) remain constant, (*2*) increase and then level off, or (*3*) show variable increase with time (77). Eventually the spores will germinate and adhesion will be further improved by production of a mucilaginous sheath around both the spore and the germ tube (76).

Table 2. Mechanisms of Spore Attachment by Marine Fungi[a]

Type	Examples
Release of drop of mucilage from polar appendages	*Kohlmeyeriella tubulata* *Lulworthia medusa*
Disc or padlike attachment	*Ondiniella torquata* *Ceriosporopsis circumvestita*
Coiling of sticky appendages around objects	*Halosarpheia retorquents*
Straplike sticky appendages	*Haligena elaterophora* *Remispora maritima* *Remispora pilleata*
Hairlike sticky appendages or pads composed of fibrillar components	*Nereiospora comata* *Crinigera maritima*

MACROFOULING: INVERTEBRATE LARVAE

Sessile invertebrates involved in fouling generally have a free-living planktonic stage for dispersal and development back into the adult stage (Fig. 3). The planktonic larvae of many sessile invertebrates are recruited to surfaces by various biochemical stimuli (78). For the purposes of this discussion, recruitment will be considered to be a two-stage process — first, an exploratory phase of repeatable behavior (settlement), and second, an irreversible developmental event that occurs once and includes secretion of a permanent adhesive (metamorphosis) (Fig. 3; 79–81). The stimuli can be broadly divided into two types — conspecific (or gregarious) and associative (79,82). Conspecific cues are those that induce the larvae to settle and metamorphose on or near their own species, while associative cues are those produced by other organisms (e.g., those in biofilms) and provide information to the larvae on the choice of habitat. Both positive and negative cues or stimuli are probably important for habitat choice. Although there is increasing evidence that some larvae can respond to soluble biochemical cues in either settlement or metamorphosis (83–91), many larvae will only metamorphose in response to specific stimuli adsorbed onto surfaces (92).

The length of time larvae remain in the planktonic stage of development varies among species. Some, including spirorbid polychaetes, are nonfeeding and generally only remain planktonic for some hours before settlement and metamorphosis (93). Others, including barnacles, have a number of larval feeding stages (naupliar) followed by a nonfeeding larval stage (cyprid) that undergoes settlement and metamorphosis, and can be in the planktonic stage for a considerable length of time (94). Once the larval stage responsible for settlement and metamorphosis is produced, hydrodynamics can affect its availability to arrive at a given substratum (95) and the settlement and attachment of larvae at a surface (96,97). For sessile organisms, such as fouling invertebrates, space is a resource (defined as something that can be consumed or made less available to other organisms, 98). As a result, it is something that can be competed for by organisms in the fouling community (98). Additionally, predation also plays

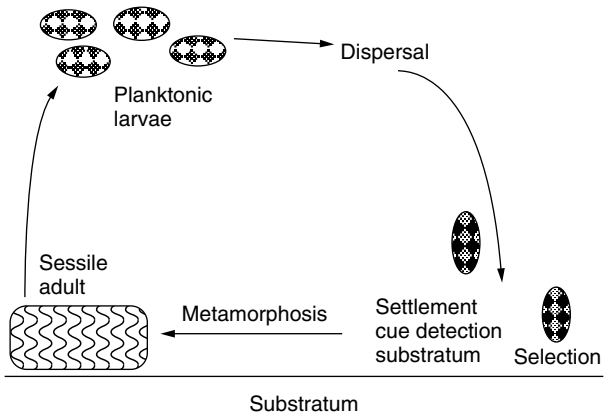

Figure 3. A generalized life history of a sessile marine invertebrate. Adapted from J. R. Pawlik, *Oceanogr. Mar. Biol. Annu. Rev.* **30**, 273–335 (1992).

a role in the community structure (98). Rittschof (3) has pointed out that it is important to remember that many invertebrate foulers have short life cycles. In fact, after they attach, the animals reach sexual maturity in about a month, and after four months the whole cohort is dead (3). After that, their remains on the substratum may act as a surface for other fouling organisms.

Biofilms and Invertebrates

The role of biofilms in invertebrate settlement and/or metamorphosis is complex (see reviews 99–101). Although a larva may not necessarily require a film of microorganisms to settle and metamorphose (102), it is likely to encounter a film on almost every surface that it comes in contact with during settlement. This occurs because although larvae may only be produced seasonally as stated earlier, microorganisms will attach continuously. As the previous information indicates, a marine microbial biofilm is quite complex, with potentially a wide variety of organic molecules that may act as associative cues for larval attachment. However, the abundance of any one cue will probably vary over space and time in any biofilm. The biofilm is particularly important for those organisms that respond to surface-associated stimuli.

Field studies have demonstrated that invertebrate attachment to substrata, with or without biofilms, is complex and potentially governed by a number of variables (103–106). The nature and beginning wettability of the substratum is important for some of the initial macrofoulers (105,106). As time passes, the wettability of the surface changes and is probably not a major influence on continued recruitment (106). Films of microorganisms can change the wettability of a substratum (107–109) and can modify the response of some larvae to surface energy (e.g., bryozoans; 107,108).

Recent field studies used natural films prepared by enclosing panels in a mesh that allowed development of a biofilm but prevented attachment of macroorganisms (110–112). Comparisons were made of filmed and unfilmed substrata, age of films, and films from different locales on the fouling of panels by macroinvertebrates and results showed that (*1*) filming generally enhanced larval attachment, although not for all type of organisms at all times (110); (*2*) some larvae responded positively to film age, some did not, and some preferred less filmed surfaces (111); and (*3*) generally, larvae could not distinguish between films developed in different areas, but were more attracted to more heavily-filmed substrata (112). From these data, it would appear that each type of invertebrate has its own response to biofilms, that there may also be variability in that response within any one group of larvae, and that biofilm density and/or age may play a role in the larval response.

Laboratory Observations

Many laboratory observations of larval interactions with biofilms have been performed without flowing water (although not always) to examine single strains of bacteria and their effects on the type of larva under study. This is particularly useful if the goal is to find bacteria and/or novel bacterial compounds that inhibit or stimulate larval attachment. However, it should be pointed out that stimulation or inhibition of larvae by a biofilm in the field may turn out to be the result of actions by a consortium of microorganisms, and focusing on films composed of a single bacteria may probably not duplicate that result. There is no way that the film produced by a single species can mimic the complex structure and function of a natural biofilm consisting of a number of microbial populations.

Natural films composed of a variety of microorganisms in laboratory tests have been reported to promote settlement and metamorphosis of spirorbid polychaetes (93,102,113), bryozoans (107,114–116), and barnacles (117,118). Factors such as composition of the biofilm (117) and its age appear to be of importance to some types of larvae (118). Natural biofilms have been demonstrated to have very different effects on the attachment of different types of larvae. For example, Crisp and Ryland (102) reported that while the bryozoan *Bugula flabellata* was inhibited by the presence of biofilms, the spirorbid polychaete *Spirorbis borealis* was stimulated. Similar results were reported for larvae of *B. flabellata* and larvae of the ascidian *Ciona intestinalis* (119).

Films composed of individual strains of bacteria can have varying effects on larval attachment (108,120–127). In fact, individual strains of bacteria isolated from surfaces may have an effect on larval settlement and metamorphosis, which was not expressed by the community it was isolated from. For example, the spirorbid polychaete, *Janua brasiliensis*, attaches to a variety of different substrata, and biofilms are an important component to the polychaetes' response to a surface (120,128). One surface that *J. brasiliensis* is commonly found on is the green alga *Ulva lobata*. When a number of bacteria were isolated from *Ulva* and films of these bacteria were tested for their effect on attachment of *J. brasiliensis* larvae, it was found that not all bacteria were effective inducers of larval attachment (120). This suggests that (*1*) the effect of a single strain of bacteria can be masked by the biofilm as a whole and that (*2*) just because a natural film does not show stimulation or inhibition of larval attachment, it does not follow that it does not contain strains of bacteria that could do either. Laboratory tests have also shown that a single bacterium can have a variety of effects on the settlement and metamorphosis of different invertebrate larvae (129). For example, the marine bacterium *Halomonas marina* (formerly, *Pseudomonas marina* and *Deleya marina*) has been reported to stimulate the settlement and metamorphosis of the spirorbid polychaete *J. brasiliensis* (120,130), inhibit or stimulate (see later) attachment of the barnacles *Balanus amphitrite* (109,123,131,132) and *Balanus improvisus* (127), inhibit the temporary adhesion of the barnacle *Elminius modestus* (133), and inhibit the attachment of the larvae of the bryozoan *Bugula neritina* (108). This implies that a single species of bacterium can possess different biochemical cues for larval settlement and metamorphosis. Some of these cues could be stimulatory to certain larvae, whereas other cues could be inhibitory to other larvae.

It has been suggested that there is an interaction between the substratum and the bacterium, which influences the response of the larvae (127,131–134). Films of single species of bacteria (e.g., *H. marina*) or their extracellular products attached or adsorbed onto one substratum are inhibitory, while on another substratum they are not inhibitory or may even be stimulatory compared to no-film controls. Bacteria have been demonstrated to have the capability of using separate mechanisms to attach to different surfaces (31,32). This may cause changes in the surface polymers that are expressed by an attached bacterium (i.e., production of a new extracellular polymer or rearrangement of an existing one to mediate adhesion). Polymers with distinct characteristics may be produced by a bacterium in response to attachment to different substrata (134). It is also important to remember that the substratum can cause new genes to be expressed (42). Thus, the response of the bacterium to the substratum before, during, or after adhesion may bring about a change in extracellular polymers, which in turn is detectable by the larval receptors.

In most cases, the stimulatory or inhibitory component of the individual strain of bacteria for larval settlement and metamorphosis has not been elucidated. A number of invertebrates, some of which are considered fouling organisms, have been shown to be stimulated to metamorphose by marine bacteria, and some of the inducing molecules have been isolated (Table 3). The marine bacterium *Pseudoalteromonas tunicata* has also been demonstrated to produce a number of compounds that are inhibitory to a variety of micro- and macroorganisms (125,135,136). In addition to the production of specific molecules, biofilms can influence larval settlement and metamorphosis in other ways. The extracellular polymers of bacteria in films provide sites for sorption or binding of metals or organic pollutants (28,137–139). For example, tributyl tin, a very toxic compound, has been demonstrated to be more concentrated in a bacterial biofilm and inhibits attachment and metamorphosis of oyster larvae (140). Thus, the cause of inhibition of larval attachment may be much more subtle than the presence or absence of a biofilm alone. Production of extracellular polymers can also been demonstrated to cause some larval types (e.g., ascidian) to become "trapped" in films, and these underwent metamorphosis and contributed to recruitment (124,119).

MACROFOULING: ALGAL SPORES

Macroalgae are also major fouling organisms in the marine environment. The macroalgae that contribute to biofouling belong to Chlorophyta (green algae), Phaeophyta (brown algae), and Rhodophyta (red algae). These may develop sequentially in the environment with green and brown algae occurring first followed by red (150). Mechanisms for the dispersion and colonization of new substrata by macroalgae in the marine environment include vegetative fragmentation (151) and young sporophytes (152). However, most of the dispersal and colonization of macroalgae occurs through the production of reproductive spore bodies formed in sporangia (153). There are two major types of spore bodies: (*1*) sexual spores (known as gametes) and (*2*) asexual spores (known as zoospores or swarmers for green and brown macroalgae and carpospores and tetraspores in red algae). The occurrence of two major types of spore bodies is the result of life cycles that contain both diploid (usually sporophytes) and haploid (usually gametophytes) vegetative phases. The distribution of sporophytes and gametophytes may depend on how rigorous the environmental conditions are (154), and their respective release of reproductive spore bodies is both seasonal and periodic (154,155). Both sexual and asexual spores are potential foulers, the latter as fused gametes or parthenospores (156).

The swarmers of green and brown algae are flagellated and motile and the length of time they exhibit motility varies among groups. In some cases they may swim for days (157–161). The asexual spores of red algae are nonmotile and colonize by sinking onto substrata (162). Their sinking rates are dependent on size, density, the amount of mucilage present on the spore surface, and hydrodynamic conditions. Water motion is a major force in the distribution of spores because the velocity of currents is generally greater than their sinking rates (163). The motility of green and brown algal swarmers may only be of value once the swarmer is out of turbulent hydrodynamic conditions and enters the boundary layer associated with the surface (164).

Motile spores go through a selection process in the search for substrata, which are suitable for colonization (160). Spores will settle on substrata of both high (hydrophilic, wettable) and low (hydrophobic, low-wettable) surface free energy (164,165). However, substrata that are more hydrophobic appear to be more

Table 3. Examples of Larvae That Have Metamorphosis Induced by Marine Bacteria

Invertebrate	Bacteria Involved	Nature of Inducer	Reference
Hydractinia echinata (hydrozoan)	*Alteromonas espejiana*	lipid material	141,142
Lytechinus pictus (sea urchin)	unidentified	unknown, <5, 000 MW	143
Cassiopea andromeda (scyphozoan)	*Vibrio* sp.	oligopeptides	144,145
Acanthaster planci (starfish)	unidentified	unknown	146
Aurelia aurita (scyphozoan)	Micrococcaceae	glycolipid	147,148
Janua brasiliensis (spirorbid polychaete)	*Halomonas marina*	unknown glycoconjugate	130
Crassostrea gigas	*Alteromonas colwelliana*	L-dopa mimetic	122
Crassostrea virginica (oysters)			
Hydroides elegans (polychaete)	unidentified	unknown, <7, 000 MW	149

attractive to some zoospores (e.g., *Enteromorpha*, 167). Before settlement, the spores switch from a random and erratic motion to a searching mode (166,167). This is followed by a spinning motion with the anterior of the zoospore down on the substratum (167,168). Initial contact with the surface was believed to be mediated by the flagella (153) but recent information using high-resolution video microscopy found no evidence to support this hypothesis (167). Once the zoospore is on the surface the flagella are adsorbed (159,169,170) and the spore flattens and contracts against the surface (167), followed by the secretion of a protein-polysaccharide adhesive (159,169,171,172). There also appeared to be gregarious settlement by *Enteromorpha* zoospores although no specific mechanism was elucidated (167).

Nonmotile spores generally have a coating of polysaccharide mucilage (164,173) and this mucilage is probably responsible for the initial spore attachment (153). After initial attachment the cell components undergo a rearrangement (174). Large quantities of a secondary adhesive is secreted and forms a pad beneath the spore (153,164,173).

Once the initial spore adhesion is completed, the spores germinate and primary and secondary rhizoid formation occurs. Primary rhizoids function to secure attachment during early development and secondary rhizoids grow in response to enlargement of the shoot. The attachment of the rhizoids is also mediated by secreted adhesives (175). The adhesion of at least one type of macroalgae (*Enteromorpha*) that were grown on substrata with a high surface free energy was found to be stronger than those grown on a low surface free energy substratum (176).

Algal Spores and Biofilms

Similar to invertebrate larvae because of the periodic and seasonal production of spores by macroalgae, the spores will usually encounter substrata, which possess a biofilm. However, little is known about how macroalgae develop on substrata with biofilms (101). *Enteromorpha* zoospores attached in greater numbers to surfaces with a natural multispecies film than to unfilmed surfaces (177,178). It was hypothesized that the presence of the film increased the surface free energy, which stabilized the adhesive of the zoospore (177). However, other studies have shown that zoospores will attach in greater numbers to hydrophobic surfaces (166), suggesting that a higher surface free energy is not the answer. Studies using individual strains of bacteria have demonstrated that some can be inhibitory to macroalgal spores while others may be stimulatory (179). The exact mechanisms for these results have not been elucidated.

CONCLUSION

The preceding discussion indicates the complex nature of biofouling. Marine biofouling occurs because humans place structures in this environment and the life cycle of many marine organisms includes a sessile phase, which ends up on these structures. Both microorganisms and macroorganisms are involved in this process. Microorganisms are participants in the biofouling process and may be sources of cues to other organisms arriving at a surface. Biofouling communities are dynamic both in their structure and function. A better understanding of these processes will be required in order to prevent or limit biofouling and its consequent deleterious effects on structures in the marine environment.

BIOFOULING OF INDUSTRIAL SYSTEMS

HANS-CURT FLEMMING
University of Duisburg and IW
Duisburg, Germany

Biofouling is referred to as the undesired development of microbial layers on surfaces. Such microbial layers are termed *biofilms* (1) and the effect is called *biofouling*. The term has been adapted from the heat exchanger technology, wherein *fouling* is defined generally as the undesired deposition of material on surfaces (2). A distinction is made between different types of fouling, including the following:

Scaling, *mineral fouling*: Deposition of inorganic material precipitating on a surface

Organic fouling: Deposition of organic substances such as oil, fat, proteins and so forth.

Particle fouling: Deposition of particles from the water phase, such as humic substances, clay, silica, debris and so forth.

Biofouling: Adhesion and growth of microorganisms on surfaces.

In the first three kinds of fouling, the increase of a fouling layer arises from the transport and abiotic accumulation of the material from the water phase on the surface. What is deposited on the surface originates quantitatively from the water. In these cases, fouling can be controlled by eliminating the foulants from the liquid phase. However, this is different from biofouling — microorganisms are pseudo "particles" that can multiply.

Even if 99 to 99.9% of all bacteria are eliminated by pretreatment, there may be a large enough inoculum, which will enter the system to become protected, adhere to

surfaces, and multiply at the expense of biodegradable substances. Thus, microorganisms convert dissolved organic material into biomass locally. This is the same mechanism that supports biofilm technology — biofouling can be considered as a "biofilm reactor in the wrong place and at the wrong time." Substances suitable as nutrients, which would not act as foulants per se, will support fouling indirectly. As most antifouling measures target the microorganisms, the role of nutrients as a potential source of biomass is overseen and biocides tend not to decrease the nutrient level. On the contrary, nutrients supplied by the oxidation of recalcitrant organics can support rapid aftergrowth (3). As it is virtually impossible to keep a common industrial system completely sterile, microorganisms on surfaces will always be present, "waiting" for nutrients.

Usually, the different kinds of fouling occur together (4). The proportion of biofouling can be considerable. An example is the development of dental plaque, namely, mineral depositions on teeth that are favored by biofilms (5). In algal biofilms, precipitation of calcium carbonate is increased, mainly because of the rise in pH resulting from photosynthesis (6).

Generally, biofouling has to be considered as a biofilm-based problem. To understand the effects and dynamics of biofouling and to design appropriate countermeasures, it is important to understand the natural processes of biofilm formation and development.

In biofilms, microorganisms live in an environment that is entirely different from that experienced by planktonic organisms (7). They are more or less immobilized, embedded in a highly hydrated matrix of extracellular polymeric substances (EPS), which is commonly described as "slime." The cell density is some orders of magnitude higher than that in suspension. Owing to the long retention time of the cells next to each other, the development of interacting aggregates is possible, leading to so-called microconsortia.

A biofilm consists of 80 to 95% water. The organic proportion is dominated by the EPS, comprising mainly polysaccharides and proteins (8), whereas the cell material usually makes up only a minor fraction. Additionally, particulate matter such as clay, humic substances, corrosion products, and so forth can be included. Chemical analysis shows that this collected abiotic material can represent the major part of the dry matter, although it is deposited mainly because of the adhesive effect of the biofilm. Thus, the analysis of unwanted deposits can be misleading when the cause of a fouling layer development is investigated.

From an ecological point of view, life in a biofilm may offer important advantages to the cells (9). Among these are (*1*) the possibility to form microconsortia; (*2*) the facilitated exchange of genetic material; (*3*) the accumulation of nutrients from the bulk water phase (10); and (*4*) protection against toxic substances and against desiccation.

OCCURRENCE OF BIOFOULING

Biofouling, by definition, can occur in extremely diverse situations ranging from space stations (11,12) to profane explanations for religious miracles like that of Bolsena (13), which is attributed to the growth of *Serratia marcescens* on sacramental bread and polenta.

Not surprisingly, biofouling occurs in toilet bowls (14) but is commonly observed in water systems in general (15) and during the filtration of seawater (16). It also represents a serious problem in fish farms where the cage netting fouls rapidly (17). The submerged structural surfaces of offshore oil and gas production platforms are covered by biofilms (18), potentially giving rise to microbially influenced corrosion (19). Little (20) has given an excellent overview on marine biofouling. Microorganisms can contribute to calcareous deposits, adding scaling to biofouling (21). Massive deposition of manganese and iron minerals is frequently due to microbial activity (22). Boreholes and aquifers can be clogged by excessive biofilm growth (23), leading to considerable technical problems. A *Thiothrix* species resistant to 200-ppm free chlorine was identified as the cause of biofouling in groundwater systems in Florida (24).

Desiccation of biofilms can also lead to the deposition of minerals (25). In some instances, unexpected biofouling has led to problems such as the deterioration of pH electrode response due to biofilm formation on the glass membrane (26). Moored spectroradiometers were stricken by biofouling (27), and the list of other water-exposed sensors that may yield erratic data because they are affected by biofilms could easily be expanded. Biofilms growing on the walls of houses can influence the surface temperature of the building walls and thus increase mechanical weathering process due to differential thermal expansion. These biofilms can increase the heat uptake, leading to an increase of energy demand for air conditioning (28).

In medicine, implant devices such as catheters are prone to biofouling (29). Dental waterlines can be seriously contaminated by pathogens (30).

Biofouling in Drinking Water

The maintenance of the hygienic and aesthetic quality of water during transport in the distribution systems still challenges drinking water technology (31). Massive growth of cells and the occurrence of pathogenic organisms are observed (32). Both can originate from growth in the water phase but also from biofilms. Thus, all surfaces in contact with water have to be considered as potential supports for biofilm growth and as contamination sources. In particular, the surface to volume ratio in distribution systems leads to the fact that more than 95% of the entire biomass is located on the walls and less than 5% in the water phase. Fouling and corrosion in water filtration and transportation systems can therefore represent a serious problem (33).

Water that leaves the water works in a hygienically optimum state can contain substantial numbers of microorganisms after passing the distribution system. This is mainly due to contamination by biofilms (34,35). Biofilms release cells both continuously by erosion and discontinuously by sloughing events (36) and by swarmer cells (37), which deliberately leave the biofilm. The contamination rate, however, is unpredictable. Thus, there is no correlation between the cell concentration in the

water and in the biofilm. Data from the water phase give no information about the extent or the site of biofilm growth. In the same system, the cell concentration in a biofilm — as compared with the water phase and expressed in relation to volume — ranges from 10^7 to 10^{10} colony forming units (cfu) mL^{-1} (38,39), whereas the cell concentration in the water phase can be as low as 10^5 cells mL^{-1} and below 10 cfu mL^{-1}.

In drinking water technology, it is assumed that a massive development of microorganisms on surfaces only occurs if the support material releases biodegradable matter (40). Certain paints and coatings have led to increased cell numbers in drinking water (41) for this reason. However, similar incidents have been observed even when the support material did not leach nutrients (34,36,42).

Pathogenic and Potentially Pathogenic Organisms in Biofilms

It is now acknowledged that biofilms can provide a habitat for pathogenic microorganisms. In medicine, mycobacteria have been known for a long time as "trumpet bacteria" occurring in the mouthpieces of musical instruments of tuberculosic performers, and, less artistically, in telephone handles (43). *Klebsiellae*, *Mycobacteriae*, *Legionellae*, *Escherichia coli*, and coliform organisms have been found in biofilms (44–48). In the presence of corrosion products, the organisms seem to be particularly protected. This is the conclusion of the study conducted by Emde and coworkers (49), which identified a much higher variety of species in corrosion product deposits, called "tubercles," compared with the free water phase, even after extended periods of chlorination. The fate of viruses in biofilms is still in question. Schmitt and coworkers (50) showed that enteroviruses could be isolated from biofilms on sand filters of drinking water plants fed with surface water.

Biofouling in Purified Water

One of the major problems in the production of purified and ultrapure water is contamination from microorganisms. Processes that depend on ultrapure water suffer accordingly. In the production of microelectronic devices, in which ultrapure water is often used to wash printed circuit boards, microorganisms can cause severe quality losses. Dial and Chu (51) found a direct correlation between the cell content in ultrapure water and the defects in the microchips. Craven and coworkers (52) attributed failures in the metal coating process to the adhesion of microorganisms. Eisenman and Ebel (53) describe horizontal and vertical dislocations in the crystal lattice during the photoresist process, which are due to microbial contamination. Microorganisms can bridge electrical circuits where the distances are below 1 μm. Electromigration and corrosion of the oxide layers have also been observed. Sodium and calcium (Ca^{2+}) ions from lysed bacteria or from bacterial metabolism can diffuse into the surface of the silicon wafer and influence field effects (54). Bacteria are carbon-containing particles, and, thus, can increase the conductivity of semiconductors (55). These microorganisms are mainly released from biofilms. In a detailed study, Patterson and coworkers (56) could demonstrate that in the ultrapure water system (18 MOhm water) of the IBM plant in Burlington, Vermont, United States, all surfaces in contact with water carried biofilms. The piping material consisted of poly(vinylidene dichloride) (PVDF). The authors found that the contamination of the water was due to the biofilms. By sequential sampling, they showed that the cell numbers in water close to the walls were significantly higher than those in the bulk liquid phase.

What can these organisms live on? There are pioneer bacteria, which can multiply in water with less than 10 $\mu g\,L^{-1}$ glucose equivalents (57). If they form biofilms, they can sequester nutrients from the flowing water phase and accumulate them in the EPS matrix. This allows the organisms to live with an even lower concentration of biodegradable material, which is why biofilm formation is considered an ecological strategy in oligotrophic environments (58). These pioneers convert the organic materials into biomass, which represents spots of high concentrations of organic material. This offers a suitable habitat to other organisms, which may have invaded the system.

A common strategy to prevent microorganisms from entering a system is the use of so-called "sterile" filters. Nevertheless, "breakthroughs" occur repeatedly. An important cause is ultramicrobacteria (59). During starvation, the morphology of cells can change drastically, resulting in cells of less than 0.2 μm in diameter. This is demonstrated with *Pseudomonas fluorescens* rods within three weeks of nutrient depletion. Cells of that size have been shown to migrate through sterile filters (60).

Biofouling in Water Treatment Plants and Membrane Systems

Water treatment plants frequently include granular filters with a large surface area, which are predestined for biofilm growth. Biofilms can grow on piping material, insulations, fittings, elastic filling materials and so forth and develop significant tolerance against disinfectants. These biofilms contribute considerably to the overall purification process because they degrade diluted organic matter. A change in nutrient concentration, temperature, or other factors can cause either mass production or sloughing of biofilms, which leads to an increasing contamination of the water. In ion exchangers, biofilms clog the material and lead to an increased pressure drop, and in membrane processes such as reverse osmosis, ultrafiltration, and others, biofouling represents a serious problem (61–63).

Biofilms form a gel layer on top of the membrane and prevent direct tangential flow adjacent to the membrane surface. This leads to concentration polarization at the feed waterside, which increases the transmembrane pressure drop ($\Delta p_{\text{membrane}}$). Thus, both permeate production and salt rejection will decrease. The costs of biofouling of membranes can be summarized as follows (64):

- Loss of product quantity
  - — Flux decline due to increased $\Delta p_{\text{membrane}}$ (see Fig. 1)
- Loss of product quality
  - — Possible microbial contamination of permeate

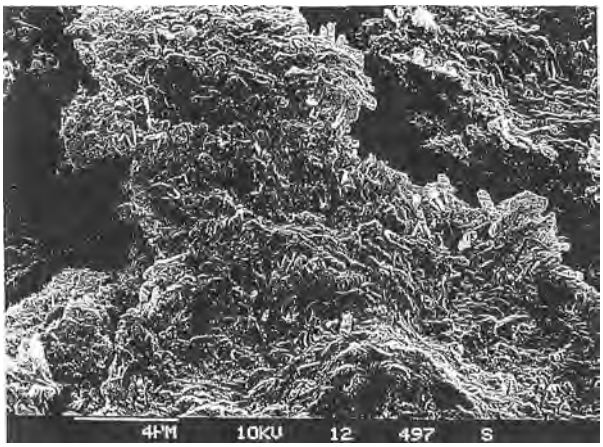

Figure 1. Biofilm on the feed side of a reverse osmosis membrane; bacteria are embedded in the slime matrix (39).

  - — Decrease of salt rejection because of concentration polarization
- Higher energy demand
  - — Increased p_{membrane} to overcome
  - — Increased concentration polarization
- Higher pretreatment and cleaning demand
  - — Chemicals (biocides, cleaners)
  - — Labor- Shutdown time
  - — Eventual treatment of effluent to meet legal regulations
- Higher replacement costs
  - — Damage by cleaning
  - — Damage by microbial attack
- Frustration and demotivation of the operating personnel

Figure 1 shows a scanning electron micrograph of the surface of an irreversibly biofouled RO membrane (39) with a biofilm that has survived many cleaning cycles.

Reverse osmosis (RO) membranes are theoretically impermeable for microorganisms as these membranes act as diffusion membranes and do not contain pores at all. However, microorganisms have been found at the permeate side of RO membranes (65). Figure 2 shows an example.

Even today, there has been no explanation for their occurrence at this site, although it has been observed in various cases. Permeate-side bound biofilm cells may seed the permeate, which will partially attach to the surfaces and form biofilms. Traces of nutrients will support their growth and, thus, further the contamination of the purified water. Indeed, this is also of great importance in the pharmaceutical industry. A detailed assessment of the costs of biofouling has been carried out for the reverse osmosis (RO) plant at Water Factory 21 in Orange County, California (64). The "bottom line" is US $730,000 spent each year to control membrane biofouling. This represents about 30% of the total operating costs for Water Factory 21.

Figure 2. Permeate side of a reverse osmosis membrane; bacteria are attached and can contaminate the permeate (Courtesy of H. F. Ridgway, in B. S. Parekh, ed., *Reverse Osmosis Technology*, Marcel Dekker, New York, Basel, 1988, pp. 429–481).

The costs of biofouling are increased by some common mistakes, which originate from the fact that biofouling is not understood as a biofilm process. Inadequate methods of detection and monitoring of countermeasures lead to delayed recognition and to suboptimal or ineffective biofouling control.

Investigations about the beginning of the fouling processes revealed that the microorganisms settle on the membrane during the first hours of operation (66). This means that every operating plant possesses a biofilm from its beginning. Only the extent of biofilm growth will decide whether biofouling occurs: only if a certain threshold of interference is exceeded does biofouling take place; thus, it is an operationally defined expression.

Biofouling on Heat Exchangers

The efficiency of a heat exchanger can be seriously decreased by biofilms (4,67). Forming a gel layer, they "insulate" the heat exchanger surface from the liquid phase. Although the heat-transfer resistance of biofilms is similar to that of water, the gel allows only diffusive heat transport. Thus, heat transfer by convective transport is inhibited. In addition, friction resistance is increased, which increases energy consumption; this aspect is

considered to be an even more costly problem in heat exchange (15). Similar to membrane systems, heat exchangers in aqueous systems operating in a temperature range between 5 and 60 °C will always carry biofilms, which remain unnoticed because their effects stay below the threshold level of interference. However, sudden biofouling problems do not arise from microorganisms that have suddenly invaded the system but are much more likely to be caused by an increase of nutrient concentration or an absence of inhibiting factors. The additives can represent such factors. As an example, chromate has been replaced by other corrosion inhibitors because of its environmentally undesirable properties. A new organic inhibitor that had excellent properties, including full biological degradability, was introduced. The system protected by this substance failed after three months. Biodegradation had started during operation and turned the exchanger into an activated biofilm sludge reactor (Fig. 3). Thus, an environmentally reasonable step has to be harmonized with all other effects in the system.

If light has access, substantial algal growth can occur. This is frequently the case in cooling towers.

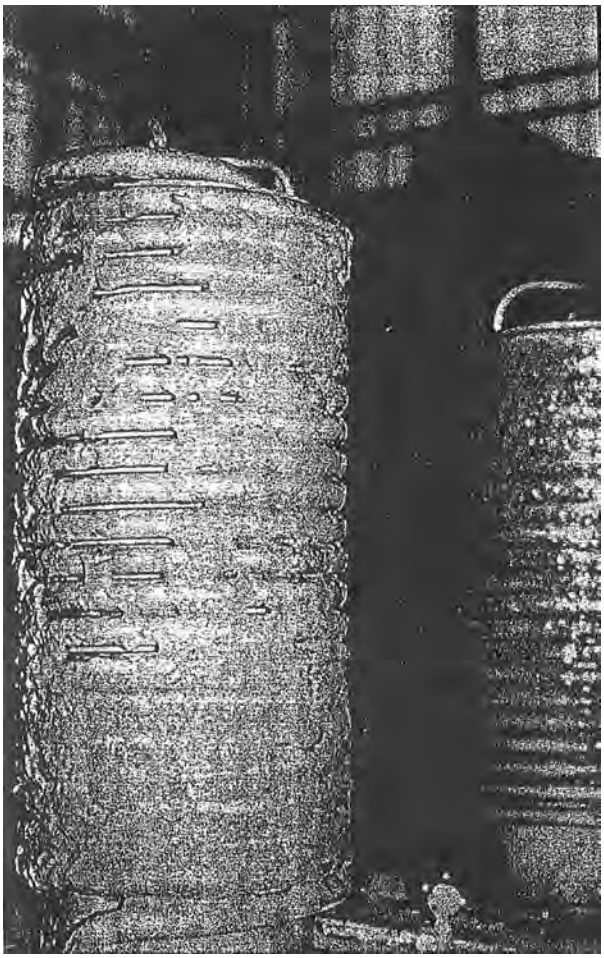

Figure 3. Heat exchanger in a cooling water cycle that was "protected" by a biologically degradable corrosion inhibitor after six weeks of operation.

The installations can be overgrown so heavily that they physically break down (4). In ocean thermal energy conversion (OTEC), biofouling is addressed as the most difficult problem, seriously limiting the use of an otherwise promising technology (68).

Biofouling in Oil Industry

The production, transport, storage, and processing of oil is stricken by severe biofouling problems (69,70). Sulfate-reducing bacteria (SRB) are of particular importance because they are responsible for souring of oil and for microbially influenced corrosion (MIC). A water content of only one percent is sufficient to support substantial development of SRB within only a few weeks (71). Microbial growth at the production sites can cause clogging, especially if water is used as replacement agent (70).

Biofouling on Ship Hulls

A classical case of surfaces prone to biofouling are ship hulls. As indicated earlier, the speed of ships can be significantly reduced even by thin biofilms. Before higher organisms such as mussels or others, a microbial biofilm develops (72). D.C. White (Inst. Appl. Microbiol., Univ. of Knoxville, Personal Communication) has assessed that the United States Navy has to spend more than US$ 500 million in additional fuel that is required to overcome the additional friction resistance caused by biofilms: a biofilm of only 100 μm thickness leads to a 10% increase in friction resistance (4). The attempts for effective antifouling coatings go back to the medieval ages when copper plating was introduced, without long-term effect. After a certain time, some organisms can tolerate the toxicity of copper, colonize it, complex the ions, and shield other organisms for which copper would be toxic. Later colonizing species do not encounter the copper surface but encounter the primary biofilm. The problem has been transiently solved by modern antifouling paints containing tributyl tin compounds. Unfortunately, they are so toxic and recalcitrant to biological degradation (73) that many countries have resorted to a partial ban. Thus, the problem remains unresolved.

Biofouling and Microbially Influenced Corrosion

In biofouling, the biofilm colonizes a given surface and creates problems by contamination of the adjacent medium or by impeding the function of the surface. However, it can also influence corrosion, as corrosion is an interfacial process, which is dependent on the physicochemical conditions at the interface such as pH value, redox potential, oxygen concentration, conductivity, and others. All of these factors are influenced by biofilms. The effect is called *microbially influenced corrosion* (MIC) and is basically a biofilm problem. Thus, biofouling and MIC are closely related (19).

COUNTERMEASURES

As biofouling often occurs far from the focus of attention, namely a product, a common practice is to ignore the

problem as long as possible. The next phase is to look for causes other than microorganisms and to test countermeasures. If none of the common causes proves to be valid and none of the countermeasures is effective, it is concluded that this must be a microbial problem. Certainly, this conclusion is true in many cases. Thus, an expert in the field of microbial deterioration is consulted. Unfortunately, this person encounters the consequences of all former attempts, and symptoms that would help identify the microbial origin of the problem are obscured by provisional repair actions. This can be a serious obstacle for the design and application of an effective counterstrategy. A checklist that links the symptoms to eventual microbially influenced corrosion (MIC) has been produced for this purpose.

If a problem is suspected to be of microbial origin, a three-step program has to be developed according to the following questions:

1. How can biofilms and biofilm-related damage be identified?
2. How can the system be sanitized?
3. What can be done to prevent future problems?

Detection of Biofilms

The presence of biofilms in a technical system is usually detected only indirectly. Operational parameters represent only the symptoms. In heat exchangers, heat transfer decreases while drag resistance increases. In membrane technology, both membrane resistance and drag resistance increase. In practice, identification of biofouling generally follows this pattern: a problem in plant performance occurs; all common countermeasures are applied; if they do not work, and there is no better explanation, the problem is attributed to biology, and in most cases, this is correct.

The Problem of Sampling

As soon as biofouling is suspected, water samples are taken and investigated microbiologically. Different methods are applied and they give different results. Cultivation methods detect only those organisms that are capable of multiplying on the supplied growth media. According to the cultivation temperature and time, the numbers of colony-forming units can vary by some orders of magnitude. The majority of bacteria occurring in natural and technical waters do not grow on common microbiological media (74). Microscopical methods give the number of all cells present in a sample but usually cannot discriminate between viable and nonviable cells.

A more fundamental problem in attempting to detect biofouling by sampling of the water phase is that there is no correlation between numbers of suspended cells detected by water sampling and the location or extent of biofilms. Although biofilms contaminate the water phase, they do so discontinuously. Cells can be eroded or leave the biofilm actively (37), and parts of the biofilm can slough off, leading to episodes of high cell numbers in the bulk liquid phase.

Even with low numbers in the water phase, considerable biofilm growth can occur, as has been shown with microbially contaminated ion exchangers: while 5 to 8 cFu mL^{-1} were found in the process water, sampling of the exchanger bed revealed cell numbers as high as 10^4 cFu mL^{-1} (75). The concentration of cells released from biofilms is usually diluted in the water body. However, in situations of stagnation, these cells can become concentrated — a frequently observed phenomenon. It does not arise because cells grow better under stagnant conditions. On the contrary, cells grow better under agitated conditions (all other conditions being favorable); this is the reason fermenters are vigorously mixed. The comparison of two ion exchanger columns, one left standing idle and the other operated with circulating water, revealed an identical extent of microbial growth (76). Similar observations were reported by other authors, who showed that the number of sulfate-reducing bacteria in the water phase was completely unrelated to the number of biofilm cells (71).

Thus, proper sampling of biofilms must be carried out on the surfaces in question or on representative surfaces and by adequate methods (77). These include either the removal of biofilms, or of biofilm-carrying surfaces, or new optical and spectroscopic methods. Special candidates for the occurrence of biofilms are crevices, holes, curves, and other areas protected from high shear stress.

Analysis of Biofilms

Biofilms in engineered systems have usually reached the plateau phase and are in most cases visible to the naked eye. Thus, optical inspection gives a first hint. In technical environments, biofilms tend to display a slimy consistency, which can be detected by wiping; thin layers can be made visible if a white tissue is used for wiping. In case of doubt about the biological origin of a deposit or layer, it is useful to take a small amount of the material and put it over a lighter until it smolders. A smell of burnt protein is characteristic of biological material. Presently, a test kit with simple dye reactions is under development to deliver reliable information about the presence or absence of biofilms and to semi-quantify them. The ultimate detection of biofilms is carried out in the laboratory. In Table 1,

Table 1. Examples of Biofilm Parameters

Parameter	Detection Method
Water content	24 hours, 110 °C
Organic carbon	TOC, COD, incineration loss
Protein	78
Carbohydrates	79
DNA	80
Lipids	81
Muramic acid	81
Polyhydroxybutyrate	81
Total cell number	82
Colony-forming units	Various standard methods
ATP	83
Hydrolase activity	84
Respiratory activity	85
Indolacetic acetic acid production	86
Catalase activity	87

some parameters suitable for the detection of biofilms are summarized.

For screening, the contents of water and organic carbon are indicative; if these are high, there is a high probability that the material is a biofilm. The presence of ATP or respiratory activity indicates living organisms. It is wise to use more than one parameter for the characterization of a biofilm. If the occurrence of a problem can be related to the actual presence of biofilms, the diagnosis "biofouling" is justified.

Sanitation

The most common practice to eliminate unwanted biofilms is the application of biocides. They are used to "disinfect" a system. This strategy is historically rooted in medicine: the germs that cause the disease are to be killed. Then, the immune system will dispose them. However, killing the organisms in an engineered system will not solve the problem because dead biomass remains. Unlike a living organism, an engineered system has no mechanism to discard dead microbes. This leads to an accumulation of readily biodegradable material and gives rise to rapid microbial regrowth. In addition, engineered systems generally cannot be run under sterile conditions (except for pharmaceutical or electronics water supply systems that are kept aseptic with great effort). Reinfection of the "disinfected" system is already assured by the water that is used to rinse the biocide. New cells encounter dead biomass that is readily biodegradable and will support rapid microbial regrowth. Thus, removal of biomass may be more important than killing. Rational cleaning measures include a step in which the physical stability of the biofilm matrix is weakened and a subsequent step in which it is removed from the system. The use of biocides can be justified in the framework of a combined strategy to minimize the biofouling potential. However, the considerations as discussed earlier must be kept in mind, particularly because "disinfection" and "cleaning" tend to be mixed up.

The variety of biocides has grown to such an extent (88–91) that it justifies the need for "biocide museums" (92) to avoid the reinvention of forgotten biocides and to collect experience and data. In the United States, Canada, England, and Australia, chlorine and chlorine-containing compounds make up most of the spectrum of biocides in industrial applications (4). Peracetic acid, the peroxide of acetic acid, has been widely applied in the former eastern block; its excellent disinfection properties were summarized by Flemming (93). Peracetic acid is an example of a disinfectant that was discovered twice, namely, in 1905 and 1947. The selection of a biocide suitable for a given system requires experience and should be supported by preceding laboratory screening. Natural product antifoulants seem to represent an interesting alternative (94). Some general criteria for the selection of biocides are summarized in Table 2. It is noticeable that they are contradictory. Economic advantages may cause increasing environmental damage or result in insufficient efficacy. Thus, a biocide that meets all of the criteria listed hereunder is not expected. It is impossible to discuss the vast range of biocides presently on the market.

Table 2. Requirements for an Ideal Biocide

Efficacy against the organisms in the system if they occur in biofilms
Compatibility with other conditioning chemicals
Satisfactory time, concentration, and temperature of action
Lack of corrosive effects on the system
Safety and health aspects concerning handling and storage
Stability
Biodegradability
Minimal effect in effluent water
Analytical detection
Low cost

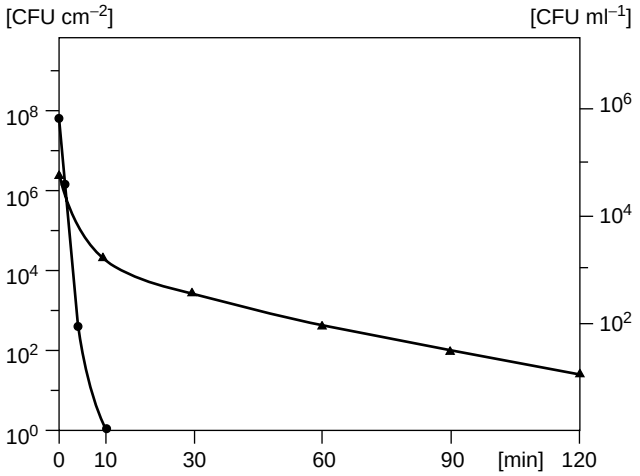

Figure 4. Survival of *P. fluorescens* in suspension (•) and in a biofilm (π) (after M. C. Mittelman, in H.-C. Flemming and G. G. Geesey, eds., *Biofouling and Biocorrosion in Industrial Water Systems*, Springer, Heidelberg, Germany, 1991, pp. 113–134).

The efficacy of biocides against biofilm organisms is known to be reduced compared with where the same organisms are suspended in the water phase (95,96). This is demonstrated by the different resistance of *P. fluorescens* shown in Figure 4 (97).

Organisms in biofilms are well known for increased tolerance toward biocides (95). Keevil and coworkers (96) reported that coliform organisms in a biofilm survived prolonged exposure to 12-ppm free chlorine. Living biofilms have been found on the inner walls of disinfectant pipes (98). In many cases, not all organisms in a biofilm are killed. They recover and metabolize the dead biomass. This leads to a rapid regrowth after a disinfection measure. Unfortunately, most data on biocides relate to suspensions of test organisms. Although this evaluation of biocide efficacy is reproducible, it does not reflect the effectiveness against biofilms. It is very difficult to obtain biofilms that can be used as reference systems with sufficient similarity to "natural" biofilms. Kinniment and Wimpenny (99) developed the "Cardiff constant depth biofilm fermenter" using *Pseudomonas aeruginosa* as the test organism and keeping the biofilm thickness constant by accurate abrasion with a razor blade. They could demonstrate that 200-ppm formaldehyde killed all planktonic cells while the

viable cell number in the biofilm was only reduced from 10^8 cells per square centimeter to 10^6 cells per square centimeter. Griebe and coworkers (100) successfully used an annular biofilm reactor to compare the efficacy of different biocides against biofilms. It was shown that chloramine was much more effective against biofilms than chlorine. However, in no case was biomass removed from the surfaces. Keevil and coworkers (96) suspected that the high nitrite levels in London tap water were caused by incomplete nitrification of monochloramine in biofilms, where ammonia oxidizers metabolized the amino groups only to nitrite.

The use of chlorine will be increasingly limited for reasons of sewage water pollution and tighter environmental regulations. Thus, ozone offers some advantages. Toxic by-products are formed to a much lesser extent and the method has been shown to be effective against biofilms (101,102). Ozone weakens the biofilm matrix and, thus, facilitates the removal of biomass by shear forces (103). A drawback is that the costs for ozone generation are about four times as high as that for chlorine treatment.

A potential problem in the application of oxidizing biocides is their effect on the bioavailability of recalcitrant organic matter. Refractory organic substances, for example, humic substances, have been shown to become biodegradable by chlorine and ozone treatment (3). The raw water was treated with 2.5 mg L^{-1} ozone for 15 minutes. Then, the water was filtered using granular activated carbon (GAC), and a concentration of 2.0 mg L^{-1} of free chlorine was maintained. The assimilable organic carbon (AOC) increased significantly after the application of ozone.

The essence of these considerations is that concentration, time of action, temperature, and interaction with dissolved substances and with biofilms must be increased if biocides are applied against biofilms.

Cleaning: Removal of Biofilms from Surfaces

For cleaning, the mechanical properties of biofilms are of fundamental importance. Although the biofilm matrix is kept together by weak physicochemical interactions (104), it is very difficult to remove it only by shear forces. Hydrogen bonds, electrostatic interactions, and dispersion forces add to an overall binding force between the EPS molecules, which is equivalent to several covalent chemical bonds per biopolymer. Oxidizing or dispersing chemicals are useful for the first step, while flushing, brushing, or similar physical techniques are useful for the second step. Of particular importance is an efficiency control in order to optimize the process.

Prevention of further microbial problems usually cannot be achieved by single measures but by a combined strategy, which can be called "good housekeeping." A very important element of this strategy will be the elimination of biodegradable material, as this represents potential biomass.

If an oxidizing biocide is used, it will weaken the biofilm matrix as a side effect. This is the case for chlorine, which is consumed by reaction with extracellular polysaccharides and proteins. As a result, the biofilm can be removed more easily from a surface. In this case, it is irrelevant whether the cells are dead — the "side effect" of decreasing matrix stability is much more important. Some biocides, however, can have the opposite effect. An example is formaldehyde that is used in microscopy as a preserving reagent because it cross-links proteins. In such a case, "disinfection" can make the problem worse, as has been reported many times in practice (105).

If a system is to be cleaned, the mechanical resistance of the slimy biofilm layer must be overcome. Although biofilms usually can be wiped off easily, they are surprisingly resistant to the shear forces of running water. This is the reason for the observation of biofilms in water pipelines with very high water velocity (4). They become thinner but more stable. Interestingly, an increase in performance after the application of cleaning substances does not necessarily have to be due to the removal of a biofilm. As an example: reverse osmosis membranes were cleaned with a commercial cleaning formulation (Ultrasil U 53, Henkel, Germany). Permeation performance increased, but biomass quantity on the membrane surface remained almost the same. The cleaning agent simply increased the permeability of the fouling layer (106), thus mitigating the original hydrodynamic resistance of the biofilm.

Time plays an important role in the mechanical resistance of a biofilm. "Young" biofilms are much easier to remove than "old" biofilms. Table 3 shows the rinsing efficacy of surface-active substances such as sodium dodecyl sulfate (SDS) and Tween 20. Cells were allowed to attach to a polyethersulfone membrane for either four hours or three days.

Subsequently, membrane samples were agitated for one hour with the surface-active agent. The number of cells per surface area was determined after this procedure. The results demonstrate that early action against an unwanted biofilm is more effective.

For an effective cleaning, the bond between the biofilm and the underlying surface must be broken. Although biofilms can develop on practically any surface, the binding force varies. A reasonable approach to better cleanability is the choice of materials or coatings with low adhesion force to biofilms (107). Low surface energy materials tend to display low adhesion forces to biofilms; this is exploited in Teflon coatings on ship hulls.

Another choice for cleaning of surfaces is ultrasound. It has been applied successfully in cleaning of medical devices, dental equipment, heat exchangers, and other surfaces. A critical appraisal of published material reveals that in almost all cases there is no specification of the ultrasound intensity to which the object is exposed. However, ultrasonic methods seem to be an attractive

Table 3. Influence of Biofilm Age on the Detachment of Cells, Expressed as Percentage of Detached Cells Compared to the Control (76)

Age of Biofilm	Control	1% Tween 20	1% SDS
4 hours	0	93	98
3 days	0	42	57

Table 4. Critical Ultrasonic Parameters for the Detachment of *Pseudomonas diminuta* from a Polyether Sulfone Membrane (95% Detachment of Cells)(108)

Variable	Value	Boundary Conditions
Intensity uptake (I)	4W	$t = 300$ s, $D = 2$ cm
Transducer distance (D)	4 cm	$t = 300$ s, $I = 4$ W
Exposure time (t)	60 s	$D = 3$ cm, $I = 4$ W

alternative to chemical cleaning. Thus, an ultrasonic bath was used to remove biofilms from separation membrane material. The sonification field was mapped with a hydrophone; this technique allowed an assessment of the energy, which arrived at the object. The critical values are summarized in Table 4 (108).

The application of ultrasonic energy seems to be feasible for the cleaning of surfaces from unwanted biofilms. However, it has to be considered that ultrasound may damage the surface on which the biofilm is growing. This was the case with membrane materials. In other cases, ultrasound may still offer a suitable method.

Cleaning Strategy

It seems wise not to rely on a single substance or method when cleaning a surface. Killing the cells, as effectively as this may be performed, and leaving them at the place will not solve the problem. Removal of biomass seems to be much more important. An effective strategy must be defined according to the system to be cleaned. If possible, facilitated cleaning should be integrated in the design of a system. In general, a cleaning strategy will include the following two steps:

1. Weakening of the biofilm matrix, mostly by chemicals such as oxidants such as chlorine, ozone, hydrogen peroxide, peracetic acid, or others; by alkaline treatment, tensides, enzymes (109), complexing substances (110), or by biodispersants (111). The latter are based on polyethyleneglycol and are supposed to weaken the interactions in the EPS matrix as well as the interaction between biofilm and support material. A combination of various agents may increase the efficacy. However, it is important to establish a system to quantify the success.
2. Removal of the biofilm by mechanical forces such as rinsing with water, air, steam, or a combination thereof; application of sponge balls, brushing, or ultrasound. Some methods are listed in Table 5.

The experience of the authors in the application of enzymes was not encouraging. This may be due to the specificity of enzymes, which are directed against certain bonds that may not be present in all matrix-forming molecules. Thus, microbial strains that form EPS against which the enzymes are not effective gain a selection advantage. Mechanical cleaning can also select those species, which form the most resistant EPS matrix, as has been reported in biofouling problems with the technique to recover ocean thermal energy (112).

Table 5. Physical Methods for the Removal of Biofilms

Method	Remarks
Rinsing	Simplest method; limited efficacy; thin biofilms are not affected; very effective if biofilm stability is first decreased, for example, by biodispersants
Backwashing	Similar to rinsing
Sponge balls, abrasive	Reasonable efficacy; may damage supporting material
Sponge balls, nonabrasive	Less effective than abrasive sponge balls; not suitable for biofilms, which display greasing effects
Sandblasting	Very effective, but difficult to focus the abrasive effect on the biofilm and not on the supporting material
Brushing	Very effective but limited to accessible surfaces; can shift biofilm population to species, which form extremely stable EPS
Hot water, steam	Especially suitable for purified water systems; efficacy against thick biofilms not yet evaluated; energy intensive
Ultrasonic energy	Good efficacy; restricted to surfaces accessible to ultrasonic energy; may damage underlying material
Ice crystallization	Application of ethyleneglycol (-12 C), destabilizes biofilm matrix (Costerton, 1983). No practical experience reported
UV irradiation	Poor efficacy against biofilms; abiotic particles may protect microorganisms; does not remove biofilm material

Control of Efficacy

In practice, the efficacy of a cleaning measure is assessed by the recovery of process parameters. However, this is an indirect method and not very well-suited to assess the success. As an example, the biofouling layer on a reverse osmosis membrane was removed by about 80% by chemical treatment. This led to a substantial improvement of the process parameters. However, the remaining 20% of the layer offered optimum conditions for the regrowth of the biofilm bacteria. Thus, after a very short time, the old situation was reestablished, which led to the well-known "saw-toothed curve" (39).

As biofouling is a biofilm problem, which in turn is related to surfaces, the latter have to be sampled for a proper effectiveness control. This can be generally achieved in several ways:

1. Integration of test surfaces, which are analyzed before and after the cleaning procedure, or,
2. Establishment of on-line, sensitive monitoring devices such as the continuous measurement of drag resistance, heat-transfer resistance, hydrodynamic resistance, weight of deposit, light transmittance, or reflectance.

Efficacy control allows the optimization of countermeasures against biofouling. Quite ineffective but widely practiced is the measurement of cell numbers in the water phase; these are relatively easy to measure but lead only to numerous data, which can never be interpreted.

PREVENTION OF BIOFOULING

Disinfection still remains the most common "prevention" practice. After considering the points discussed earlier, it is not surprising that disinfection tend to display transient effects. The disinfectant is usually rinsed out with nonsterile water, which leads to reinfection of the system. This explains why disinfection should not be expected to offer a suitable choice in prevention of biofouling.

As biofouling is a biofilm problem, prevention of primary adhesion seems to be the most reasonable strategy. The first steps in microbial adhesion are dominated by physicochemical forces rather than by physiological activity of microorganisms (114). Among the abiotic parameters, surface energy is considered to be of particular importance (115). Surfaces used in water technology will display different surface energies. When in contact with water, a conditioning film arises, formed by traces of macromolecules present in water. Among these are proteins, polysaccharides, humic substances, and others. Although they do not provide specific binding groups, many parts of a macromolecule can interact by weak forces such as van der Waals and electrostatic interactions and hydrogen bonds. However, the molecules possess many binding sites and will bind to a given surface. Thus, they will adhere irreversibly and result in a slightly negative overall surface charge (116). The conditioning film is not a prerequisite for microbial adhesion but only a result of the fact that macromolecules reach the surface faster than microorganisms. In some cases, the conditioning film may decrease the adhesion rate (117). Hydrophobic surfaces will become more hydrophilic, leading to a surface tension in the range of 30 to 40 $mJ\,m^{-2}$ (115). Slowest microbial adhesion is reported between 23 and 27 $mJ\,m^{-2}$; below these values, the adhesion rate is higher (118). Thus, efforts to use surfaces with very low surface energy will not succeed in preventing microbial adhesion. An example is given by leaves in autumn. The wax layer provides a high hydrophobicity, which allows the leaves to float on water. After a while, specifically hydrophobic microorganisms such as *Rhodococcus* sp. will colonize leaf surfaces, resulting in a hydrophilic biofilm, which causes the leaves to sink.

Primary adhesion occurs very rapidly, within the first hours of contact between water and surface. It is not necessary that the microorganisms are viable; it has been shown that adhesion to polysulfone membranes was equally rapid both with living and dead cells of *P. diminuta* ["passive adhesion," Flemming and Schaule (119)]. In other cases, cells excrete EPS in response to surface contact ["active adhesion" (114)]. In a biocoenosis of water, there will be various species present, some of them adhering even when dead and others developing contact-specific adhering substances.

Roughness of the surface will support colonization. However, smoothing of a surface will not completely prevent microbial adhesion. Electropolishing of metal heat exchanger surfaces only slightly prolonged the induction phase of biofilm development (4); EPS provide a "glue" that can stick to the smoothest surfaces. A certain success has been reported with anionic block copolymers (114,120). An interesting approach is coating with biocidal compounds (121). However, the coating can be dissolved or covered with dead microorganisms, which could nullify the effect. Practical applications of these approaches have not been reported. A similar case may be the use of plaque inhibitors, namely, substances that prevent microbial adhesion to teeth. Among these are quaternary ammonium compounds, biguanidines such as chlorhexidine, uncharged phenolic compounds ("Listerine"), enzymes, peroxides, and surface-active substances (122). All of these substances are candidates for the extension of the induction phase of colonization in closed systems.

Open systems such as ships in seawater are protected by antifouling paints. Success is always transient (123), implying that frequent cleaning is necessary. Tributyltin compounds are the only really effective substances known. However, they are perhaps too successful, as they belong to the most toxic materials (73) and are going to be banned worldwide because of their negative impact on the biosphere. Copper is widely believed to be bactericidal and copper plating belongs to the first antifouling measurements in naval history. However, colonization of copper surfaces is a well-known phenomenon (98,105) and once covered with a primary biofilm, even copper-sensitive organisms can survive in a biofilm on a copper surface. Copper still plays an important role in marine antifouling as an additive to Teflon coatings. Biofilm growth is not prevented but slowed down, and cleaning is easy.

Another so-called biocidal element is silver, to which an "oligodynamic effect" is attributed. In fact, most microorganisms are killed by very low concentrations of silver ions ($<10\ \mu g\,L^{-1}$), and silver is not known to be toxic to humans. Unfortunately, microorganisms develop a tolerance within a few weeks, allowing them to multiply in the presence of more than 1 $mg\,L^{-1}$ of Ag^{+} (76).

Highlighted by these observations, inhibition of primary adhesion is not a very promising strategy to prevent biofouling. Microorganisms are ubiquitous, and among these, there will always be some that can colonize in spite of the inhibitor. If UV light is used, the prospects are not much better. Only on surfaces that are directly irradiated, biofilm growth can possibly be prevented. As soon as abiotic particles adhere, microorganisms can be protected and can grow (Huber and Flemming, unpublished obs.). Additionally, UV light may oxidize humic acids and make

them more bioavailable, therefore creating more problems than what it solves.

The most common technical measure to prevent biofouling is the permanent dosage of biocides. This is usually performed with chlorine. Bott (102) showed that a concentration of at least 0.2 ppm had to be maintained in a technical system. Below this concentration, rapid biofilm growth was observed. In many cases, permanent dosage of biocides is undesirable for environmental reasons. Biocides and their toxic by-products contaminate the sewage water and require special attention in terms of storage and handling.

Living with Biofilms

Prevention of biofouling can only be achieved by a combined strategy. It must be based on a "clean system philosophy" that includes all surfaces in contact with water. It includes the minimization of biodegradable organic substances, good access of surfaces that must be kept clean, surfaces that are easy to clean, and no or very few crevices, fittings, edges, or other niches predestined for biofilm growth. Ultrapure water technology provides many experiences and solutions for less pure water systems. The elements of good housekeeping can be summarized as follows:

- Minimized nutrient concentration
- Monitoring of biofilm development on representative surfaces
- Strong shear forces
- Frequent cleaning (if possible, mechanical)
- Easy-cleaning design
- Effectiveness control and optimization of cleaning measures

The importance of effective monitoring systems must be pointed out clearly. Such systems allow for early intervention in a biofouling process and optimization of countermeasures.

All approaches to prevent biofouling as discussed earlier are based on killing and cleaning. A completely different strategy can be developed from some basic considerations. Almost all surfaces in contact with water carry biofilms, but not all water systems suffer from biofouling. It has been shown that biofilms are involved in the separation process on reverse osmosis membranes right from the beginning: after a few hours of operation, a biofilm develops and participates in separation (64). Biofouling occurs only when biofilm development exceeds a certain "threshold of interference." This is the case when performance parameters remain below certain limits (Fig. 5).

In technical systems, biofilms usually reach the plateau phase relatively rapidly. What happens is a natural phenomenon: microorganisms settle on surfaces and convert diluted nutrients into metabolic products and locally immobilized biomass. This is exploited in the design of a biofilm reactor. Biomass accumulates in the reactor, and the effluent water will support microbial growth, including the development of biofilms, to a lesser extent. Separation membranes, filter beds, pipe surfaces, and other technical environments offer large surfaces,

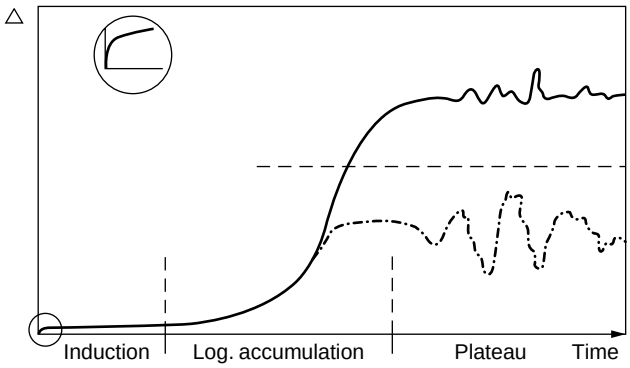

Figure 5. Schematic depiction of biofilm development. Dotted line: biofilm below the threshold of interference.

Table 6. Biofilm, Water, and Performance Parameters as Determined by Experimental Membrane Test Cells Before and After Sand Biofilter (After 125)

	Before Sandfilter	After Sandfilter
Biofilm		
Biofilm thickness	(27.3 ± 3.1) μm	(3.0 ± 0.5) μm
Protein content	77.7 $\mu g\,cm^{-2}$	3.6 $\mu g\,cm^{-2}$
Carbohydrate content	22.5 $\mu g\,cm^{-2}$	2.6 $\mu g\,cm^{-2}$
Uronic acid content	10.6 $\mu g\,cm^{-2}$	2.3 $\mu g\,cm^{-2}$
Water		
BDOC of water	0.325 $mg\,L^{-1}$	0.125 $mg\,L^{-1}$
Microbial content	1×10^7 cfu mL^{-1}	1.2×10^6 cfu mL^{-1}
Performance		
Flux decline	40% in 30 days	<2% in 30 days

encouraging the same phenomenon until the extent of biofilm growth exceeds the level of interference. This is why biofouling can be considered as a "biofilm reactor in the wrong place." The main factors, which govern biofilm growth, and biofouling potential, are the ubiquitous biofilms, the nutrients available, and the shear forces. As the occurrence of biofilms cannot be avoided without extreme efforts (e.g., as performed by the pharmaceutical and microelectronics industries), only nutrients and shear forces remain as variables. Shear forces can be increased quite easily in some systems but not in all. Thus, nutrient concentration represents a candidate for limiting biofilm growth: the lower the nutrient concentration, the less biofilm will form. This effect is well known in biofilters, where most biomass accumulates in the area with the highest nutrient concentration. The biofilm reactor can be "put in the right place" if positioned in front of the system to be protected from biofouling: the biofilm will develop mainly in the reactor. In the subsequent areas, biofilm growth will occur, but below the threshold of interference if the system is run properly. For example, river water was run through a sand bed as a biofilter. Before and after the filter, a reverse osmosis test cell had been installed, one operating with raw water and the other with water after the biofilter. Permeate production was taken as performance parameter (125). A BDOC of 0.125 $mg\,L^{-1}$ was sufficient to stay below the threshold of interference. Such a value can be reached easily with common biofilters.

Biofilm thickness was reduced to 10%. The microbiological data of the water reveal that the biofilter does not cause additional microbial contamination but rather removes cells from the process stream.

The results indicate that an antifouling strategy, which refrains from using chemicals and relies simply on nutrient depletion, can be successfully applied to technical water systems. Obviously, it is not necessary to kill *all* biofilms — it is only necessary to keep their development below the threshold of interference. Thus, it is possible to live with biofilms without biofouling. Of course, this is not feasible in all cases, but if it is applied where it is appropriate, unnecessary usage of biocides can be avoided. It may be pointed out that this approach is only one of a few that are based on the laws of biofilm development. We expect that in the near future more biocide-free strategies will be developed.

Microorganisms are used worldwide for the extraction of valuable metals. The technique established in the last decades, is known as *bioleaching* (1). For this purpose, the world's largest bioreactors have been built. Stirred tank reactors of 900 m^3 have recently been constructed in Ghana (2) (Fig. 1) for treatment of sulfide concentrates containing a considerable amount of precious metals. In Uganda, reactors with a volume of 1,350 m^3 for cobalt leaching went into operation in 1998 (3). The leaching microorganisms dissolve the usually poorly water-soluble, metal-containing minerals due to an attack by biogenic compounds. The dissolution is achieved by complex interactions of biological, chemical (especially electrochemical), and physical processes. Nevertheless, the processes are not yet fully understood nor is their interdependence elucidated. Bioleaching of nonsulfidic minerals, that is, oxides, carbonates, and silicates, occurs by simple acid attack and/or complexation, whereas for dissolution of metal sulfides a combined acid and oxidative attack is needed. The products of these processes are metal cations dissolved in aqueous acidic solutions. The protons originate from biogenic acids. The most important acid is sulfuric acid, whereas relevant organic acids with good metal-complexing properties are oxalic and citric acid. Bacterially produced iron(III) ions are responsible for primary oxidation of the sulfur moiety of sulfides. In addition, intermediary sulfur compounds are oxidized by bacteria. Therefore, metal sulfide leaching bacteria are iron and sulfur compound–oxidizing species. The most important ones belong to the genera *Acidithiobacillus*, *Leptospirillum*, *Metallogenium*, *Acidianus*, and *Sulfolobus*.

Bioleaching occurs as a natural process in almost all climates, as long as water is available and the temperature does not exceed 114 °C, which is the the upper limit for microbial life (4). Bioleaching is applied in technical conditions for metal winning from raw materials that are not processable by conventional (usually pyrometallurgical) techniques. In most cases, low-grade ores are concerned, but increasingly even complex concentrates are treated by bioleaching techniques, such

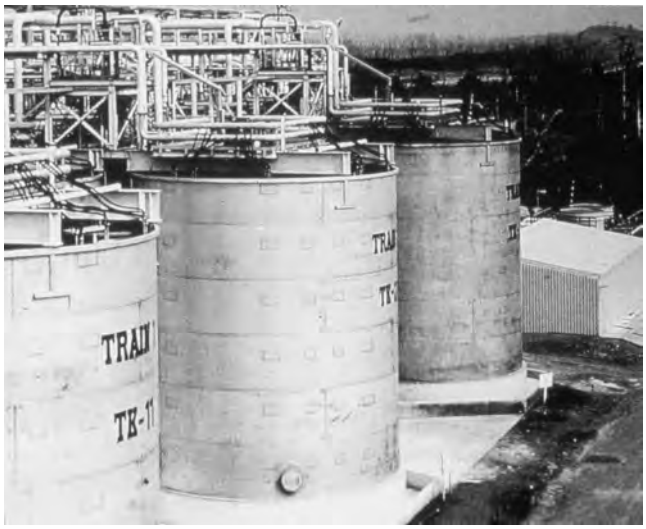

Figure 1. Stirred biooxidation tanks of the Ashanti's gold recovery plant in Obuasi, Ghana, for the bioleaching of refractory ores before cyanidation.

Figure 2. Dump bioleaching of copper ore in Peru. The dump is irrigated by sprinklers with acidified water.

as heap and dump leaching (Fig. 2) or tank leaching. However, anticipated bioleaching operations need to be empirically tested in the lab before realization, thereby requiring expensive scale-up. Especially the mineral itself, because of the occurrence of minor elements, plays an unpredictable role and causes many uncertainties in the design of the process and plant. It is well known, for example, that in heap leaching operations treating chalcopyrite ore, rarely more than 15% of the copper will be dissolved within a "reasonable" time of one to two years (5). The remaining part has to be deposited on waste dumps. However, the bioleaching process continues slowly and tends to pollute the environment with acidic solutions containing heavy metal ions. Similar uncontrolled bioleaching is encountered in abandoned mines, shafts, mine waste dumps, and so on and is known as "acid mine/rock drainage" (AMD/ARD). It is obviously caused by human activities in most cases but some natural bioleaching sites exist, too. In the past, spontaneous leaching has been used as an indicator of ore bodies because the colored waters attracted attention.

MINERALS

Technical applications of leaching processes for the extraction of valuable metals from natural raw materials must consider the quantitative description of the dissolution process. Physicochemical properties of the minerals subjected to dissolution and of the reaction products and reaction kinetics are of great importance for the economy of a process. Because pure minerals are not available in large quantities, an appropriate process design for technical applications has to consider the presence of invaluable constituents. More and more low-grade ores must be processed as high-grade ores are used up. Hence, because of impurities and/or gangue material, huge quantities of ore are mined, which consequently need large amounts of reagents for the extractive processes with all the inherent technical, economical, and environmental consequences.

Classical mineralogy is a descriptive science, which succeeded to identify and classify numerous minerals. Relationships between genesis, chemical composition, structures, and properties have been thoroughly described (6). Oxides and silicates are the most frequently encountered minerals but only few of them bear valuable metals that can or need to be extracted by (bio)leaching techniques. However, metal sulfides are a very important class of compounds because some of the base metals occur mainly in sulfidic ore deposits. Therefore, examples will focus on this class of minerals. The possible number of minerals having different compositions and properties is enormous because of traits classified as:

- *Polymorphism* (the same composition but a different crystallization system: pyrite-marcasite/FeS_2, sphalerite-wurtzite/ZnS),
- *Polytypism* (the same composition and the same crystallization system but different periodicity of crystal layers of the same arrangement: wurtzite-2H, -4H, -6H, -8H, -10H, -3R, -15R, and so on),
- *Isomorphism* (reciprocally unlimited exchangeable elements: sphalerite-hawleyite/ZnS-CdS, guadalcazarite Hg, Zn/S, Se; villamaninite Cu, Ni, Co, Fe/S_2, Se_2, irarsite Ir, Ru, Rh, Pt/AsS), and
- *Diadochism* (limited, nonreciprocal replacement of an element by another: up to 20% of zinc atoms replaceable by iron in sphalerite, but iron in pyrrhotite not replaceable by zinc atoms).

Additionally, chemical analysis revealed the existence of apparently nonstoichiometric compounds, that is, when calculating the chemical formula; the stoichiometry does not fit with simple valence states of the elements involved. Besides minerals, where the involved elements have quite well-defined valence states, such as FeS, FeS_2, ZnS, CuS, Cu_2S, $CuFeS_2$, and so on, minerals are known in which one element exists in several different valence states, for example, Cu_9S_5 or $Ag_3Fe_7S_{11}$. Moreover, different minerals may crystallize jointly to form intergrown crystals. Hence, obviously mineralogically approximately similar minerals present in ores from different sites may show differences in their physicochemical properties and a different behavior in technical processes such as flotation (7). Some minerals were also (re)produced experimentally (synthetically, in pure or deliberately impure state), showing that major differences in specific physicochemical properties may result from only minor compositional differences (8). Semiconducting properties (*n*- or *p*-conductivity) depend on the nature of minor amounts of impurities included in the crystal lattice, for example, *n*-pyrite contains Co and Ni ions, *p*-pyrite contains As-ions. These pyrite types show different behavior in the leaching process. Leaching of *n*-pyrite starts rapidly but slows down after a certain degree of dissolution is reached. On the contrary, leaching of *p*-pyrite starts slowly, but subsequently continues at an enhanced rate (9). Even in homeotypic minerals (different composition but the same crystallization system: pyrite-hauerite/FeS_2-MnS_2, molybdenite-tungstenite/MoS_2-WS_2, sphalerite-chalcopyrite/ZnS-$CuFeS_2$) electronic structures

are not identical. Different energy levels of the atomic and molecular orbitals cause different stability, reactivity, and even different reaction mechanisms. Hence, under certain conditions one mineral may dissolve and the other may not, or perhaps they may dissolve but by different pathways (10). Electrochemical properties like electrode potential and polarization also play an important role for the specific leaching behavior of a mineral complex. Intergrown particles of different minerals may form galvanic cells, causing preferential reaction sites at the solid interface (9). In modern materials sciences, sophisticated procedures have been established to obtain special materials with unique, useful properties. From this experience, it became understandable why naturally occurring mineral samples in many cases are also unique. Hence, it should also be clear that each ore deposit, in many cases each mineral vein, must be tested for technologically reliable process data. For practical purposes, a scale-up also must be done.

MICROORGANISMS

The bacterially catalyzed oxidation of metal sulfides (mediated by iron(III) ions) was discovered only half a century ago (11,12). Because of the rod-shaped morphology of the cell and its ability to oxidize both reduced iron and sulfur compounds, this first isolate of a bioleaching bacterium was named *Thiobacillus ferrooxidans*. This systematic name is no longer valid and the species is now called *Acidithiobacillus ferrooxidans* (13). Leaching bacteria have been detected all over the world and representatives are found in both bacterial domains (i.e., the *Archaea* and the *Bacteria*) (14). Bioleaching research and application focus on the metal and sulfur compound–oxidizing bacteria. In the following, the biology of these classic leaching bacteria is described. A short characterization of the only recently investigated metal-complexing chemoorganoheterotrophic microorganisms is also given.

Biology of Metal Sulfide Oxidizing Bacteria

At first sight, the biology of the acidophilic metal and sulfur compound oxidizing bacteria seems to be complicated. The bacteria can use the oxidation of metal sulfides as an energy source and thrive in heavy metal–containing solutions at pH 2 (14). However, the main metabolic pathways do not differ significantly from those found in other bacteria and the most investigated leaching bacterium, *A. ferrooxidans*, is a close relative of the most thoroughly characterized living organism, that is, the γ-proteobacterium and gut inhabitant *Escherichia coli*. Nevertheless, the adaptation to environments, such as natural, sulfur-rich hydrothermal springs and mining sites created by humans, gives the leaching bacteria a combination of several biotechnologically interesting physiological abilities. One of the major characteristics of these bacteria is their ability to oxidize inorganic sulfur compounds to sulfuric acid and/or iron(II) to iron(III) ions. In several bacteria, these abilities are found in combination, for example, *A. ferrooxidans*, *Sulfobacillus acidophilus*, and *Acidianus brierleyi* (14). These species can live chemolithoautotrophically with reduced sulfur or iron compounds and carbon dioxide as the sole electron, energy, and carbon sources, respectively. Furthermore, some strains can grow by oxidizing molecular hydrogen and are able to fix nitrogen from air. In leaching biotopes, these physiologically versatile species are often accompanied by less versatile bacteria. *Acidithiobacillus thiooxidans* (formerly *Thiobacillus thiooxidans*, 13) can only oxidize sulfur compounds, whereas for *Leptospirillum ferrooxidans*, iron(II) ions are the sole electron donors. External organic compounds are, if at all, used only to a minor extent and surprisingly, many organic substances are toxic to these bacteria (14). Therefore they are classified as strictly chemolithoautotrophic organisms. Besides these bacteria, mixotrophic species able to grow on both inorganic and organic substrates have been isolated from leaching biotopes. For instance, *Acidiphilium acidophilum* (formerly *Thiobacillus acidophilus*, 15) oxidizes sulfur and organic compounds such as sugars. *Acidimicrobium ferrooxidans* cannot only live autotrophically on iron(II) ion oxidation but also grow mixotrophically or even chemoorganotrophically, if yeast extract is added to the cultures. The oxidation of sulfur compounds and iron(II) ions is not limited to organisms growing in an aerobic environment but has also been observed in the presence of alternative electron acceptors others than oxygen. Some species of the genus *Acidithiobacillus* and *Acidiphilium* have been found to oxidize elemental sulfur and other sulfur compounds with iron(III) under anaerobic conditions (14). The reduction of nitrate can be coupled to bacterial oxidation of both reduced sulfur compounds and iron(II) ions (16,17), however, these latter processes have so far not been demonstrated in acidophilic leaching bacteria. Generally, for the characterization of the bacterially catalyzed reactions, concerning the sulfur and iron cycles in leaching biotopes, aerobic and anaerobic processes have to be considered. In addition to the anaerobic reactions mentioned earlier, the reduction of sulfate, tetrathionate, thiosulfate, and elemental sulfur may play an important role in anoxic zones. Furthermore, the disproportionation of elemental sulfur and other sulfur compounds is discussed as energy-yielding pathways to support bacterial growth. Bioleaching occurs in arctic regions with temperatures below 0 °C and in hot springs at temperatures around 100 °C. Although, leaching sites with cold and moderate temperatures (up to 40 or 50 °C) are dominated by the mesophilic, eubacterial genera *Acidithiobacillus* and *Leptospirillum*, other leaching bacteria thrive at elevated temperatures. Moderately thermophilic genera are the eubacteria *Sulfobacillus* and *Acidimicrobium* that oxidize metal sulfides at temperatures up to 60 °C. The upper temperature range of bioleaching is exclusively occupied by the extremely thermophilic archaebacterial genera *Sulfolobus*, *Acidianus*, *Metallosphaera*, and *Sulfurococcus* (14). The latter two groups of bacteria are of great interest for the design of new bioleaching plants and, therefore current research is focused on the metal sulfide oxidation potential of these thermophiles (18). If the operating temperature in stirred tank reactors could be permitted to increase to

60 or even 80 °C, cooling costs would be significantly reduced (see Section on Applications). Furthermore, recalcitrant metal sulfides such as chalcopyrite become more readily oxidizable at elevated temperatures. To date, commercial bioleaching processes operate at temperatures below 50 °C (2). The bacterial communities in these reactors are dominated by *Leptospirillum*-like bacteria and *Acidithiobacillus caldus* (formerly *Thiobacillus caldus*, 13) rather than by *A. ferrooxidans* and *A. thiooxidans* (19). For the latter, the conditions in the continuous-flow bioreactors with constantly high redox potentials above 700 mV (SHE), pH around 1.5, and temperatures above 40 °C are not conducive for growth. Defined inocula of pure or mixed bacterial cultures are not applied to industrial bioleaching processes. Mostly, poorly characterized enrichment cultures or endemic bacteria are used. More thoroughly selected or even genetically engineered organisms may have a potential to optimize leaching operations; however, the industrial applicability of these bacteria still remains to be demonstrated. Besides the bacteria described previously, leaching biotopes are inhabited by acidophilic, chemoorganoheterotrophic bacteria and fungi, as well as by protozoa, grazing on bacteria, and by photoautotrophic algae (14,20). The primary (biomass) producers in these generally oligotrophic biotopes are the chemolithoautotrophs because, in most cases, the biomass production of phototrophs is negligible. Interactions between chemolithoautotrophs and chemoorganoheterotrophs may beneficially affect leaching activity. As leaching bacteria usually excrete low molecular weight organic compounds, which inhibit their own growth, the presence of organotrophs can prevent the accumulation of these compounds and enhance leaching performance (14).

Biology of Chemoorganoheterotrophic Leaching Microorganisms

Bacteria, algae, fungi, and consortia such as lichens have the potential to extract metals of interest from nonsulfide ores or metal-containing industrial wastes such as fly ash and slag. A general characteristic of these organisms is the production and excretion of high amounts of organic acids and other metal-complexing compounds, basically because of an imbalance of their metabolism. Mainly organic acids are relevant, such as oxalic, citric, malic, succinic, pyruvic, acetic, glucuronic, and amino acids. Furthermore, they exhibit a rather high heavy metal resistance. These abilities are widespread among chemoorganoheterotrophic species and such diverse genera as *Bacillus*, *Pseudomonas*, *Penicillium*, and *Aspergillus*, are investigated in this context (21,22).

MECHANISMS OF MICROBIOLOGICAL METAL SULFIDE DISSOLUTION

Dissolution of metal sulfides is achieved by acid attack and the oxidation of the sulfur moiety. The first oxidation step is carried out by an electrochemical surface reaction of iron(III) ions with the sulfide species. Subsequently, the released intermediary sulfur compounds are further oxidized by iron(III) ions or oxygen, abiotically or enzymatically, to sulfate and protons. There is a long-standing debate in the literature about the mechanism of bioleaching, whether cells are able to oxidize the sulfur moiety at the metal sulfide surface enzymatically ("direct mechanism") or whether the primary oxidant are iron(III) ions and the role of bacteria is to reoxidize the resulting iron(II) ions and sulfur compounds ("indirect mechanism") (23). The differentiation between direct and indirect bioleaching was developed at a time when only *A. ferrooxidans* and *A. thiooxidans* were known as leaching bacteria. As soon as *L. ferrooxidans* (24) was discovered, a serious contradiction became evident: the cells of this bacterium dissolve metal sulfides exclusively by regeneration of the iron(III) ions; no sulfur compounds can be catabolized by this organism. The direct mechanism is considered disproved because of these and other contradictions (10,23) and, especially, because the required enzyme system has never been demonstrated. The most widely agreed scheme of bioleaching integrates findings from microbiological, chemical, electrochemical, and mineralogical studies. Together with images obtained by light microscopy, and scanning and transmission electron microscopy (SEM, TEM), as well as atomic force microscopy (AFM), a holistic theory on bioleaching of metal sulfides has been developed (10,25,26). Accordingly, observations regarding bacterial attachment, reaction pathways, and kinetics fit together.

Attachment of Bacteria to Mineral Surfaces

Leaching bacteria attach to metal sulfide surfaces (Fig. 3). From biofilm research it is known that attachment occurs via diffusion, convection, and chemotaxis. Although the first two are mostly random processes, chemotaxis is the active orientation of the bacterium in a chemical gradient. The bacterium is able to detect the site of active metal

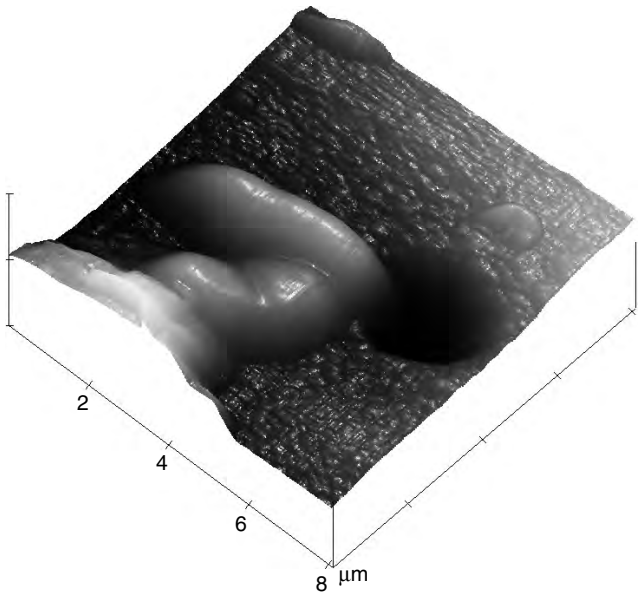

Figure 3. Atomic force microscopic image of a cell of *Acidithiobacillus ferrooxidans* attached to the surface of a pyrite crystal.

sulfide dissolution by sensing the resulting gradients (e.g., dissolved iron(II) ions and sulfate) and actively swimming in the direction of an increased concentration of the attracting ions (27). There, the bacterial cell attaches to the metal sulfide surface by mostly unknown processes. The extracellular polymeric substances (EPS), surrounding the cells play an important role in the attachment of the leaching bacteria. In the cases of *A. ferrooxidans* and *L. ferrooxidans* grown on pyrite, the exopolymers contain, besides neutral sugars and lipids as their major quantitative constituents, some glucuronic acid residues and complexed iron(III) ions (26,28). The stoichiometry of glucuronic acid to iron(III) ions amounts to a molar ratio of 2 : 1 for the strains of *A. ferrooxidans* and *L. ferrooxidans* tested so far (26,28). This indicates that regardless of the phylogenetic class of the leaching bacteria, the physicochemical characteristics of the environment enforced a similar adaptation. According to the stoichiometry, a net positive charge can be attributed to the EPS of the leaching bacteria. At the extremely acidic pH of the leaching environment, pyrite has a net negative charge. Thus, an attachment of a positively charged bacterium to a negatively charged surface may take place because of an electrostatic interaction between the two surfaces. Once the bacterium has attached, additional processes cause an intimate and tight adhesion to the respective mineral surface. These processes have not yet been elucidated. Besides, nothing is known about the specificity of the EPS for various metal sulfides. To date, only data for EPS of pyrite- and of sulfur-grown cells are available. They indicate that the bacteria change the composition of their EPS according to the substrate or substratum, which they use. In the EPS of *A. ferrooxidans* grown on sulfur, more lipids, less neutral sugars, and only traces of glucuronic acid were present as compared to those of pyrite-grown cells (26).

Reaction Pathways

Experimental results indicated that reaction pathways of metal sulfide dissolution are not determined by the crystal structure (10,25). The reactivity of the minerals with protons is the only relevant criterion. For instance, acid-nonsoluble monosulfides such as molybdenite and tungstenite are degraded by the same mechanism as the acid-nonsoluble disulfide pyrite. In contrast, the structurally similar disulfides pyrite and the acid-soluble hauerite are dissolved by different mechanisms.

Thiosulfate Pathway. The following reaction mechanism describes the degradation of acid-nonsoluble metal sulfides such as pyrite, molybdenite, and tungstenite (25,29). Pyrite is dissolved *via* electron extraction by hydrated iron(III) ions from the crystal lattice according to equation (1):

$$FeS_2 + 6[Fe(H_2O)_6]^{3+} + 9H_2O \rightarrow S_2O_3{}^{2-} + 7[Fe(H_2O)_6]^{2+} + 6H^+ \quad (1)$$

Thiosulfate subsequently yields via a series of reactions either sulfate and protons or higher polythionates

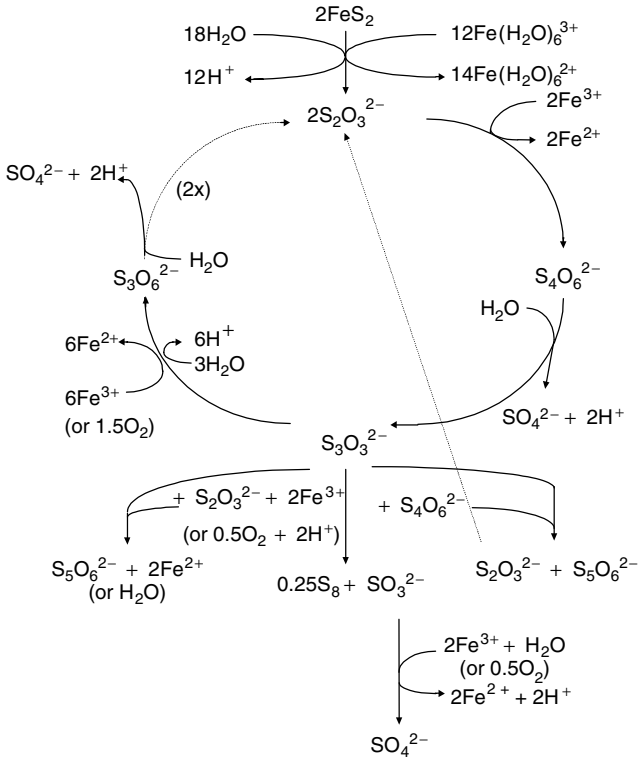

Figure 4. Cycle of oxidative pyrite degradation by bacterial and/or chemical leaching (29).

and elemental sulfur, as indicated in Figure 4. Some of the reactions occurring in the cyclic thiosulfate degradation have been described to be mediated by enzymes. For example, the enzyme for the oxidation of thiosulfate to tetrathionate (thiosulfate dehydrogenase) has been isolated from cells of *A. ferrooxidans* (30), as has been the enzyme for the hydrolysis of tetrathionate (tetrathionate hydrolase) from cells of *A. ferrooxidans* and *A. thiooxidans* (31–33). The extent to which enzymatic catalysis contributes to thiosulfate degradation has to be clarified. Yield calculations, using the amount of biomass produced in the course of pyrite dissolution, indicated that some of these reactions must release electrons at a level sufficient for cytochrome b/flavine reduction (34). This would consequently allow for two oxidative phosphorylations, whereas electrons at the cytochrome c level, as provided by iron(II) ions, would give only one ATP per mol of oxidized substrate. The increased growth yields, as measured, are explainable only with this assumption. The question whether the tetrathionate degradation is dominated by abiotic or by enzymatically catalyzed reactions is important because these reactions determine the end products: whether a considerable amount of elemental sulfur is formed or mainly sulfate and protons. In the first case, acidification in ARD could be reduced. In the second situation, full sulfuric acid production would enhance ARD problems. A regulation and control of this reaction is, furthermore, of high value for industrial application of pyrite bioleaching before gold extraction by cyanidation. The presence of elemental sulfur in the leach residue causes unnecessary

cyanide consumption as a result of the formation of isothiocyanates.

Polysulfide Pathway. The mechanism for metal sulfide degradation with the main intermediate polysulfide is valid for acid-soluble sulfide minerals, for example, hauerite, sphalerite, galena, chalcopyrite, or arsenopyrite (25). Here the attack on the crystal lattice (MS) is carried out by a combined action of protons and iron(III) ions. Protons induce polarization of a surface sulfide ion and enables its liberation from the crystal lattice concomitantly with an electron transfer to an iron(III) ion (25). The first free intermediate of this attack is a H_2S^+ cation radical, which after a series of reactions ends in a polysulfide, H_2S_n (35). The latter compound decomposes to H_2S and elemental sulfur (S_8 in the case of H_2S_9). The reactions may be summarized as shown in Eq. (2).

Subsequently, bacteria regenerate the protons by further oxidizing the elemental sulfur to sulfuric acid.

Hydrogen Sulfide Pathway. In the absence of iron(III) ions, readily acid-soluble metal sulfides such as sphalerite can be dissolved by simple acid attack, liberating hydrogen sulfide. Sulfur compound oxidizing bacteria oxidize it to sulfate and release protons, which can enter the cycle again to dissolve additional metal sulfide. Hydrogen sulfide is oxidized stoichiometrically to elemental sulfur in *A. thiooxidans* (36). The reaction is probably catalyzed by a sulfide : quinone oxidoreductase because the gene sequence of this enzyme has been detected in the genome of *A. ferrooxidans* (37).

Galvanic Influences

Besides the direct attack of iron(III) ions, protons, and complexing agents, in the case of intergrown crystals of different minerals, galvanic interactions have to be considered (9). Because of their different electrode potentials, a polarization can occur between different metal sulfides in an ore, if these are in direct electrical contact. The sulfide with the lower potential functions as the anode, whereas the metal sulfide with the higher potential represents the cathode. At the anode, the metal sulfide is dissolved by electron transfer to the cathode where iron(III) ions are then reduced without oxidation of the cathode itself. As long as the electrical contact between the different sulfides exists, the sulfide with the higher electrode potential is protected against oxidant attack and is dissolved at slower rates than the isolated (galvanically unprotected) sulfide and vice versa. For example, pyrite could be protected by intergrown chalcopyrite or sphalerite that have lower electrode potentials (38,39). Hence, these electrochemical effects may influence considerably the dissolution rates.

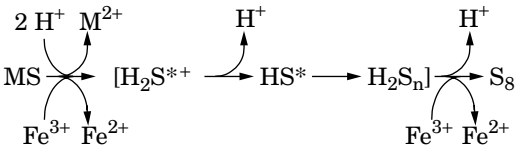
Kinetics of Metal Sulfide (Bio)leaching

The kinetics of metal sulfide dissolution in the presence of iron(III) ions is controlled by the charge-transfer reactions at the mineral surface (the shrinking-core model has to be considered). Reoxidation of the iron(II) ions in acidic solutions is primarily performed by bacteria because enzymatic catalysis is 10^6 times faster than abiotic oxidation (40). These two subprocesses are linked by the redox potential (41). Because in leaching experiments only a control of the bulk solution is possible, differences existing between the conditions in the bulk compared to the solid–liquid interface, for example, concentrations of iron species, pH, and oxygen, could be kinetically relevant. Such differences might occur if a delimited reaction space is assumed either because of solid reaction products remaining at the mineral surface (e.g., formation of a layer of elemental sulfur or iron precipitates) or because of the defined space, created by attached bacteria and the mineral surface (25,26). Solid–liquid, solid–solid–liquid, and solid–biofilm–liquid interfaces should be considered. Mainly concentration gradients of reactants and/or reaction products, as well as reduction of diffusion rates are the consequence but also other mechanisms of diffusion control can be imagined. Furthermore, in the case of intergrown sulfide minerals galvanic effects may cause preferential dissolution. Hence, dissolution kinetics is strongly dependent on the purity of the investigated materials.

Recent work focused on the comparison of abiotic and bioleaching of sphalerite and pyrite at electrolytically controlled redox potentials. Abiotic leaching was performed at similar high iron(III) to iron(II) ratios as are typical for bioleaching, where recycling of the iron(III) ions is enzymatically catalyzed. Comparative experiments without redox control showed that bioleaching rates were up to 20 times higher than in sterile controls started at the same initial amounts of iron(III) ions (42). However, in the absence of bacterial iron(III) reoxidation, the redox potential decreased rapidly as a result of the reduction of the iron(III) ions by the metal sulfide. Therefore, solution conditions in bioleaching experiments and sterile controls were not identical during the entire experiments and the data obtained are not comparable.

Leaching of Sphalerite in Acidic Iron(III) Solutions. The kinetics of sphalerite dissolution under potentiostatic conditions is determined by two processes. High leaching rates are achieved at high redox potentials where no significant difference between bacterial and abiotic leaching is observed. In this case, the dissolution kinetics is controlled only by the electrochemical reaction at the sphalerite surface (43). According to the polysulfide mechanism, this reaction consists of the proton-mediated electron extraction by iron(III) ions, which yields elemental sulfur as the first stable intermediate (Eq. (2), (25)). This could form a layer on the solid surface if no bacterial sulfur oxidation occurs. However, only at low leaching rates (low redox potentials) the kinetics becomes diffusion-controlled in the absence of sulfur-oxidizing bacteria (44). Consequently, sulfur compound–oxidizing bacteria enhance sphalerite dissolution at low redox potentials even under potentiostatic conditions by preventing the accumulation of elemental sulfur on the sphalerite (44). Generally, the formation of a diffusion barrier of elemental sulfur has to be taken into account in all cases in which the

polysulfide mechanism is involved (e.g., for the leaching of chalcopyrite).



(2)

Leaching of Pyrite in Acidic Iron(III) Solutions. In contrast to the dissolution kinetics of sphalerite, the rate-determining step of pyrite leaching is always the electrochemical reaction at the mineral surface. Because pyrite is oxidized via the thiosulfate pathway with water-soluble tetrathionate as the first detectable intermediate, no diffusion-controlling sulfur layer can develop on the mineral surface. The surface reaction is dependent not only on the redox potential, as it is for sphalerite oxidation in acidic solutions, but it is also influenced by the pH (45) because the oxygen incorporated into sulfate originates from water (46), probably via hydroxyl ions (46). In potentiostatic and pH-static experiments, bacterial pyrite leaching was enhanced over sterile controls by a factor of about 1.3 (48). As the reaction orders with respect to iron(III) ions are identical in biotic and abiotic experiments but differ with respect to pH, it was concluded that bacteria enhance pyrite dissolution by increasing the pH at the mineral surface, whereas the bulk pH is kept constant. This pH increase could be caused by the combined actions of bacteria and their EPS in the biofilm, that is, the proton consumption during bacterial iron(II) oxidation and the buffering properties of the EPS (48). Additionally, the positively charged EPS of the leaching bacteria (26) may obstruct influx of protons from the more acidic bulk solution.

APPLICATIONS

The industrial application of bioleaching for the winning of metals is often called biomining. At the end of the twentieth century, it has become one of the main processes used in biotechnology (1). The gigantic dimensions of the bioreactors at the Ashanti plant in Ghana for the pretreatment of gold ores (about 1,000 t ore concentrate are processed per day in 24 stirred tanks of 900 m^3 each since 1995, Figure 1), mentioned earlier (2), even surpassed the biological steps of sewage treatment plants as the largest bioreactors on Earth. It has been estimated that bioleaching is yielding up to 25% of the world's copper and about 10% of the uranium production (49,50). The total value of the products generated by this technology was assessed at U.S. $10 billion in 1998 (51). One of the major reasons for the increasing use of biomining is that conventional means such as ore dressing, followed by smelting techniques are uneconomical for low-grade ores. The oxidation efficacy of metal sulfides by bioleaching bacteria is nearly independent of the metal content, therefore extremely low-grade ores, in the case of copper, typically containing less than 0.3% of the metal, can be mined and processed besides concentrates. With the easy-to-mine rich surface ore deposits becoming exhausted, bioleaching is the alternative for metal winning from previously uneconomic ores. Secondly, in comparison with the nonbiological ore-processing techniques, bioleaching stands for low energy–consuming processes with reduced soil, water, and air pollution problems. Environmental laws increasingly regulate the emission of sulfur dioxide and heavy metals in the flue gas from smelters in many countries. Consequently, bioleaching or biohydrometallurgy turn out to be an important alternative to the conventional pyrometallurgy (1). In addition, no proper pyrometallurgical technique is available for processing of complex concentrates (Cu–Zn–Pb–Ni–Co), therefore hydrometallurgical alternatives to smelting are increasingly investigated. It is well known that zinc and lead contained in copper concentrates and copper contained in lead-zinc concentrates are undesirable because they generate major problems in the specific pyrometallurgical processes.

Current Biomining Techniques

Microbiological leaching is used for two different purposes. First, it is applied to mobilize the metal species of interest from insoluble compounds. For metal sulfides and uranium(IV) oxides, the formation of dissolved metal ions is achieved by oxidation processes. Furthermore, the metals can be extracted from nonsulfide ores and industrial wastes containing metal oxides, by microbially produced inorganic and organic acids. To date, the latter technique is not applied on an industrial scale, whereas the solubilization of base metals such as copper by bacterial oxidation of the corresponding sulfides plays an increasingly important role in commercial mining operations. Furthermore, bioleaching is applied to remove interfering metal sulfides before the conventional extraction of gold and silver from refractory ores by cyanidation or other solubilizing reagents. In refractory ores, the gold and silver are entrapped within the metal sulfide matrix such as pyrite and arsenopyrite. Because the precious metals must be reached by the leaching solution to become oxidized and subsequently complexed by cyanide, they need to be at least partially liberated from the surrounding compounds. As a result of the small size of the encased particles, even intensive grinding is often insufficient, and the interfering metal sulfides have to be oxidized by conventional pyrometallurgy (i.e., roasting, smelting, or pressure leaching), nitric acid oxidation, or bioleaching. In the last decade, the latter technique has turned out to be economically and environmentally the most beneficial option (2). The pretreatment of gold ores by bioleaching even allows to process ores from deposits that were previously considered uneconomical.

Several simple, low-cost techniques are applied for the winning of metals from low-grade sulfidic ores by bioleaching (1,9,52). Generally, an acid leaching solution with a pH around 2, containing the appropriate bacteria is pumped through an ore-bearing material. The metal-containing (pregnant) leachate is collected for recirculation or further processing. In underground and in situ leaching, the metal sulfide oxidation takes place directly in the

natural ore body. Leaching solutions are pumped into a fractured deposit. The pregnant leachate is collected at impermeable sites below the ore body or pumped from new boreholes back to the surface. This technique is often used for the solubilization and winning of uranium(VI) ions from underground uranium ore deposits. In dump leaching, the ore material is piled in heaps 10 to 20 m high on an impermeable base (liner, clay, and so on) and irrigated by sprinklers or flooded temporarily (Fig. 2). The drainage is collected and recirculated several times. Dump leaching is the oldest bioleaching technique. It is generally used to oxidize metal sulfides in waste rock (run-of-mine) that was deposited in the course of exploiting ore bodies for high-grade deposits. Furthermore, it was uneconomical to process this rock by conventional techniques. Both the underground and in situ and the dump leaching methods are rather inefficient processes with low oxidation rates and low total metal yields. The leaching solution often cannot uniformly percolate the underground deposit or the dump because of the low degree of fragmentation of the ore body or waste material. The conditions for bioleaching cannot be rigorously controlled, especially insufficient oxygen supply will limit the dissolution. A more sophisticated low-cost bioleaching technique is called heap leaching. The process is similar to dump leaching but the dimensions of the pile are limited to about 2 m in height, to facilitate oxygen diffusion. Furthermore, usually fine-ground ores or even concentrates are used. Before piling, the ore material is mixed with sulfuric acid to form an agglomerate. This process prevents the segregation of fine and coarse particles and causes a uniform permeability of the heap. For the circulation of the leaching solution, drip-type irrigation above and below the heap surface instead of sprinklers are installed to prevent cooling of the heaps by evaporation. The leachate is collected by a drainage tubing system above an impermeable liner. Heap leaching is mainly used for the winning of copper from chalcocite and covellite. Once concentrations of 1 g/L for copper ions have been achieved in this pregnant solution by continuous cycling, techniques such as solvent extraction and electrowinning are used to produce cathode copper. In contrast to the above-mentioned low-cost techniques for the winning of base metals from low-grade ores, more expensive methods can be applied where high-grade ores and/or precious metals such as gold and silver are concerned. For this purpose, stirred-tank reactors are used (1,9,52). Tank or reactor leaching operate with a sophisticated process control for optimum leaching conditions. In the newest tank bioleaching plants, several huge reactors with single volumes of about 1,000 m^3 are continuously fed with fine-ground, high-grade concentrates at pulp densities of up to 20% (w/v). The main operating costs result from the highly energy-consuming stirring and aeration of the leaching suspension. In addition, because of the high oxidation rates that are achieved with the sulfide-rich concentrates (>20%, w/w), cooling systems have to remove the evolving heat of the exothermic oxidation reactions to maintain a temperature below 50 °C. This is the temperature limit of the usually applied moderately thermophilic bacteria (2). Tank leaching is mainly used to decompose the metal sulfide matrix of recalcitrant gold and silver ores to facilitate the contact of the encased precious metal particles with the cyanide solution. If the interfering metal sulfides contain chalcopyrite, the tank leaching process could combine both the winning of the base metal (copper) and the extraction of the precious metals.

Research and Future Applications

Today, bioleaching research focuses on the optimization of the biooxidation processes in stirred tank reactors. With tank bioleaching becoming an accepted alternative for the pretreatment of recalcitrant gold ores in countries such as South Africa, Ghana, Brazil, and Australia, the mining industry also intends to use bioleaching tanks for the recovery of base metals such as copper, cobalt, nickel, and zinc (1). For instance, the Kasese Cobalt Project in Uganda represents the first large-scale cobalt bioleaching plant (3). The development of bioleaching plants, as with every large-scale biotechnological process, has scale-up problems. Laboratory experiments in shake flasks and percolation columns are often used to determine optimum particle size, ore composition, and other bioleaching parameters but cannot simulate the real conditions in a stirred reactor with 1,000 m^3 ore pulp. The conditions in the final design still have to be conducive for the bacteria, for example, agitation and aeration should balance the oxygen demand without killing the bacteria by detrimental shear forces. In addition, the bacterial process has to be integrated and linked to the other nonbiological units of the plant, for example, the upstream and downstream processing. Bacterial demands on the feed and the composition of the leaching product can have a significant influence on the total metal recovery process. For instance, if the leaching solutions are to be recycled to reduce process water demand, toxic substances added (e.g., in the course of solvent extraction) have to be sufficiently removed. Besides reactor design and total flow sheet development, one of the major current research topics deals with the operating temperature in bioleaching plants. To date, because of the generally applied mesophilic and/or moderately thermophilic leaching bacteria, bioleaching in stirred tanks is limited to temperatures of 40 to 50 °C. As a result of the high sulfide oxidation rates, and consequently, high heat evolution obtained in these reactors, cooling contributes significantly to the total operating costs. Therefore, the development of bioleaching processes that can operate at 60 to 80 °C are of great interest. Besides the reduction of cooling costs, bioleaching activities would be enhanced at these elevated temperatures and metal sulfides difficult to leach, such as the commercially important chalcopyrite, could be biooxidized with sufficient efficacy (53). In addition to the extraction of base and precious metals, bacterial metal sulfide oxidation could also be applied for the depyritization of coal before combustion, thus drastically reducing sulfur dioxide emission from power plants, especially in cases where expensive flue gas cleaning is not available. Despite several positive feasibility studies, this interesting technique has not been tested yet beyond pilot-scale dimensions (54).

In contrast to the biooxidation of metal sulfides, other bioleaching methods for the winning of metals are at present not applied commercially (21). Metals from nonsulfide ores, that is, metal oxides, carbonates, and silicates, and from industrial wastes, containing metal oxides such as fly ash, incineration slag, and contaminated soil, can be extracted by inorganic and organic acids and alcohols. For instance, sulfuric acid produced from the bacterial oxidation of inexpensive elemental sulfur has been used successfully to solubilize copper, cadmium, and zinc from solid-waste incineration fly ashes (55). Furthermore, the potential of heterotrophic bacteria and fungi to produce organic compounds with good metal complexation properties is under investigation (22,56).

ENVIRONMENTAL PROBLEMS CONNECTED WITH BIOLEACHING

The discovery of bioleaching resulted from research conducted on an environmental problem: the acidic drainage, containing heavy metals, which resulted from a waste heap of a coal mine (11). Consequently, bioleaching does not only help in an economic production of valuable and precious metals but also causes serious environmental problems known as AMD/ARD. Leaching bacteria are ubiquitous whenever metal sulfides become exposed to air and water. Most of these bacteria are chemolithoautotrophs, hence, only carbon dioxide from the atmosphere is needed for cell carbon generation (fixation). The degradation products of bioleaching, sulfuric acid and dissolved heavy metals, if not neutralized and precipitated by endogenous buffer material such as carbonates, will enter into the soil and/or the water paths and cause environmental pollution. In the case of a sufficiently high amount, all neutrophilic life will vanish, leaving an acidophilic ecosystem. In addition, the acidity may seriously reduce the fertility of the affected soils and waters. This has happened to the river Rio Tinto (Spain) as a result of mining activities for more than two thousand years, or naturally in the geothermal areas of Yellowstone National Park (U.S.A.) and similar environments. Soils, rivers, and lakes polluted in this manner serve as a source of heavy metals for incorporation into the food chain, either via plant uptake (and accumulation) or via predation, grazing, and so on. Finally, the heavy metals contaminate food products intended for consumption by humans.

Another connected problem is the generation of dust and fine particles. Because of the biological degradation of metal sulfides, the rock containing these compounds becomes fragmented and breaks down to small (microscopic) particles, especially under a combined action with water and freeze-thaw attack (57). These become wind-borne and because they may still contain some heavy metals, they may pollute the environment as dust. Often, tailings that have not properly been protected against wind and water erosion are located within inhabited areas or even within cities (e.g., Johannesburg, South Africa). The dust causes heavy metal pollution, in addition to respiratory diseases like false (mild) croup. In the case of radioactive wastes, another problem occurs: the liberation of usually entrapped radon gas into the atmosphere. Radon, formed as an intermediate of uranium (^{238}U) decay to lead (^{206}Pb), usually remains in the mineral in which the uranium is located. However, if the uranium is enclosed into pyrite or other metal sulfides, bioleaching may result in the liberation of this gas to the atmosphere. Because radon (^{222}Rn, half-life time of about 4 d) may be taken up for example, by humans and in the worst-case decay to a solid radioactive isotope of lead (^{210}Pb, half-life time 21 a), it may contaminate the lung for decades with an increased level of radioactivity. Besides these processes, which are directly and/or indirectly related to oxidative metal sulfide dissolution, reductive microbiological processes may also contribute to pollution with heavy metals. Manganese(IV) and iron(III) ion–reducing bacteria thrive under anaerobic conditions, oxidizing organic substances present and reducing the inorganic heavy metal ions to their soluble forms, manganese(II) and iron(II) ions, respectively. These tend to migrate. In addition, other coprecipitated metals become mobile too, causing a spreading of heavy metal pollution, in fact due to the availability of degradable organic matter. This natural process is believed to be the major process for mineralizing organic matter in anaerobic sediments (23,58,59,60) and thus cannot be avoided.

Countermeasures for problems connected with ARD/AMD deal mainly with a reduction of oxygen and/or water access to the metal sulfides because these are the two essential compounds needed for (bio)degradation. For this purpose, sophisticated systems have been developed, including multilayered covers, geotextiles, clay, limestone, organic substrates, antimicrobials, or underwater storage (also artificial dams). The use of reactive, neutralizing walls only stops the underground migration of unavoidably released acidity and heavy metals. Often, these systems function well for a while but fail unpredictably some time in the future. Too often, microbiologists have not been consulted in the design of these systems to improve their reliability. The interested reader can find plentiful information on these subjects (61–63).

BIOLEACHING OF METALS

FRANCISCO F. ROBERTO
Idaho National Engineering and Environmental Laboratory
Idaho Falls, Idaho

Bioleaching is the term used to describe the microbial dissolution of metals from minerals. The commercial bioleaching of metals, particularly those hosted in sulfide minerals, is supported by the technical disciplines of biohydrometallurgy, hydrometallurgy, pyrometallurgy, chemistry, electrochemistry, and chemical engineering. The study of the natural weathering of the same minerals, above and below ground, is also linked to the fields of geomicrobiology and biogeochemistry. Studies of abandoned and disused mines

indicate that the alterations of the natural environment caused by human activities leave microbiological activity as remnants, which continues the biologically mediated release of metals from the host rock known as *acid-rock drainage* (ARD). A significant fraction of the world's copper, gold, and uranium is now recovered by exploiting native or introduced microbial communities. Although some members of these unique communities have been extensively studied over the past 50 years, our knowledge of the composition of these communities and the function of the individual species present remain relatively limited. Nevertheless, bioleaching represents a major strategy in mineral resource recovery, and its importance will increase as ore reserves decline in quality, become more difficult to process (because of increased depth and increased need for comminution), and as environmental considerations eliminate traditional physical processes such as smelting, which have served the mining industry for hundreds of years.

HISTORY OF BIOLEACHING

Microbial oxidation of iron and sulfur present in sulfide minerals is an important part of the natural iron and sulfur geochemical cycles. This biological weathering of sulfides, whether it occurs above or below ground, is frequently evident as surface seeps of acidic water, primarily sulfuric acid that is generated by microorganisms acting on these deposits.

Humans have exploited these biological phenomena for centuries. For example, cementation of copper with iron from naturally occurring acidic leachate in the Rio Tinto (so-called because of the deep red color resulting from dissolved ferric iron; Fig. 1) of Spain appears to have been practiced since the time of the Tartessians 5,000 years ago (1). The Chinese emperor Liu-An (177 to 120 B.C. (2)) describes this process in detail. Recent analyses of Greenland ice cores showed increased atmospheric copper deposition dating back 2,500 years, which is attributable to crude smelting technologies used by the Romans and Chinese (3). Similarly, vestiges of iron and copper mining during Roman times can be observed throughout Wales in the United Kingdom (e.g., Parys Mountain on Anglesey, North Wales; Fig. 2) and across Europe.

The Rio Tinto mine has played a prominent role in the history of hydro- and biohydrometallurgy. It was the first documented site to perform heap leaching on an industrial scale in the 1700s and the first large-scale open pit copper mine was excavated here. Until the connection between the chemolithotrophic bacterium, *Acidithiobacillus ferrooxidans* (formerly known as *Thiobacillus ferrooxidans*; (4)) and acid mine drainage in Pennsylvania (5,6) was established, it was generally thought that the Rio Tinto ore was uniquely suited to heap leaching, and this approach was not applied to low-grade copper ores in the United States. Today it is estimated that 25% of the world's copper is derived from dump and heap bioleaching.

With the association of *At. ferrooxidans* with sulfide mineral leaching, commercial exploitation of bioleaching was quick to follow. Researchers at the Kennecott Bingham Canyon mine near Salt Lake City, Utah, patented a process for biological dump leaching in 1958 (7).

Figure 1. The Rio Tinto, Spain, passing through the historic mining area. Note the ochre-colored water, which is reported to have dissolved ferric iron concentrations exceeding 2 g/L (1). See color insert.

Figure 2. A view of the Roman era iron mines at Parys Mountain, Anglesey, Wales. See color insert.

What began as a process used largely for the recovery of copper from low-grade mine refuse, or as a means of getting value from old tailings, is now a significant operation at virtually all open pit mines in the United States where billions of tons of low-grade ore are treated (8).

Heap leaching, in which ores are crushed to a defined size range, pretreated with acid, acidic ferric iron solutions containing bacteria, or other materials, and then stacked onto impervious pads, is employed to leach copper and recover gold from refractory ores. This strategy is selected to overcome a variety of economical considerations, which can include the low-grade nature of the ore, long distances from smelter facilities that would lead to prohibitive shipping costs, the small size of the projected mine, which restricts the total capital that may be invested at the site, and higher smelter costs (penalties) caused by contaminants in the ore (such as mercury). In some cases, the value of the metal recovered from low-grade reserves can be used to provide additional financial justification for a project (8).

Perhaps the most important development in the bioleaching of sulfide minerals since 1985 has been the

deployment and increasing scale of stirred tank biooxidation plants for the pretreatment of refractory gold ores. Biooxidation is distinguished from bioleaching in that it pertains primarily to the release of particulate gold and silver through the partial microbial oxidation of sulfides in pyrite or arsenopyrite ores hosting the precious metals. The first biooxidation plant for treatment of refractory gold ore was brought on-line at the Fairview site in South Africa by GENCOR Process Research (now Billiton Process Research; commercial operations are marketed by Gold Fields Ltd.) to treat 10 metric tons per day of flotation concentrate. The success of the initial operation led to the plant being expanded to treat the entire mine concentrate production of 40 metric tons in 1991, and the elimination of the previous roaster technology, with substantial environmental and economical benefit (9). Today one of the world's largest contained bioprocesses operates at the Ashanti Gold Fields Obuasi mine in Ghana, where 960 tons of ore concentrate per day have been processed since 1996 (9). The solid commercial success of these operations has established a momentum in the field of biohydrometallurgy, which is evidenced by the current consideration of bioleaching/biooxidation for a wide range of base metals, including copper, zinc, nickel, and lead. The benefits of the current commercial biooxidation plants include significantly reduced capital investment in physical plant, reduced operating costs when compared with smelting (10 to 15% estimated reduction), and stabilization of arsenic-containing waste (in the case of arsenopyrite ores). Knowledge gained from the long-term operating experience with these plants has also raised interesting scientific questions about the microbiology associated with these engineered environments such as what the actual microbial composition of the bacterial populations is during operation, whether thermophilic bacteria are more appropriate to use because of practical considerations such as cooling costs and many others. Most exciting to researchers in the field is the serious commercial consideration being given to bioleaching/biooxidation as an alternative to smelting in the recovery of metals besides gold from ore concentrates.

THE MICROBIOLOGY OF SULFIDE MINERAL LEACHING

Since the discovery of *T. ferrooxidans* (now *At. ferrooxidans*) and its role in the generation of acid mine drainage from pyrite in abandoned coal piles, extensive research has focused on the metabolism, physiology, and genetics of this microorganism. The recent reclassification of *T. ferrooxidans*, *Thiobacillus thiooxidans*, and *Thiobacillus caldus* into the new genus *Acidithiobacillus* (4) recognized sulfur-utilizing species of the genus *Thiobacillus*; these particular species inhabited a unique environmental niche of low pH and high dissolved metal concentrations. Much of our understanding of how inorganic substrates such as Fe^{2+} and sulfur are oxidized by chemolithotrophs has come from the study *of At. ferrooxidans* and *At thioxidans*. It is important to note that although *At. ferrooxidans* is able to oxidize both iron and sulfur, *At. thiooxidans* can only oxidize sulfur species.

The acidithiobacilli are gram-negative, obligately acidophilic, chemolithotrophic proteobacteria in the gamma subdivision of the proteobacteria. Genetically, they resemble other γ-proteobacteria such as *Escherichia coli* in terms of genetic organization and regulation. The physiology (10) and genetics (10,11) of *At. ferrooxidans* have been reviewed in detail recently, and the reader is directed to those excellent reviews for additional details. Although they must inhabit environments in which the pH is below 3.5, it has been determined that these bacteria maintain a circumneutral internal pH by actively pumping protons against the steep pH gradient between the cytoplasm and the external environment (12). Although these organisms have been the focus of intense study in relation to the microbial dissolution of sulfides, another phylogenetically unrelated eubacterium, *Leptospirillum ferrooxidans*, is perhaps even more important in natural and engineered leaching environments.

In 1964, Silverman and Ehrlich (13) published a comprehensive analysis of microbial metal interactions, and suggested for the first time that there must be both an indirect mechanism of microbial leaching of sulfide minerals (in which ferric ion plays a primary role, and where microorganisms accelerate the observed rate of mineral dissolution by regenerating ferric ion) and a direct mechanism, in which the microorganism attaches to the mineral surface, and enzymatically attacks the sulfide. These two mechanisms have till recently been universally accepted as the means by which sulfide minerals are leached, and many kinetic and mechanistic studies have explained observed results in terms of these mechanisms.

In the indirect mechanism, a metal sulfide, MS, is attacked by ferric ion:

$$2Fe^{3+} + MS \rightarrow 2Fe^{2+} + M^{2+} + S^0$$

The resulting ferrous ions could be oxidized by *At. ferrooxidans* (sulfur could also be oxidized by *At. thiooxidans*):

$$2Fe^{2+} + 0.5O_2 + 2H^+ \rightarrow 2Fe^{3+} + H_2O$$

(*At. ferrooxidans*, *L. ferrooxidans*, others)

$$S^0 + 1.5O_2 + H_2O \rightarrow H_2SO_4$$

(*At. ferroooxidans* and *At. thiooxidans*)

According to the direct mechanism, after attachment to the mineral surface, enzymatic oxidation of a metal sulfide occurs as follows:

$$MS + 1.5O_2 + H_2O \rightarrow M^{2+} + 2H^+ + {SO_4}^{2-}$$

Bacterial attachment to the sulfide mineral occurs rapidly, and several recent studies have provided ultramicroscopic examples of such interactions between *At. ferrooxidans* and synthetic pyrite (14,15) using scanning electron microscopy (SEM) or atomic force microscopy, and sphalerite (16) using SEM. In the case of sphalerite (ZnS), the SEM micrographs also show quite dramatically the difference in mineral surface appearance

when the bacteria are present, as opposed to when the mineral is leached chemically (substantial deposits of material "cladding" the mineral surface that were shown to be primarily sulfur, when examined by electron dispersive *x*-ray analysis, EDAX; 16). Attachment has been shown to be a function of the extracellular polysaccharide (EPS) layer of the bacterial cell, and ferric ion has been demonstrated to be bound within the EPS (15). In the direct mechanism, this ferric ion would be reduced to ferrous ion through interaction with the sulfide at the mineral surface, and then recycled by respiratory enzymes at the cell surface (rusticyanin is believed to be a key enzyme in the respiratory chain of *At. ferrooxidans* responsible for the extraction of energy from the oxidation of $Fe^{2+} \rightarrow Fe^{3+}$; 17,18).

Since 1996, a major debate has emerged concerning the validity of the direct mechanism of sulfide mineral bioleaching (16,19–21). Sand's group in Hamburg and other proponents have performed in-depth studies of sulfur intermediates formed during microbial attack of pyrite and other reduced sulfur minerals, and concluded that the sulfur compounds observed during microbial attack on sulfides substantiate only an indirect leaching mechanism that involves Fe^{3+} and the extracellular polysaccharide (EPS) layer of the microorganism. The nature of the sulfur compounds produced during this process are a function of the type of sulfide and whether the sulfide is soluble in acid (19,20). For acid-insoluble sulfides, including FeS_2, MoS_2, and WS_2, ferric ion extraction of electrons from the sulfide requires water to induce corrosion and release sulfur intermediates upon disruption of the metal-sulfur bond. Thiosulfate has been proposed as the initial sulfur compound released from the sulfide, which is rapidly oxidized further to sulfate (thiosulfate mechanism). Acid-soluble sulfides, such as sphalerite (ZnS), galena (PbS), hauerite (MnS_2), chalcopyrite ($CuFeS_2$), and realgar (As_4S_4), are argued to be readily susceptible to metal-sulfur bond dissociation by protons, with the resulting sulfur reacting with ferric ion to produce a reactive sulfhydryl radical that leads to the generation of polysulfides and ultimately, elemental sulfur (polysulfide mechanism). They propose that direct leaching does not actually occur, but rather, the indirect action of ferric ion facilitated by contact of the EPS of the microbe with the mineral surface accounts for the sulfide dissolution historically ascribed to the direct mechanism. Tributsch (22) has suggested that direct leaching should more accurately be termed *contact* leaching. Other researchers employing a suite of microscopic techniques to study the interactions of *At. ferrooxidans* and *At. thiooxidans* with colloidal sulfur and thin films of synthetic pyrite concluded that the chemolithotrophs present at the surface of the sulfides accumulate sulfur colloids within the EPS layer, and release excess sulfur species into the surrounding media that could be used by unattached bacteria (23). This has been termed *cooperative leaching*. Tributsch (22) and colleagues (24) provide a discussion of these various proposed mechanisms, integrated with electrochemical mechanisms associated with chemical and microbial interactions with the sulfide, and environmental conditions to explain the interactions leading to dissolution and the resulting products. There is still much support for the original direct mechanism of Silverman and Ehrlich, however, and ultimately, any postulated mechanisms must support the observed kinetics and energetics of microbial mineral leaching.

A schematic depiction of sulfide leaching, including key features of the direct and indirect mechanisms is shown in Figure 3.

Only since the 1990s has there been a widespread acknowledgment that the acidithiobacilli are merely part of a more complex acidophilic microbial community associated with the oxidation and weathering of pyrites, in which they may in fact only be minor players. From studies of acidic mine drainage (25,26), heap leaches (27–30), and commercial stirred tank bioreactors (31), it has become clear that the iron-oxidizing bacterium, *L. ferrooxidans* (32), is a dominant and important microbe that survives under conditions in which *At. ferrooxidans* is less active. In fact, there is certainly a succession of microbial populations that occur during the leaching of sulfide minerals. Acidophilic, heterotrophic bacteria of the genera *Acidiphilium* and *Acidocella* are often found in close association with *At. ferrooxidans*, *At. thiooxidans*, and *L. ferrooxidans*. The affinity of these organisms for one another is remarkable, and it has been noted several times in the literature that *At. ferrooxidans* cultures are often contaminated with these heterotrophic microorganisms (33–35). The first such contaminant, originally described as *Thiobacillus acidophilus* (33), has since been reclassified on the basis of 16S rDNA sequence and a variety of biochemical markers as another member of the genus *Acidiphilium*, *A. acidophilus* (36). It has long been thought that these heterotrophic species scavenge organic molecules that are metabolic by-products of the chemolithotrophic microbes in acidic environments, which have been shown to be detrimental to the growth of the chemolithotrophs (especially *L. ferrooxidans*; 35). More recently, it has been suggested that increased rates of iron oxidation observed when *L. ferrooxidans* and an *Acidiphilium sp*. are coinoculated on pyrite are due to the heterotroph consuming EPS on the pyrite surface, providing more sites for the chemolithotroph to attach and dissolve the sulfide (20,29). Although the acidophilic heterotrophic bacteria are nutritionally quite versatile as a group (37), it is still not clear what natural form(s) of organic carbon these microorganisms use.

As the temperature of acidic environments increase, *At. ferrooxidans* activity has been noted to decline (>45 °C). In this case, *L. ferrooxidans*, *At. thiooxidans,* and *Acidithiobacillus caldus* are the dominant leaching organisms. The impact of environmental conditions, including temperature, on the dominance of *L. ferrooxidans* in commercial leaching operations has recently been discussed in depth (24). *At. caldus* (38) had been known for some years as a moderately thermophilic sulfur-oxidizing species, which could complement *L. ferrooxidans* (iron oxidation capacity only) in the bioleaching of chalcopyrite concentrate (39). A similar synergistic effect has been seen between *At. caldus* and *Sulfobacillus thermosulfidooxidans* (40).

As the temperature increases beyond 50 °C, moderately thermophilic, gram-positive and gram-variable bacteria

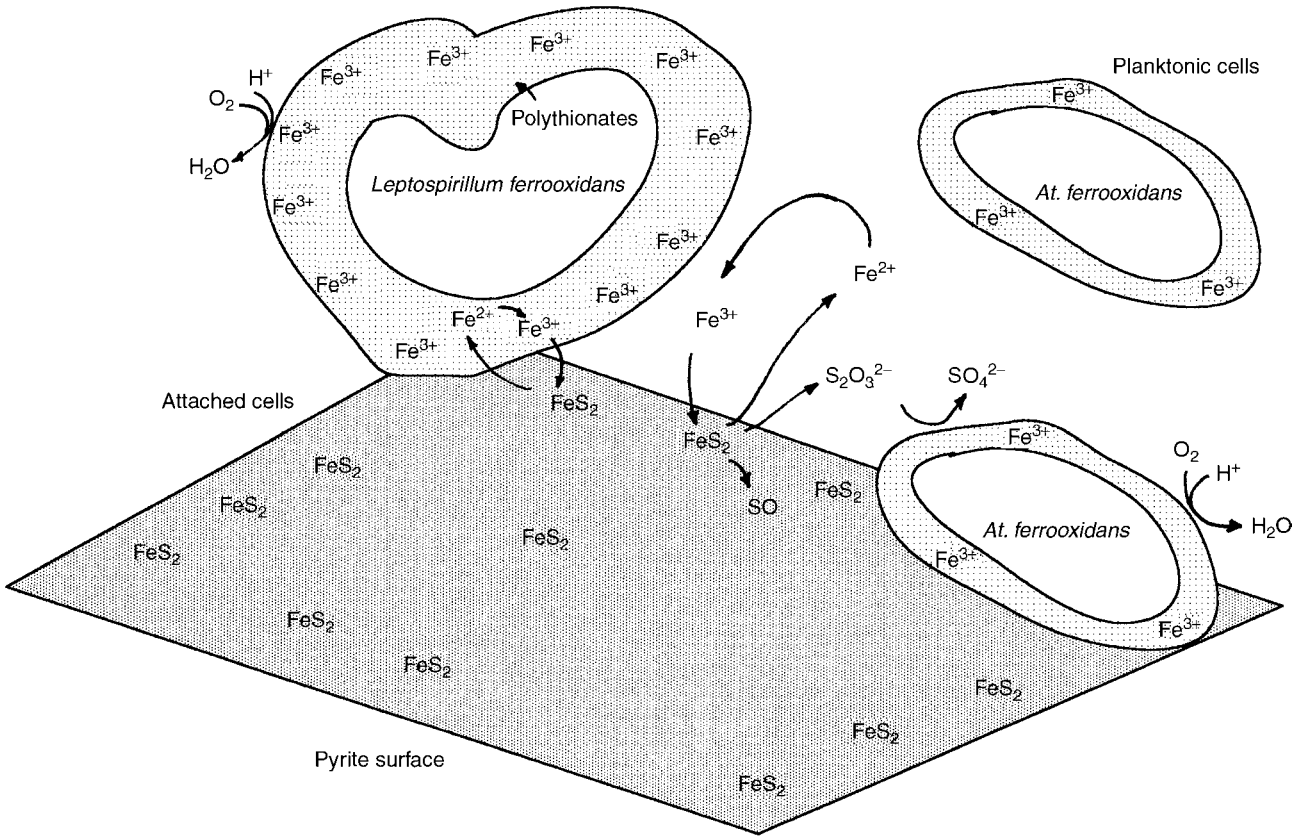

Figure 3. A schematic depiction of the mechanisms of microbial sulfide dissolution, including direct and indirect mechanisms. Cells attached to the surface of pyrite (shaded surface) are meant to depict not only the direct mechanism of sulfide leaching (consuming oxygen through the metabolic activity of the attached cell), but indirect leaching by attached and planktonic cells (such as *At. ferrooxidans*, *L. ferrooxidans* can also oxidize ferrous iron as a planktonic cell, but is not shown for clarity). Attack is either by attached cells, or bulk ferric ion. The lightly shaded cell walls of the various cells depict EPS embedded with polythionates and ferric ion. Note that although thiosulfate is indicated as an intermediate species of pyrite oxidation, it is unstable at pH less than 5, breaking down to sulfite and elemental sulfur.

are observed, including a range of gram-positive organisms comprising the *Alicyclobacillus* group of the high G+C% gram-positive bacteria. These organisms were first isolated from hot pools in Iceland and thought to be thermophilic relatives of *Thiobacillus* because they used sulfur (41). The original TH1 isolate has since been determined to be a strain of *Sb. thermosulfidooxidans* (42). *Sulfobacillus acidophilus* is another iron-oxidizing species in this group. The iron-oxidizing sulfobacilli are capable of growing autotrophically on pyrite, but require carbon dioxide supplementation to achieve reasonable growth rates. They can also grow mixotrophically using both carbon dioxide and glucose, and heterotrophically (43). Other heterotrophic thermophiles appear to be phylogenetically closer to the species *Alicyclobacillus acidoterrestris* and *Alicyclobacillus acidocaldarius*, first isolated by Brock in Yellowstone in the early 1970s. *Acidimicrobium ferrooxidans* is an unrelated eubacterial thermophile that grows readily on iron or pyrite without carbon dioxide supplementation, and which has been shown to promote the growth of *Sb. acidophilus* when both are grown together, presumably by providing organic nutrients to the latter organism (44) as a consequence of its own more rapid growth. There is currently substantial interest in the use of moderately thermophilic bacteria in heap and stirred tank leaching, as these organisms appear to be more efficient in the dissolution of complex sulfides such as chalcopyrite ($CuFeS_2$). Because cooling of stirred tank biooxidation reactors is one of the major costs in the operation of such plants, use of moderate thermophiles would also have an economic benefit, and this alternative is being pursued aggressively (see discussion later in this article).

Beyond 70 °C, chemolithotrophic and heterotrophic archaea dominate acidic mineral environments. Typical of these microorganisms are Crenarchaeota, such as *Acidianus brierleyi* (45; originally identified as *Sulfolobus acidocaldarius*; 46). There was immediate interest in evaluating the utility of these thermophilic microorganisms in bioleaching (47). Since that time, other thermophilic species have been identified and studied in the context of mineral leaching, including *Sulfolobus metallicus* (48,49) and *Metallosphaera sedula* (50). The application of these organisms, particularly in stirred tank bioreactors, has

been hampered by their inherent physiology. Because they lack a conventional cell wall, they are especially susceptible to physical damage from shearing by the mineral particles as the solutions are stirred, effectively limiting the amount of solids that can be introduced.

Figure 4 depicts the spectrum of acidophilic bacteria when considering changes in pH and temperature. There is considerable overlap in populations as environmental conditions change, but in both natural and artificial environments, the shifts in active iron- and sulfur-oxidizing species have been well documented. Organic carbon is indicated in Figure 4 as playing a role in the interactions of leaching microorganisms, whereby autotrophic species may provide substrates for the growth of strictly heterotrophic species. As mentioned earlier, iron oxidation by more rapidly growing species, as in the case of *At. ferrooxidans*, may also stimulate slower growing thermophilic iron-oxidizing species (such as *Sb. acidophilus*) when organic carbon is released into the environment. As was noted before, it is still not clear what form(s) of organic carbon may be involved in these microbial interactions.

Additional dimensions can be included in the consideration of how environmental conditions affect the microbial population of iron and sulfur-oxidizing species. For example, *L. ferrooxidans* has been noted to be more tolerant of high [Fe^{3+}] and lower pH (<1.5) than *At. ferrooxidans*, which explains the larger numbers of *L. ferrooxidans* found in the commercial BIOX® process, heap leaches, and in acidic mine drainage (24,26,27–30). In their comprehensive analysis of the factors that might influence the selection of *L. ferrooxidans* over *At. ferrooxidans* in commercial processes, Rawlings and coworkers (24) took into account the effects of redox potential (*L. ferrooxidans* favored at $> +700$ mV), pH (*L. ferrooxidans* is more tolerant of acidic pH), temperature (*L. ferrooxidans* is active beyond 35 °C), high [Fe^{3+}] (*At. ferrooxidans* is inhibited at ferric concentrations more than 10 times lower than that which inhibits *L. ferrooxidans*), and low [Fe^{2+}] (*L. ferrooxidans* demonstrates a K_m for ferrous iron six times lower than *At. ferrooxidans*).

Recently, Banfield and coworkers (26,51) studying the massive Iron Mountain site in California, have discovered that *L. ferrooxidans* is distributed widely in waters and sediments at the site, but were unable to find significant numbers of *At. ferrooxidans*. They concluded that *At. ferrooxidans* did not play a significant role in pyrite oxidation in this environment. It would be interesting to consider the microbial ecology of this extremely acid environment in light of the discussion of Rawlings and coworkers (24). Further, they have isolated a hitherto unknown species of Archaea, *Ferroplasma acidarmanus* (52), which appears to be a dominant microorganism at the extremely low pH (<0.5) found in the Iron Mountain environment. *Ferroplasma acidarmanus* is not an obligate chemolithotroph, however, because comparable growth rates were observed when the organism was grown on 0.02% yeast extract without added ferrous sulfate. Interestingly, although the total iron concentration measured at Iron Mountain is more than 20 g/L (some locations within the study site have measured iron concentrations exceeding 100 g/L), more than 90% is ferrous iron, which is quite different from many ARD sites, where most of the iron exists as dissolved ferric ion.

The preceding discussion has focused on the dissolution of sulfide minerals by chemolithotrophic acidophilic bacteria and archaea, and associated heterotrophic species. However, the field of biohydrometallurgy has not ignored oxide, silicate, and carbonate ores where heterotrophic microorganisms are likely to be most important to any eventual commercial application. Ehrlich (53,54) has recently provided excellent overviews of our state of

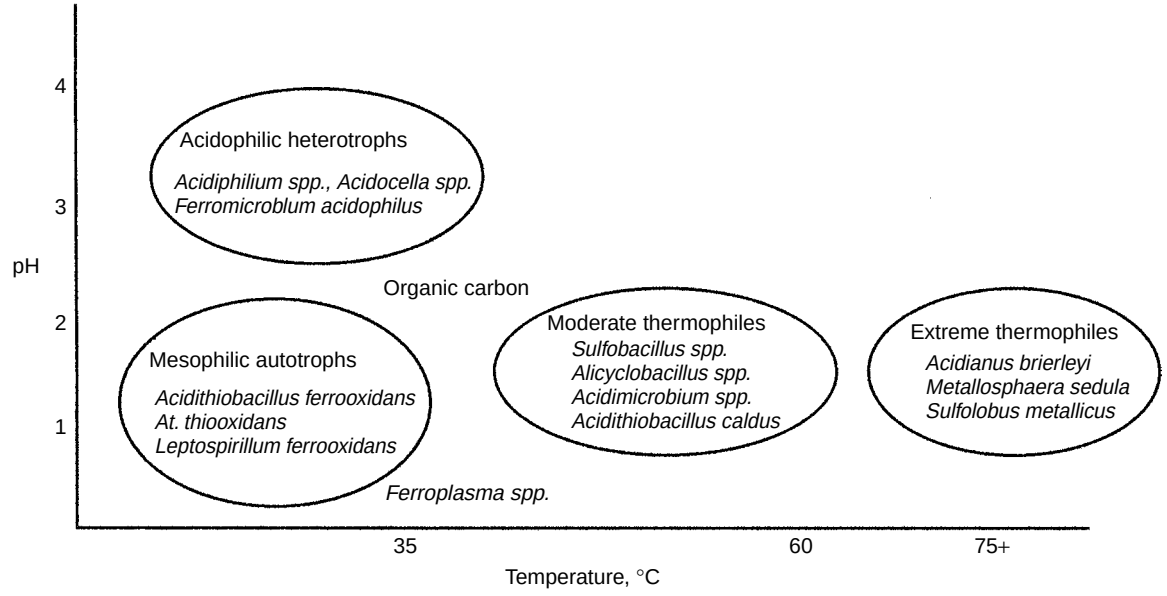

Figure 4. The microbial ecology of acidic environments as a function of temperature and pH.

understanding with respect to microbial attack of these minerals. In many cases, fungi producing organic acids, such as oxalate and citrate, have been demonstrated to leach aluminum ores (55) and lateritic nickel ores (56). Anaerobic bacteria may also be useful in the release of metals from metal oxides (57,58). Heterotrophic leaching is likely to be a more complex process because the ores cannot be sterilized, and environmental conditions are not highly selective as is the case in the leaching of sulfides by obligately acidophilic microorganisms. Inexpensive carbon sources will also be required to facilitate economically feasible microbial oxide leaching (53).

COMMERCIAL PRACTICE

BIOX®

Dew and coworkers (9) recently provided a comprehensive picture of the development of Billiton Process Research's BIOX® process. From a pilot study handling 10 metric tons per day (tpd) to the current full-scale operation in Ghana handling 960 tpd, considerable process knowledge has been obtained to characterize the operating parameters of these plants that have become an economically viable alternative to pressure oxidation and smelting.

The typical plant design is composed of a series of stirred tanks, with up to three being operated as primary reactors in parallel, and the downstream reactors functioning in series. Total residence time of the arsenopyrite flotation concentrate in the reactor train is four days. The ore concentrate is ground to 75 μm particle size (>80%, 100% <150μm) and the solids loading is 20 to 30%. Phosphorus, potassium, and nitrogen amendments are made to provide essential nutrients to the microbial consortium. The temperature of the process is controlled between 30 to 45 °C, with a desired average ceiling temperature of 40 °C to provide some cushion in the case of loss of cooling. Operating pH is maintained between 1.2 to 2.0. Aeration (maintained near saturation; 2.2 kg O_2/kg sulfide consumed) and agitation to maintain the ore particles in suspension account for 30 to 40% of the overall power consumption of the process. After biooxidation, the treated ore concentrate is washed extensively to remove iron and other cyanide consuming materials, and the dried ore is then removed for cyanidation to recover gold. Liquid effluents from the process, containing iron, arsenic, and other undesired metals, are treated with lime to neutralize, precipitate, and stabilize the waste. The solid precipitates are deposited in a tailings impoundment. The overall process is presented in a simplified process diagram in Figure 5.

BacTech

A similar process description has been made for the moderately thermophilic BacTech process (59). The BacTech process is distinguished from the BIOX® process in operating between 45 and 55 °C, where a different microbial consortium, dominated by sulfobacilli, *At. ferrooxidans*, and *At. caldus* have been described. The overall layout of such a plant is very similar to that of the BIOX® process, although special considerations must be made to the materials from which the reactors are constructed, owing to the elevated temperature and low pH of the operating environment. Special grades of stainless steel have been described to be more appropriate for construction of these systems, as compared with the 304-L stainless steel

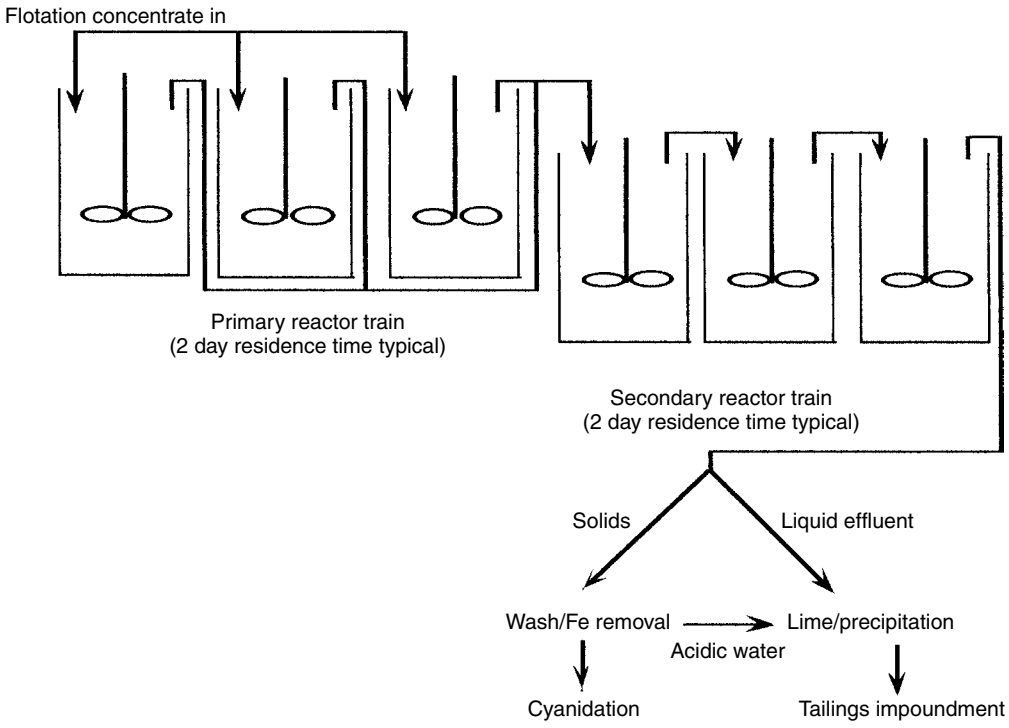

Figure 5. Schematic representation of commercial biooxidation plants in operation today.

commonly used for mesophilic processes. Corrosion resulting from elevated chloride ion appears to be a particular concern. As in the BIOX® process, aeration, mixing, and temperature control are major contributors to the overall power requirements of these plants. It is estimated that 3 to 12 MW of heat is produced in a typical 100-tpd plant. Interestingly, oxygen requirement does not appear to be higher in the BacTech plant, although the solubility of oxygen is lower in water at the higher operating temperatures of this process.

Heap Leaching

Heap leaching is without question the largest scale application of microbial mineral leaching now practiced (dump leaching, in which no attempt is made to optimize particle size is included in this statement). It has been noted that although the principles used in the commercial operation of these plants were developed in North America, virtually all commercial plants have been constructed in the Southern Hemisphere (60). Copper sulfide bioleach plants range from just over 1,000 tpd to over 17,300 tpd at Quebrada Blanca in Chile. At Lo Aguirre, Chile, 16,000 tpd were processed continuously from 1980 to 1996. The use of heap leaching, in which finely ground ore is agglomerated and placed on highly engineered heaps, is now being considered for the biooxidation of refractory gold ores. Brierley (61) has provided extensive details of such a plant that has been designed and tested by Newmont Gold Company. This state-of-the-art gold heap leach operation, with an idea of the scale of such operations, is depicted in Figure 6. The sheer scale of just a single such operation, in which millions of tons of ore are treated, substantiate claims that bioleaching of metals represents the largest bioprocessing application extant. In optimizing these heap leach operations in the future, more understanding of thermophilic bacteria and archaea and their ability to oxidize sulfides will be necessary because, unlike stirred tank reactors for the biooxidation of valuable gold concentrates, temperature control will be limited or nonexistent, and internal heap temperatures are known to exceed 65 °C.

Figure 6. One of the three biooxidation pretreatment heaps measuring approximately 1,000 by 500 feet, with ore stacked to 30 feet, containing 709,000 tons of low-grade refractory ore. Courtesy of Dr. J. Brierley, Newmont Mining Corporation. See color insert.

THE FUTURE

Since the first association of the acidophilic chemolithotrophic bacterium, *At. ferrooxidans*, with sulfide mineral leaching some 50 years ago, there has been a tremendous growth in our understanding of the microbes associated with natural and engineered bioleaching. Commercial practice of bioleaching has grown from a peripheral operation treating marginal ores and waste rock to highly optimized heap and stirred tank processes that handle thousands of tons of valuable ores and concentrates each day. The efforts of many scientists, engineers, and mine operators have resulted in the largest bioprocesses currently practiced. There is a great promise that bioleaching and biooxidation of minerals will increase the efficiency with which the Earth's metal resources are utilized, reduce the impacts associated with the extraction of metals from often deeply buried ores, and replace more energy intensive, polluting technologies. However, there is still much to be learned. Brierley (62) has noted that many of the environmental factors associated with bioleach operations that may influence microbial populations, including acid conditioning of ores, sulfide concentration, internal heat generation, dissolved solutes (Cl^-, NO_3^-, heavy metals, total dissolved solids), aeration, nutrients, and organic carbon, have rarely been considered from the context of the microorganisms operating in the commercial environment. Some modern heap leach operations now incorporate design features, such as aeration systems, to accommodate microbial activity, but there is still much to be learned with respect to optimizing these artificial environments for optimum activity of the biological catalysts present. Even our understanding of the mechanisms involved, let alone the genetic regulation of those mechanisms, is incomplete. The recent partial sequencing of the genome of *At. ferrooxidans* (63) raises the hope that our future understanding and control of these important biogeochemical and commercial processes will be extensive enough to permit the utilization of genomics and bioinformatics in the control of commercial operations.

TERMINOLOGY AND DEFINITIONS

Bioleaching

The liberation of metal values into solution from minerals and ores through microbiological action.

Biooxidation

The liberation of metal values (typically as microscopic particles) from ores. In this process, microbial oxidation of sulfides in the ore leads to deterioration of the rock matrix, and release of the bound metal (e.g., gold), which can then be recovered with increased efficiency through other physical and chemical treatments such as cyanidation and flotation. Often only partial oxidation of the sulfides

present is required to achieve efficient liberation of the metal values.

Dump Leaching

The leaching of run-of-mine ore placed in large piles. Because of environmental regulations, this frequently is done on impervious pads today to prevent escape of the leachate into the environment, but always involves run-of-mine ore.

Heap Leaching

The leaching of ores on prepared pads (geotextile membrane, concrete pad, sometimes including provisions for aeration, fluid collection, etc.) where the ore has been crushed to a particular size range, and may have been coated or mixed with microorganisms and/or nutrients to promote more rapid leaching.

Run-of-Mine

Ore as it is extracted from the mine, which can contain rock ranging from fine particles to hunks approaching 1 ton in weight, and perhaps a meter or more in linear dimension. No attempt is made to fractionate the ore further before other operations (such as dump leaching).

Acknowledgments
I am indebted to Dr. James Brierley for the use of the photograph appearing in Figure 6, and to Dr. Henry Ehrlich for his willingness to read a draft of this manuscript and provide suggestions that have strengthened this contribution. The reader is directed to Dr. Ehrlich's authoritative book, *Geomicrobiology*, (4th edition, Marcel Dekker, in preparation) for a comprehensive treatment of this and other topics relating to microbe-mineral interactions.

BIOLOGY OF CRYPTOSPORIDIUM

DEBRA E. HUFFMAN
University of South Florida
St. Petersburg, Florida

TAXONOMIC CLASSIFICATION

Cryptosporidium is an obligate intracellular parasite belonging to the phylum Apicomplexa, order *Eucoccidiida*, suborder *Eimeriina*, and family *Cryptosporidiida*. *Cryptosporidium* was first diagnosed as an agent of disease in humans in 1976 (1,2). Since that time, it has been well recognized as a cause of diarrheal illness throughout the world (3). Currently, there are approximately 23 named species of *Cryptosporidium* infecting a wide range of vertebrates, including humans. However, many of these species are considered to be misidentified. There are 10 species commonly recognized today (Table 1; 4–6). These species include five mammalian (*C. parvum, C. muris, C. wrairi, C. andersoni, C. felis*), two avian (*C. meleagridis and C. baileyi*), two reptilian (*C. serpentis, C. saurophilum*), and one fish (*C. nasorum*). Speciation of isolates, in accordance with the practice for other coccidians, has primarily been based on host specificity, oocyst morphology, and site of infection. However, these traits have been shown to be insufficient to accurately identify separate species of *Cryptosporidium*. Much of the information, regarding host specificity has been based on a limited number of studies

Table 1. Named Species of Cryptosporidium and Their Hosts

Species	Hosts
Cryptosporidium baileyi	Chicken
Cryptosporidium meleagridis	Turkeys, immunocompromised human
Cryptosporidium muris	Mice
Cryptosporidium felis	Cats, immunocompromised human
Cryptosporidium serpentis	Reptiles
Cryptosporidium saurophilum	Skunk
Cryptosporidium nasorum	Fish
Cryptosporidium wrairi	Guinea pig, immunocompromised human
Cryptosporidium andersoni	Cattle
*Cryptosporidium parvum**	Cow, mouse, human

*Appears to be infectious for 152 species of mammals (6).

using a small number of *Cryptosporidium* isolates that render this information inconclusive (7,8). Finally, *Cryptosporidium* has been shown to infect numerous sites in the body including the upper and lower respiratory tracts, the uterus, bladder, and also the liver and pancreatic systems, rendering the site of infection a relatively useless tool to describe a species (9).

Two different genotypes of *Cryptosporidium parvum* have been shown to be infectious in humans (10). Genotype-1 isolates have been shown to be infectious only in humans, while genotype-2 isolates have been shown to be infectious in mice, calves, lambs, goats, and horses, as well as humans. This suggests the possibility that there are two distinct populations of oocysts cycling in humans with distinct transmission cycles; (*1*) zoonotic transmission from animal to human with subsequent human to human and human to animal transmission and (*2*) a transmission cycle exclusively in humans.

BASIC BIOLOGY

The environmentally stable stage of this organism is known as an oocyst. The oocysts of *Cryptosporidium parvum*, the species infecting humans, are 4 to 6 μm in size and have been shown to survive in the environment for extended periods of time, depending on temperature and water quality conditions because of the robust nature of the oocyst wall (11). The oocyst wall of *C. parvum* and related species appears to be composed of three layers when viewed by electron microscopy (7,12–14). The inner layer is relatively thick and is thought to be a filamentous glycoprotein (11,15). The middle layer is thought to be a more rigid layer composed of a complex lipid, whereas the outer layer is thought to be composed of acidic glycoproteins (11). Spanning one-third to half of the oocyst wall is a linear suture, which under the proper conditions opens to release the four internal sporozoites that are capable of initiating infection within the host.

REPRODUCTION

The reproductive life cycle of *Cryptosporidium* is complex, with both sexual and asexual reproduction cycles being completed within a single host (16, Fig. 1). Infection begins with the ingestion of an oocyst. Once ingested, excystation (release) of the four sporozoites from the suture line located along the side of an oocyst begins. Sporozoites once released from an oocyst may penetrate individual epithelial cells located in the region of the ileum and begin reproduction.

The initial phase of reproduction begins when the parasite attaches itself to the host cell by means of a feeder or attachment organelle that appears to be used to facilitate the exchange of materials. The sporozoites and all subsequent lifecycle stages are intracellular beneath the host cell membrane, but are extracytoplasmic. Once the sporozoite enters the host cell, it begins to differentiate into a spherical trophozoite with a prominent nucleus. The division of this nucleus signals the start of asexual reproduction known as *merogony* or *schizogony*.

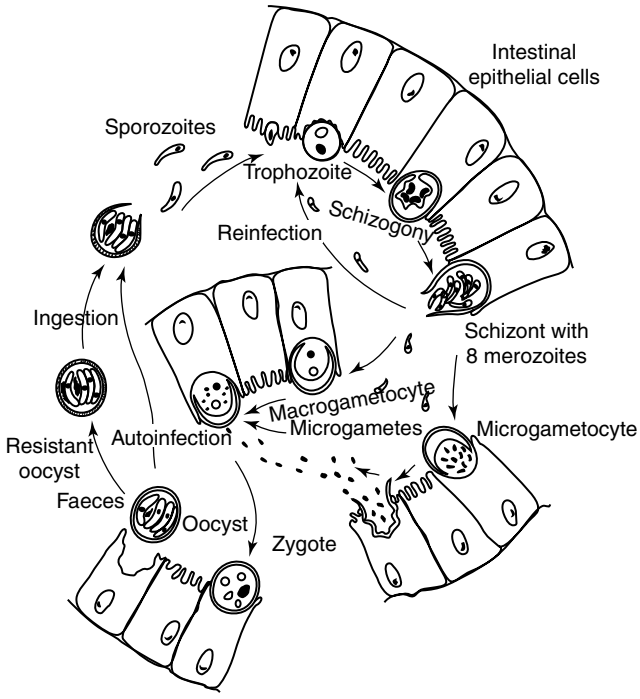

Figure 1. Reproductive life cycle of *Cryptosporidium parvum*.

Two morphologically different types of schizonts have been observed. Type-I schizonts contain six to eight nuclei. When the schizont matures, each nucleus becomes incorporated into a merozoite. Each merozoite can either develop into another Type-I schizont or a Type-II schizont, which will produce 4 merozoites. Merozoites formed from Type-II schizonts initiate sexual reproduction known as *gametogony*. During gametogony, the merozoite can invade other host cells where they may differentiate into either microgametes or macrogamonts (male and female stages). When the microgamont develops, it becomes multinucleate. Each nucleus, eventually, becomes incorporated into the equivalent of a sperm, which will fertilize the macrogamont. After fertilization, the macrogamont develops into an oocyst. After sexual reproduction is complete, the oocysts will be released in excreted feces. Approximately 80% of the oocysts excreted in the feces are thick-walled oocysts. These oocysts have multilayered walls that allow them to remain infective outside of the host. The remaining 20% of the oocysts produced are thin-walled oocysts that can rupture within the host, releasing their sporozoites and initiating an autoinfectious life cycle. Infected hosts may excrete between 10^9 and 10^{10} oocysts per day during the course of the disease (17).

CLINICAL ASPECTS

The incubation (or prepatent period) time between ingesting oocysts and shedding of oocysts varies among species. In humans, the average incubation period ranges from 5 to 10 days with a mean of 7.2 days (18–20). Oocyst shedding can last anywhere from 3 to 15 days and may continue well past the cessation of symptoms (18,19,21).

The severity and duration of the disease will vary greatly, depending on the status of the host's immune system (22). In immunocompetent individuals, symptoms including fever, malaise, nausea, and diarrhea typically lasts 10–14 days. Immunocompromised patients, such as patients with AIDS, patients undergoing immunosuppressive therapy, those with immunoglobulin deficiencies, or with concurrent viral infections affecting immunity may suffer a prolonged, life-threatening illness either because of dehydration or secondary complications or both.

Chemotherapy is currently not available for treatment of this disease, although more that 100 therapeutic agents have been studied. Supportive therapy, including the use of intravenous fluids is considered to be the treatment of choice. Treatment of HIV-infected patients may include the use of antiretroviral therapy, including the use of protease inhibitors to improve the immune status of the patient. This treatment regime has been shown to result in both clinical and parasitological improvement in the infected host (23).

Studies to determine the number of oocysts necessary to cause infection in humans have produced differing results. The first human-feeding study in healthy volunteers suggested that the infectious dose ID_{50} or the dose that is required to establish infection in 50% of the persons exposed was approximately 132 oocysts, although one recipient was infected with as few as 30 oocysts (24). A similar study using three geographically diverse isolates of genotype 2 showed a variance in the ID_{50} of 9–1042 oocysts (25). The variability between infectious doses is most likely because of the susceptibility of the host and the virulence of the particular isolate. Interestingly, the isolate with the lowest ID_{50} also had the highest illness attack rate (86% versus 50–55%) (25).

PREVALENCE OF CRYPTOSPORIDIOSIS IN HUMANS

Because cryptosporidiosis infections are generally self-limiting and often symptomatically similar to other diarrheal diseases, the disease may often be undiagnosed or misdiagnosed in the absence of a recognized outbreak. Incidence of *Cryptosporidium* infections in the population range from 0.6 to 20%, depending on the geographical locale with a peak incidence of the disease in children one to five years of age with no sex related disposition (26). Approximately 60% of all positive stool samples come from children with 30% coming from adults less than 45 years of age (26). Although clinical infection is uncommon over the age of 40, it does occur from time to time, and there is currently no evidence of increased incidence in the elderly.

Most early reports of human cryptosporidiosis were single sporadic cases or small clusters of cases. In 1983, population surveys began to be reported from Australia, Finland, the United Kingdom, and numerous other countries (23,27–33). Unfortunately, many of these surveys were not well controlled with data being derived from selected populations, using specimens that had been routinely submitted to the laboratory. Furthermore, accurate identification of the parasite could not be assumed in all studies. For these reasons, the information produced by these surveys may not provide an accurate assessment of the prevalence or incidence of the disease, and they should be viewed with caution. Further analysis of data compiled from 40 countries between 1983 and 1990, excluding outbreaks, suggests that the prevalence rates in industrialized countries of North America and Europe are between 1 and 3% and the rates in developing countries are approximately 5% in Asia and 10% in Africa (34).

It has been estimated that *Cryptosporidium* accounts for 13 to 16% of diarrheal cases in AIDS patients in developed nations, with that number climbing to 24 to 50% in developing nations (35,36,26,24,4). A prospective long-term study in Europe suggests that 3 to 4% of person with HIV will have cryptosporidiosis when diagnosed with HIV, and that an equal number of them will develop it, during the course of their disease (37). A study in Los Angeles in 1994 suggests that 3.4% of HIV patients in the USA will become infected with cryptosporidiosis during their symptomatic period (38).

Several studies have noted a temporal or seasonal peak in levels of cryptosporidiosis. However, these tend to vary from country to country, including summer in Australia, rainy season in Central America and India, spring or late summer in North America, and late summer in Germany (26). These trends may reflect rainfall patterns, farming events such as calving and lambing, or fertilization practices. However, outbreaks still remain unpredictable.

OCCURRENCE IN THE ENVIRONMENT

Cryptosporidium oocysts have been detected in 4–100% of surface waters sampled at levels of 0.0012–5800/L, depending on the impact from sewage and animals (39–41, Table 2). A survey performed by LeChevalier in 1991 found 87.1% of the surface water sites sampled positive for *Cryptosporidium* with maximum concentrations ranging from 10 to 484 oocysts/L, with the highest levels being found in the Mississippi, Ohio, and Missouri Rivers (43). A similar study by Rose in 1991 noted a tenfold difference in oocyst densities between urbanized and pristine watersheds (43). In pristine watersheds, concentrations ranging from 0.003 to 0.29/L have been detected (39).

Groundwater, previously thought to be a more protected water source, has shown between 9.5 and 22% of samples positive for *Cryptosporidium* (44). A similar survey of groundwater in the United Kingdom (258 samples) revealed a slightly lower percentage of positive samples (5.8%) (40). A U.S. survey of wells that were shown to be coliform-positive was also shown to be contaminated with *Cryptosporidium* oocysts at concentrations of 0.004–0.922/L (39). Outbreaks of cryptosporidiosis caused by the contamination of a drinking water well have been documented on four occasions in various geographical areas (Texas, Pennsylvania, Yakima, Washington, and Walla Walla, Washington). Two of the outbreaks (Pennsylvania and Yakima, Washington) were associated with shallow wells where the ground water was suspected of being under the influence of surface water. The outbreaks in Texas and Walla Walla, Washington, were due to the direct contamination from wastewater and irrigation water, respectively (45).

Table 2. Occurrence of Cryptosporidium in the Aquatic Environment. Adapted from H.V. Smith and J.B. Rose, *Parasitol. Today* 14, 14–22 (1998).

Country	Number of Samples	% Positive Samples	Oocysts/L

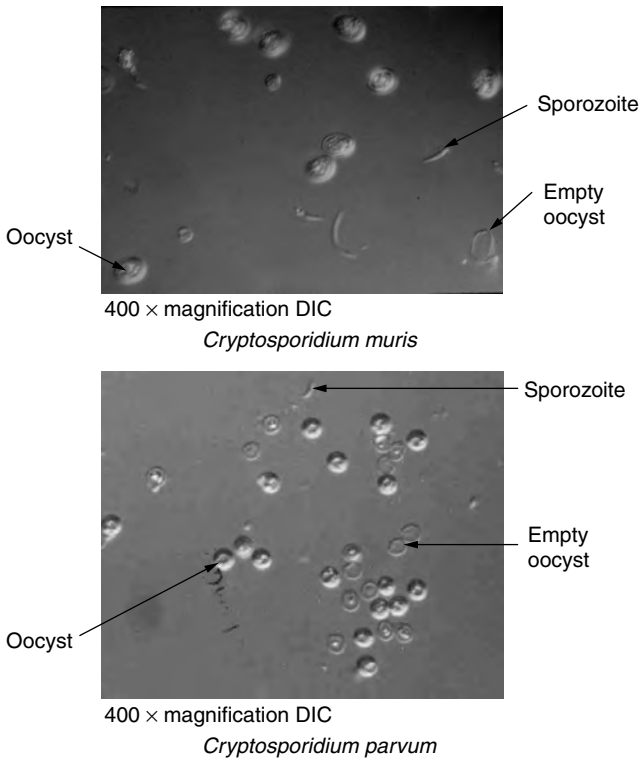

Figure 2

Cryptosporidium oocysts by nature are very robust and have been shown to survive for extended periods of time in the environment. They have also been shown to survive in both human and cattle fecal material, which can protect them from desiccation. Therefore, the practice of disposal of both human and animal waste, by land application may lead to indirect contamination of water supplies or food crops. Large amounts of contaminated fecal material can also provide a source of viable oocysts that may contaminate surface or groundwater through infiltration or run-off during periods of peak rainfall. Once deposited in receiving waters, oocysts have been shown to survive in river water up to six months with a die-off rate of 94% after 176 days (46).

The effects of both high and low temperatures on the survival of *Cryptosporidium* have been investigated using animal infectivity analysis (47). Inactivation greater than 99.9% can be achieved by raising the temperature to 70 °C for 1 min. These findings suggest that *Cryptosporidium* oocysts can be rendered noninfectious when held for relatively short times at temperatures far below boiling. A similar level of inactivation was shown at extremely low temperatures. When oocysts were held at −15 °C, they gradually became noninfectious and after a period of 7 days no infectious oocysts could be detected. At −20 °C and −70 °C a >99.99% inactivation could be achieved after 8 h and 1 h, respectively (48).

TRANSMISSION

Several factors related to the genus *Cryptosporidium* have contributed to their high incidence of disease in the population. These factors include the organism's ability to complete its lifecycle in a single host, the robust, environmentally stable infective oocyst stage and the large number of infectious oocysts excreted from infected hosts. These factors along with the broad host range for this organism increases the potential for waterborne, foodborne, person-to-person, and also zoonotic transmission.

Waterborne Outbreaks

Numerous waterborne outbreaks of *Cryptosporidium* both in the United States and throughout the world have been documented (6,40). Outbreaks have been attributed to all water types including contaminated rivers, lakes, springs, and groundwater sources. The first reported outbreak in the United States occurred in 1984, in Braun Station, Texas, with 368 cases identified (49).

This was followed by a larger outbreak in 1987 in Carrollton, Georgia, with an estimated 13,000 cases of cryptosporidiosis (50). The largest reported drinking water outbreak of cryptosporidiosis in the United States took place in Milwaukee, Wisconsin, in 1993, with an estimated 403,000 cases — 4,000 hospitalization and several deaths (51). The outbreak was caused by oocysts that had passed through the filtration system of the city's southern water treatment plant. It has been hypothesized that heavy spring rains and runoff from melting snowfall led to the contamination of the city's source water (Lake Michigan) with agricultural wastes (51,52). This outbreak was estimated to have cost the community $53 million in lost wages, lost productivity, medical bills, and emergency room visits. Further, the outbreak is said to have cost upward of $100 million in claims for loss of life (53).

Although treatment failures have been documented to have occurred during outbreaks situation, numerous waterborne outbreaks of *Cryptosporidium* have occurred in communities within the United States where evaluation of the water treatment plant during outbreak periods revealed no violations for turbidity, chlorine concentration, or coliform levels (54). Because of the small size of this organism (4–6 μm), the optimization of filtration for the removal of oocysts during drinking water treatment is extremely important. Similarly, the use of alternative disinfectants that have been shown to inactivate *Cryptosporidium* oocysts, such as ozone and ultraviolet light, are also important factors to be considered for the prevention of drinking water outbreaks.

Although the source of contamination during an outbreak often goes undetected, suspected sources of contamination include wastewater and heavy rainfall events, which can lead to increasing agricultural and other nonpoint source inputs. Although the agricultural runoff from cattle and sheep raising areas have been repeatedly implicated as sources of contamination during waterborne outbreaks both in the United States and abroad, only once has the bovine genotype been identified as being present, during an outbreak within North America. This outbreak occurred in Cranbrook, British Columbia, with approximately 2,000 cases of cryptosporidiosis. The bovine isolate (genotype 2) was detected in human fecal specimens, in cattle manure specimens found near the watershed, and in water samples collected from the reservoir (10).

Recreational Outbreaks

Several recreational outbreaks of gastrointestinal illness from *Cryptosporidium* have been reported during recent years, both in the United States and abroad (Table 3.) Fecal accidents from a person with current or recent diarrhea were suspected in most of the outbreaks. Infected individuals may continue to excrete large numbers of infectious oocysts for weeks after symptoms cease (55). Attack rates during outbreaks have been estimated to be as high as 78% (56). Although there have been documented outbreaks of cryptosporidiosis associated with freshwater sources, many more cases have been associated with swimming pool exposures (57). This is not surprising because a single fecal accident can input high number of oocysts into a confined body of water, causing an immediate risk to the pools occupants. Further, the oocysts are extremely resistant to chlorine levels used in conventional swimming pools and their small size enables them to pass through filter systems, which are not operating optimally.

Table 3. Outbreaks of *Cryptosporidium* Attributed to Recreational Exposure

Date	Number of Outbreaks/Facility	Reference
1988	2/pool	(58,59)
1990	1/pool	(56)
1992	2/pool, 1/wave pool	(60,61)
1993	4/pool	(62,63)
1994	2/ pool, 1/lake	(64–66)
1995	1/pool, 2/water park	(67)
1996	1/water park, 2/pool, 1/lake	(68)
1997	1/river, 2/pool, 1/fountain	(69)
1998	4/pool	(70,71)
1999	1/fountain	(57)

Foodborne Outbreaks

Although *Cryptosporidium* appears to be spread more often by a waterborne route, contamination of food products either by infected food handlers or through the use of contaminated processing or irrigation waters has been documented (72–75). It has been suggested that the high prevalence of *Cryptosporidium* species in some food animals increase the risk for contamination of other food products.

In nonindustrialized countries, the use of excreta as fertilizer or the use of irrigation water that has been contaminated with industrial, domestic, or agricultural wastes can also lead to increased risk of foodborne cryptosporidiosis, especially from consumption of raw vegetables (76). In a study in Costa Rica, oocysts from *Cryptosporidium* species were detected in 5.0% of cilantro leaves, 8.7% of cilantro roots, and 2.5% of lettuce samples (77). In Peru, a survey of vegetables collected from small rural markets detected the presence of *C. parvum* oocysts in 14.5% of the samples that were collected (78). Although these studies reveal the presence of oocysts in raw produce, it is often impossible to detect the presence of *Cryptosporidium* oocysts in food products because of the lack of sensitive detection methods and the potential for inhibition of detection when using molecular methods. Similarly, the long incubation period and potential for person-to-person transmission of the disease make epidemiological investigation of potential foodborne outbreaks of cryptosporidiosis extremely difficult.

The first foodborne outbreak of *Cryptosporidium* in the United States was reported in 1993. The outbreak was associated with fresh-pressed apple cider (72). An environmental survey revealed that the apples had been collected from uncultivated trees on the edge of a pasture where cows had recently been grazing. The apples were harvested both from trees and from the ground. The apples were then stored overnight and sprayed with municipal water from a hose on the morning that the

cider was prepared. Frozen samples of the cider revealed the presence of *Cryptosporidium* oocysts at levels of 375 to 750 oocysts per liter. There were 160 primary cases of cryptosporidiosis with a 15% rate of secondary household illness transmission.

Three other outbreaks have been reported since then, one was associated with chicken salad, one with green onions, and the third was also associated with apple cider (73–75). Suspected foodborne transmission of *Cryptosporidium* has also been reported from travelers visiting Mexico, the United Kingdom, and Australia. Suspected foods include salad, raw milk, sausage, and tripe. It has been proposed that livestock infection and water contamination are the two major causes of food contamination with *Cryptosporidium* oocysts (26).

Cryptosporidium oocysts have currently been detected in shellfish such as oysters, mussels, clams, and other bivalves that were harvested from both U.S. waters and abroad (79,80). Studies have shown that shellfish are capable of concentrating pathogenic bacteria, virus, and parasites from the large volumes of water that they pass over their gills. Because many of these filter feeders are consumed raw, they can present a significant public health risk to consumers. Currently, no outbreak of cryptosporidiosis caused by the consumption of raw shellfish has been reported.

Zoonotic Transmission

Zoonotic transmission of the organism is well recognized, and domestic cattle have been implicated in both direct (fecal–oral) and indirect (via water) outbreaks of human infection (24,27). Seasonal peaks in the detection of *Cryptosporidium* oocysts in the environment tend to coincide with lambing and calving, in spring and autumn. Although symptomatic infection in animals generally occurs only in the very young, adult animals such as deer, horses, pigs, and sheep may excrete low number of oocysts (81). These adult animals may provide a reservoir for transmission of this organism to the young of their own species and also to humans. Studies conducted by the U.S. Department of Agriculture, Animal Plant Health Inspection Service, and Veterinary Services (82) have found *Cryptosporidium* species commonly in dairy and beef calves in the United States. It has been estimated that this parasite is present in more than 90% of the dairy farms and nearly 40% of the beef operations.

Companion animals, such as cats and dogs, have also been implicated in the transmission of cryptosporidiosis to humans on rare occasion (5,26). However, they may represent an important reservoir for human infection (83). A recent study using genetic sequencing of the small subunit ribosomal RNA (SSU–rRNA) has identified the first human cases of infection by a canine and a feline species of *Cryptosporidium* in AIDS patients (84). Transmission by arthropods and by houseflies and wild-filth flies that were exposed to feces containing Cryptosporidium oocysts has been documented (85–87).

Secondary spread of cryptosporidiosis through person-to-person transmission has been well documented within families, in day care centers, and also in other institutional settings (88–91). Day care centers have also been linked to transmission of cryptosporidiosis through contact with contaminated toys, surfaces, and other fomites (89). Although the main route of infection remains the fecal-oral route, *Cryptosporidium* oocysts have been detected in sputum and vomit, and these may provide alternate modes of transmission.

CONCLUSION

Cryptosporidium has been endowed with a number of physical and physiological characteristics that have enabled it to become an important cause of waterborne disease throughout the world. Although our body of knowledge, concerning the biology and epidemiology of this organism continues to grow, we have only recently gone beyond the tip of the iceberg with regard to understanding this organism's place in the microcosm of waterborne disease.

BIOLUMINESCENCE, METHODOLOGY

Pamela Contag
Xenogen Corporation
Alameda, California

Bioluminescence is the capacity of certain living organisms to emit visible light. The species that exhibit bioluminescence are found in many environments, but especially in the deep sea. They have achieved bioluminescence through different evolutionary processes. The responsible genes in bacteria, algae, coelenterates, beetles (fireflies), and fish are all unrelated to one another (4). The fundamental biochemistry of light production in these organisms consists of the oxidation of a luciferin, a cellular substrate, under the catalysis of luciferase enzymes, which produces, as a decay product of the chemical reaction, an almost heatless, bluish green light until the excited-state molecules return to the ground state. The luciferin substrates and the structures of the luciferase enzymes vary by organism, as do the mechanisms controlling the speed and intensity of the luminescence. Certain cofactors, such as the nucleotide ATP, may need to be present for the conversion of the substrate to take place (5).

Because these reactions can be replicated outside the organisms to which they are native, bioluminescence has proven extremely useful for research at the cellular and molecular levels (6). The availability of instrumentation that can measure the light emitted in these reactions with great sensitivity and dynamic range has made them powerful tools for biochemical and clinical analysis because the involved components can be detected at a very low level (7). Compared with other techniques, such as colorimetric or spectrophotometric indicators, bioluminescent analysis offers the advantages of high sensitivity, wide linear range, low cost per test, and relatively simple and inexpensive equipment (8). Because of their sensitivity, immobilized bioluminescent reagents have come into widespread use in biochemical analysis over the last 20 years.

Firefly and bacterial luciferases are the two most commonly used bioluminescent systems in research (5). The latter is the light-producing reaction of the North American firefly *Photinus pyralis*, which is also the most extensively studied bioluminescent system. Firefly bioluminescence, for example, allows the presence of the ATP nucleotide, which supplies energy to cells for many important biochemical processes, to be determined in reactions with extreme sensitivity (7). Although most enzyme assays yield either a product or the disappearance of a substrate, firefly luciferase acts as a quantifiable reactant rather than as a catalyst, whose most significant and easily measured product is light (9).

Bioluminescence has proven important for a wide range of disciplines central to the study of human disease, including hematology, immunology, bacteriology, and pharmacology, and clinical chemistry (8). More generally, it has stimulated studies in analytical biochemistry, molecular biology, cell-based assays, and various environmental applications (10).

Specific examples of bioluminescent-facilitated research include work with pathogens such as the *Mycobacterium tuberculosis*, which not only pose biosafety hazards but grow very slowly in laboratory conditions. An enhanced luciferase-expressing mycobacterial strain has been used to evaluate antimycobacterial activity in mice (11), permitting evaluation of drugs, with significant savings in time, labor, and expense. A pharmaceutical application, in vivo tracking of cells and monitoring of gene expression (12) has broad applications to the study of infectious disease. Currently, this technology has developed into widely applied methods for monitoring biological events noninvasively in living animals.

IN VIVO BIOPHOTONIC IMAGING

In vivo biophotonic imaging is a noninvasive means of tracking pathogens, tumor cells, or molecular events in live animal subjects that exploits the light-emitting properties of photoproteins such as luciferase enzymes. Typically, animal models for biological assessment represent late or end stages of a disease, usually require sacrifice of the animal, and employ cumbersome ex vivo assays to reveal the disease process. Moreover, much contextual information is lost that an in vivo analysis might yield, because late stage protocols, more distressful to experimental animals, are likely to miss important information about events in the early stages of a disease and from intact systems.

Biophotonic imaging holds great promise for the acceleration of data generation and analysis for the development of new drug candidates by the pharmaceutical industry.

This is because 80% of drug candidates fail to satisfy safety and efficacy requirements in clinical trials, and the need to conduct biological assessments in animal models to determine safety and efficacy is the principal obstacle in making the development process more efficient and effective. In vivo biophotonic imaging offers a rapid means of conducting in vivo analysis to improve the predictive quality of data used in the assessment of new drug candidates. The technology provides data sets from relevant, intact animal systems, increasing both the efficiency and the effectiveness of selecting new drug candidates for clinical development. Because it is an in vivo technology, fewer animals are needed, whereas time and costs are reduced and more data per protocol are obtained.

Before the advent of biophotonic imaging, noninvasive in vivo assays were based on magnetic resonance imaging (MRI), positron-emission tomography (PET), and X-ray (computerized tomography) technologies. Although these methods are useful for monitoring structural changes due to disease processes and, on occasion, the response to

therapy, they required relatively expensive devices that are not practical for use with most animal models and very long scan times. Moreover, specific contrast agents that could reveal the cellular and molecular changes relating to the disease processes were not readily available.

In vivo biophotonic imaging technology is based on the observation that light is transmitted through living tissue with efficiencies suitable for use in monitoring both structure and function. The external application of light as a biological monitor currently has both routine clinical uses (e.g., pulse oximetry) and novel experimental applications in medicine. Biophotonic imaging, however, employs photoproteins, internally emitted biological sources of light, to tag such biological functions as infection and gene expression (12–16).

Use of in vivo luciferase monitoring in living mammals was first described in 1995 with an infectious disease model, gastrointestinal infections by *Salmonella typhimurium* (12). This study indicated that the technique was not only feasible but that it yielded quantitative data that provided more information in less time than could be obtained from conventional assays. Because a large variety of bacterial species can be labeled with luciferase, this approach is generally applicable to microbiological investigations (see Fig. 1, Gastrointestinal infection with *S. typhimurium* and treatment with ciprofloxacin). Ongoing research is showing that mammalian cells can be labeled in the same way as bacterial species, indicating that the method is applicable to the evaluation of genetic- and cell-based therapies, anticancer drugs, studies of gene expression and development.

A significant advantage of in vivo luciferase monitoring is that bioluminescent tags allow for an integrated approach in which the same label can be used for in vitro, for quantitation and in cell culture correlates of in vivo processes, and then in vivo to test predictions made in vitro. In this way, a predictable animal model with highly correlative data can offer validation of an in vitro assay approach. Several parameters of drug efficacy and pharmacokinetics can be monitored in the same animal over time, yielding benefits for the discovery and development stages of drug evaluation.

In animal studies, the number of subjects required is reduced, and the issues of animal-to-animal variation are overcome by the zero time point functioning as an internal control, improving biostatistics. In bacterial models, bioluminescent tags are useful for distinguishing infecting pathogens from normal flora.

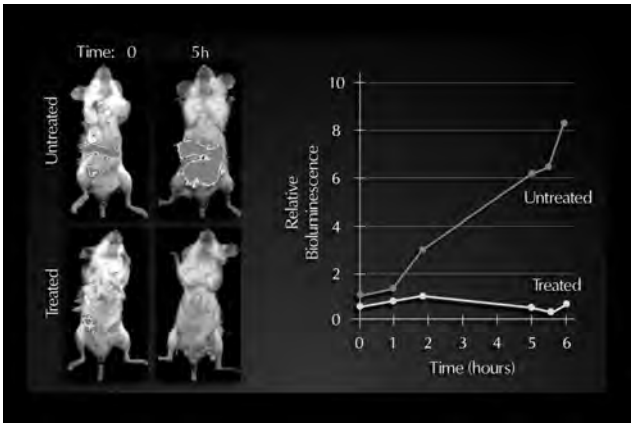

Figure 1. Gastrointestinal infection/Salmonella. The pseudocolor image is a color depiction of the intensity and quantity of photons with red being most intense and violet least intense. Untreated and treated mice are depicted at time zero (eight days after oral inoculation) with SL1344 lux *S. typhimurium*, but before treatment with ciprofloxacin. The same mice were imaged five and a half hours after treatment with ciprofloxacin (untreated control-received injection of phosphate-buffered saline). The graph shows relative bioluminescence intensity measured from the abdominal area at the time after treatment for both treated and untreated animals. See color insert.

METHODOLOGY

Labeling Bacterial Cells

Lux operons are ideal for labeling bacterial pathogens because they not only encode the luciferase genes but also the genes for the biosynthetic enzymes (fatty aldehyde synthases) for the substrate decanal. Use of these operons obviates the need for an exogenous supply of substrate. Few deleterious effects of substrate biosynthesis on bacterial metabolism or virulence have been observed. Among the *lux* operons from bioluminescent bacteria, which from *Photorhabdus luminescens*, previously known as *Xenorhabdus luminescens*, appears to be ideally suited for use in mammalian models (17,18), given that mammalian body temperatures lie within the temperature optimum for this enzyme (19–21), unlike beetle luciferases (*Luc*) and other characterized bacterial luciferases (from the genus Vibrio) that have low-temperature optimum.

Well-characterized vectors are used for the expression of the *lux* operons in gram-negative organisms. The original pUC-based plasmid used to clone the *lux* operon from *P. luminescens*, including the promoter region (vector designated pCGLS1) is well suited for expressing luciferase from common gram-negative organisms such as *Escherichia coli* and *Salmonella* (19,21,22). Standard methods of bacterial cell transformation for these organisms are used to introduce the *lux*-encoding vector into cells of these bacterial species.

Bacteria may be labeled with luciferases from either a bacterial or eucaryotic source (as shown in Fig. 2). Several arrangements for the expression of luciferase have been used, namely, the *lux* AB genes from firefly with luciferin as the substrate, the *lux* AB genes from *Vibrio* or *Photorhabdus* with decanal as substrate, or finally the entire *lux* operon from *Photorhabdus* with no exogenous substrate requirement.

Transposon-based vectors have been used to introduce *lux* genes modified for optimum expression in both gram-positive bacteria, such as *Staphylococci* and *Streptococci*, and gram-negative organisms outside the *Enterobacteriaceae*. The in vitro sensitivity for the labeled bacterial strains is approximately 10 to 100 bacterial cells (*Salmonella*, LB5000 lux) that yields a signal in culture over background, regardless of whether an absorbing and scattering biological medium such as blood is present. The lower limit of detection in some in vivo models is 1,000 bacterial cells.

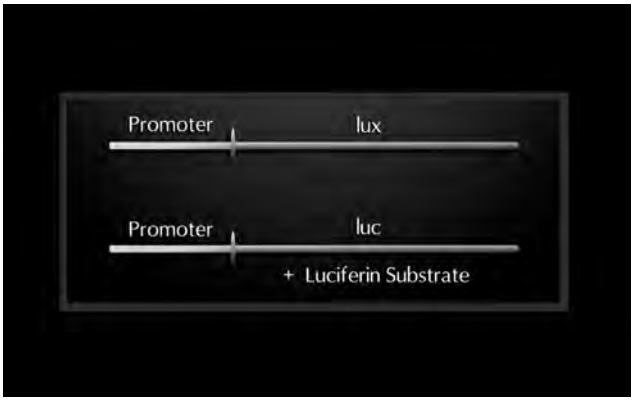

Figure 2. Prokaryotic expression. For expression of light from prokaryotic cells, a construct is used that includes the *lux* operon from *P. luminescens* in an appropriate gram-negative or gram-positive plasmid vehicle. More recent constructs include transposons for chromosomal integration. Expression of the *luc* gene from the North American firefly may also be used in prokaryotes as long as the luciferin substrate is administered. See color insert.

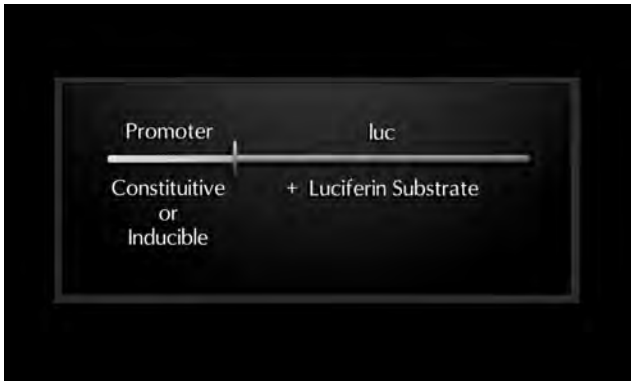

Figure 3. Eukaryotic expression. Expression of light from Eukaryotic cells may be accomplished with the *luc* gene of the North American firefly regulated by an SV40 viral promoter. Luciferin is administered introperitoneally as the substrate for the enzymatic reaction. See color insert.

Cell culture correlates for pathogenesis and expression can provide a rapid means of evaluating tagged events before introduction into living animals. Although correlates have not been established for some systems (e.g., propagation of human papillomavirus), when they are available, they can accelerate the development of in vivo assays and, in combination with luciferase tags, the same reporter can be used in vitro, in vivo, and finally as an ex vivo assay to confirm in vivo observations. In the case of bacterial infections, such assays have been described for many organisms, and some have been adopted for use with bioluminescent reporters, including for microscopic detection. In the case of mycobacterium, use of luciferase as a reporter can significantly accelerate in vitro assays and such labeled strains have also begun to be used in vivo.

Cultured Mammalian Cells

Reporter genes, such as firefly luciferase or variants of green fluorescent protein (GFP), in transformed cells can be employed to reveal the molecular and cellular features of cancer. In a recent study (23), tumor cells were labeled with pGL3, a luciferase gene driven by the SV40 viral promoter. Eucaryotic expression of the firefly luciferase in both cultured tumor cells and transgenic animals is accomplished by placing a constitutive or inducible promoter in front of luciferase, transfection of the vector into the chromosome, and then finally, the light from luciferase expression in stable transfectants is seen following the addition of luciferin (see Fig. 3).

Determination of Luciferase Activity Ex Vivo and In Vitro

A commercially available assay kit that includes acetyl CoA to prolong light emission can be used to determine luciferase activity for the firefly enzyme expressed in mammalian cells for tissue homogenates. Tissues are removed and homogenized with a tissue disrupter in minimal volumes. A lysis buffer containing luciferin, ATP, and acetyl CoA is added to samples and read in a standard luminometer.

For cells in culture, 10 μl of a 15 mg/mL stock solution of luciferin (per 1 mL of medium) is added to cells for a final concentration of 150 μg/mL. Cells are imaged immediately after substrate addition. Bioluminescent signals are apparent in these cultures hours later. Increased bioluminescent signals are obtainable by increasing the substrate concentrations. An ultrasensitive camera is used to measure the signals in living cells. The cells can be lysed and luciferase activity measured in a luminometer with the standard assay procedure if the signals produced, are too weak to be detected by camera.

Substrate Delivery to Tissues

An aqueous solution of the substrate, luciferin (50 mM), is injected into the peritoneal cavity 20 minutes prior to imaging for systemic delivery at a dose of 126 mg/kg. Alternatively, substrate can be applied topically (50 mM) in 100% DMSO for transdermal delivery to monitor luciferase expression in the skin. Luciferin has also been electroporated (ionophoresis) into the skin of the ear, using a caliper electrode connected to an electroporator. The duration of detectable luciferase activity in tissues varied with the different modes of delivery. With introperitoneal (IP) delivery, peak activity is detected at 20 minutes in the brain and at five minutes in other tissues with proximity to the peritoneal cavity.

Anesthesia

For imaging, mice and rats were anesthetized using pentobarbital (35–70 mg/kg body weight) (12). Low doses are used with neonatal mice and rats sensitive to the effects of pentobarbital. Animals are observed carefully while under anesthetic and their respiration is monitored. Following the imaging, the animals are kept warm and allowed to recover.

Imaging

Anesthetized animals need to be placed in a light-tight box. A gray-scale body surface image is collected

for reference in low light. Even the smallest light leaks can present significant background when using sensitive imaging devices and long integration times. The potential sites for light leaks are the door closure, camera mount (if camera is mounted externally), and the entry point for the cables (if camera is mounted internally).

Photons emitted from luciferase within the animal, and then transmitted through the tissue, are collected and integrated for 5 to 30 minutes. A pseudocolor image representing light intensity (generally blue representing least intense and red representing most intense light) is generated on an image processor. The images are transferred using a plug-in module for image processing software to a microcomputer. Gray-scale reference images and pseudocolor images are superimposed using the image software, and saved as PICT files. Superimposed images are opened within a graphics software package and composites made and annotations added. An intensified charge coupled device (CCD) camera, described in the following section, outfitted with a 50 mm f 1.2 lens and an image processor, has been successfully used in research studies.

Use of the CCD Camera

Low light imaging systems employ technologies that either reduce the background noise or increase the signal. By cooling the CCD chip in a video camera to temperatures of about $-30\,^{\circ}C$ the background caused by infrared irradiation (so-called *thermal noise*) can be reduced permitting detection of low light signals. An alternative is to specifically increase the signal using an image intensifier. Intensifiers are designed around a high voltage microchannel plate technology that amplifies signals in the form of electrons. A photocathode is used to convert photons to electrons that are then amplified over the microchannel plate; the increased number of electrons contact a phosphor screen generating photons that are then focused on a CCD video camera. The materials used in the photocathode determine the spectral sensitivity of the intensifier. To reduce thermal noise blue-sensitive materials can be employed. Alternatively, thermal noise on the intensifier is reduced by cooling intensifiers with photocathodes made of materials that are sensitive to longer wavelengths of light-cooled intensified cameras.

In a comparison between a cooled camera and an intensified camera, essentially equivalent signals are obtained from neonatal Tg mice expressing luciferase in their eyes and skin. In adult mice with bioluminescence originating from deeper tissues, differences have been apparent between cooled intensified systems (sensitive to light $\leq$850 nm) and the C2,400-32 ICCD camera (sensitive to light $\leq$600 nm). This is likely because of a suspected filter effect of the tissues in which shorter wavelengths of light are more readily absorbed by mammalian tissues, and the longer wavelengths of light (luciferases have rather broad spectral peaks of up to 50 mm bands) may preferentially pass through tissues and more red-sensitive instruments may be well suited for collecting this light.

Applications and Discussion

In vivo monitoring of luciferase is widely applicable for tracking pathogens and other disease processes, yielding more information in less time than conventional assays. Noninvasive monitoring of light emitted from within a living mammal, in which the light is constitutively expressed or is reporting fluctuations in gene expression, is a platform technology that results in increased information about specific physiological processes as well as integrated, whole biological systems. The monitoring of biological light requires less time and fewer animals, reducing the cost of analyses. This is especially relevant to the costly processes of drug discovery in which significant advances have been made in generating large numbers of potentially useful therapeutic compounds (e.g., combinatorial chemistries, genomics, and high-throughput screening).

In the absence of significant advances in in vivo analyses, the bottleneck in drug development is at the animal model step, and improvements in the earlier steps only accentuates this problem. In vivo luciferase monitoring addresses this limitation (16) with broad applications.

In studies of infectious disease, for example, the in vivo biophotonic monitoring technology can be superimposed over current methodology to perform faster experiments, and use fewer animals, while still extracting relevant data that provides more information relating to early stages of disease and patterns of disease.

In Figure 4, a lung model illustrates a high level of bacteria in the lung and nasopharangeal area that can be specifically characterized as pneumonia, with the lungs clearly outlined. In Figure 5, a typical model used to evaluate antibiotics, the soft tissue thigh model, can now be used as a fast screen for effective antibiotics. Biophotonic imaging allows this model to be run in half the time of the traditional thigh model. In Figure 6, labeled tumor cells allow researchers to follow the expansion and regression of tumors in response to therapy. This is especially important as tumor diagnostics leap ahead and

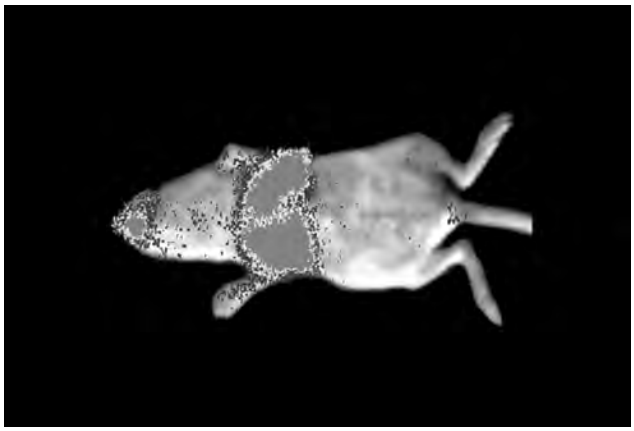

Figure 4. Lung model. Neonatal mice (under two weeks of age) are susceptible to lung infection following oral inoculation with *S. typhimurium* SL1344 lux. A nasopharyngeal infection is common in both adults and neonates from this mode of inoculation. See color insert.

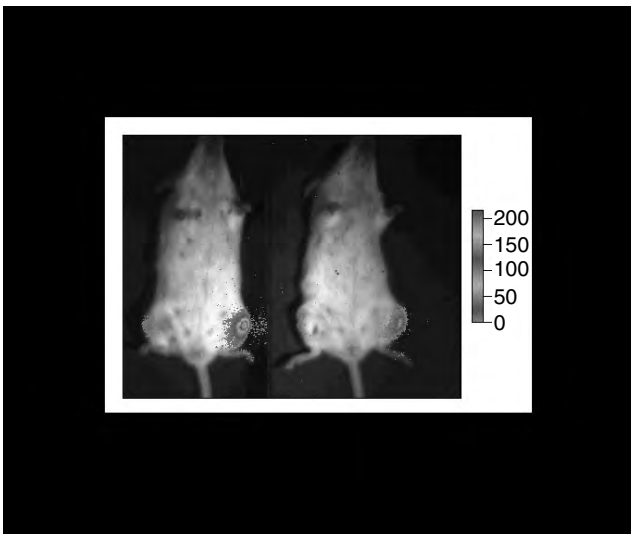

Figure 5. Soft tissue thigh model *Lux* tagged *E. coli* are injected at 10^4 bacteria/mL (right thigh) and 10^5 bacteria/mL (left thigh). Bacteria can then be quantified noninvasively with and without antibiotic treatment. See color insert.

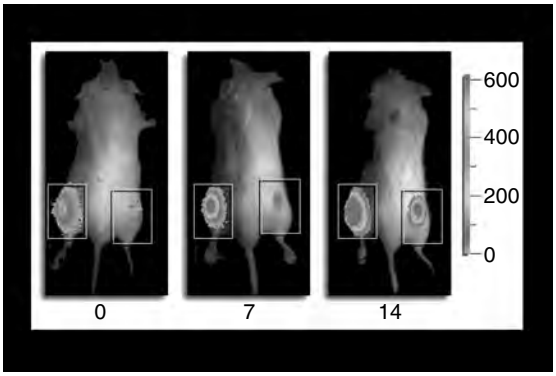

Figure 6. Labeled tumor cells. Labeled NIH 3T3 cells were injected with matrigel at zero time [10^4 cells (right thigh) and 10^5 cells (left thigh)] and mice were imaged between 7 and 14 days to monitor the increase in cell number, as demonstrated by the increase in red pixels of the pseudocolor image. See color insert.

we need tumor therapies that provide earlier intervention in the disease process. Virtually the first steps in the disease can be monitored, including metastatic disease.

Light-producing transgenic animals have allowed scientists to follow gene expression spatially and over time. The power of this technology rests in the ability to measure from baseline to maximum gene expression in one animal over time and during the changing conditions of disease state, therapy, and toxic events. We can now begin to understand the relationship between the level at which a gene is expressed in any given animal and the concomitant change in phenotype. Thus, it is possible to have surrogate markers of gene expression for specific biological events.

In a recent study, a transgenic animal was created using the promoter for hemooxygenase (also known as *heat shock protein* (HSP) (32)) placed in front of luciferase. Thus, because the endogenous gene was not altered, events that

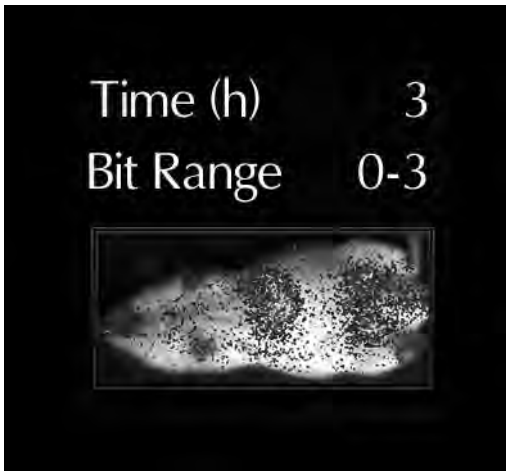

Figure 7. Transgenic animal exposed to heavy cadmium. A mouse line transgenic for a cadmium-regulated element, the hemooxygenase promoter, demonstrates in vivo monitoring of cadmium induction of *luc* in front of the *luc* gene. 10 mM cadmium was delivered IP and the mouse was imaged at zero and three hours. The three-hour time point with a camera sensitivity set at a bit range of zero to three is shown here. See color insert.

affect gene expression can be monitored noninvasively. This transgenic animal was exposed to the heavy metal cadmium, which is known to induce gene expression, and three hours after exposure, the liver and testes show a specific increase in gene expression (see Fig. 7). The changes in gene expression were monitored and it was demonstrated that they occurred in a dose-dependent fashion. By Northern analysis it was also demonstrated that HO protein was present.

CONCLUSION

It has been demonstrated that in vivo biophotonic imaging can deliver higher throughput animal models for a variety of pharmacological screens. The variety of animal models that this technology can be applied to is very broad and includes bacteria (gram-negative and gram-positive) and tumor models. Increasing the efficiency of the drug development process, although laudable, is only a small part of the story.

Gene sequencing has made it possible to assess the relatedness of species. More recently, there have been increases in our ability to group genes into families and to draw possible conclusions about relatedness of function. But what remains elusive is a true understanding of pathways, system connections, and the multifunctionality of genes in metabolism and development. This is because our in vitro assays are essentially two-dimensional; pathways may be connected but total systems, such as the central nervous system, and the immune system are not part of the assay. Current animal models are less robust than desired because of artifacts of ex vivo analysis and end points that do not reveal the biological process. In vivo biophotonic imaging, however, allows real-time data to be collected noninvasively; thus, the animal subject functions as its own internal control. This means that investigators

are no longer limited to a snapshot of biological data but now can watch the actual process of metabolism and disease.

Bioluminescent-based assays have also shown promise as a means of rapidly and reliably measuring biological and chemical contamination of the environment and for detecting pathogens that are undetectable by standard techniques, yet still threatening to human health (5). Other recent environmental applications include luciferase-based measurement of water contaminants (24), luminescence-facilitated detection of mercury in natural waters (25), and firefly luciferase-tagged bacteria in environmental samples (26).

The ability to collect quantitative data that preserves spatial and temporal context with extraordinary sensitivity opens new avenues for exploring in situ various environmental mechanisms of growth, colonization, and community structure and organization. Using a bacterial biosensor (27,28) that produces light in the presence of a particular signal would be very helpful in isolating crucial molecular communication among bacteria. We may speculate that this knowledge, along with two to three-dimensional organizational structure, would give us a clearer picture of microbial communities in nature.

BIOMASS: SOIL MICROBIAL BIOMASS

WILLIAM R. HORWATH
University of California
Davis, California

Soil microbial biomass is an important component of soil that regulates many processes associated with energy transfers and nutrient cycling. These functions are critical to maintaining ecosystem productivity at all levels of the food web. The soil biomass is composed of a wide range of microorganisms including viruses, bacteria, fungi, microfauna, and macrofauna. The soil microbial biomass expresses functions to take advantage of the multitude of soil niches composed of different habitats and substrates. These functions range from pathogenesis, symbiosis, and heterotrophic to chemoautotrophic activities.

The soil microbial biomass is a component of the soil that is considered to be part of the active fraction. The active fraction includes the microbial biomass, recently deposited plant residues, root exudates, and easily degradable portions of the soil organic matter such as light fraction, which are thought to play a prominent role in nutrient cycling and major energy transfers (1). In most soils, the soil microbial biomass comprises about 5% of total soil carbon and about 1% of total soil nitrogen (2). The microbial biomass is most active in the surface soil where most of the recent plant and litter inputs, mainly from above and belowground production and turnover, provide substrate (food) for microbial activity. Deeper soil horizons contain less plant input, and therefore a corresponding decrease in microbial population size and activity. However, in most soils, microbial biomass is present at all soils depths to the depth of the bedrock including deep sediments of 1,000 feet or more (3).

The most important function of the soil microbial biomass is decomposition of organic material. During decomposition, the microbial biomass releases nutrients from plant litter and gains energy for metabolic processes. Without this function, dead plant material would accumulate and limited nutrients would be available for plant uptake. Depending on the quality of litter, the microbial biomass either utilizes the nutrients (immobilize) or if there are excess of nutrients, they become available (mineralize) for other organisms or plant uptake. In this respect, the soil microbial biomass acts as a source and sink for nutrients in the soil. For these reasons, the soil microbial biomass is the main regulator of nutrient cycling in the soil, and therefore, regulates net primary production of ecosystems.

The importance of the soil microbial biomass goes beyond nutrient cycling. One of the important by-products of decomposition is the formation of stable organic matter. The soil organic matter, through its interaction with minerals, serves many functions that increase soil quality through enhancement of physical, chemical, and biological characteristics of the soil matrix. An important consequence of an increase in soil organic matter is the storage of vital plant nutrients, such as nitrogen, phosphorus, sulfur, and trace metal elements. The diversity of soil microbial biomass leads to other important biogeochemical processes, which regulate gaseous flux of carbon, nitrogen, and other nutrients. In contrast, other functions of the soil microbial biomass, such as the production of growth regulators, can serve to be detrimental or enhance plant growth. The amazing diversity of the soil microbial biomass is the foundation of a complex ecosystem component that regulates the productivity of the earth's biomes. This article will concentrate on the soil microbial biomass, which is composed mainly of bacteria and fungi and will emphasize carbon and nitrogen cycling in soil.

HABITAT OF THE SOIL MICROBIAL BIOMASS

Soils are formed through the dissolution of primary minerals and subsequent reformation of secondary minerals, such as clays and sesquioxides. The secondary minerals are rich in ion exchange activity and form stable complexes with organic matter. The interaction of minerals and soil organic matter lead to the formation of soil structure through the creation of aggregates and porosity. This complex three-dimensional matrix produces a wide variety of habitats in which the soil microbial biomass exist. The three-dimensional matrix is composed of solid, liquid, and gas phases. Characteristically, a well-developed soil contains 50% solids and 50% pores. The pores in the soil matrix contain the soil solution and air. The ionic exchange capacity of the minerals act to adsorb nutrients required for the growth of the soil microbial biomass and act as a surface to exist on. The wide array of habits in soil creates a complex predator-prey interaction, which is unrivaled compared to aboveground ecosystems (Fig. 1).

Soil microorganisms inhabiting larger pore areas are subject to grazing by larger organisms, such as protozoa and nematodes. However, soil organisms living in larger spaces normally have access to a greater food supply through the movement of the soil solution and exploration by plant roots. Microorganisms inhabiting smaller areas, such as capillary spaces, are protected from predation by larger organisms. However in these confined spaces, microorganisms are often subject to oxygen limitations

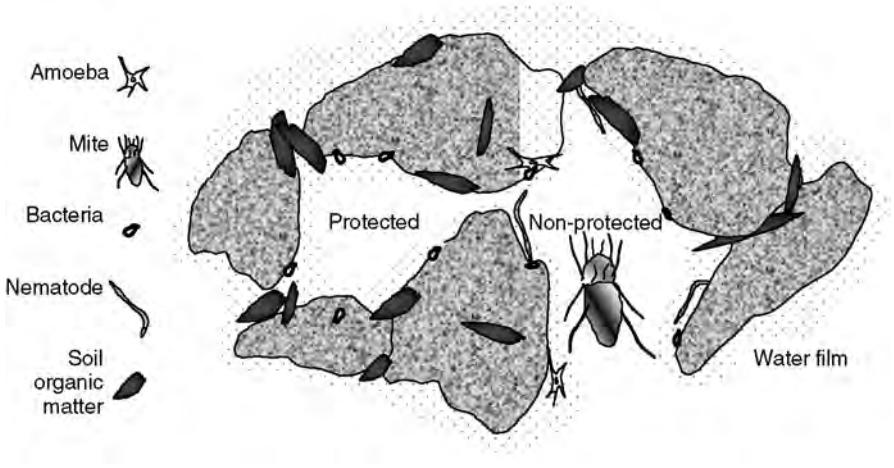

Figure 1. Depiction of the soil habitat showing soil structure and the interaction of organisms inhabiting various niches. The trophic level interactions depict protected and nonprotected regions of the soil matrix.

and substrate availability. The variety of habitats is directly responsible for influencing the immense diversity of the soil microbial biomass. Through long-term adaptive strategies microorganisms have adapted to these specialized niches in the soil.

The ecological theory that examines the distribution of species based on substrate availability and growth involves the concept of r and K selection (4). A soil microorganism adapted to bountiful energy and nutrient sources are designated as r-selected. Microorganisms existing under low energy and nutrient deprived conditions are termed K-selected. Selection pressures and physical environment would be unique to r- and K-selected organisms leading to diversity of function (5). The K-selected organisms would strive to produce a high growth- rate per unit of substrate because food supply would be erratic in the smaller capillary pores or protected spaces in the soil. The r-selected organisms on the other hand would put much energy into competitiveness to be able to survive the predation pressures, which exist in the larger soil pore spaces. This interesting ecological hierarchy has led to the notion of protected and nonprotected soil microorganisms (1). The concept has been widely used in simulation efforts to describe microbial activity in soil. It is believed that K-selected or protected organisms live mainly dormant existences until exposed to a new food supply. Predation pressure, substrate availability, and specialized habitats lead to selection of microorganisms with specific functions creating a complex nutrient cycle for all of the essential elements in soil.

THE COMPOSITION OF THE SOIL MICROBIAL BIOMASS

The soil microbial biomass is composed of a large number species that vary widely in their function. The soil microbial biomass is generally considered to be composed primarily of bacteria and fungi. Bacteria and fungi normally compose over 70% of the total soil biomass (Table 1). Faunal components make up a significant portion of the total soil biomass and also contribute to carbon cycling and other biogeochemical processes. The importance of the microbial and faunal components of the soil biomass to soil processes can often lead to a contentious debate among scientists. The size of soil microbial biomass and all of its major components is described in Table 1. (see SOIL BACTERIA and SOIL FUNGI: NATURE'S NUTRITIONAL NETWORK, this Encyclopedia, for more information on these soil organisms).

Table 1. The Mass of Soil Biomass Components in Soil

Soil Biomass Component	Tonnes Per Hectare
Bacteria	1 to 2
Fungi	2 to 5
Actinomycetes	1 to 2
Protozoa	Up to 0.5
Nematodes	Up to 0.2
Earthworms	0 to 2.5
Other fauna (collembola, mites, arthopods etc.)	Up to 0.5

Source: K. Killham, *Soil Ecology*, Cambridge University Press, New York, 1994.

Because they represent the majority of the soil microbial biomass, bacteria, and fungi are considered responsible for the majority of the energy flow and nutrient cycling that occur in soil. However, the faunal component of the soil biomass is responsible for influencing the size of the soil microbial biomass through predation thus influencing their ability to process plant litter and soil organic matter. Soil fauna also increases microbial substrate availability by physically burying plant litter in the soil. Larger soil fauna are also responsible for reducing the size of plant litter thus increasing its surface area, making it more accessible to the soil microbial biomass.

The functional diversity of the soil microbial biomass is required to be able to take advantage of the wide array of plant materials and habitats found in the soil. The soil represents an oligotrophic environment, becoming more nutritionally limited as the depth of soil increases. In the soil surface, soil aggregates also represent oligotrophic environments. For example, the interior of an aggregate may have extremes in pH, aeration, and redox potential. The soil has a wide variety of these niches, sometimes called hot spots, producing an array of microhabitats,

which maintain the immense diversity of the soil microbial biomass.

DISTRIBUTION OF THE SOIL MICROBIAL BIOMASS

The soil microbial biomass requires energy, nutrients, and habitat to exist. The soil horizon containing the most organic matter, nutrients, and plant influence normally contains the most soil microbial biomass. Soils are typically composed of distinct layers or horizons formed from the depositional, eluvial, and illuvial processes. The surface soil horizon, called the A horizon, is generally rich in organic matter as a result of plant litter deposition and root turnover. Eluvial and illuvial processes and plant root exploration deposits organic matter and nutrients in deeper soil horizons. Deep sediments and buried soils can also contain significant amounts of organic matter, however the bulk of the organic matter is usually located in the A horizon. Beneath the A horizon is the B horizon, which often contains appreciable amounts of eluviated clay or other amorphous minerals, depending on soil age. Beneath the B horizon is the C horizon containing unweathered parent material. Having additional or not well-defined horizons can often complicate soil horizon determination. The A horizon, because of the large organic matter input from the above- and belowground plant production, forms a friable structure because of a wider range of aggregates sizes promoting good aeration and moisture holding capacity. For these reasons, the greatest number of microorganisms exist in the A horizon (Fig. 2).

There are a number of exceptions in which the number of microorganisms can be influenced by soil characteristics such as the type of mineralogy, ecosystem, and water regime. A young or highly weathered old soil may influence the number of microorganisms because of low organic matter content. An example of this type of soil is a tropical soil, which is highly weathered and contains most of its organic matter in a quickly decomposed litter layer. Conifers forests and bogs, often produce acidic soil affecting the number of microorganisms in the upper soil layers. Extreme climatic conditions produce soils with prolonged dry (arid) or wet (aquic) regimes. Arid soils can accumulate salt and/or sometimes sodium causing high electrolyte potential in the soil solution thus affecting the number of microorganisms. On the other hand, in wet climates the landscape often contains areas with frequent or sustained high water tables leading to lower aeration and thus a decrease in the activity of microbial biomass.

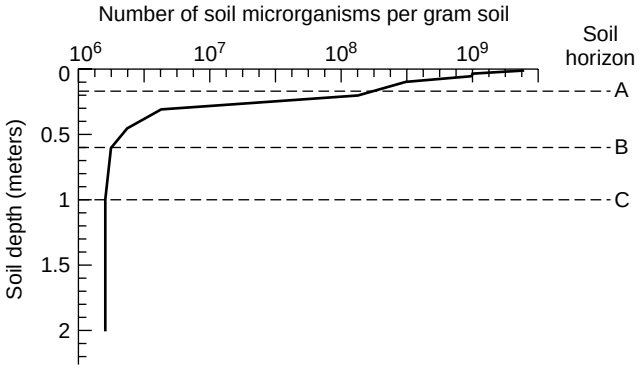

Figure 2. The carbon and nitrogen cycle in soil.

The rhizosphere effect or plant root effect dramatically affects the number of microorganisms distributed throughout the soil profile. In the vicinity of plant roots, high microbial activity exists due to increased deposition of compounds, such as amino acids and carbohydrates. The rhizosphere affect exists wherever plant roots explore different soil horizons. The rhizosphere effect is temporary and is maintained as long as the plant root is alive and immediately following its death during decomposition processes.

METHODS TO ASSESS MICROBIAL BIOMASS IN SOIL

The size of the soil microbial biomass is primarily dependent on soil type and ecosystems productivity. Finer textured soils and soils with more silt and clay tend to have a larger soil microbial biomass. Finer textured soils have more surface area and structure leading to greater number of niches for the soil microbial biomass to inhabit. Plant detrital input from aboveground production and root turnover regulates the size of the soil microbial biomass through substrate (food) availability. Other factors, such as soil temperature and moisture, also regulate the soil microbial biomass but manifest themselves more in regulating microbial activity and turnover. The following discussion will focus on methods to determine soil microbial biomass carbon and nitrogen. These two elements have been examined extensively especially in their relationship to nutrient cycling in soil. A multitude of other methods exist to describe specific microbial components and are described elsewhere in Quantification of Microbial Biomass, this Encyclopedia)

Collection of Soil Samples

The appropriate selection of soil samples dictates the kind of information needed to assess soil microbial biomass size and activity. Soils are not uniform and often vary dramatically on scales of less than a meter. Table 1 lists the physical, chemical, and biological factors, which influence the distribution in size of the soil microbial biomass.

One of the most important considerations when taking soil samples is the representativeness of the sample. Nontypical areas, such as low spots, steep slopes, eroded areas and so on should be avoided if they represent only a small fraction of the landscape of interest. Statistically speaking, soil sample collection should strive for reducing the error of the measurement to less than 20% and preferably 10% of the sample population mean. Depending on the uniformity of a landscape, 4 to 10 samples are required to determine statistical significance when comparing treatments or other experimental variables. Compositing a number of soil samples to produce up to five individual samples may often reduce the error of the measurement. Heterogeneous landscapes may require a form of geostatistics called “Kriging” to determine the dependence of soil properties on microbial biomass size or activity.

Soil samples taken under field conditions should be stored at 4°C until analyzed. If samples cannot be immediately transported to the laboratory, they should be stored at field soil temperatures taking care to avoid exposure to direct sunlight. Soils samples should be analyzed within one week after sampling and preferably in less than three days (6).

Microscopy

The oldest method used to examine soil microbial biomass size is microscopic examination. Dutch merchant A. Van Leeuwenhock first saw microorganisms through a microscope in the seventeenth century. The examination of a dispersed soil suspension is the most common procedure for counting soil microorganisms with a microscope. The advent of fluorescence microscopy utilizing ultraviolet light combined with flurogenic vital stains, which fluoresce under ultraviolet light enables the observation of living microorganisms in a soil dispersion preparation (7). Many stains have been developed to assist in identifying microorganisms in the dark background of a soil dispersion. Dyes that bind DNA (acridine orange) sulfhydryl groups in protein (5-(4,6-dichlorotriazin-2-yl) aminofluorescein) and helical DNA (4,6-diamidino-2-phenylindole-2-HCl) are available. Other dyes can probe metabolic activities, such as electron transfer, with the reduction of sensitive dye tetrazolium chloride. Immunofluorescent techniques using specific antigens are also available to count specific bacteria or fungal groups or species. The use of dyes and microscopic counting permits counting of both bacteria and fungi to estimate their mass in soil. Many of the methods to determine microbial biomass size and carbon and nitrogen content are calibrated using the microscopic counting techniques.

The volume of carbon and nitrogen and their content in the soil microbial biomass can be estimated using microscopic counts of bacteria and fungal hyphal length. Bacteria and fungal volumes and mass can be derived using average cell lengths and diameter. The number of microorganisms and their approximate carbon and nitrogen content can be determined as shown in the formulas presented in Table 2.

The carbon content of bacteria and fungi is assumed to be constant using the factors shown in Table 2. The nitrogen content of bacteria and fungi can be estimated assuming a carbon to nitrogen ratio of six to one for bacteria and eight to one for fungal biomass. The carbon to nitrogen ratio for bacteria and fungi were developed from pure culture studies. The carbon to nitrogen ratio under field conditions may vary substantially depending on substrate availability and species, leading to some uncertainty in the exact estimation of microbial carbon and nitrogen. Besides estimating true carbon and nitrogen contents, other limitations of microscopic counting include the tedious nature of counting microorganisms and soil colloidal interference. These shortcomings often lead to nonstandard approaches among users of microscopic counting techniques. Chemical analysis of soil microbial biomass carbon and nitrogen can avoid some of these problems; however, it must be stressed that these methods are calibrated with the microscopic counting technique.

Table 2. Soil, Environmental, and Organismal Factors Affecting the Distribution and Activity of the Soil Microbial Biomass

Soil Factor	Environmental Factor	Organismal Factor
Mineralogy	Rainfall	Plant cover
Parent material	Temperature	Net primary production
Soil age	Rain shadow	Vegetation history
Topography	Exposure (north vs. south)	Animal (grazing)
Soil pH	Elevation	Human influence
Water-holding capacity	Landscape depression	Animal (burrowing)
Water infiltration	Water springs	
Particle size(sand, silt, and clay)	History of burning	
Bulk density (g/cc)	Cultivation	
Soil organic matter content	Riparian influence	
Fertility	Pollution	
Erosion		

Chloroform Fumigation Incubation Method to Estimate Soil Microbial Biomass

A number of chemical techniques have been used to estimate soil microbial biomass and activity. The most popular approach to estimate soil microbial biomass is the use of chloroform vapor followed by incubation. Other methods utilizing chloroform with direct extraction techniques and metabolic approaches have also been utilized (6). Exposing the soil microbial biomass to chloroform vapor dissolves lipids in their cell walls allowing the cytoplasmic constituents to leak into the soil. For the determination of microbial carbon and nitrogen, the soil can be incubated for 10 days following exposure to chloroform vapor and the amount of carbon dioxide and ammonium determined (8). Because not all microorganisms are killed during the chloroform-fumigation procedure, the surviving biomass quickly consumes the labile components of the dead biomass mineralizing both carbon and ammonium. The fraction of the mineralized carbon and ammonium is used to estimate the original standing microbial biomass (9,10). Soil microbial biomass carbon is calculated as follows:

$$B_C = \frac{F_C - UF_C}{0.41}$$

Where B_C is soil microbial biomass carbon, F_C is the carbon dioxide produced from the chloroform treated soils after 10 days of incubation and UF_C is the carbon dioxide produced in an untreated control sample during a period of 10 days following a preincubation of 10 days (8). The proportion (0.41) used to convert the measured carbon dioxide into standing microbial biomass carbon was determined using radioactively labeled microbial biomass (9). The use of the 10- to 20-day control often leads to small or negative microbial biomass carbon values leading to the following equation, which subtracts

a partial control:

$$B_C = \frac{(F_C - F_C K_1) - (UF_C K_2)}{0.41}$$

Values for K_1 and K_2 are 0.29 and 0.23, respectively. The use of this formula strongly correlated to soil microbial biomass estimations obtained by microscopic counting (11). The preceding equation corrects for control soils having high background carbon dioxide production rates. These types of soils often have high organic matter content or recently added plant residues.

The determination of soil microbial biomass nitrogen is calculated with the following equation:

$$B_N = \frac{F_N - UF_N}{0.54}$$

Where B_N is soil microbial biomass N, F_N is the ammonium mineralized in the chloroform treated soils and UF_N is the ammonium mineralized in an untreated control sample incubated for 10 days in conjunction with the chloroform-fumigated sample. The proportion (0.54) used to convert the measured ammonium into standing microbial biomass nitrogen was proposed for samples with a F_C to F_N ratio of <6.7 (9). As with microbial carbon, the use of the 0- to 10-day control often leads to small or sometimes large microbial biomass nitrogen values, which can be corrected using the following equation:

$$B_N = B_C \left(K_C \left(\frac{F_N}{F_C} \right) + \frac{1 - K_C}{L} \right)$$

B_C is soil microbial biomass carbon, F_C is carbon dioxide produced in the chloroform treated soils, K_C is the proportion of microbial carbon mineralized after fumigation and L is the carbon to nitrogen ratio of the post chloroform-fumigated biomass (12). The chloroform fumigation of soils to estimate soil microbial biomass carbon and nitrogen has been used extensively to determine microbial biomass size and processes associated with nutrient cycling.

CARBON AND NITROGEN CYCLING

The soil microbial biomass is the "waste management" crew of an ecosystem. The enormous amount of plant detrital material produced annually is processed by the soil microbial biomass and other faunal components of soil. The processes that degrade and consumes plant litter, both leaves and roots, play an important role in maintaining the global carbon budget by balancing the carbon dioxide fixed through photosynthesis and released through decomposition activities. A by-product of the consumption and respiration of plant litter is the production of waste materials. These waste products, consisting of unpalatable plant litter components and microbial products, form soil organic matter, a relatively stable pool of soil carbon. Soil organic matter represents approximately two-thirds of the total terrestrial carbon pool (13). The importance of this large carbon pool lies in its ability to store nutrients and alter soil properties, which affects net ecosystem productivity. In addition, the large store of soil carbon acts as a buffer in regulating atmospheric carbon dioxide. Manipulating the soil carbon pool through increased storage of organic matter is thought to be a viable soil management approach to mitigate rising levels of atmospheric carbon dioxide and associated global warming effects. Therefore, the importance of the soil microbial biomass cannot be understated in its ability to influence ecosystem carbon and nutrient budgets.

Soil Carbon Turnover

Carbon inputs to soil come primarily from plant production. The heterotrophic soil microbial biomass and fauna consume plant production according to the following:

$$CH_2O + O_2 \rightarrow CO_2 + H_2O + \text{energy}$$

The oxidation of carbohydrates and other plant carbon provides the soil microbial biomass with an energy source for metabolic activity and growth. The effect of soil and crop management can greatly impact standing soil carbon pools. For example, soil tillage and reduced plant carbon input under conventional agriculture is suspected to have led to a 50% decrease in soil carbon over a 50-year period (14). Soil tillage is thought to affect soil microbial biomass activity through aeration and liberation of soil carbon from protected areas, such as within aggregates. For these reasons, it is thought that practices such as no-till and off-season cover crops can be used as management techniques to store more soil carbon and to mitigate rising atmospheric carbon dioxide levels. These management techniques may make it is possible to manipulate soil carbon storage through management of heterotrophic microbial biomass size and activity leading to the formation of stable soil carbon.

The turnover of soil organic carbon is often related to ecosystem productivity. Soil carbon normally turns over rapidly in productive ecosystems. The rapid turnover of carbon can often be attributed to higher temperatures and/or nutrient availability. In tropical rainforests, the soil carbon pool is smaller compared with temperate forests or grasslands yet ecosystem productivity is four times higher in the tropical forest as a result of the rapid turnover of nutrients from plant litter (5). Temperate grasslands store more soil carbon compared with other ecosystems in temperate and tropical biomes. In grasslands, the increase in soil carbon storage can be attributed to large belowground productivity leading to a rhizosphere effect that deposits more soil carbon leading to increased microbial biomass production and activity. Other ecosystems that can store more soil carbon than grasslands are peat bogs, tundra, and boreal forest. The storage of soil carbon in these ecosystems can often be attributed to anaerobic conditions and low temperature.

Rates of Soil Carbon Turnover

The rate of soil carbon turnover is intimately tied to the activity and turnover of the soil microbial biomass. The fate of soil carbon has become an important issue

in determining the role of terrestrial soil carbon in influencing the global carbon budget. Therefore, the importance of the soil carbon cycle and the factors affecting its stability are important global warming research topics.

The competitive and synergistic interactions among components of the soil microbial biomass may affect the fate of soil carbon by affecting the decomposer community composition and/or its activity. However, the inoculum potential or diversity of the soil microbial biomass is assumed to be rarely limiting unless the soil environment has been drastically disturbed (1). Examples of soil disturbance include erosion, fire, and volcanic deposition, which either remove surface soil or bury it. Other disturbance events that affect certain components of the soil microbial biomass such as pollution or flooding may have the same effect. Besides all the biological interactions of soil, soil physical properties, particularly those that affect temperature and moisture, will greatly influence the activity of the soil microbial biomass.

The quantity and quality of plant litter will determine how carbon becomes metabolized and stabilized in soil. Similarly, the potential to utilize and mineralize nitrogen in plant components is linked to the metabolism of carbon. The forms of plant litter entering the decomposition stream are a complex mixture of products with various degrees of biodegradability. Plants are composed of various labile (cytoplasm) and structural (cell wall) chemical components listed in Table 3. Each component has an inherent degradability based on its chemical structure. For example, proteins are much easier to degrade than polymeric substances such as cellulose and lignin. In addition, to the chemical recalcitrance of plant components, the nitrogen content of each component is also a good indicator of its biogradability. The lower the carbon to nitrogen ratio of the plant material the more likely it is easier to degrade. The carbon to nitrogen ratio or the nitrogen to lignin ratio has often been used to predict the degradability of plant litters. However, the carbon and nitrogen ratio of specific plant litter components is not a reliable index of decomposition (15). For example, because lignin contains no nitrogen it would be very difficult to degrade without an external nitrogen source. Therefore, nitrogen availability during degradation ultimately controls the decomposition of plant litter.

Table 3. Factors Used in Estimating the Carbon and Nitrogen Content of the Soil Microbial Biomass Using Microscopy

Bacterial Numbers

$N = nf\frac{A}{F}\frac{v}{V}\frac{W}{D}d$

N = number of bacteria per gram soil
n = bacteria per field of view
A = smear of filter area
F = counting field area
v = volume of sample applied to smear or filter
V = volume of dispersed soil
d = dilution factor
W = wet weight of soil
D = dry weight of soil

Bacterial Carbon Content

$B = NUeSC\ (10^{-6})$
B = bacterial biomass carbon (microgram (μg) per gram soil)
N = number of bacteria per gram soil
U = average bacterial volume (μm^3)r^2L; r = bacterial radius, L=bacterial length
e = bacterial density ($1.1 \times 10^{-3} mm^{-3}$)
S = bacterial solids content (0.4 in soil)
C = % bacterial carbon (0.45)

Fungal Biomass Carbon

$F = \pi r^2 LeSC\ (10^6)$
F = fungal biomass carbon (microgram (μg) per gram soil)
r = average hyphal radius (1.13μm)
L = hyphal length cm/g soil
e = density in soil (1.1)
S = solids content (0.3 in soil)

Factors Controlling Nitrogen Availability During Decomposition

Nitrogen is an essential component of many cellular building blocks including nucleotides, protein, and cell walls. The competition for nitrogen in soil by plants and the soil microbial biomass is fierce. The large surface area and distribution of the soil microbial biomass compared with plant roots often gives them an advantage in competing for soil nitrogen. In general, plant roots explore approximately 1% of the total surface area of the soil. Because the soil microbial biomass is distributed widely in soil, it has a competitive advantage over plant roots in capturing nutrients in the soil solution moving by both mass flow and diffusion. The competition for nitrogen in soil among plants and the soil microbial biomass controls nitrogen availability during decomposition. The soil microbial biomass contains significant amounts of nitrogen often equivalent to the entire needs of plants during one growing season. The soil microbial biomass nitrogen content and that nitrogen becoming available during decomposition of plant residues and organic matter are the primary sources of available soil nitrogen for plants. As stated earlier, for this reason the soil microbial biomass is often considered the source and sink of nitrogen in soil.

The soil nitrogen cycle is complex and often the different components of the nitrogen cycle compete for different forms of nitrogen. The nitrogen cycle is a complex set of processes converting elemental nitrogen to organic forms and back to elemental nitrogen or other gaseous inorganic forms of nitrogen. The forms and availability of plant residue and soil organic carbon influence the formation of different nitrogen forms in the nitrogen cycle (Fig. 3).

Nitrogen mineralization is the primary nitrogen cycling process determining the availability of nitrogen for plants and decomposition processes. The availability of organic nitrogen to be mineralized to ammonium is the limiting process that controls nitrogen available to plants and the soil microbial biomass. Sources of organic nitrogen include soil organic matter, plant litter residues, and

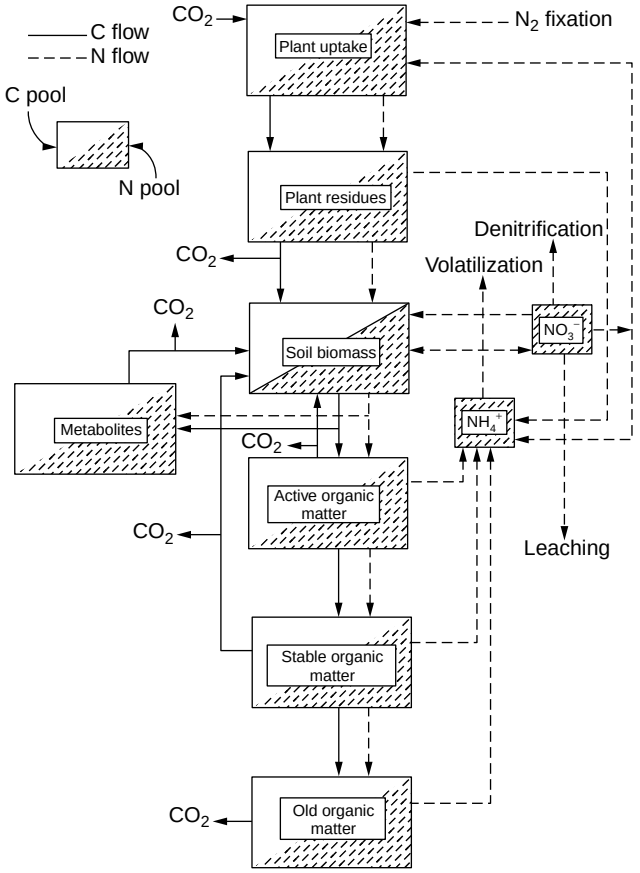

Figure 3

Table 4. Mass of Cytoplasmic and Cell Wall Components in Plants

Plant Component	% of Total
Waxes and pigment	1
Amino acids, sugars, nucleotides and so on	5
Protein	5–7
Hemicellulose	15–20
Cellulose	4–50
Lignin	8–20

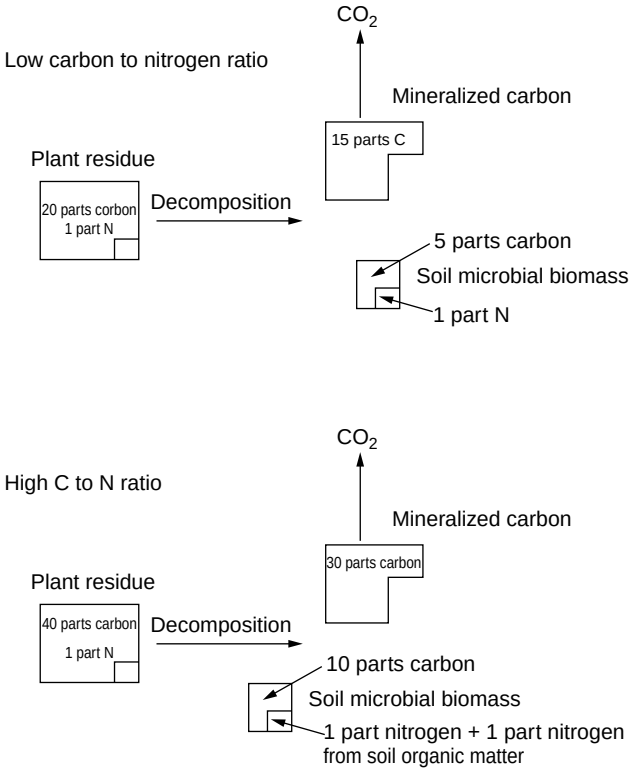

Figure 4. The influence of carbon to nitrogen ratio on the decomposition of plant litter. The scenarios assume that the soil microbial biomass will utilize 25% of the plant carbon and produce additional biomass at a carbon to nitrogen ratio of 5 to 1. Under low carbon to nitrogen ratio plant litter, 15 parts of carbon are mineralized leaving five parts of carbon and one part of nitrogen, thus no additional soil nitrogen is required. Under high carbon to nitrogen ratio, 10 parts of carbon and one part of nitrogen are used to produce new biomass thus requiring an additional one part of nitrogen from the soil. This is termed nitrogen immobilization. Nitrogen mineralization would occur when the carbon to nitrogen ratio is less than 20 to 1.

root exudation. Because extra nitrogen is often required for the decomposition of plant residues, other sources of nitrogen primarily from soil organic matter are utilized for the decomposition process. The amount of nitrogen made available from the mineralization of soil organic matter for degrading plant residues depends on the amount of nitrogen already present in the plant residue. When the plant litter has a carbon to nitrogen ratio of 20 to 25 to one the decomposition process has sufficient nitrogen and no nitrogen is required from the soil organic matter or other sources (Fig. 4). Plant litter carbon to nitrogen ratios above 25 to 1 require additional nitrogen from other sources to complete the degradation process leading to nitrogen immobilization in the soil. Carbon to nitrogen ratios of less than 20 to 1 often lead to mineralization of nitrogen to the soil from the plant litter. Although Figure 4 is simplistic it does show how the carbon to nitrogen ratio control decomposition process in soil and the availability of nitrogen for plant and microbial uptake.

Conversion of Plant Carbon into Soil Organic Matter

During the decomposition process, plant residues are converted into microbial biomass energy, microbial production, carbon dioxide, and water. Figure 5 shows how plant residue components disappear during decomposition and microbial production increases. As decomposition proceeds more microbial production occurs. Microbial production is the living soil microbial biomass and metabolic and turnover products that are difficult (recalcitrant) to process any further. The metabolic products contain carbon and nitrogen from plant, microbial, and faunal origin. The recalcitrant products are probably difficult to degrade

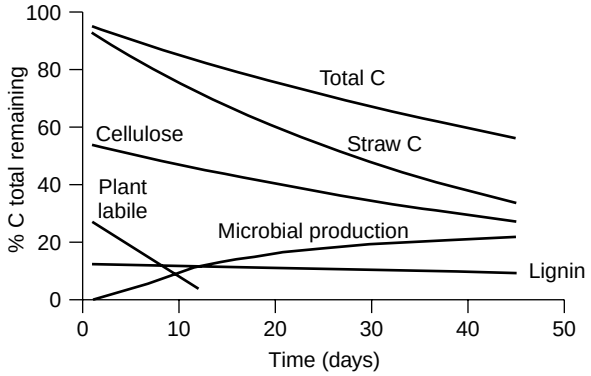

Figure 5. Loss of total carbon and plant components during decomposition. Microbial production increases during the decomposition process leading to the production of soil microbial biomass and soil organic matter (11).

or they are protected from degradation by their association with soil mineral colloids. The formation of soil aggregates is an example of a soil structure containing protected carbon.

The microbial production and resistant plant litter components are the source of soil organic matter. Soil organic matter formation is the result of life in soil. The formation and maintenance of soil organic matter creates habitats through the formation of soil structure and provides a source of nutrients for plants and decomposition processes. The formation of soil organic matter is a beginning and an end in itself because it creates a favorable habitat for both the soil microbial biomass and plants.

CONCLUSION

The soil microbial biomass plays an important role in ecosystem function primarily through the regulation of nutrient cycles. In their search for energy to grow, the soil microbial biomass relies on nutrients in plant litter and soil. Because of its competitive ability, the soil microbial biomass is often considered the source and sink of essential plant nutrients. As result of the heterotrophic activities, the soil microbial biomass greatly influences the terrestrial carbon cycle. The disturbance of ecosystems leads to net carbon losses to the atmosphere by exposing protected soil carbon and affecting the activity and turnover of the soil microbial biomass accentuating the greenhouse effect. Future management of ecosystems will need to consider the role of the microbial biomass in sequestering and producing stable soil carbon. The wide diversity and function of the soil microbial biomass exemplifies its role in a wide variety of processes including parasitism, pathogenesis, and symbiosis. This wide functionality has made the study of soil microbial biomass problematic and often leads to misinterpretation of its importance in ecosystem function.

BIOMINERALIZATION BY BACTERIA

TERRY J. BEVERIDGE
ANTON KORENEVSKY
SUSAN GLASAUER
University of Guelph
Guelph, Ontario, Canada

Biomineralization is the process by which organisms form minerals; this ability is widespread among all taxa (1). The diversity of biogenic minerals is remarkable: more than 60 different minerals have been identified and the number continues to increase (1,2). Bacteria produce practically all types of biominerals including amorphous and crystalline varieties (e.g., carbonates, phosphates, silicates, sulfates, sulfides, oxalates, oxides, hydroxides, etc.). Moreover, because bacteria can inhabit extreme environments enriched with heavy metals, minerals

uncommon to eukaryotes are formed from elements such as Ag, As, Au, Cr, Me, Sb, Tc, Ti, V, and U. Microorganisms play principal roles in biogeochemical cycling and form some biominerals on a huge scale. Many sediments, sedimentary rocks, and ore deposits are formed by the direct participation of microorganisms.

MECHANISMS OF BIOMINERALIZATION

All biomineral-forming processes can be divided into two types, "biologically induced" and "biologically controlled" (3,4). When an organism influences solution chemistry and, thus, creates favorable conditions for mineral formation, it is biologically induced mineralization (BIM). Bacteria release different types of metabolites or ions, which change the oxidation state of metals and introduce charged surfaces (cell walls, capsules, etc.) that can induce mineral formation. The minerals produced, if they are crystalline, have a wide range of sizes and are usually randomly aggregated (1). For biologically controlled mineralization (BCM), the mineral nucleation site is separated from the external environment. Bilayer lipid vesicles (e.g., magnetosomes; Fig. 1) and proteins (e.g., ferritin) can serve as such sites and allow better regulation of the physicochemistry for mineralization (1). BIM is the predominant process among bacteria. Only a few examples of bacterial BCM are known; that is, the formation of magnetite (Fe_3O_4) or greigite (Fe_3S_4) in magnetotactic bacteria (5,6), magnetite and ferrihydrite in ferritin (7), and sulfide clusters in metalloproteins such as metallothioneins.

A necessary precondition for mineral formation is the development of supersaturation in the fluid phase. At this point, ions begin to associate into small unstable clusters. The rate of cluster dissociation prevails, however, over the rate of mineral growth. To exceed the critical nucleus size, above which further crystal growth is thermodynamically possible, certain energy barriers must be overcome. The level of supersaturation must be high enough to promote spontaneous crystallization (homogenous nucleation) or centers of crystallization must be introduced (heterogeneous nucleation). Particulate surfaces make excellent crystallization centers because their interfaces reduce the free energy necessary for mineralization at lower ion concentrations.

For this reason, bacteria, with their high surface area-to-volume ratio, make exceedingly good foci for mineral nucleation; their highly reactive surfaces are good templates to initiate and promote further mineral growth (Fig. 2). These surfaces consist of biopolymers (lipopolysaccharides, phospholipids, peptidoglycan, polysaccharides, proteins, etc.; see Reference 8 for more structural details) bearing important ionizable functional groups at physiological pH (e.g., amine, amide, carboxyl, carbonyl, phosphate, sulfhydryl, and hydroxyl groups). However, the most abundant are carboxyl, hydroxyl, phosphate, and amino groups (9). The ratio of acidic to basic groups in these biopolymers is generally greater than 1 and, overall, bacterial surfaces have an isoelectric point of 2 : 3. Above this point, bacteria are usually negatively charged and below it they are positively charged (10,11).

Because of this, the interaction of metal ions with bacterial surface polymers is strongly pH-dependent; pH not only dictates metal ion speciation but also activates surface functional groups for metal ion–polymer complexation. All metallic ions, as well as the lanthanides and actinides, have been implicated in these interactions (12,13). Generally, the sorption of the metal cations increases with pH, whereas that of anionic forms decreases. The sorption of Ag^+, Hg^{2+} and $[AuCl_4]^-$ does not, however, change much over a wide range of pH (14).

Metal sorption is facilitated by cation hydrolysis (hydroxo-complex formation) or protonation of oxyanions and negatively charged complexes. If ion concentration exceeds 10^{-3}–10^{-7} M, hydrolyzed and protonated metal ion species will polymerize. Compared to "free" metal ions these polymeric species are less hydrated and more hydrophobic. This should reduce the amount of free energy required for sorption, which appears to be noncoulombic (mainly via hydrogen-bonding and van der Waals cohesive forces). The amount sorbed exceeds the number of potential functional groups (13,15–17).

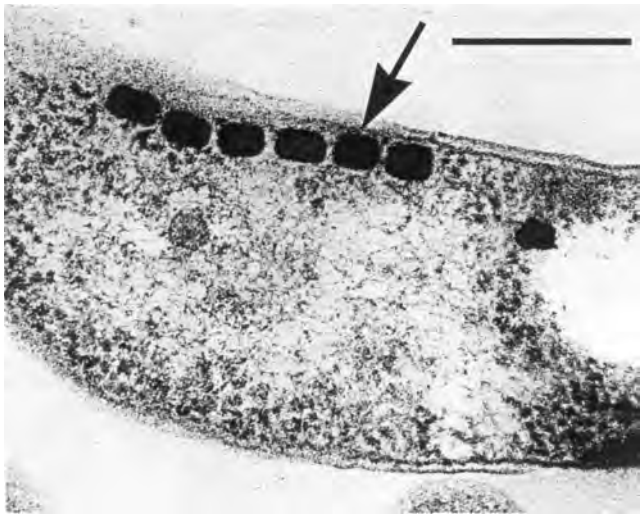

Figure 1

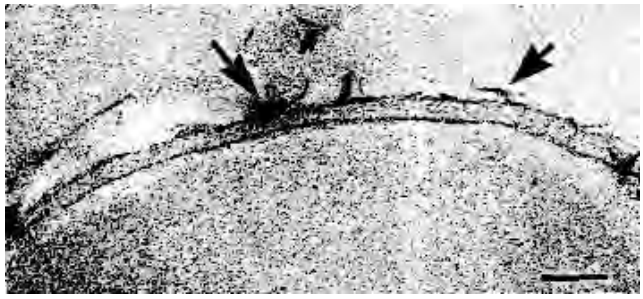

Figure 2

The strength of the metal–polymer bond is important because loosely bound metals can be more easily displaced. However, these can also attract anions to form ion pairs at the nucleation site. The anions at these sites can coordinate with secondary cations so that more and more metal is deposited. This is called *ionotrophy* and both high-binding capacity and low-binding affinity are necessary for this type of nucleation. Usually amorphous phases result, which are transformed (over time) through dehydration to crystalline phases (18,19). Strongly bound metals are not easily displaced and will frequently react with bacterial metabolites (e.g., HS^-, HPO_4^{2-}, and HCO_3^-), or undergo hydrolysis, or redox transformations to form mineral phases.

In addition to the de novo development of fine-grained minerals by surface polymer–metal ion interaction, bacterial surfaces also sorb particulate, finely dispersed mineral phases such as colloidal hydroxides and clays (20–22). These serve as new reactive surfaces for subsequent metal ion interaction (21,23) but they do not bind the ions as strongly as the biopolymers (24).

Carbonate Minerals

Bacteria are active agents of carbonate mineral formation because they release bicarbonate during respiration while at the same time increasing pH in their immediate surroundings (25). These factors, together with the processes mentioned in the preceding section, account for several biocarbonate formations. Hydromagnesite ($Mg_5[CO_3]_4[OH]_24H_2O$) and needlelike aragonite (orthorhombic $CaCO_3$) deposits have been found in association with mucous biofilms in a karstic cave (Altamira, Spain). Such mineral crystals are usually embedded in mucilaginous (producing hydromagnesite) or filamentous (aragonite) microbial films. In this case, abiotic hydromagnesite precipitation seems improbable because the cave waters are oversaturated with respect to calcite, aragonite, and dolomite ($CaMgCO_3$) but are strongly undersaturated with respect to hydromagnesite and other magnesium carbonates (26).

The crystal type and mineral composition are obviously dependent on solution chemistry and rate of precipitation. Laboratory simulations with pure cultures of different bacterial and cyanobacterial strains demonstrated that either calcite or aragonite can develop, but not simultaneously. In all cases, calcite was precipitated in the viscous medium close to cells, whereas aragonite was precipitated in the fluid phase. This is in good agreement with observations of bacterially mediated calcium carbonate deposition in natural environments (27,28).

Accordingly, slime-producing bacteria not only influence the viscosity of their immediate surroundings but also control the mineral composition of their precipitates.

Heterotrophic anaerobes frequently employ electron acceptors such as sulfates, nitrates, ferric iron, and manganite compounds, resulting in an increase in pCO_2 and pH. Deposition of a dolomite-ankerite ($CaFeCO_3$) phase was observed in the presence of sulfate-reducing bacteria (SRB; mostly *Desulfovibrio*) in Lagoa Vermella, Brazil. Geochemical solid field analysis showed that under the given conditions, inorganic precipitation of dolomite was impossible (29). Moreover, bacteria are able to release metal ions (Ca, Fe, and Mn) from insoluble forms thereby promoting carbonate deposition of these metals. For example, rhodochrosite ($MnCO_3$) and siderite ($FeCO_3$) deposition in the oligotrophic Punnus Yarvi Lake (Karelia, Russia) was attributed to the activity of manganese-reducing bacteria (30).

Cyanobacteria can produce significant carbonate deposits in carbonate-saturated waters (31). The giant towerlike microbialites (or bioherms) of Lake Van (Turkey) are a dramatic example of recent thrombolite formation, being up to 40 m high (32). Here, at sites where calcium-rich groundwater seeps into the alkaline (pH~9.7) soda lake water, inorganic calcite precipitation occurs. Microbial colonization of these crusts results in the formation of 10–40 μm biofilms, which are dominated by small coccoid cyanobacteria (*Pleurocapsa* spp.). Scanning electron microscopy (SEM) revealed that their gelatinous sheaths were heavily encrusted by aragonite that cemented and stabilized the soft porous calcite crust. Because groundwater is forced up and through this matrix, the tower grows. When the towerhead rises 8–10 m in height, noncalcifying cyanobacteria (predominantly *Oscillatoria*) begin to dominate the biofilm. This replacement makes further upward growth of the microbialites impossible (32).

Extensive studies by Schultze-Lam and coworkers and Thompson and coworkers on carbonate mineralization in Fayetteville Green Lake provided unequivocal evidence of this biogenic process (33–37). This lake contains Ca^{2+}-, Mg^{2+}- and SO_4^{2-}-rich waters with a pH of 7.9. *Synechococcus* GL24, a small cyanobacterium, dominates the mixolimnion because of high oligotrophic conditions. This cyanobacterium can be planktonic or it can form biofilms. In both cases, it contributes to an active biomineralization of calcium carbonate. As planktonic cells, it precipitates calcite so that a gentle but continuous rain of calcite contributes to the marl sediment of the lake. When it grows as a biofilm, it also precipitates calcite, which contributes to the size of the microbialites. Transmission electron microscopic (TEM) analysis showed that the surface of GL24 consisted of an S-layer of hexagonally arranged proteinaceous subunits. Strategically placed carboxyl groups on the S-layer interact with Ca^{2+}, thereby nucleating mineral formation; the mineral initially mimics the large lattice structure of the S-layer (Fig. 3). Here, there is a remarkable dependence on pH for mineral type. Because the solid field of the circumneutral pH lake waters is for gypsum, photosynthesis and respiration increase the pH immediately surrounding the cells so that a calcite solid field is produced. Laboratory studies in which Ca^{2+} is replaced by Sr^{2+}, Mg^{2+}, or a mixture of the two has revealed that strontianite, hydromagnesite, and celestite can be formed (33,34).

Silicate Minerals

Bacteria play a role in the formation of silicate minerals because their sorption of monosilicic acid at low Si concentrations (~0.5–3.0 mM) promotes silica polymerization (autopolymerization of monosilicic acid occurs at concentrations greater than 3.5 mM). Moreover,

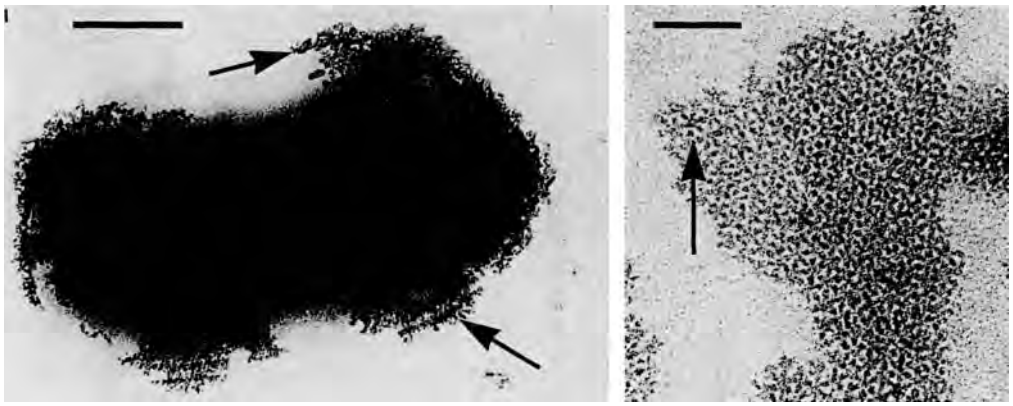

Figure 3

silica mobilized from quartz by *Bacillus mucilaginosus* or *Thiobacillus thiooxidans* was found to be mainly bound to cells and their exopolysaccharides (38). There are several ways in which silicate ions can bind to a bacterial surface, that is, through ionic condensation with phosphoryl, carboxyl, or hydroxyl groups (39), via H-bonding with =O, $-NH_2$, $-COOH$, $-OH$, and other groups (40,41), and by electrostatic interaction of silicate anions with positively charged groups (e.g., amines; 42,43). Covalent binding appears to have minor significance. Another mechanism, adsorption of multivalent metal cations on bacterial surfaces, results in reduced or reversed surface electronegativity, and facilitates silica sorption; silica-binding occurs through cationic bridging by preexisting wall-bound metal cations or via binding to surface hydroxyl groups of metal hydroxides adsorbed to the cell surface (42–44).

Numerous electron microscopy (EM) studies of environmental samples from river sediments, hot springs, mine tailings, and so forth have revealed bacterial cells to be partly or completely encrusted with different silicate minerals. Living cells have silicates associated with their surfaces or slimes, but when they die, silicates can be found within the cytoplasm (Fig. 4). These silicates exhibit a wide range of size (15 nm to >1 m), morphology, and chemical composition, and greatly differ from suspended minerals found in water samples. The mineral phases most frequently associated with bacteria are complex polymorphic silicates ranging from amorphous silica or poorly ordered chamositic clays [$(Fe_5Al)(Si_3Al)O_{10}(OH)_8$] to well-crystallized kaolinitic [$Al_4(Si_3O_{10})(OH)_4$] or glauconitic [$K(Al_{0.38}Fe_{1.28}Mg_{0.34})(Si_{3.7}Al_{0.3})O_{10}(OH)_2$] clays. Thus the most abundant elements of these minerals are Fe, Al, and Si, although Mn, Mg, K, and Ti are often present (44–52).

Interestingly, there seems to be no relationship between different taxonomic groups of bacteria and their silicate mineral type (46,47) and this has been verified by laboratory simulations using *Bacillus subtilis* cells to nucleate poorly ordered allophanes and serpentines. However, more crystalline kaolinite phases and (possibly)

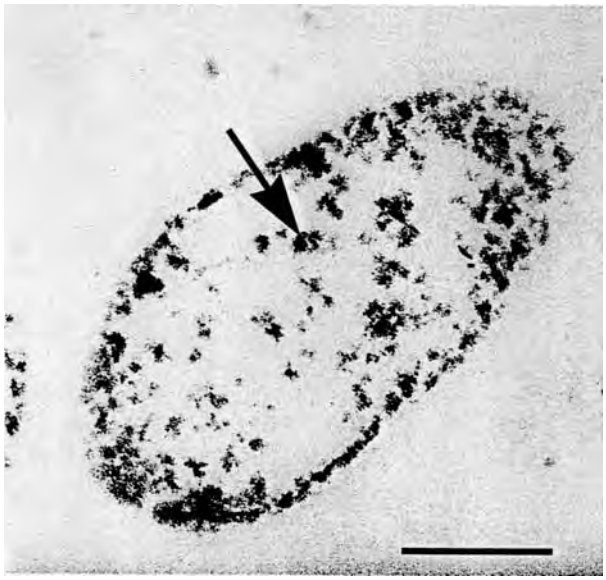

Figure 4

2 : 1 phyllosilicates have been detected as well (42,43). It seems that (Fe-Al) silicates, like other biominerals, mature over time from amorphous phases into crystalline forms by dehydration during which more Fe and Si are added (42–44,46,47,53).

Mineralization Coupled to Redox Transformations

Bacteria are able to oxidize or reduce metals such as Fe, Mn, As, Cr, U, and Au via enzymes (oxidases and reductases), metabolites (peroxides and thiols), inorganic substances (H_2S), and cellular redox potential (25,54,55). This can impact biomineralization processes because when a metal valency is changed, an insoluble

product can be formed by hydrolysis or anion interaction (e.g., with phosphates, sulfides, or carbonates). For instance, *Pseudomonas vanadiumreductans* and *P. isatchenkovii* can produce V_2O_3 from vanadate ions (56), *Desulfovibrio desulfuricans* and *Escherichia coli* deposit low-valence hydroxides and oxides (e.g., TcO_2, Tc_2O_5) from Tc(VII) (57–59), and several bacteria, for example, *Desulfovibrio* spp., *Geobacter metallireducens*, and *Shewanella* spp., reduce UO_2^{2+} to form insoluble uraninite ($UO_2{\cdot}nH_2O$) (60–63).

Reduction of Fe(III) (e.g., from iron oxides) by dissimilatory iron-reducing bacteria serves as a good example of complex interactions occurring between the solution and a solid phase. For example, simple solution chemistry dictates that as the concentration of Fe(II) increases, siderite ($FeCO_3$) and vivianite ($Fe_3(PO_4)_2{\cdot}8H_2O$) phases should result. Yet, because bacteria can modulate the Fe(II/III) couple as they grow with an iron oxide, ferrous ions often interact with amorphous ferric hydroxides resulting in the additional formation of crystalline magnetite (Fe_3O_4) and green rust $[Fe^{II}_{(6-x)}Fe^{III}_x(OH)_{12}]^{x+}(A^{2-})_{x/2}{\cdot}yH_2O$ (64–67). If Cr(VI) is also in the system, its reduction by bacteria leads to mixed Cr(III)-Fe(oxy)hydroxide phases (Fig. 5) (68,69). Such systems show that the dominant mineral phase depends on a complex interplay between bacterial reduction processes, the aqueous geochemistry, and the surface chemistry of an oxide (66,70).

Metal ions with high electrochemical potentials (>700 mV), such as those formed by Ag, Au, Hg, and Pt, can be readily reduced by bacteria. The resulting precipitates may grow on the cell surface and intracellularly as metal colloids. The metal ions easily damage the normal permeability of the plasma membrane; the membrane is breached, killing the cell and allowing intracellular mineral growth (Fig. 6) (71–73). The biosorption

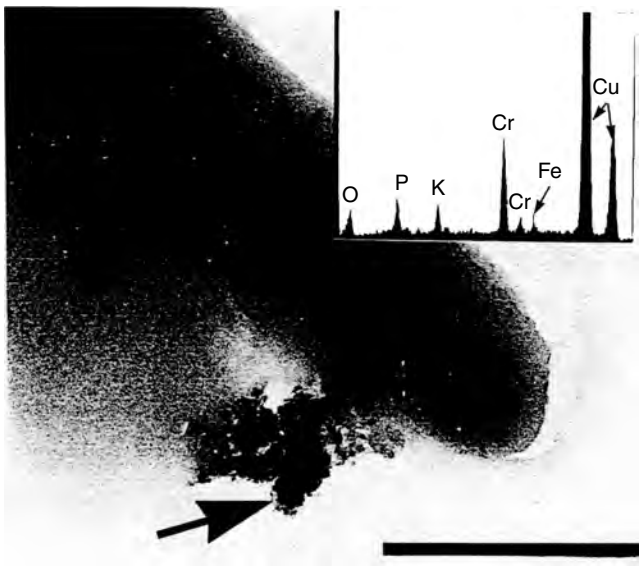

Figure 5

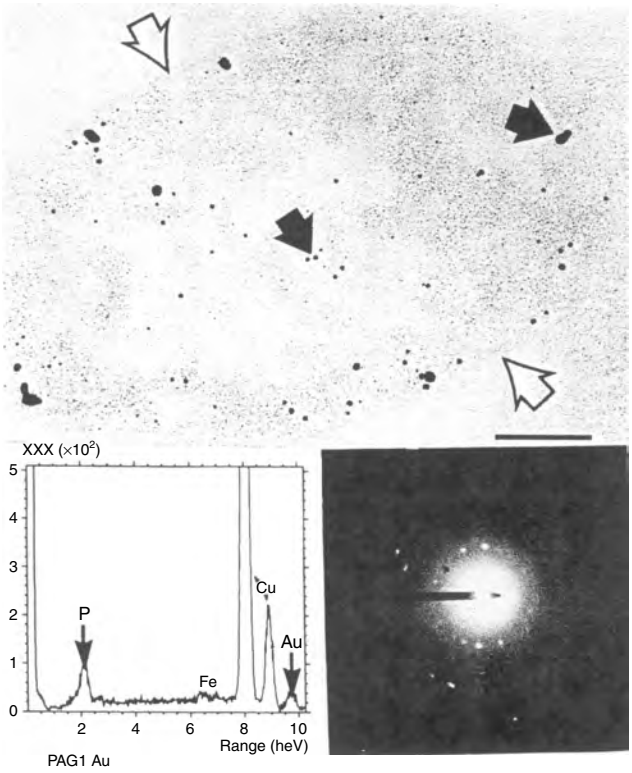

Figure 6

of Ag, Au, Hg, Pt, and so forth is a relatively quick process, occurring within 15 minutes in the *B. subtilis* system of Beveridge and Murray (74,75). Interestingly, once small metallic colloids are formed, they coalesce to form macroscopic crystalline phases (pseudotrigonal and hexagonal-octahedral forms) similar to placer gold (76). Similar results have been reported by Russian researchers using *Bacillus cereus* and *Micrococcus luteus* systems in which approximately 80% of the colloidal particles annealed into 0.2–0.8-mm-sized crystals after 8 to 10 months (77). The *M. luteus* culture was isolated from a gold ore deposit and is capable of sorbing up to 45% of its weight in gold, producing a crystal size similar to that found in the deposit. For these systems, the production of the gold crystals depended on the physiological activity of growing cells because metabolically inactive and dead cells sorbed the gold poorly (77–81). In field studies, bacterial numbers coincide well with the number of gold particles in oxic zones of gold deposits and in placers of Far East Russia (77). Sometimes gold deposits contain microfossils and these prokaryotic remnants possess golden castes in the shape of bacteria, suggesting that lithification developed over living cells (82).

If protein sulfhydryl groups are available (−SH groups are rare on bacterial surfaces but can be present in the periplasm), they will dominate the binding of gold ions, presumably via ion–ion interaction or complexation. It is also possible that gold and its analogs can bind

to oxygen- and nitrogen-containing functional groups of surface biopolymers (83,84).

Oxidation of Iron and Manganese

These oxidation processes deposit Fe and Mn oxides, have been found in gram-positive bacteria, gram-negative bacteria, and mycoplasmas, and are well studied. Fe–Mn-oxidizing bacteria are widespread in nature, being found in marinewaters, freshwaters, and groundwaters, sediments, and soils (85,86). The mechanism of Fe–Mn deposition involves both metabolic activity and sorption. As with other metal ions, anionic polymers of capsules, sheaths, and cell walls readily sorb ionic and colloidal forms of these metals. For example, distribution coefficients (K_d values), calculated as the ratio between sorbed Fe and Mn (on marine bacteria) and dissolved metal concentration, were as high as 10^7 (87). Metal accumulation on the bacterial surface structures is poised for subsequent oxidation and mineralization.

Ferrous iron is unstable at pH higher than 5.5 because of autooxidation, and it is difficult to distinguish between abiotic and microbial precipitates formed during the oxidation of iron. Microbial surfaces lower the free energy barrier for precipitation, but physiological processes seem to be necessary for large depositions. In this way although nonliving cells of *Leptothrix*, *Sphaerotilus*, and *Pedomicrobium* accumulate iron via sorption at autooxidation pHs (88,89), the amounts are low when compared to living cells because active oxidative processes occur at rates that are ~8 to 10 times higher than for dead cells (85). At neutral pH, Mn^{2+} is more stable than Fe^{2+} and the rate of its microbial oxidation can be ~500 times higher than abiotic oxidation. The processes of Fe–Mn oxidation are complex and are complicated by the fact that different bacteria can have distinctly different oxidative pathways; in some instances, oxidation occurs via enzymatic routes, whereas in others no enzymes are required.

Nonenzymatic Reactions. During their metabolism, bacteria will frequently excrete oxidants or bases while at the same time consuming organic anions. These processes will increase the pH and redox potential of the ambient solution, thereby promoting Fe–Mn autooxidation. It has also been shown that hydrocarboxylic acids, acidic exopolymers, and some proteins produced by the cells enhance this same reaction (25,86,90).

Enzymatic Reactions. The enzymatic mechanisms of Fe–Mn oxidation can be separated into three major groups:

1. Oxidation of free Mn–Fe ions by constitutive or inducible oxidases that transfer electrons to oxygen via cytochrome systems:

$$Mn2^{+} + 1/2O_2 + H_2O \Rightarrow MnO_2 + 2H^{+}$$
$$Fe^{2+} + 1/2O_2 + 2H^{+} \Rightarrow Fe^{3+} + H_2O$$

This pathway for Mn oxidation is found in *Pseudomonas* sp. S-36 (91), *Pseudomonas putida* MnB1 (90), *Citrobacter freundii* E_4, and *Pseudomonas* sp. E_1 (25). It has been shown that some anaerobic phototrophic purple and green bacteria (e.g., *Rhodobacter*, *Rhodomicrobium*, and *Chlorobium*) are able to oxidize Fe^{2+}, $FeCO_3$, and FeS, with concomitant reduction of carbon dioxide to produce cell material (92,93).

2. Oxidation of Mn bound to a manganese(IV) oxide:

$$Mn{\bullet}MnO_2 + 1/2O_2 + H_2O \Rightarrow 2MnO_2 + 2H^{+}$$

Some bacteria (e.g., *Arthrobacter*, *Vibrio*, and *Oceanospirillum*) are unable to oxidize free Mn^{2+} but oxidize the ion when it is bound to manganese(IV) oxides, ferromanganese, or some clays (e.g., montmorillonite and kaolinite). For a more complete summary of this work, see Reference 25.

3. Oxidation catalyzed by catalase during hydrolysis of metabolic H_2O_2:

$$Mn^{2+} + H_2O_2 \Rightarrow MnO_2 + 2H^{+}$$
$$2Fe^{2+} + 3H_2O_2 \Rightarrow 2Fe(OH)_3$$

This mechanism is widespread in various heterotrophic bacteria (85,94,95).

In acidic environments, chemolithoautotrophic and mixotrophic bacteria play a principal role in Fe(II) oxidation by enzymatically increasing chemical oxidation as much as six orders of magnitude. These acidophilic bacteria can be mesophilic or thermophilic and usually belong to the genera *Thiobacillus*, *Leptospirillum*, *Sulfobacillus*, and *Sulfolobus*. To obtain energy and reducing power for CO_2 fixation they can use as electron donors not only Fe(II) but also Cu(I), U(IV), Se(II), reduced sulfur species and sulfide minerals (96). It has recently been shown that acidophilic filamentous bacteria (similar to the *Leptothrix-Sphaerotilus* group) and acidophilic–heterotrophic unicellular bacteria can oxidize Fe^{2+} and pyrite (96–98). Bacterial Fe(II) oxidation results in extensive formation of jarosites, (crystalline basic iron sulfates), amorphous ferric hydroxides, ferrihydrite, lepidocrocite (γ-FeOOH), and magnetite. In the case of arsenopyrite oxidation, the deposition of iron arsenate takes place as well (99,100).

Depending on the conditions, Mn(II) oxidized by bacteria can be deposited as manganese(IV) oxides or as mixed manganese(II,III)/manganese(IV) oxides and oxyhydroxides. Thus in these precipitates the following minerals have been detected: vernadite, δ-MnO_2; todorokite, [Ca,Na,K][Mg,Mn]$Mn_5O_{12}{\bullet}H_2O$; buserite, [Ca,Na,K][Mg, Mn]$Mn_6O_{14}{\bullet}5H_2O$; feitknechtite, β-MnOOH; manganite, γ-MnOOH; hausmannite, Mn_3O_4 (101,102–104).

Localization of deposited Fe and Mn usually occurs on bacterial surface structures such as cell walls, capsules, sheaths and, in the case of mycoplasmas, on the plasma membrane. The most striking example is the sheath of *Leptothrix discophora*. Here, manganese is oxidized enzymatically on this outermost structure (105). The cells depart from old sheaths leaving them totally encrusted in manganese oxides (Fig. 7). Sometimes cells become so completely encrusted with metal oxides that the weight of the deposited mineral can exceed the cell weight

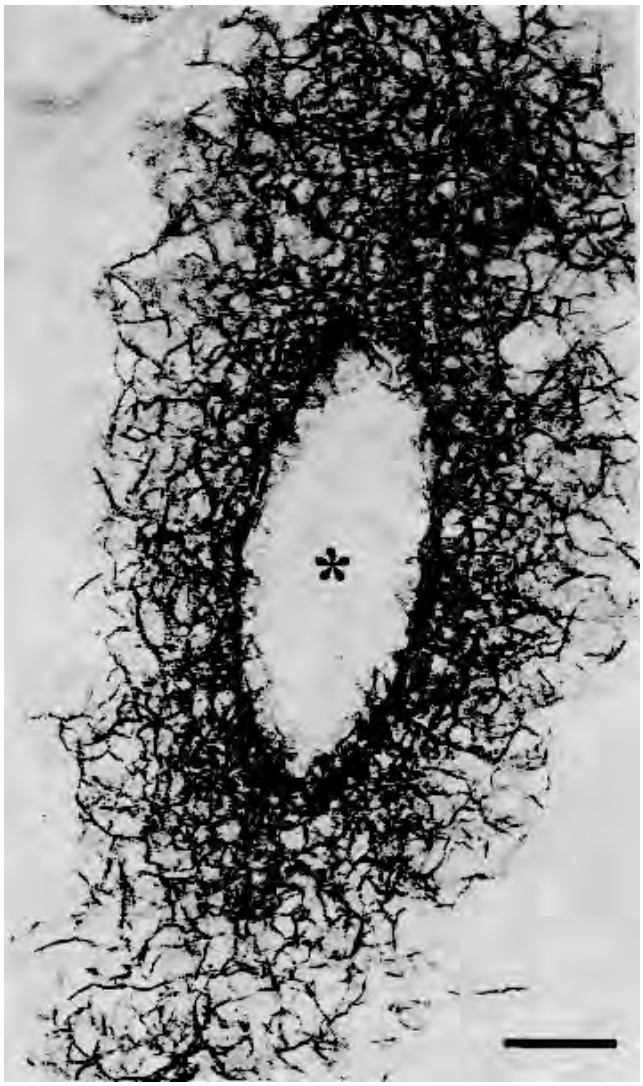

Figure 7

by an order of magnitude. However, deposition can also take place in the surrounding medium, especially when hydrogen peroxide is involved in the oxidation reaction (25,86).

Deposited Fe and Mn biominerals are finely dispersed and possess a high specific surface area. It has been reported that the specific surface area of *Leptothrix*-oxidized Mn is about four times the specific surface area of fresh abiotic precipitates and more crystalline manganese oxides. Biogenic manganese oxides have a high affinity for trace metals; the adsorption of Pb is more than four times that of abiotic crystalline oxides (106).

GEOLOGICAL EVIDENCE OF BIM

That bacteria can biomineralize under laboratory conditions has been shown for many combinations of bacteria and minerals (107); however, conclusive evidence in ancient sedimentary horizons for biogenic mineral formation is harder to find. Sometimes, the most that can be concluded is that biomineralization is the likeliest explanation for what is observed, given the difficulties in identifying remnants of bacteria in situ and relating their activities to a specific mineral or geological structure. The existence of an unusual mineral (in an environment in which it would not normally form) is a first clue that microbes have been active. Stronger evidence comes from electron microscopy studies of more recent horizons where visual observations have been combined with element analysis (energy dispersive X-ray spectroscopy; EDS) and selected area electron diffraction (SAED) (Fig. 6). These allow precipitates associated with cells to be characterized, and make it possible to identify those minerals around the cell perimeter, which have been mentioned in our previous sections. Isotope fractionation is another in situ method that has been used to identify past geological activity of microbes; it is based on the fact that life-forms (in this case early microorganisms) prefer to metabolize the lighter isotopes of elements such as C, H, O, N, S (25). Radioisotopes can be used for in situ studies of present microbial action (25).

Mineral Deposits

Iron Ores. Iron in ore deposits may be in the form of oxides, sulfides, or carbonates, each of which can be formed by bacteria. Clues that bacteria have been active include the presence of fossilized or living microbes possessing probable iron-metabolizing or iron-accumulating potential, or the existence of environmental conditions (at the time of formation) that enabled biogenic iron deposition (25). An example of modern iron ore deposits is found in some bogs overlying sediments rich in ferrous minerals such as glauconite or pyrite. Groundwater brings Fe^{2+} to the surface, where the rapid rate of oxidation is attributed to biocatalysis (see previous section on redox transformations); bacteria involved in the oxidation include *Leptothrix*, *Crenothrix*, *Siderocapsa*, *Metallogenium*, *Thiobacillus*, and *Gallionella*. Rivers and swamps in the Pine Barrens in southern New Jersey contain such oxidized iron deposits (108). The iron there was mined until it became economically unfavorable in the mid-1850s.

Banded iron formations are remarkable ancient stratified deposits that were formed throughout the world in the Precambrian era; most deposits formed around 2.2 to 1.9 billion years ago. The bands occur as continuous layers of alternating iron-rich and iron-poor minerals, with the total iron of a quality and quantity in some places to be a valuable ore. The microbial origin of these deposits is still controversial; one theory, based in part on fossil evidence, favors oxidation of ferrous iron by anaerobic photosynthesizing bacteria and algae (109). Another theory considers that bacteria oxidized carbon to produce the carbonate minerals characteristic of these formations, particulate Fe(III) serving as the electron acceptor (110).

The role of bacteria in forming ore deposits of other metals is still debatable but the evidence points increasingly toward biogenesis. The formation of uranium

ores is one example for which bacterial activity seems likely. The ore bodies develop when mobile hexavalent uranyl ions are reduced to insoluble tetravalent uranium forms. A likely reductant is hydrogen sulfide, given the close proximity of pyrite (FeS_2) to tetravalent ore minerals, and (at the generally low temperatures of sedimentary ore-forming environments) bacteria are the most likely source of H_2S. Indeed, sulfate-reducing bacteria (SRB) have been found in uranium ores in Hungary (111). Further support for biogenic formation of ores comes from laboratory studies showing that both gram-negative and gram-positive bacteria can concentrate silver and gold as particles in the cell wall (see previous section on redox transformations; 76,112).

Coal, Peat, and Oil. These share steps in their initial formation. Both coal and peat begin with large accumulations of biomatter that were most likely initially degraded by bacteria and fungi. Microbial activity stopped once all of the easily metabolizable compounds and some of the more refractory substances were consumed, the latter probably by anaerobic bacteria (25). Microbial evidence comes from remains of microorganisms identified in coal and from signature isoprenoid substances found in ancient oils. Further physical and chemical processes, such as heat and pressure, converted peat to coal or oil.

Mine Tailings and Their Leachates

Base metals (Cu, Zn, Fe, Ni, etc.) are generally mined from metal sulfide ores, most often pyrite. Exposure of sulfidic rock to air begins a slow oxidation process that is accelerated by native bacteria grouped together under the term *acidophilic chemolithotrophs*. The oxidation process generates acidity and dissolves the metal, creating acid mine drainage in the process. This natural process is exploited by mining companies to harvest metals from low-grade ores; however, higher-grade ores are extracted by more efficient means and the finely ground waste rock is deposited in tailings dumps (25). This mineral waste represents an oxidizable energy source to the bacteria, as exemplified by the activity of *Thiobacillus ferrooxidans*. These bacteria oxidize Fe^{2+} and sulfide, thereby generating Fe^{3+}, sulfuric acid, pH values as low as 1–2, and solutions with high metal concentrations (113). Drainage of acid leachates from the tailings represents some of the worst environmental problems worldwide. Hence, there is increasing pressure to understand the ecology and microbiology of these environments.

In addition to the *Thiobacilli*, researchers have shown that SRB play a significant role in tailings environments (107,114). These anaerobic, generally heterotrophic, bacteria require neutral to alkaline pH. Their numbers increase with depth in tailings deposits, although they are also found in the oxic zone where *Thiobacilli* are active. The H_2S generated by SRB reacts strongly with metal ions and the resulting precipitates are found both on the cell surface and throughout the environment surrounding the cell. The diagenetic minerals associated with SRB in Cu-Zn ore tailings from Kidd Creek Mine in Ontario, Canada, included amorphous FeS, mackinawite (FeS_{1-x}) and pyrite (114). Although the sulfate-oxidizing activity of bacteria dominates tailings, it is quite possible that *Thiobacilli* and SRB continuously recycle the sulfur in these minerals from soluble to insoluble forms. In another example in the oxic zone of tailings derived from a copper mine in Quebec, Canada, diagenetic iron phosphates and iron chlorides were detected associated with thiobacilli cell surfaces (76). The formation of minerals in the tailings piles shows the potential for the genesis of a mineral soil.

Freshwater Lakes and Rivers

Microbial populations in lakes tend to be much greater than those found in the open waters of seas; freshwater systems have populations approximately 10^2 to 10^5 per milliliter of water and approximately 10^6 per gram of sediment (25). The range reflects the wide variation in conditions that can be found in these environments, which are particularly susceptible to fluctuations in oxygen, temperature, and nutrient status. As mentioned previously (in the carbonate section), calcium mineralization at Fayetteville Green Lake, New York is mediated by *Synechococcus* GL24. Here the mineral phase alternates between gypsum and calcite, each being nucleated by the S-layer on the cyanobacterium. Because photosynthesis and respiration determine the pH of each cell's microenvironment, *Synechococcus* precipitates gypsum during the cold winter months (poor growth and circumneutral pH promotes gypsum) and calcite during the warmer summer season (good growth and a more alkaline pH promotes calcite). For more details on this study, see Reference 113.

Biomineralization can be a way to neutralize the toxicity of metals introduced to a lake. Lower Moose Lake in Ontario, Canada receives mine tailings drainage containing sulfate and other sulfur- and metal-containing compounds (44). Studies by TEM-EDS-SAED revealed that bacteria in the lake sediment served as nucleation sites for metal sulfides and (Fe,Al)-silicates. The formation of the minerals was explained by a combination of conditions including circumneutral pH, high metal concentrations, and low levels of sulfate reduction by bacteria, demonstrating again the specificity of the minerals to the environment that forms them.

In contrast to lakes, rivers tend to be uniform in temperature with depth and are usually well aerated. In addition, rivers vary in water velocity and turbulence. As with lakes, the nutritional status of rivers is variable and depends on the environmental setting. Researchers studying two rivers in the Amazon region of Brazil found that bacteria collected from the solute-rich Rio Solimões were encrusted with mineral precipitates, whereas bacteria sampled from the solute-deficient Rio Negro were not mineralized (46). The bacteria grew as biofilms on plant and sediment surfaces in the river and sequestered iron, as well as traces of Mn and Ni, in their capsules, suggesting a selective accumulation of these elements on the cell surface. Among the minerals found in these biofilms was a complex claylike (Fe,Al) silicate that has also been detected in other freshwater environments on other bacteria (115). Several characteristics point to a biogenic origin for these minerals, that is, the size of

the precipitates (~100 nm), their crystal structure, the tendency to form a crust around bacteria, and their chemical composition (which differed significantly from that found in other suspended material in the water). As discussed with respect to other minerals in the previous sections, an amorphous Al–Fe–Si phase forms, which dehydrates slowly and rearranges into a more crystalline form. In time, this process could form large deposits of minerals.

Hydrothermal Environments

The term *hydrothermal* encompasses a variety of natural terrestrial or marine environments that have exposure to water heated by geological activity. Often these regions have high concentrations of soluble silica and reduced metals. Although these are hostile environments, the metal-rich waters can provide energy — from reduced sulfur compounds or metals — to bacteria and large microbial populations may be found. Because silica and metals can embalm cells, preserving their natural arrangements in biogenic minerals, a fossil record is formed. Because of the extreme conditions [high temperature, high reduced metal concentrations, sulfide, salinity, and (sometimes) high pressure], these microorganisms often possess unique adaptations (116). They frequently belong to the *Archaea*. Three examples of biomineralization in different hydrothermal environments will be described — an ocean vent, a hot spring, and sediments from a shallow water hydrothermal system. For a review of microbiology in hydrothermal environments, see References 116 and 117.

Bacteria living near hydrothermal vents of the Southern Explorer Ridge in the Pacific Ocean provide nucleation sites for the growth of poorly ordered iron oxide, manganese oxide, and iron silicate particles, which coat cell surfaces and cell-associated filaments (118). A direct metabolic role for bacteria in mineral formation at ocean vent sites has not been shown. Researchers observed a similar preservation of bacterial cells in clay and mud sediments collected from an acidic hot spring at Yellowstone National Park (45). *Gallionella ferruginea* associated with hydrothermal brines in shallow waters around the Greek island of Santorini have a direct role in oxidizing Fe(III) bubbling up from vents, forming at least two meters of gellike sediments that contain poorly crystalline hydrous ferric oxide (HFO) precipitated around bacterial stalks (119). Transformations to more crystalline phases such as goethite (iron oxyhydroxide), siderite, and pyrite take place at greater depths, and pyrite formation is probably mediated by the activity of SRB.

Stromatolites

Stromatolites are ancient microbiolites that have been preserved by the minerals fixed in their biofilm communities as these communities grew. They are interesting because they record the presence of complex microbial ecosystems living up to 3.5 billion years ago during the Middle Archean period (120). The oldest known formations are the Onverwacht group in South Africa and the Warawoona group in Western Australia.

In cross section, stromatolites are finely laminated, with darker organic-rich cherts alternating with lighter carbonate-rich bands that have been cemented together over time. In form and shape they are similar to present-day microbial mats. Because they appeared at a time when the earth's atmosphere was reducing, it is thought that the organisms may have been lithoautotrophs or anaerobic photoautotrophs (120). These may have induced carbonate precipitation by creating an alkaline environment around the cell, although abiotic precipitation may also have contributed. For more information about stromatolites, see Reference 121.

Magnetotactic Bacteria

The term *magnetotactic bacteria* has no taxonomic significance and encompasses a diverse group of bacteria that display magnetotaxis. They are found throughout aquatic habitats, most often at the transition zone between oxic and anoxic conditions (6). Two regions where magnetobacteria have been studied in detail are Pettaquamscutt Estuary (Rhode Island, U.S.A.), and Salt Pond (Massachusetts, U.S.A.). Researchers studying magnetic properties within the water column at Salt Pond found that the peak in magnetic remanence (the magnetization recorded in the mineral) occurred in the oxic-anoxic transition zone. At this depth a great number of bacteria and the highest available Fe^{2+} (needed to form magnetite or greigite) were found (6).

Magnetotactic bacteria form unique structures (magnetosomes) that are aligned in rows to the cell axis and that contain membrane-bound single-domain magnetic particles of either magnetite or greigite (Fig. 1; 6). Magnetosomes can be preserved in sediments after these bacteria die and thus contribute to the paleomagnetic record if the concentration is sufficient. Some limitations are the detrital input of magnetic material, secondary formation of magnetic minerals, and mineral transformation of magnetosomes at depth. For example, Snowball (1994) found that the high concentration of biogenic magnetite in the upper portion of a Swedish lake sediment declined with depth (122). Bacteria can mediate chemical reactions leading to dissolution of magnetite or they can dissolve the mineral directly. The discovery that a Mars meteorite (ALH84001) contained magnetite particles similar in size and morphology to those produced by magnetotactic bacteria on earth has researchers speculating about interplanetary life (124). Such a discovery, if true, would considerably widen the geographic distribution of bacterial mineral formation. For a detailed review of magnetotactic bacteria, see Reference 6.

SIGNIFICANCE OF BIOMINERALIZATION

Iron Where It Is Not Wanted

Oxidation of reduced iron by bacteria is a worldwide nuisance. It results in plugged water pipes, wells, bore holes and field drains, as well as contaminated lakes and rivers. The slimy orange (although color and texture may vary) precipitates, consisting of iron oxyhydroxide or HFO, can be produced in copious amounts. Although the significance of Fe-oxidizing microbes in producing the deposits is controversial, researchers have

shown that both autotrophic and heterotrophic bacteria are responsible; the species depends on environmental conditions. *G. ferruginea* is found at neutral pH and low dissolved O_2 concentration. The characteristic twisted stalks of *Gallionella*, which extend from one side of the bean-shaped cells, become coated with HFO. *Thiobacillus ferrooxidans* is an example of a Fe-oxidizing chemoautotroph that also grows at the oxic–anoxic interface, although it prefers pH ~1 to 4. The bacterium, as previously described, produces acidity and ferric iron from pyritic ores. This iron leaches from the tailings to precipitate when it encounters higher pH, such as in a river or lake. See References 115 and 124 for more information on Fe-oxidizing bacteria.

Bioremediation

Bioremediation strategies that use bacteria exploit the affinity of bacteria for metals as well as their ability to reduce and oxidize metals. The latter requires living cells, whereas the former can use both living and dead biomass. Living systems include natural settings in which existing landforms such as ponds or streams are used to remediate metal contamination. These may already be in place, but are often simulated and have some kind of containment layer (e.g., a mine tailings leachate pond). In this case, immobilization of the metals is based on the interactions of an entire ecosystem, and contamination levels must be low enough that the microbes are not poisoned, although through natural selection heavy metal-resistant microorganisms often evolve. Over time, in aqueous systems, metals become part of the anaerobic sediments when the metal-loaded microorganisms die and sink to the bottom. Other kinds of living systems are those constructed to use organisms in an artificial environment for metals removal. One example is publicly owned treatment plants, which may incorporate a biological system to remove metals that remain after primary sedimentation; usually this is an activated sludge or trickling filter system. The metals are most often accumulated in the biopolymers produced by floc-forming microorganisms (usually bacteria) and not within the cells themselves (125). Another type of system uses cells colonized and immobilized (as a biofilm) on support material with the metal-loaded water flowing past. Good removals may be achieved with such systems, which can be tailored to immobilize specific metals (12).

Methods using sorption of metals by dead bacterial biomass are viable technologies for scouring metals from wastewaters and recovering valuable metals from ore-processing (126). Systems using dead biomass have the advantage that they are not susceptible to transient highly toxic concentrations of metals or other conditions; most waste streams are variable and can be toxic to living biomass. Furthermore, dead microorganisms can have higher metal-sorption capacities than living material (127). The dead biomass may be processed into a form in which it acts as an ion-exchange resin so that it can be regenerated by simple acid or alkali treatment. This makes such systems more economically competitive because the sorbed metals are easily recovered and the biomass can be reused (126).

Broad Implications

Biomineralization is a remarkably young science and has taken great strides in maturity over the last two to three decades. Who would have believed that the world's smallest life forms could have such a great impact on the earth's sedimentary fine-grained minerals? It is clear that one of the fundamental traits of microbial cells is to interact with the metal ions that surround them and, in so doing, profoundly affect geochemical conditions. Eh, pH, metal speciation, and interfacial chemistry are all affected, and sometimes enzymes act as catalysts for geochemical processes. It is imagined that since the dawn of life almost four Ga ago, prokaryotes have been reworking the earth, immobilizing metals with appropriate counter-ions and (presumably) even altering the primitive recipe of the oceans. Global carbon, hydrogen, nitrogen, oxygen, sulfur, phosphorus, and (now) metal cycling are all tied, at least partially, to microbes and their growth. With respect to mineralogy, bacteria have added their own particular flavor by instigating the production of a wide range of fine-grained minerals and by making possible the formation of some unusual minerals under geochemically unfavorable conditions. Exploring deep subsurface and (even) extraterrestrial microbiology may broaden the significance of bacteria to biomineralization.

Every living organism produces a tremendous variety of biopolymers. Each organism contains DNA, RNA, and proteins, but other important macromolecules found in living systems include polysaccharides (such as starch, cellulose, and xanthan gum), polyphosphates, polysulfates, polyphenols (such as lignin), isoprenoids (such as natural rubber), and polyhydroxyalkanoates (PHAs). PHAs are unique among the biopolymer groups in that they are all genuine thermoplastics — plastic materials that can be melted, formed, and reset. PHAs are unique among the plastics in that they are made inside living organisms, and thus they may be called "bioplastics." Sometimes materials such as polylactide are called "bioplastics" as well, but the polymerization is synthetic, using lactic acid produced by bacteria. This article focuses on PHAs because they are plastics made entirely by biological systems.

PHAs are water-insoluble polyesters that accumulate in the form of inclusions or granules inside microbial cells. The purified polymers have properties ranging from hard and brittle to soft and rubbery, depending on the composition. Many different kinds of monomers can be incorporated into PHAs, but the backbone of all of these monomers is essentially the same; they are all hydroxyalkanoic acids activated by linkage to coenzyme A. The polymerization is a process by which an enzyme called PHA synthase, or PHA polymerase, adds the activated monomer to the end of the growing polymer chain, yielding free coenzyme A and a polymer chain that has become one unit longer. The basic structure of PHAs is shown in Figure 1.

PHAs are made naturally by many species of bacteria as a carbon and energy storage compound, often under conditions where the carbon source is present in excess and the availability of some other element required for growth (such as nitrogen or phosphorus) is low. The polymer can accumulate to as much as 90% of the dry cell weight under controlled fermentation conditions, but generally much less under natural conditions. Table 1 shows some of the PHA-producing organisms and typical composition ranges for their PHAs. It is by no means an exhaustive list; more than 300 organisms are known to produce PHAs (1). Note that the absence of a composition in Table 1 does not necessarily signify the inability of the organism to produce that composition; these are only compositions that have typically been reported.

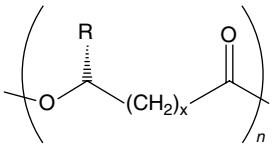

Figure 1. Chemical structure of PHAs. **R** represents a side chain having from 0 to 14 carbon atoms, **x** may range from 0 to 4, and **n** is an integer such that the molecular mass of the chain is higher than about 100,000 Da, typical of biologically produced PHAs. PHB: $\mathbf{R} = CH_3$, $\mathbf{x} = 1$. P(4HB): $\mathbf{R} = H$, $\mathbf{x} = 2$. PHO: $\mathbf{R} = (CH_2)_4CH_3$, $\mathbf{x} = 1$.

The occurrence of PHAs in living cells has been known since the 1920s. Maurice Lemoigne of Institut Pasteur first discovered in 1925 that *Bacillus* spp. can synthesize 3-hydroxybutyrate (3HB) (2), the first reported production of 3HB by a microbe. In the two years that followed, he definitively identified a polymer of 3HB units having the formula $(C_4H_6O_2)_n$ and melting point 157 °C to be present as a reserve material in certain *Bacillus* spp. (3,4). He also observed that the polymer could be degraded by the organism under autolytic conditions to a material having a lower molecular weight, lower melting point, and different solubility characteristics.

The notion that PHAs are a carbon and energy storage material was solidified by the work of Macrae and Wilkinson, who set out to determine the physiological role of poly(3-hydroxybutyrate) (P(3HB), or simply PHB) formation in *Bacillus* spp. in 1958 (5,6). They observed the necessary conditions for demonstrating that PHB is a reserve carbon and/or energy source: that the accumulation of PHB increased as the carbon-to-nitrogen ratio increased, that PHB was rapidly degraded in the absence of a carbon/energy source, and that the degradation of PHB in the absence of a carbon/energy source could prevent cell autolysis and death. This degradation makes PHB not only useful to the cells as an energy source, but it also makes PHB useful to humans for its biodegradability.

Direct confirmation that PHB was the main constituent of the insoluble granules observed in bacilli occurred in 1958, when Williamson and Wilkinson (7) demonstrated that PHB within cells could be isolated and quantified by treating whole cells with sodium hypochlorite. Among their many analyses of the isolated material was the precipitation of a film of PHB from chloroform by evaporation, and they described it as "somewhat reminiscent of plastic sheeting." They also showed that the material underwent thermal decomposition, giving crotonic acid as a main product.

PHB was the only known naturally occurring PHA until 1974, when Wallen and Rohwedder (8) reported the isolation of a polyester containing 3HB, 3-hydroxyvalerate (3HV), and 3-hydroxyhexanoate (3HH) units from activated sludge. Nine years later, Findlay and White (9) found PHAs with monomer units having four to eight carbons in marine sediments and in *Bacillus megaterium* extracts, and in the same year, de Smet and coworkers (10) isolated a polymer composed predominantly of 3-hydroxyoctanoate (3HO) units from *Pseudomonas oleovorans* grown on octane. Presently, at least 100 different monomer types have been found in PHAs, ranging from three to fourteen carbons in length, and the position of the hydroxyl group has ranged from C-2 to C-6 (the α to ε carbon). The constituents found thus far have invariably been (*R*)-hydroxyacids; the (*R*) configuration, the hydroxyl group, and activation with CoA are characteristics to which no exceptions have yet been found. For a comprehensive review of the diversity of monomer types found in PHAs, the reader is encouraged to consult Steinbüchel and Valentin (11).

The thermoplasticity and biodegradability of PHAs has led to more than just academic interest in these compounds. W. R. Grace & Co. were the first to recognize the commercial potential of PHB. They used *B. megaterium* and *Rhodospirillum rubrum* for production, and in 1960 the company filed the first patent concerning efficient production of PHB (12). W. R. Grace eventually abandoned the project, but Imperial Chemical Industries (ICI), later Zeneca, revived it in the 1970s, with an important modification: the efficient introduction of monomers other than 3HB. They found that the crystallinity of PHB could be reduced in this way, thus making the polymer more flexible and commercially of greater potential (13). This led to the development of Biopol, a copolymer of 3HB and 3HV units in about a 4 : 1 ratio. Biopol first became commercially available in 1990 in the form of shampoo bottles in Germany (14). The Monsanto Corporation acquired the technology in 1996, but it discontinued production of Biopol, which had reached about 800 tons per year (15), blaming lagging market interest in renewable materials (16). The Biopol composition will become public domain in 2001 on the expiration of the original ICI patent.

The remainder of this article explores in more detail the following aspects of PHAs: metabolism (both naturally occurring and via metabolic engineering), material properties and applications, production and recovery, and market and economics.

PHA METABOLISM

There are three main modes of PHA production in naturally occurring organisms: (*1*) condensation of acetyl-CoA, (*2*) fatty acid β-oxidation, and (*3*) fatty acid biosynthesis. It is possible, of course, for these organisms to derive hydroxyalkanoyl-CoAs from closely related carbon sources such as the corresponding hydroxyacids, but the three modes discussed here are concerned primarily with PHA production from common carbon sources such as sugars and oils. The final PHA composition is affected strongly by the mode or modes employed for its synthesis. Condensation of acetyl-CoA generally leads to short-chain PHAs, commonly defined as having monomer units of up to 5 carbon atoms, whereas fatty acid β-oxidation generally leads to medium-chain PHAs having units of 6 to 14 carbon atoms. Long-chain PHAs have 16 or more carbon atoms per unit, and these have appeared in PHAs only in small proportions from β-oxidation of long-chain fatty acids (17). Metabolic engineering of PHA pathways is also discussed in the following sections because it provides both flexibility and novelty in polymer compositions, and it also can enable PHA production in nearly any organism desired.

Condensation of Acetyl-CoA

Macrae and Wilkinson (5) speculated in 1958 that PHB is synthesized via acetoacetate by the condensation of acetate and some other two-carbon compound, and that the active compound for polymerization is 3HB-CoA. A direct demonstration that 3HB-CoA is the species used for polymerization was given by Merrick and Doudoroff in 1961 (18). They also provided evidence that 3HB was not directly activated with CoA. On the basis of

assays of 3-ketothiolase and 3HB-CoA dehydrogenase in cell extracts, Schindler (19) correctly concluded in 1964 that the pathway shown in Figure 2 is the one employed by *Ralstonia eutropha*. The PHB pathway proceeds by condensation of two acetyl-CoA molecules to form acetoacetyl-CoA, followed by a reduction to 3HB-CoA and polymerization. The most common implementation of this pathway is that found in organisms such as *R. eutropha* and *Zoogloea ramigera*, where the reduction specifically produces the (*R*) isomer of 3HB-CoA. A more complex pathway exists in *R. rubrum*, however; the overall reduction to (*R*)-3HB-CoA appears to be accomplished first with a reduction of acetoacetyl-CoA to (*S*)-3HB-CoA, followed by the action of two enoyl-CoA hydratases with the intermediate crotonyl-CoA (20).

The first step in the PHB pathway, the reversible condensation of two acetyl-CoA molecules to acetoacetyl-CoA with the release of free CoA, is catalyzed by a 3-ketothiolase. The substrate specificity of these enzymes dictates that one reactant is always acetyl-CoA, but the other reactant can vary in length. Many organisms possess more than one of this type of enzyme. *Ralstonia eutropha*, for example, has at least two 3-ketothiolases that can participate in PHA synthesis. One will condense acetyl-CoA with acetyl-CoA or propionyl-CoA, and the other appears to accept all acyl-CoAs from acetyl-CoA to octanoyl-CoA (21). Condensation of acetyl-CoA with propionyl-CoA yields 3-ketovaleryl-CoA, which is reduced to 3HV-CoA. Propionyl-CoA, not nearly as common as acetyl-CoA in biological systems, is an end product of the catabolism of fatty acids with odd numbers of carbon atoms, but it is also derived in some organisms from succinyl-CoA via methylmalonyl-CoA (22,23). 3-Ketothiolase has a regulatory role in PHA synthesis by this route. In many cases, the condensation reaction is strongly inhibited by free CoA (21,24–27). In *R. eutropha*, the PHB pathway is constitutively expressed (28), so the regulation of 3-ketothiolase activity seems to be at the enzymatic level (25). The intracellular free CoA level does appear to be significantly lower during PHB-producing conditions (29).

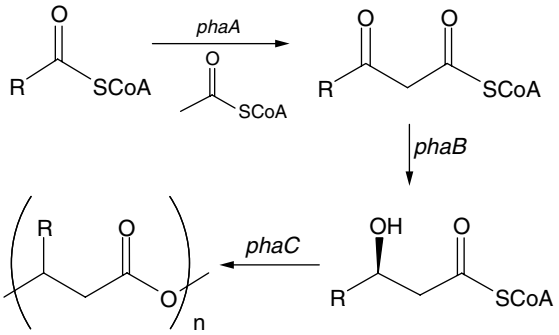

Figure 2. Pathway from acetyl-CoA and other acyl-CoAs to PHAs. When $\mathbf{R} = CH_3$, two acetyl-CoA molecules are condensed by 3-ketothiolase (EC 2.3.1.9), the product of the *phaA* gene. The resulting acetoacetyl-CoA is reduced to (*R*)-3-hydroxybutyryl-CoA by 3-ketoacyl-CoA reductase (EC 1.1.1.36), the product of the *phaB* gene, and finally PHA synthase (no EC number), the product of the *phaC* gene, incorporates an (*R*)-3-hydroxybutyrate unit into PHA with the release of CoA. When $\mathbf{R} = C_2H_5$, propionyl-CoA is condensed with acetyl-CoA, and ultimately an (*R*)-3-hydroxyvalerate unit is incorporated into PHA.

The reduction of acetoacetyl-CoA to (*R*)-3HB-CoA is accomplished in most cases by a single stereospecific reductase. Most of the reductases characterized to date have shown a preference for NADPH over NADH as cofactor (30–32), but there is at least one case where NADH is preferred (33). This second step of the pathway exerts some thermodynamic control over PHB synthesis. The 3-ketothiolase reaction is thermodynamically more favorable in the direction of cleavage, not condensation (34). Therefore, for PHB synthesis to proceed, the acetoacetyl-CoA concentration must remain low. This can be accomplished with a high NADPH/$NADP^+$ ratio, which will thermodynamically favor (*R*)-3HB-CoA formation. Provided that the PHA synthase activity is sufficient, the NADPH/$NADP^+$ ratio is instrumental in fueling the pathway (35).

PHA synthase is the final step of all the pathways to PHA, so the substrate specificity of this enzyme controls the polymer composition to some degree regardless of the pathway employed. Most synthases have a preference for either short-chain or medium-chain PHAs, although some recent exceptions have been reported. The *Aeromonas caviae* synthase accepts both 3HB-CoA and 3-hydroxyhexanoyl-CoA (3HH-CoA) (36), and the *Thiocapsa pfenigii* synthase accepts a broad range of substrates (37,38). The majority of synthases have only one type of subunit, but of the first 30 to be sequenced, four have two subunits (39).

Fatty Acid β-Oxidation

The β-oxidation pathway (Fig. 3) is the most common mode of fatty acid catabolism. Some bacteria, most notably the pseudomonads, can divert carbon flow out of β-oxidation to store the carbon as PHA. Fatty acids are first activated with CoA, then undergo repeated rounds of removal of two-carbon units, ultimately in the form of acetyl-CoA, by a thiolase. This is the same type of reaction catalyzed by 3-ketothiolase, but the reaction proceeds predominantly in the direction of cleavage. Hydroxyacyl-CoAs are intermediates in β-oxidation, but they appear in this pathway as the (*S*) stereoisomer. The diversion of these intermediates therefore requires the conversion of the (*S*) form to the (*R*) form. Alternatively, the (*R*) form can be formed directly by the action of an enzyme that is not part of the β-oxidation pathway.

The pathways that organisms actually use to divert carbon flow from β-oxidation to PHA synthesis have only recently begun to be explored. It has been known since 1983 (10) that *Pseudomonas* spp. can effectively synthesize medium-chain PHAs from fatty acid feeds. Precisely how they do this is still not known, although it is presumed to be via one of the three possible activities for the generation of (*R*)-hydroxyacyl-CoAs shown in Figure 3. Expression of *Pseudomonas aeruginosa* PHA synthase in *E. coli* fatty acid degradation mutants resulted in medium-chain PHA production (40). This suggests that *Escherichia coli* possesses at least one of these three activities, although it does not normally synthesize PHAs

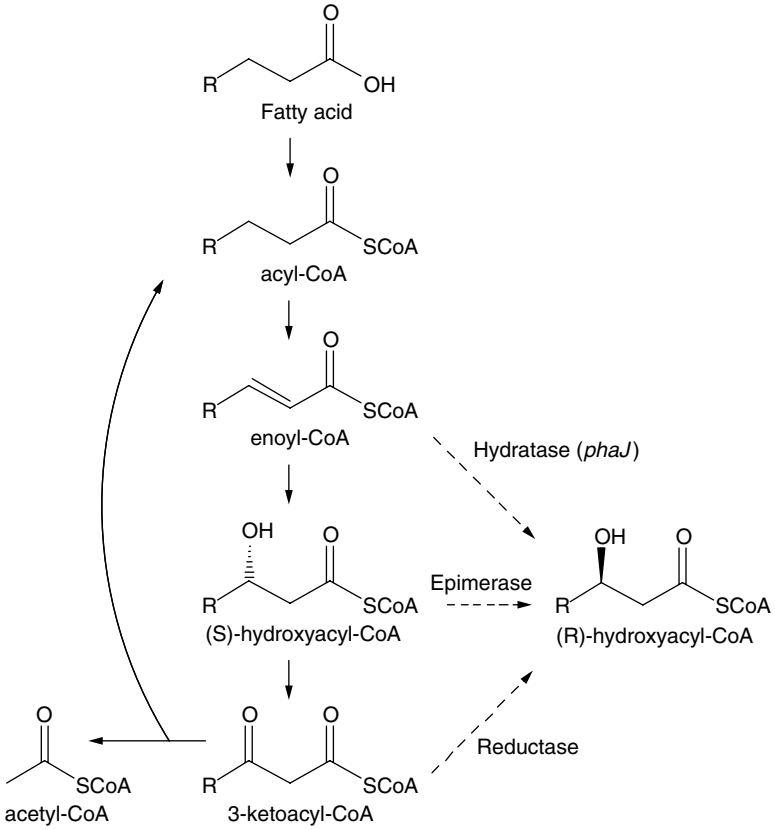

Figure 3. The derivation of PHA precursors from the β-oxidation pathway. The solid arrows represent reactions that are known to occur widely in biological systems. The dashed arrows represent reactions that can generate (*R*)-3-hydroxyacyl-CoAs, the precursors of PHA. In each round of β-oxidation, the alkyl group **R** becomes shorter by two carbons.

at all, and it also suggests that these additional activities are common in nature. Only one of the three activities has actually been found, but not in *Pseudomonas*: an (*R*)-specific enoyl-CoA hydratase. The first example of this activity was found in *A. caviae*, which can synthesize P(3HB-co-3HH) from fatty acids or oils (36,41). Another example of the activity was found in *R. rubrum* (42). Both genes have been cloned and are denoted as *phaJ*. Both of these hydratases accept enoyl-CoAs of four to six carbons, but not eight. The *R. rubrum* enzyme, when expressed in *E. coli* with the promiscuous PHA synthase of *Thiocapsa pfenigii*, produced P(3HB-co-3HH) when the carbon source was oleic acid. This shows how enzymes other than PHA synthase can at least partially dictate polymer composition.

Fatty Acid Biosynthesis

Both prokaryotes and eukaryotes synthesize fatty acids. Both use them for lipids to construct membranes. Many eukaryotes store energy by fatty acid synthesis in the form of fats and oils, but bacteria generally do not. Some bacteria, however, can use PHA synthesis to divert carbon flow from fatty acid synthesis to store carbon and energy (Fig. 4). In this sense PHAs can be thought of as "bacterial fat."

In 1990 it was found that many pseudomonads can synthesize medium-chain PHAs when fed gluconate (43,44), suggesting that the fatty acid biosynthesis pathway might be involved. Later it was shown in *Pseudomonas putida* grown on glucose that the degree of unsaturation in the PHA side chains decreased with temperature, as is generally also true of membrane lipid composition, offering more evidence that the fatty acid biosynthesis pathway can be used for PHA synthesis (45).

PHA synthesis using the fatty acid biosynthesis pathway, just as from the β-oxidation pathway, requires at least one additional activity for the synthesis of (*R*)-hydroxyacyl-CoAs. The intermediates of fatty acid biosynthesis are all of the (*R*) form, but the prosthetic group is the acyl carrier protein (ACP). Therefore, ACP must be exchanged for CoA, either directly by a transacylase or by two sequential activities, a thioesterase to remove ACP and a transferase or synthetase to activate with CoA. One development in this area was the discovery of the *phaG* gene in *P. putida* and the demonstration that it is a 3-hydroxyacyl-ACP : CoA transferase (46). The gene was also found in *P. aeruginosa* (47).

Metabolic Engineering

Naturally occurring PHA-producing organisms certainly generate a wide array of polymers. The diversity of PHAs and their numerous potential applications have motivated a great deal of effort in metabolic engineering of PHA production in both academia and industry. The main advantages that metabolic engineering offers in PHA production are that it can generate novel PHA compositions, allow PHA synthesis from less expensive substrates, improve the characteristics of the material, give better control over composition, improve the efficiency of production, and enable PHA synthesis in almost any

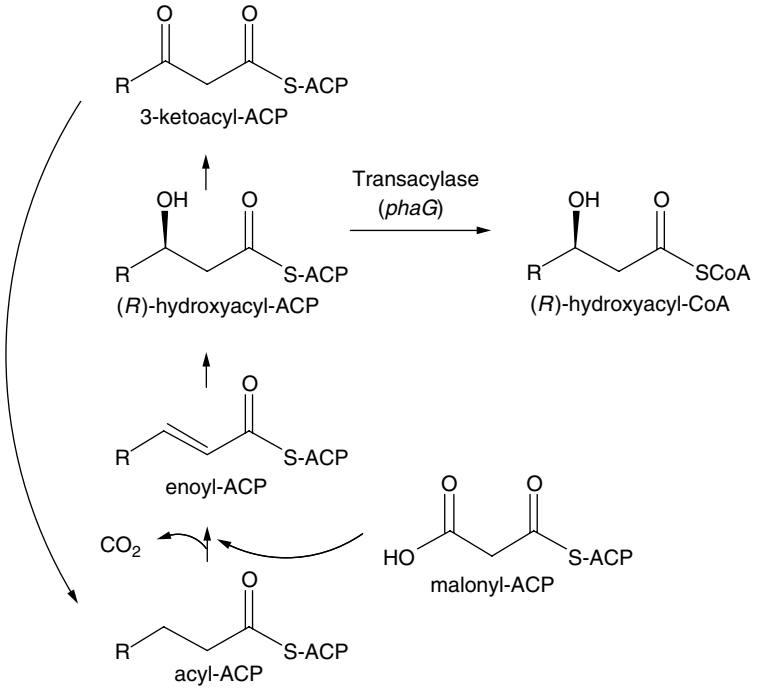

Figure 4. The derivation of PHA precursors from the fatty acid biosynthesis pathway. In each instance of condensation with malonyl-ACP, the alkyl group **R** becomes longer by two carbons.

desired organism. These advantages are summarized in Table 2, with an example of each.

Metabolic engineering of PHA production became possible in the late 1980s, when three independent groups cloned the PHA biosynthetic genes (*phaCAB*) from *R. eutropha* (48–50). Much progress has been made since then in assembling a library of cloned genes useful for PHA synthesis. For example, at least 30 PHA synthase genes have been cloned (39).

The host organism of choice for metabolic engineering of PHAs has most often been *E. coli*. PHAs with monomer units ranging from 3 to at least 12 carbons have been synthesized in engineered *E. coli* (42,51–54). The use of *E. coli* for PHA production is desirable for technical as well as economic reasons. The genome of *E. coli* has been sequenced in its entirety, and its metabolism and genetic techniques are well understood. Because *E. coli* does not naturally produce PHAs, it possesses no ability to degrade PHAs or synthesize unwanted PHA constituents. Unlike many natural PHA producers, *E. coli* grows at 37 °C and is relatively easily lysed. Furthermore, the use of a single organism to make an array of compositions necessitates only one general fermentation procedure, even if feeding strategies and operating conditions vary. Good control over composition allows the tailoring of material properties within a design space, a theme that is explored in the next section.

Table 2. Some Advantages of Metabolic Engineering in PHA Production

Advantage	Example	Ref.
Novel compositions	Poly(3-hydroxyhexenoate) with polyketide synthase	121
Inexpensive substrates	P(3HB-co-3HV) from glucose in *E. coli*, from CO_2 in plants	122
Characteristics of material	Molecular weight control	123
Control over composition	P(4HB) with no residual PHB	124
Efficiency of production	Reduction of *Pseudomonas putida* lysate viscosity	125
Any desired organism	PHB synthesis in cotton fiber	126

Properties and Applications

Because more than 100 different constituents have been incorporated into PHAs, and because these can be mixed in the same polymer chain, the number of compositions that can be generated is quite large. The constituents vary in length, position of the hydroxy group, and presence of functional groups and double bonds. As a result, the material properties and applications of PHAs are quite diverse. All of the possible combinations of monomer constituents make up the design space in which the engineering of PHA material properties can take place. The first conscious exercise of this nature was undertaken by ICI. They wished to develop PHAs commercially, but PHB by itself suffers from some disadvantages. Its melting point (about 180 °C) is very close to the temperature at which it begins to undergo rapid loss of molecular weight by thermal degradation, making melt processing somewhat difficult. When processed conventionally, it is also too brittle a material to be useful in many applications because of its very low nucleation density and high crystallinity. On adding propionate to an *R. eutropha* fermentation as a cofeed, it was found that significant amounts of 3HV were incorporated into the polymer. This increased the flexibility of the material, as measured by

modulus, elongation to break, and impact strength, and it significantly depressed the melting point (13). Thus began the endeavor to explore more fully the PHA design space.

Material Properties

Many PHAs have been evaluated for basic material properties over the last two decades. The short-chain PHAs tend to be more crystalline than the medium-chain PHAs, and hence generally the short-chain PHAs are more rigid, whereas the medium-chain PHAs are more rubbery. Table 3 gives an overview of the material properties of some PHAs. Its purpose is to illustrate the range of properties that exists; certainly many more compositions have been characterized.

Biologically produced PHAs can have molecular masses of more than 1 million daltons. Although the ring-opening polymerization of lactones to produce PHAs is a well-known procedure, its main drawbacks are that its products are generally of lower molecular weight and that, in cases where chirality is an issue (when the hydroxyl group is not terminal), its products are not stereoregular, and hence not isotactic (61). Molecular weight problems become more pronounced for the products of less strained lactones such as P(4HB) from γ-butyrolactone.

PHB does not have especially advantageous properties, as discussed earlier, but it is evident from Table 3 that copolymerization with another monomer type can improve the situation. In many cases, even a few percent of another constituent lowers the melting point and apparent crystallinity significantly. Sometimes the other constituent can cocrystallize with PHB to some extent, as has been reported for 3HV (56), so a somewhat higher percentage may be required to achieve the same plasticizing effect. PHB copolymers of this type are similar to commodity plastics such as polypropylene and high-density polyethylene, hence the first commercial application of P(3HB-co-3HV) as shampoo bottles (14). As the PHB comonomer fraction increases, material properties may change significantly. For example, P(3HB-co-15% 4HB) stretches and recovers like a rubber band but is translucent. P(4HB) homopolymer is extremely tough but also is very flexible. Medium-chain PHAs such as poly(3-hydroxyoctanoate-co-20%-3-hydroxydecanoate) are translucent and rubbery but somewhat stiff, and they can be tacky due to their low melting points.

Biodegradability and Biocompatibility

A distinguishing feature of PHAs is that they are fully biodegradable (can be reduced to carbon dioxide and water in a natural environment in a relatively short time) and often biocompatible (do not cause adverse reactions when present in living biological systems). Although they are degraded by microorganisms in composting, PHAs are stable in everyday environments; they do not break down on the shelf.

The environmental degradation of PHAs primarily is due to the action of microbially secreted depolymerases, which hydrolyze the polymer to compounds that are taken up by bacteria, fungi, and algae and converted ultimately to carbon dioxide and water. Methane can also result from anaerobic biodegradation. The depolymerases only hydrolyze ester linkages of monomers in the (*R*) configuration (63), and thus synthetic nonstereoregular PHAs are not completely biodegradable in this sense. The rate of degradation varies with composition and molecular weight, and it also varies with the type of natural environment. A bottle made from P(3HB-co-3HV), for example, will degrade completely in 5 to 10 years in a freshwater lake (64) but within 12 weeks in sewage sludge (65). P(3HB-co-4HB) degrades in seawater at about the same rate as P(3HB-co-3HV) (66) and somewhat faster than PHB and P(3HB-co-3HV) in soil (67). In sterile aqueous environments, polymers such as these hydrolyze very slowly. Doi and coworkers (68) showed that after 180 days at 37 °C in 0.01 M phosphate buffer at pH 7.4, PHB and copolymers with 3HV and 4HB had not lost significant mass, but their molecular weights (or average polymer chain lengths) began to decrease, apparently due to simple hydrolytic chain scission.

The biocompatibility of several PHAs has been evaluated. PHAs can perform very well in this capacity,

Table 3. Range of PHA Material Properties in Comparison with Those of Common Plastics

Composition	M_w (kDa)	T_m (°C)	T_g (°C)	ΔH_m (J/g)	Crystallinity (%)	Tensile Strength (MPa)	Elongation to Break (%)	Ref.

High-density polyethylene		135	−80		80–95	30	30–1,000	137,138

provided they are extremely pure. Medium-chain PHAs, for example, have been shown not to elicit a significant inflammatory response after 40 weeks subcutaneously implanted in mice and not to elicit an allergic response on 48-hour exposure to the skin of guinea pigs (69). In many cases, PHAs are also resorbable in animal systems, meaning they can be completely metabolized over time by the host without production of toxins or adverse health effects. Short-chain PHAs such as PHB have been shown to be both biocompatible and resorbable in a relatively short time (70,71). PHB is actually present as low molecular weight oligomers at a few milligrams per liter in human blood plasma (72), and 3HB is a commonly encountered ketone body (73); significant toxicity of PHB hydrolysis products thus seems unlikely.

Applications

PHAs can be processed like commonly used thermoplastics. They can be useful in the form of containers and other molded items, disposable packaging and articles, medical implants and devices, coatings and paints, and in many specialty applications. Different compositions of PHA will, of course, find uses in different areas, especially when the distinction between the more rigid character of short-chain PHAs and the more rubbery character of medium-chain PHAs is considered.

PHAs can be recycled like many commodity-based thermoplastics, but because they are biodegradable, they lend themselves especially well to applications in which recycling is not practical, such as in single-use disposable food packaging and garbage bags, in which the plastic is mixed with food or garbage, and personal care items, in which the plastic is either contaminated or the article is made of different types of plastic that are too difficult to separate. Biodegradation can be a useful alternative to recycling in some cases. Mixtures of polyethylenes of different molecular weights, for example, often suffer deterioration of mechanical properties on repeated recycling and processing to the point when the material becomes unusable (74). P(3HB-co-3HV) did in fact appear in disposable applications during the 1990s, while Zeneca still produced Biopol. It was used not only in bottles in Germany, Japan, and the United States, but it also appeared in disposable razors and refrigerated meat trays (75). Compostable diapers and sanitary napkins made from PHAs are of current industrial interest (74,76–79). These are a good illustration of the utility of PHAs; diapers, for example, may be composed of nonwoven absorbable material, backsheet, and pressure-sensitive adhesive tape, made from PHAs and fully biodegradable.

The biocompatibility and in some cases resorbability of PHAs make them very useful as medical materials. Applications include tissue coatings, stents, sutures, tubing, prostheses, bone and tissue cements, tissue regeneration devices, wound dressings, drug delivery materials, and diagnostic and prophylactic uses (80). An active area of research with PHAs is tissue engineering (81), in which a resorbable material is used as a scaffold to "grow" human tissue from the patient's own cells. Recently, trileaflet heart valves were formed from P(3HO-co-3HH) and from P(4HB) and were seeded with mammalian cells, and each material showed a good level of cell attachment and collagen formation (82). These materials offer the added benefit of moldability and pliability; in the same study, a working valve could not be formed from polyglycolic acid, a traditional medical material. PHAs have already been successfully used to regenerate pericardial tissue and limit postoperative pericardial adhesions (83,84) and to correct atrial septal defects (70) in vivo. In drug delivery applications, PHAs can be used subcutaneously or in pill form in humans or as a stomach bolus in animals (85). In either case the composition of the PHA can be tailored so that the approximate release rate of the drug is appropriate without the need for frequent dosing. In any surgical or dressing application, bits of material left in the body are of no concern as they are simply resorbed (85).

PHA granules produced in biological systems are usually amorphous, either because of very low nucleation density, as with short-chain PHAs, or to low crystallization rates or lack of inherent crystallinity, as with medium-chain PHAs (62). Aqueous processing of these granules can yield a slurry of granules called latex. On spreading the latex onto a surface, it dries and can crystallize either spontaneously or when stimulated by heat or a nucleating agent. Medium-chain PHAs with unsaturated side chains can even cross-link during drying (86). Such latexes can be used to coat paper or plastic and as water-based paint ingredients (86,87) or to coat cheese and other foods (88). P(3HB-co-3HV) received food contact approval in Europe in 1995 (87).

Specialty applications of PHAs are too numerous to list here. PHAs can be used in agricultural applications such as planters and films, where biodegradability eliminates the need for removal, and they can be used as vehicles for controlled release of pesticides, with biodegradation being the means to liberate chemicals embedded in the polymer (85). They are useful as binders, where they hold powders or small pieces of another material together and are subsequently burned out cleanly (89). Intriguing food applications include chewing gum base (90) and fat substitute (91). PHAs with unsaturated side chains can be cross-linked to form materials that behave similar to rubber, yet are still fully biodegradable (62).

An often overlooked but potentially very important application of PHAs is not as polymers, but as chemicals derived from those polymers hydrolyzed chemically or biologically. (*R*)-hydroxyalkanoic acids can be used to synthesize antibiotics, vitamins, aromatics, and pheromones (92). (*R*)-3HB is used as a starting material for the Merck antiglaucoma drug Trusopt (93). Other chemicals with existing markets can be derived from PHAs by simple chemical reactions; for example, PHB can yield 1,3-butanediol, crotonic acid, β-amino acids, butyl esters, lactones, and other compounds (94). Analogous arguments can be made for P(4HB), P(3HO), etc.

Production and Recovery

The two types of organisms that are most favorable for industrial production of PHAs are bacteria and plants. Bacterial fermentation can be carried out as Zeneca

developed the process, with natural PHA producers such as *R. eutropha*. With the advent of routine bacterial genetic manipulation since that time, recombinant producers such as *E. coli* have been developed as well. The engineering of PHA production in plants is a longer-term solution because plant genetic manipulation is not routine. The reward, however, would justify the task; the resulting large scale and low cost of PHA production could make them a real alternative to commodity plastics derived from fossil fuels.

Fermentation and agricultural production of PHAs ideally coexist. Plants are suited to large-scale commodity applications without much complexity in composition. Crops are subject to variations in climatic and soil conditions, and they must synthesize all polymer constituents from carbon dioxide. Therefore, fine control of PHA composition and characteristics is likely not possible in plants. Bacterial fermentation is more expensive, relatively small-scale, and rather energy-intensive, making it questionable for long-term commodity production. However, bacterial fermentations can be controlled precisely, and any feedstock desired may be used. Medical and other specialty applications require this flexibility and do not require the immense scale of agriculture.

The most commonly used organisms in fermentation have been *R. eutropha* for short-chain PHAs and *Pseudomonas* spp. for medium-chain PHAs. Both types of cells are cultured aerobically in a fed-batch mode. Typically, the natural producers of PHA require limitation in some nutrient other than the carbon source to accumulate PHA to more than a few percent of the dry cell weight. Limitations in nitrogen and phosphorus are typically used in practice. This can be implemented by including in the medium all the nitrogen or phosphorus needed to achieve the desired cell density; when this is completely consumed, growth ceases and PHA accumulation begins. For example, *R. eutropha* accumulated 137 g/L of P(3HB-co-29% 3HV) at 67% of the dry cell weight in 65 hours with a feed of corn oil and propionic acid under phosphorus limitation at 34 °C (95). An interesting alternative to *R. eutropha* is *Alcaligenes latus*, which can accumulate PHA in significant amounts during exponential growth and can be cultured at up to 42 °C (96). *Pseudomonas putida* accumulated 73 g/L of medium-chain PHA, containing predominantly 3HO and 3HD at 51% of the dry cell weight in 38 hours on oleic acid and phosphorus limitation at 30 °C (97).

Transgenic PHA production has been developed primarily with *E. coli*, although genetic manipulations have been made on natural PHA producers as well. There are currently many advantages to the use of transgenic *E. coli*: genetic manipulations are routine, the metabolism is well understood, the genome has been completely sequenced, minimal medium can be used with many types of feedstocks, nutrient limitation is not necessary, the cells lyse easily, growth at up to 42 °C is possible, no depolymerases are present to degrade the product, and the choice of one organism eliminates the need to develop a markedly different fermentation process every time a new polymer composition is sought. *Escherichia coli* is capable of performance at least on a par with natural producers; a strain expressing the *R. eutropha* PHA synthesis genes from a plasmid accumulated 157 g/L of PHB at 77% of the dry cell weight in 49 hours with a glucose feed at 30 °C (98).

PHA production in plants has been implemented only on a very small scale. The first difficulty to be overcome with plants is the achievement of high, stable expression of multiple foreign genes in the same plant. The compartmentalization and complexity of metabolism is an added difficulty. However, there is reason to be optimistic; in 1994 it was reported that *Arabidopsis thaliana* plants could produce PHB at up to 14% of the dry cell weight and still develop normally when the *R. eutropha* PHA synthesis genes were targeted to the plastid (99).

The two main modes of PHA recovery from biomass are solvent extraction and aqueous processing. Solvent extraction consists of suspending biomass, usually dried, in a solvent that can dissolve the PHA of interest, removing solids, then precipitating the polymer either by the addition of a poor solvent, by evaporation, or by cooling. Aqueous processing is a general term for recovery techniques that begin with wet biomass, as from a fermentation or wet milling operation, and proceed in the presence of water to yield either an aqueous, largely amorphous latex or dry polymer with some degree of crystallinity, depending on its composition. An amorphous latex can be reconstituted from a crystalline PHA (100).

Large-scale application of solvent extraction suffers from the need to use large volumes of solvents; PHA solutions become viscous even at relatively low concentrations. The most useful solvents for short-chain PHAs are chlorinated solvents such as chloroform and 1,2-dichloroethane, which must be contained carefully. The latter problem has been addressed to some degree by the use of nonchlorinated solvents at higher temperatures (101,102). Medium-chain PHAs can readily be extracted with relatively benign solvents such as acetone, isopropanol, and hexane (103,104).

There are many variations of the aqueous processing theme, but generally aqueous processing consists of one or more of the following steps: separation of solid biomass from bulk liquid, mechanical or enzymatic cell breakage, solubilization of non-PHA biomass, and isolation of polymer. Usually the polymer remains in amorphous granule form throughout the procedure, although exceptions exist, such as melting and coalescence of granules followed by settling of bulk polymer (105). Initial reduction of the liquid volume is especially useful when bacterial cells are taken from a fermentation and the reduction is accomplished by centrifugation, filtration, or flocculation. Bacterial cells can be broken by heat treatment (106), homogenization (107), or chemical treatment with hypochlorite (108,109), alkali (110), surfactants or water-soluble copolymeric dispersants (111), or oxidants such as hydrogen peroxide (112) or ozone (113). Heat treatment may be followed by digestion with enzymes such as proteases, lysozyme, and DNase, which can become costly (106). Homogenization is rather energy-intensive (114) and does not effect any purification. The chemical treatments have the advantages of being inexpensive and facilitating purification by solubilizing non-PHA biomass (115). Recovery of the polymer granules from the resulting solution is generally done by washing and centrifugation, but other

methods such as sedimentation fractionation (116) and air classification (117) have been described.

Market and Economics

Above all else, the factor that will determine the fate of PHAs on the market is the price. There is no question about the usefulness and favorable properties of these materials, but the last sales of any volume to take place were of Biopol in the 1990s, for about $8/lb (118). Even with all the goodwill of biodegradability and derivation from renewable resources, bulk commodity applications certainly cannot take hold at this price. With larger scale and established markets, come lower costs, but these have not yet developed because plastic users in many cases have little experience with PHAs. At present only very small quantities of PHAs are available commercially, so market development is crucial.

One exception to the price issue is the medical use of PHAs. Here performance is much more important. The cost of the polymeric material in, for example, a heart valve replacement procedure is of little consequence, but the specifications on the material are quite exacting. The main hurdles to market acceptance in this area still lie in regulatory approvals and in confident acceptance by medical associations. The overall yearly demand for vascular grafts and heart valve replacements worldwide corresponds to approximately 1 million procedures (81).

A few analyses of expected cost of PHA production have been conducted recently by van Wegen and coworkers (107) and by Choi and Lee (118,119). These studies estimated the cost of producing short-chain PHAs using technology that is currently available. Both used a process consisting of fermentation followed by centrifugation, hypochlorite treatment, two more rounds of centrifugation, and finally drying. The main difference between the studies was that one used homogenization (three passes) and the other simply used a surfactant to complement the hypochlorite treatment. The studies agreed that the cost would be approximately $2.50 to $2.80/lb for a scale of 5 to 10 million lb/yr. These studies also agreed that improvements to the current pilot-scale process could readily be made, and that these could reduce the cost, especially at a larger scale, to $1.20 to $1.40/lb. The most sensitive parameter according to both studies is the PHA content as a percentage of the dry cell weight because fewer impurities means less energy expended on downstream processing. Other reasonable improvements cited were reduction of raw material cost (i.e., using hydrolyzed corn starch at $0.10/lb instead of glucose at $0.24/lb), efficiency of centrifugation, optimization of the chemical treatment, and higher productivity during the fermentation. Less-detailed studies were conducted to determine potential costs of medium-chain PHA production, and in the best case the estimate was about $2.30/lb, again with PHA content of cells being the most important parameter (120).

Citric acid and glutamate are produced by established large-scale fermentation processes at nearly 2 billion lb/yr, approaching that of smaller-scale bulk petrochemical processes. The selling price of these bioproducts tends to be in the neighborhood of $1/lb (121). These processes set an optimistic example for the foray of fermentation technology into the plastics market, and they demonstrate the legitimacy of the industrial effort to produce bioproducts on a large scale. Industry has become committed to the development of biodegradable plastics on a large scale as well. For example, Cargill Dow is expanding its capacity for polylactic acid (synthetically polymerized from fermentation-derived lactic acid) from 16 million lb/yr to 280 million lb/yr (122), and DuPont is developing Biomax, a polyethylene terephthalate with monomers vulnerable to hydrolysis incorporated (123). The most promising sectors for growth of biodegradables in the near future are predicted to be food packaging, compost bags, paper coatings (milk, juice, frozen food, etc.), dishes and cutlery (of which 100 million lb/yr can be replaced with biodegradables), and disposable hygiene products; forecasts for the 2003 biodegradable plastics market range from 50 million to 200 million lb/yr (122).

The maturation of transgenic PHA plant technology would bring about a sea change in the economics of PHA production. This is a long-term goal in comparison with fermentative production, so predictions are not as easy to make. Preliminary estimates put the price of plant-derived PHAs at $0.25 to $0.60/lb (94,124), competitive with petroleum-based commodity thermoplastics, which typically sell in this range (125). For PHAs to assume a volume of billions of lb/yr, however, certain milestones must be met. Starch or oil carbon flux must be diverted by metabolic engineering to achieve a polymer content of about 30 to 40% of the plant dry weight. Aside from technical issues, regulatory approval must be obtained for the transgenic plant to be used in the field as well as for the use of the particular polymer in applications such as food contact. Companies with the ability to develop applications on a large scale must be involved, and further development of composting infrastructure would be necessary if the biodegradability aspect of PHAs is to be very meaningful. If these milestones are met, the stage is set for the release of commodity plastic production from dependence on feedstocks such as crude oil, which is projected to run out during our century (126).

BIOREMEDIATION: AN OVERVIEW OF HOW MICROBIOLOGICAL PROCESSES CAN BE APPLIED TO THE CLEANUP OF ORGANIC AND INORGANIC ENVIRONMENTAL POLLUTANTS

ROGER C. PRINCE
ExxonMobil Research and Engineering Co.
Annandale, New Jersey

BIOREMEDIATION, ECOLOGY, TECHNOLOGY

Bioremediation

Bioremediation relies on encouraging biological processes to minimize an unwanted environmental impact; usually it is the removal of a contaminant from the biosphere. A narrow definition of bioremediation might focus on the conversion of contaminating organic molecules to carbon

dioxide, water, and inorganic ions, and the oxidation or reduction of contaminating inorganic ions. A broader definition would include biological processes for ameliorating extremes of pH, concentrating contaminants so that they can be more easily removed by physical techniques, converting toxic species to less toxic or less bioavailable forms that pose less of a threat to the environment, and restoring functional ecosystems in contaminated or disturbed sites when the contaminants or disturbance cannot be removed. This article focuses on biological treatments for contaminants when they have escaped into the environment, particularly on the initial microbial reactions that remove or convert the contaminant.

Many approaches are being used effectively to catalyze bioremediation. Sometimes the simple addition of an otherwise limiting nutrient is appropriate, while at other times microbial inocula are needed. In other situations, it may be important to add readily degradable substrates to foster cometabolism of a contaminant or to drive an environment toward anaerobiosis to stimulate anaerobic degradation. Alternatively, it might be necessary to add surfactants or other chemicals to increase the bioavailability of a contaminant.

Bioremediation therefore overlaps several older biotechnologies. Municipal and industrial wastewater treatment is a well-established industry and while it can be distinguished from bioremediation in that the pollutants are under physical control during treatment, many of the fundamental biological processes are the same. Similarly, composting is a well-established phenomenon, currently gaining popularity in the municipal solid waste treatment industry, and the biofiltration of waste gases is becoming a useful technology. Development of these technologies, for cases in which the contaminant is already under physical control, will undoubtedly aid the development of bioremediation as an accepted tool for dealing with similar wastes when they have escaped our control.

Bioremediation is already a commercially viable technology, with estimates of aggregate bioremediation revenues of $2 to $3 billion for the period 1994 to 2000 (1). There are significant opportunities to enlarge upon this success. Bioremediation has applications in the gas phase, in water, and in soils and sediments. For water and soils, the process can be carried out in situ or after the contaminated material has been moved to some sort of contained reactor (ex situ). The former is generally rather less expensive, but the latter may be so much faster that the additional cost of manipulating the contaminated material is overshadowed by the time saved. Bioremediation may explicitly exploit bacteria, fungi, algae, or higher plants, although our focus here is on the microbes. Each, in turn, will be part of a complex food web, and optimizing the local ecosystem may be as important as focusing solely on the primary degraders or accumulators.

Bioremediation always competes with alternative technologies for achieving an environmental cleanup goal. Bioremediation is typically among the least expensive options, with the additional important advantage that in many cases bioremediation is a permanent solution to the contamination problem because the contaminant is completely destroyed or sequestered. Some alternative technologies, such as thermal desorption and destruction of organic contaminants, are also permanent solutions, but the simplest and most widely used remediation option, that of removing a contaminant to a dump site, merely moves the problem, and may well not eliminate the potential liability. Furthermore, by its very nature bioremediation addresses the bioavailable part of any contamination, and when biodegradation or bioaccumulation ceases this probably means that the bioavailable part of the contamination has been addressed. Residual concentrations of contaminants, while perhaps detectable by sensitive analytical techniques, may have only minimal residual environmental impact. The same cannot necessarily be said for nonbiological technologies, which may leave bioavailable contaminants at low levels.

Bioremediation also has the advantage that it can be relatively nonintrusive, and can sometimes be used in situations in which other approaches would be severely disruptive. For example, bioremediation has been used to cleanup hydrocarbon spills under buildings, roads, and airport runways without interfering with the continued use of these facilities.

Ecology

The biosphere plays a major role in the great elemental cycles of our planet (2), and bioremedation must be placed in this context if we are to appreciate its broadest ramifications. One of the underlying fundamental truths of biological diversity is that if there is free energy available in the metabolism of a substrate, there is probably a guild of organisms that has evolved to make use of it. This is particularly important for the biodegradation of organic molecules. For example, crude oil seeps, to land and water, have occurred for millennia, and as a consequence, aerobic oil-degrading microorganisms are ubiquitous. If biology does not yet take advantage of a source of free energy, then we can expect that there will be strong selection pressure in favor of any organism that develops an ability to exploit it. This has been seen with by-products of nylon manufacture, where *Pseudomonas aeruginosa* has gained the ability to degrade the novel compound 6-aminohexanoate linear dimer, a by-product of nylon-6 manufacture, as the sole source of carbon and nitrogen (3). The successful bioremediation of xenobiotic compounds, such as pesticides and herbicides, may sometimes represent a similar acquisition of genetic traits.

Not all organic molecules provide a source of free energy, however. Some, such as small halogenated solvents, provide no significant source of nutrients or energy, and their aerobic destruction can only occur cometabolically with the degradation of a more nutritious substrate (4) or anaerobically as a terminal electron acceptor (5). The white-rot fungi offer another variation on this theme. These organisms seem to be unique in their ability to degrade lignin, the structural polymer of higher plants. They may not gain any direct energetic benefit from lignin degradation, but it clearly allows them access to cellulose, which is a substrate for their growth. Lignin degradation is catalyzed by a group of extracellular peroxidases that generate nonspecific oxidants, and there

have been several proposals to use these systems for destroying contaminating organic compounds (6).

With successful bioremediation, organic compounds are eventually converted to carbon dioxide, water, and biomass. Similarly, nitrogenous molecules, such as excess ammonia or nitrate in groundwater, can be converted to gaseous nitrogen. Other nonorganic contaminants provide a different challenge for bioremediation. A few, such as mercury and selenium, are volatized by some biological processes, but it is not clear that this is always beneficial. In some cases, such as chromium and arsenic, there is a dramatic difference in environmental toxicity depending on the redox state of the contaminant. In these cases, bioremediation has sometimes focused on this detoxification by bacterial processes. A more satisfying approach would be to use a biological process to accumulate and concentrate the contaminant so that it can be removed for safe disposal; fungi, algae, and higher plants have all been used in these efforts.

Technology

Successful bioremediation hinges on the effective application of the biology discussed above. Sometimes the contaminant is on the surface, so access to it is reasonably simple. In these cases the required technology may be as simple as broadcast spreaders or sprayers to apply fertilizers, or tilling the soil to allow good aeration. Of course this is not necessarily as simple as it sounds, since contaminated sites are often very different from agricultural fields, and the technology has to be significantly stronger to "plow" the soil. Frequently the contaminant is below the surface, and applying even simple bioremediation strategies provides quite a challenge. Table 1 lists some of the technologies in use today.

This article addresses bioremediation in its broadest sense. The main sections address organic and then inorganic compounds. Key classes of contaminants are discussed, and for each I focus on the contaminants that can be treated, the underlying biological processes that can mitigate the contamination, and the technologies that have been used, or are being developed, to treat them.

ORGANIC CONTAMINANTS

Hydrocarbons

Constituents. Hydrocarbons are ubiquitous in the environment, from fossil, biogenic, and anthropogenic sources, and they provide readily digestible food for oil-degrading microbes (7). Bioremediation is thus an important potential technology for remediating hydrocarbons in oil spills and at contaminated creosote and town gas plants. Crude oils are very complex mixtures, primarily of hydrocarbons, although some components do have heteroatoms such as nitrogen (e.g., carbazole) or sulfur (e.g., dibenzothiophene). Chemically, the principal components of crude oils and refined products can be classified as aliphatics, aromatics, naphthenics, and asphaltic molecules, and representative examples are shown in Figure 1. The ratio of these different classes varies in different oils, but a "typical crude oil" might contain the four classes in a ratio of approximately 30 : 30 : 30 : 10. Most crude oils contain hydrocarbons ranging in size from methane to molecules with hundreds of carbons, although the lightest molecules are usually absent in oils that have been partially biodegraded in their reservoir. When crude oils reach the surface environment the lighter molecules evaporate, and are either destroyed by atmospheric photooxidation or are washed out of the atmosphere by rain, and are biodegraded. Some molecules, such as the smaller aromatics (benzene, toluene, etc.), have significant solubilities and can be washed out of floating slicks, regardless of whether these are at sea or on terrestrial water tables. Fortunately the majority of molecules in crude oils, and refined products made from them, are biodegradable, at least under aerobic conditions.

The other major sources of hydrocarbon contamination were the town gas and wood treatment industries. Town gas was made locally in many towns and cities by heating coal in the absence of air. Methane was produced and used, but the residue included coke and tarry material rich in polycyclic aromatic hydrocarbons. The production and use of creosote was quite similar, and again it gave rise to contamination with polycyclic aromatic hydrocarbons. The 16 polycyclic aromatic hydrocarbons on the U.S. EPA priority pollutant list are shown in Figures 2 and 3; all are abundant in creosote and coal tar, but only naphthalene, fluorene, phenanthrene, and chrysene are relatively abundant in petroleum.

Biodegradation

Methane and the volatile plant terpenes are fully biodegradable by aerobic organisms, and most refined petroleum products are essentially completely biodegradable under aerobic conditions. Estimates for crude oil biodegradability range up to 90% (7), and the least biodegradable material, principally polar molecules and asphaltenes, lack the "oily" feel and properties that we associate with "oil." Indeed they are essentially impossible to distinguish from more recent organic material in soils and sediments, such as the humic and fulvic acids, and appear to be biologically inert.

Numerous bacterial and fungal genera have species that can degrade hydrocarbons aerobically, and the pathways of degradation of representative aliphatic, naphthenic, and aromatic molecules have been well characterized in at least some species (7). It is a truism that the hallmark of an oil-degrading aerobic organism is its ability to insert oxygen atoms into the hydrocarbon, and there are many ways in which this is achieved (Figs. 4 and 5). Once a hydrocarbon possesses a carboxylate or alcohol functionality it is almost invariably a readily degradable compound that can eventually be attached to coenzyme A and mineralized in the ß-oxidation pathway. A simple example at the human level is the difference between oleic acid, present in olive oil, and octadecane, present in mineral oil, which is so inert that it serves as an intestinal lubricant!

For many years it was assumed that oil biodegradation was an exclusively aerobic process as any degradation must involve oxidation. Indeed, the very existence of oil reservoirs indicates that anaerobic degradation in

Table 1. Some Technological Definitions Relevant to Bioremediation

Technology	Description
Air sparging, Aquifer sparging, Biosparging	Injection of air to stimulate aerobic degradation. May also stimulate volatilization.
Air-stripping	Injection of air to stimulate volatilization. Contaminant is usually removed by subsequent adsorption.
Aquifer bioremediation	In situ bioremediation in an aquifer, usually by adding nutrients or cosubstrates through injection wells.
Aquifer sparging	Injection of air into a contaminated aquifer to stimulate aerobic degradation. May also stimulate volatilization.
Batch reactor	A bioreactor loaded with contaminated material, and run until the contaminant has been consumed. It is then emptied, and the process is repeated.
Bioactive Barrier, Bioactive Zone, Biowall, Wall-and-gate	A zone, usually subsurface, where biodegradation of a contaminant occurs so that no contaminant passes the barrier. Sometimes impermeable walls funnel contaminants to this reactive zone.
Bioaugmentation	Addition of exogenous bacteria with defined degradation potential (or rarely indigenous bacteria cultivated in a reactor and reapplied).
Biofilm Reactor	A reactor where bacterial communities are encouraged on a high surface area support. Biofilms often have a redox gradient so that the deepest layer is anaerobic while the outside is aerobic, allowing both aerobic and anaerobic processes to occur.
Biofiltration	Usually, an air filter with degrading organisms supported on a high surface area support, such as granulated activated carbon or compost.
Biofluffing	Augering soil to increase porosity.
Bioleaching	Extracting metallic contaminants at acid pH, perhaps while attempting to optimize fungal degradation of organic contaminants.
Biological fluidized bed, Fluidized bed bioreactor	Bioreactor where the fluid phase is moving fast enough to suspend the solid phase as a fluidlike phase.
Biological Plug	In-ground actively aerated bioreactors containing adapted microbial consortia to degrade contaminants of concern.
Biopile, Soil heaping	An engineered pile of excavated contaminated soil, with engineering to optimize air, water, and nutrient control.
Bioslurping	Vacuum extraction of the floating contaminant and water, and vapor from the vadose zone. The airflow stimulates biodegradation.
Biostimulation	Optimizing conditions for the indigenous biota to degrade the contaminant.
Biotransformation	The biological conversion of a contaminant to some other form, but not to carbon dioxide and water.
Biotrickling Filter	A reactor where a contaminated gas stream passes up a reactor with immobilized microorganisms on a solid support, while nutrient liquor trickles down the reactor.
Bioventing	Vacuum extraction of contaminant vapors from the vadose zone, thereby drawing in air to stimulate the biodegradation of the remainder.
Borehole bioreactor In well bioreactor	The addition of nutrients and electron acceptor to stimulate biodegradation in situ in a contaminated aquifer.
Closed-loop Bioremediation	Groundwater recovery, a bioreactor, and low-pressure reinjection to maximize nutrient use, and maintain temperature in cold climates.
Composting	Addition of biodegradable bulking agent to stimulate microbial activity. Optimum composting generally involves self-heating to 50-60°C.
Constructed Wetland	Artificial marsh for bioremediation of contaminated water.
Continuous stirred tank reactor (CSTR)	A bioreactor that is completely back mixed.
Digester	Usually, an anaerobic bioreactor that generates methane.
Ex-situ bioremediation	Usually, the bioremediation of excavated contaminated soil in a biopile, compost system, or bioreactor.
Fixed-bed bioreactor	Bioreactor with immobilized cells on a packed column-matrix.
Land-farming, land treatment	Application of a biodegradable sludge as a thin layer to a soil to encourage biodegradation. Tilling and fertilizing is usually required.
Natural Attenuation, Intrinsic bioremediation	Unassisted biodegradation of a contaminant.
Pulsed bioremediation	Alternating injection of a cosubstrate for the contaminant, and oxygen.
Pump and treat	Pumping groundwater to the surface, treating, and reinjecting.
Rhizosphere bioremediation	Stimulating the bacteria in the rhizosphere (root-zone) to carry out biodegradation of a soil contaminant.
Rotating biological contactor	Bioreactor with rotating device that moves a biofilm through the bulk water phase and the air phase to stimulate aerobic degradation.
Sequencing Batch Reactor	Periodically aerated solid phase or slurry bioreactor.
Soil vapor extraction	Vacuum assisted vapor extraction.

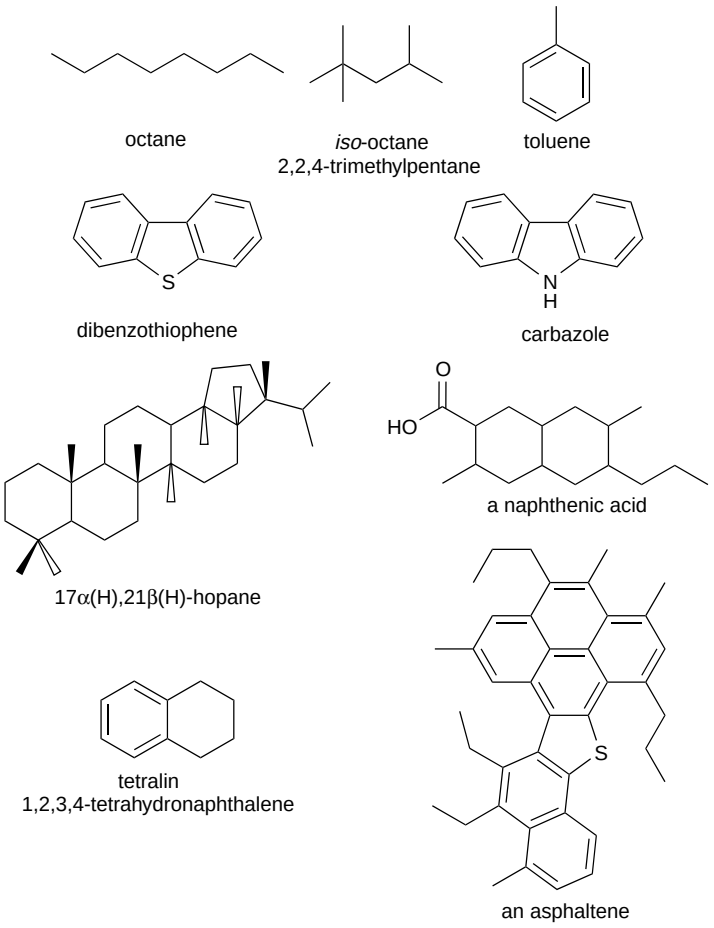

Figure 1. Some petroleum hydrocarbons. As in all figures in this article, hydrogens are omitted unless on a heteroatom. Octane is an example of a paraffin, iso-octane an isoparaffin, toluene is an aromatic. Benzothiophene and carbazole are heterocycles, but they are considered aromatics by the oil industry, as is tetralin. Hopane is an example of a biomarker that is recognizably derived from bacterial lipids, in this case from bacteriohopanetetrol. Naphthenic acids and asphaltenes are hard to characterize, but the structures shown are likely representatives.

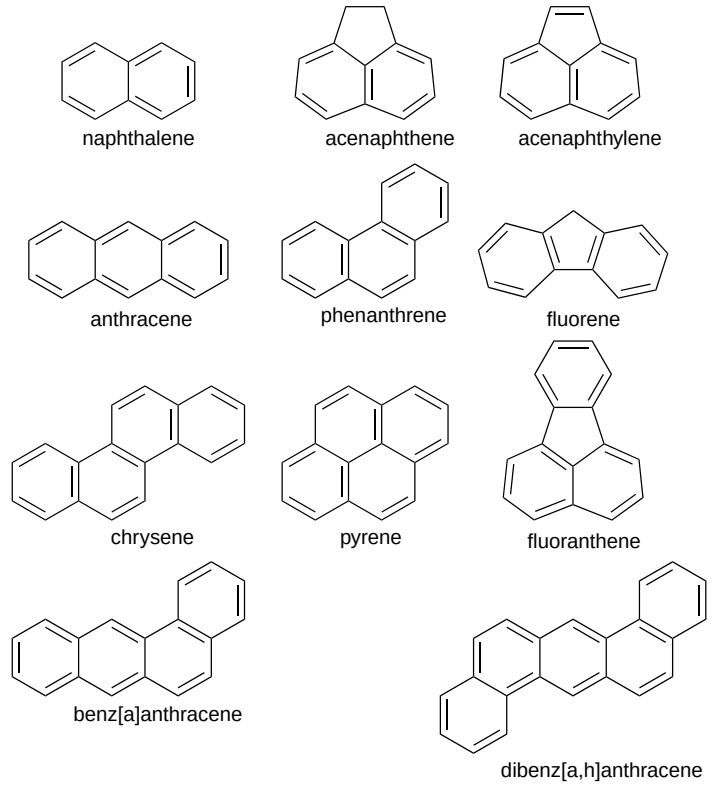

Figure 2. Some of the 16 polycyclic aromatic hydrocarbons on the U.S. EPA list of Priority Pollutants. Only naphthalene, phenanthrene, and chrysene are abundant in crude oils, the others are abundant in coal tars and other thermally treated materials.

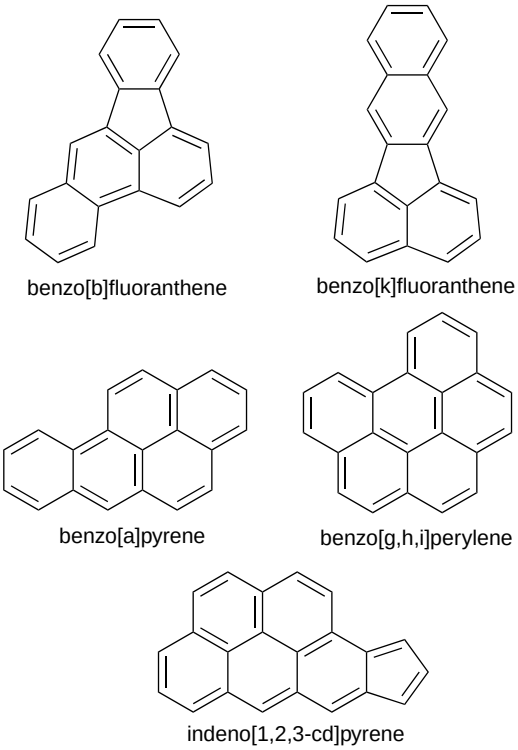

Figure 3. More of the 16 polycyclic aromatic hydrocarbons on the U.S. EPA list of priority pollutants. These are present in only tiny amounts in crude oils, but they are generated during incomplete combustion of carbonaceous materials, and can be abundant at coal gasification sites.

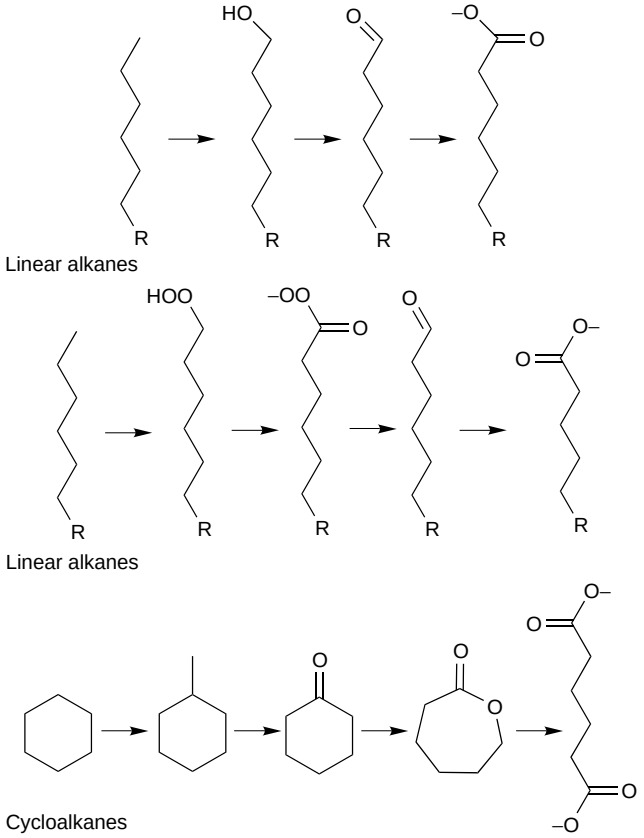

Figure 4. Schematics of the initial aerobic biodegradation steps for alkanes and cycloalkanes. The upper pathway is found in *Pseudomonas oleovorans*, the middle in *Acinetobacter* species, and the lower in *Nocardia* species.

such environments must be very slow. Nevertheless, in recent years it has become clear that bacteria under completely anaerobic conditions can oxidize many hydrocarbons (7). Hydrocarbon biodegradation has now been shown under sulfate-, nitrate-, chlorate-, perchlorate-, carbon dioxide- and ferric iron-reducing conditions (8). Pathways have not been characterized in detail, but current research suggests that a common motif in anaerobic hydrocarbon degradation is the addition of the hydrocarbon to the double bond in fumarate (Fig. 6) to produce alkyl- or aromatic-succinates (9,10). These are readily degraded after the addition of Coenzyme A. The anaerobic biodegradation of hydrocarbons, particularly of small soluble aromatics such as toluene, is now recognized as an important part of the natural attenuation of hydrocarbon spills, and is being exploited in active bioremediation protocols on a large scale.

While the majority of molecules in crude oils and refined products are hydrocarbons, the U.S. Clean Air Act amendment of 1990 mandated the addition of oxygenated compounds to gasoline in many parts of the United States. The requirement is typically that 2% (w/w) of the fuel be oxygen, which requires that 5 to 15% (v/v) of the gasoline be an oxygenated additive (e.g., methanol, ethanol, methyl tertiary butyl ether (MTBE) etc.). While methanol and ethanol are readily degraded, the degradability of MTBE remains something of an open question. The compound was previously very rare in the environment, but now it is one of the major chemicals in commerce. At first it seemed that the compound was completely resistant to biodegradation, but complete mineralization has now been reported (11,12).

Bioremediation

Crude oil and refined products are readily biodegradable under aerobic conditions, but they are only incomplete substrates since they lack any significant nitrogen, phosphorus, and essential trace elements. Bioremediation strategies for removing large quantities of hydrocarbon must therefore include supplementation with nutrients in a bioavailable form.

Air. Airborne hydrocarbon vapors are readily treated with biofilters. These are typically rather large devices with a very large surface area provided by bulky material such as shredded compost (see Biofiltration, this Encyclopedia). The contaminated air, perhaps from a soil vapor-extraction treatment or a factory using hydrocarbon solvents, is blown through the filter, and organisms, usually indigenous to the filter material or provided by a soil or commercial inoculum, grow and consume the hydrocarbons. Adequate moisture and nutrients must be maintained for effective operation. Alternatively, trickling biofilters with recycled water can be used. Bacteria and fungi readily colonize such filters, and they can be very

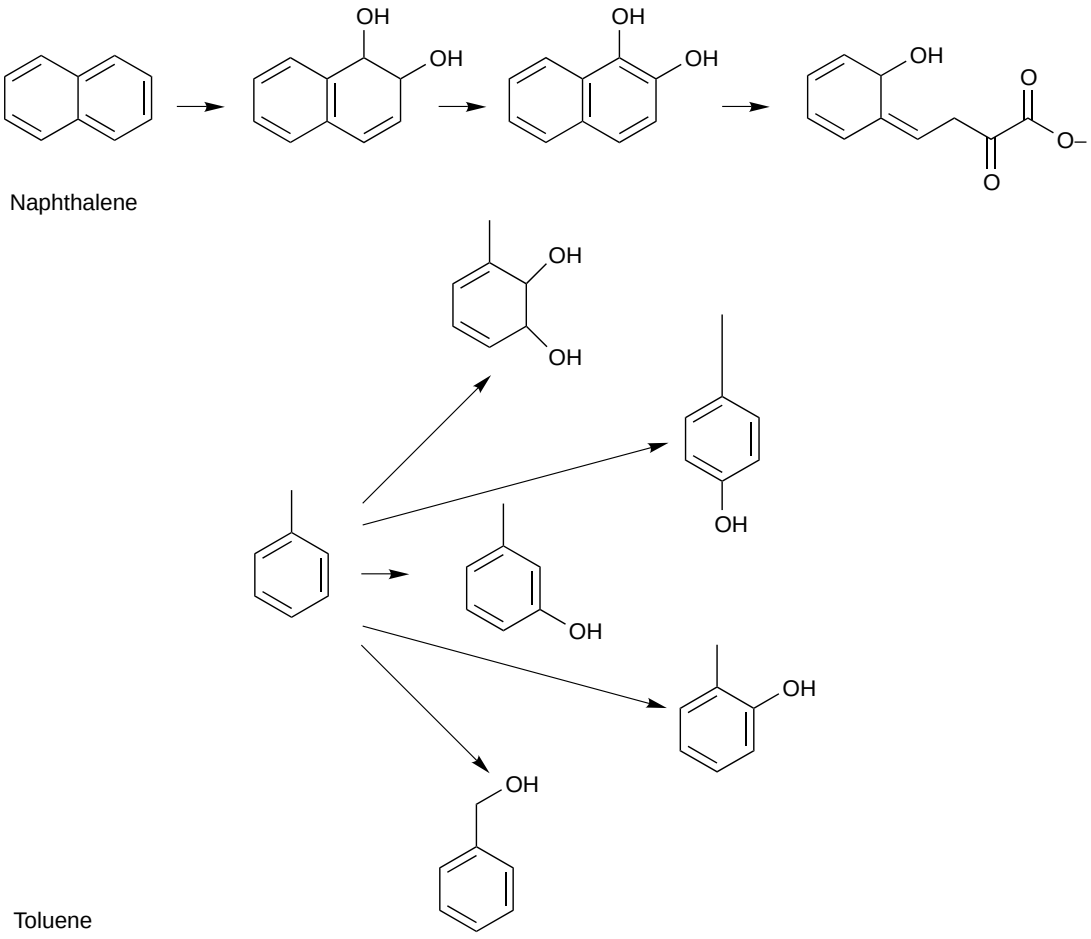

Figure 5. Schematics of the initial biodegradation steps for naphthalene and toluene. The upper pathway is found in many Pseudomonads, and the lower panel illustrates the many ways that toluene is activated in different Pseudomonads.

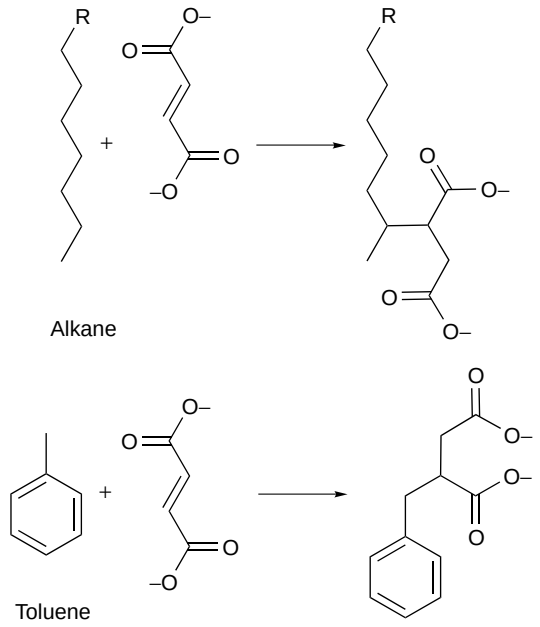

Figure 6. The initial reactions of anaerobic biodegradation of alkanes and toluene. In both cases the substrate is activated by addition of fumarate.

effective. Nevertheless, biofilters are usually equipped with a small granulated activated carbon "backup" filter to handle any sudden pulse loads that might overwhelm the biological capacity of the filter. Biofilters compete with granulated activated carbon filters, and are often less expensive because they minimize the cost of the granulated activated carbon and the energy required to destroy the contaminant and the granulated activated carbon when the latter is saturated (13). Potential problems include plugging and uneven air or water flow, but successful designs work for many years with minimal maintenance except for the occasional addition of nutrients and stirring of the bed.

Sea. Crude oil spills at sea are perhaps the most widely covered environmental incidents in the national and international media. Despite their notoriety, catastrophic tanker spills and well blowouts are fortunately rather rare, and their total input into the world's oceans is approximately equivalent to that from natural seeps; significantly more oil reaches the world's oceans from municipal sewers (14). Physical collection of the spilled oil is the preferred remediation option, but if skimming is unable to collect the oil, biodegradation, and perhaps combustion

or photooxidation, are the only routes for elimination of the spill. One approach to stimulating biodegradation is to disperse the oil with chemical dispersants (15). Patents have been issued for dispersant formulations that specifically include nitrogen and phosphorus nutrients, but the products are not currently commercially available.

Bioremediation by the addition of oil-degrading microbes is often promoted as a treatment option for floating spills, but this approach has not yet met with any documented success (16).

Shorelines. The successful bioremediation of shorelines affected by the spill from the *Exxon Valdez* in Prince William Sound, Alaska, was the largest bioremediation project to date; more than 111 km of shoreline was treated (17), usually after bulk oil had been collected. Residual oil had typically penetrated into the shoreline gravel, occasionally getting as deep as 30 cm into the sediment. Since the gravel was typically very permeable, oxygen availability was unlikely to be the limiting factor for biodegradation, and indeed this was subsequently shown to be correct. Bioremediation therefore focused on the addition of nitrogen and phosphorus fertilizers to partially alleviate the nutrient-limitation of oil degradation. Of course this was complicated by the fact that oiled shorelines were washed by tides twice a day. These tides would have rapidly removed any soluble fertilizer, so a strategy was sought that would provide nutrients for a significant length of time. Various approaches to applying fertilizers were tried, including standard and slow-release nutrients, oleophilic nutrients, and solutions of liquid fertilizers. Two fertilizers were used in the full-scale applications; one, an oleophilic product known as Inipol EAP22 (CECA, Paris, France), is a microemulsion of a concentrated solution of urea in an oil phase of oleic acid and trilaurethphosphate, with butoxyethanol as a cosolvent. This product was designed to adhere to oil and to release its nutrients to bacteria growing at the oil-water interface. The other fertilizer is a slow-release formulation of inorganic nutrients, primarily ammonium nitrate and ammonium phosphate, in a polymerized vegetable oil skin. This product, known as Customblen (Grace-Sierra, Milpitas, Calif.), released nutrients with every tide, and these were distributed throughout the oiled zone as the tide fell. Fertilizer application rates were carefully monitored so that the nutrients would cause no harm, and the rate of oil biodegradation was stimulated between two- and fivefold (17).

Subsequent work has shown that fertilizer application is likely to be a useful remediation approach in many situations, including in the Arctic. It is unlikely though that the addition of fertilizers will have a dramatic effect on situations in which agricultural or municipal runoff maintains elevated levels of nutrients, as happens in some estuaries and bays. Here, aeration is likely to be most effective.

Bioremediation by the addition of oil-degrading microbes has been promoted as a treatment for oiled shorelines, but the approach has not yet met with any well-documented success (16).

Areas where there are currently few remediation options include oiled marshes, mangroves, and coral reefs. These environments are generally easily damaged by human intrusion, and physical cleaning options may not provide any net environmental benefit. Bioremediation may provide some attractive options, and some success has been claimed, on a small scale, with fertilizer applications. Marshes and mangroves offer the additional complication that they are typically anoxic. Perhaps the anaerobic degradation of oil could be stimulated by inoculation with anaerobic hydrocarbon-degrading microbes or perhaps gentle aeration or the addition of slow-release oxygen compounds, such as some inorganic peroxides, might stimulate aerobic degradation without significantly changing the redox balance of these environments. This is an area where research is very much in its infancy, and there are no well-documented success stories to date.

Bioremediation also offers options for dealing with oiled material, such as seaweed, which gets stranded on shorelines; composting has been shown to be effective.

Groundwater. Spills of refined petroleum products on land and leaking underground storage tanks sometimes contaminate groundwater. Bioremediation is becoming an increasingly popular treatment for such situations.

Hydrocarbons typically have a density of less than 1, and refined products usually float on the water table if they penetrate soil that deeply. In the parlance of the remediation industry, such floating spills are often called NAPLs (nonaqueous phase liquids). Indeed they are sometimes known as LNAPLs (light nonaqueous phase liquids) to distinguish them from more dense materials such as halogenated compounds. While standalone bioremediation is an option for these situations, "pump and treat" is the more usual treatment, in which contaminated water is brought to the surface, free product is removed by flotation, and the cleaned water is reinjected into the aquifer. Adding a bioremediation component to the treatment, typically by adding oxygen and low levels of nutrients, is an appealing and cost-effective way of stimulating the degradation of the residual hydrocarbon that was not extracted by the pumping, and this approach is becoming widely used (18).

Hydrocarbons are not very soluble in water, but the most soluble components will leach out of a spill if there is continual flushing. Typically, only small aromatic molecules, the infamous BTEX (Fig. 7), are soluble enough to contaminate groundwater, although with the advent of oxygenated gasolines, these oxygenates [ethanol, methanol, MTBE (methyl tertiary butyl ether), etc.] are being found in groundwater (11,12). Remediation of such situations usually involves "pump and treat" methodologies, although these methods are slow and may leave behind reservoirs of contaminants in pockets that are poorly connected to the main water body. Of course the contaminant is biodegradable, and some biodegradation is probably already occurring when the contamination is discovered. The simplest approach to remediation is thus to allow this intrinsic process to continue. Evidence that it is indeed occurring can be found in the selective disappearance of the most biodegradable compounds in the

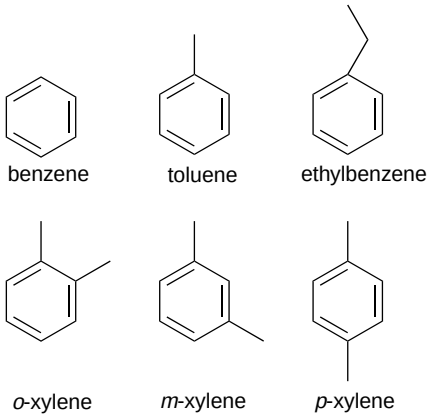

Figure 7. The principal water-soluble components of refined fuels; benzene, toluene, ethylbenzene, and the xylenes, commonly referred to as BTEX.

contaminant mixture, and the concomitant disappearance of electron acceptors from the groundwater. Thus, oxygen is depleted as the preferred terminal electron acceptor for metabolism, followed by nitrate, ferric iron, sulfate, and finally carbon dioxide for methanogenesis (19).

Intrinsic bioremediation is becoming an acceptable option in locations where the contaminated groundwater poses little threat to environmental health (20). Nevertheless, while it is appealingly simple, it may not be the lowest cost option if extensive monitoring and documentation is involved. In such cases it may well be more cost-effective to optimize conditions for biodegradation. One way to do this is to funnel the contaminated water through a reactive zone where biodegradation can be stimulated and monitored. The simplest intervention is a line of wells for "pump and treat," but including a biological component may be more cost-effective. This can range from the installation of a sparge line for aerating the contaminated plume (18), to installing some form of semi-contained bioreactor where nutrients can be applied with some modicum of control (21,22). Often these designs are combined with barriers to ensure that the entire contaminated plume passes through the reactive zone. These designs have a variety of names, including "biowall," "trench biosparge," "funnel and gate," "bubble curtain," "sparge curtain," and "engineered trenches and gates" (22). Both aerobic and anaerobic designs have been successfully installed. Another approach is to optimize the levels of electron acceptors in the contaminant plume. Oxygen can be pumped in as the pure gas (23), or as air, although this is relatively energy intensive since oxygen is so poorly soluble. Hydrogen peroxide has been used in some situations (24), but there have been problems with biomass plugging near the injection wells. Slow-release formulations of inorganic peroxides, such as magnesium peroxide, have recently been used with success (25,26). Nitrate may be added, although there are sometimes regulatory limitations on the amount of this material that may be added to groundwater (27). Ferric iron availability may be manipulated by adding ligands (28), and recent success at stimulating the biodegradation of benzene in groundwater by the addition of sulfate (29) suggests that stimulating the anaerobic biodegradation of hydrocarbons will become a broadly useful remediation technology.

If there are significant amounts of volatile and nonvolatile contaminants, remediation may be achieved by a combination of liquid and vapor extraction of the former, and bioremediation of the latter. This combination has been termed "bioslurping," where the act of pumping out the liquid contaminant phase draws in air at other wells to stimulate aerobic degradation (25). Such bioremediation requires that there be enough nutrients to allow microbial growth, and fertilizer nutrients are frequently added at the air injection wells. Bioslurping has had a number of well-documented successes (18).

Where there are large volumes of contaminated water under a small site, it is sometimes most convenient to treat the contaminant in a biological reactor at the surface. Considerable research has gone into reactor optimization for different situations, and a variety of stirred reactors, fluidized bed reactors, and trickling filters have been developed (21). Such reactors are usually much more efficient than in situ treatments, although correspondingly more expensive.

Of course, the presence of a liquid phase of hydrocarbon in soil gives rise to vapor contamination in the vadose zone above the water table. This can be treated by vacuum extraction, and the passage of the exhaust gases through a biofilter (mentioned earlier) can be an inexpensive and effective way of destroying the contaminant permanently.

Soil. Hydrocarbon contamination of soils runs the gamut from crude oils at production wells and pipeline spills to refined products at refineries, distribution centers, service stations and accident sites, and polycyclic aromatic hydrocarbons at wood-treatment facilities, town gas manufacturing sites, railroads, and their terminals, and various military bases. Sometimes the contamination is the result of leaking underground storage tanks and pipelines, leading to subsurface contamination, but surface spills also occur. Physical removal of gross contamination is an obvious first step at all locations, and bioremediation is an appealing option for remediating residual contamination in many of these sites (18,30).

Spills from production facilities and pipelines often involve both oil and brine, since most oil reservoirs float on top of concentrated brines and both are produced in later stages of production. The brine is typically separated from the oil and reinjected into the reservoir, but some is retained in many production pipelines. The environmental impact of spilled brine can be quite deleterious. Salt is not only toxic to most plants and inhibitory to many soil bacteria, but can also affect soil structure by altering the physical properties of clays. Successful bioremediation strategies must therefore include remediating the brine. In wet regions, salt is eventually diluted by rainfall, but in arid regions and to speed the process in wetter regions, gypsum is often added to restore soil porosity (31).

Many hydrocarbons bind quite tightly to soil components and are thereby less available to microbial degradation. The kinetics of binding seem to be complex, and the process of "aging" is only poorly understood. Nevertheless, it seems clear that hydrocarbons that have been in contact

with soil for a long time are not as available for biodegradation as fresh spills (30). Several groups of researchers have suggested the addition of surfactants to overcome this limitation, but this approach is not yet widely used. A significant potential concern is that the surfactant may be degraded in preference to the contaminant of concern.

Intrinsic biodegradation occurs, but it usually only removes the lightest refined products, such as gasoline, diesel, and jet fuel (20). Active intervention is typically required. Usually, the least expensive approach is in situ remediation (18,30), typically with the addition of nutrients and the attempted optimization of moisture and oxygen by tilling. Various approaches to applying fertilizers have been tried, including standard and slow-release nutrients, oleophilic nutrients, and solutions of liquid fertilizers. Oxygen is likely to be limiting in many cases, and soil tilling is widely practiced. This in situ bioremediation of hydrocarbon-contaminated soils is akin to the old practice of "land-farming" (32), wherein sludges and other refinery wastes were deliberately spread onto the soil and tilled and fertilized to stimulate biodegradation. Although this practice is now discontinued in the United States, it was quite widely used.

Deeper contamination may be remedied with bioventing, by which air is injected through some wells and extracted through others to both strip volatiles and provide oxygen to indigenous organisms (18). Fertilizer nutrients may also be added. This is usually only a viable option with lighter refined products.

When soil contamination extends to some depth, it may be preferable to excavate the contaminated soil and to put it into "biopiles" in which oxygen, nutrient, and moisture levels are more easily controlled (21). Biopiles can also be kept warm during winter months, increasing the amount of time available for biodegradation in colder climates. Since the soil is well mixed during the construction of the pile, there is an opportunity to add selected microbial and fungal strains in an additional attempt to maximize biodegradation.

Composting by the addition of readily degradable bulking agents is also a useful option for relatively small volumes of excavated contaminated soil (21). Since efficient composting invariably involves self-heating as biodegradation proceeds, this also offers an option for extending the bioremediation season into the winter months in cold climates. A potential drawback of composting is that it usually increases the volume of contaminated material, but if fully successful, the finished compost can be returned to the site as a positive contribution to soil quality.

Slurry bioreactors offer the most aggressive approach to maximizing contact between the contaminated soil and the degrading organisms (21). Both lagoons and reactor vessels have been used, but the former is often not optimally designed for all the soil to be partially suspended by the mixing impellers. Contained reactor designs include mixing tank, airlift, and fluidized-bed aeration. A major advantage of contained slurry bioreactors is the potential to continually optimize nutrients, aeration, and degradative inocula as fresh soil is added, and to control waste materials, including gases. Slurry bioreactors are usually the most expensive bioremediation option because of the large power requirements, but under some conditions this cost is offset by the rapid biodegradation that can occur.

In all these cases, it is important to bear in mind that while the majority of hydrocarbons are readily biodegraded, some, such as the steranes and hopanes, are very resistant to microbial attack. Estimates of oil biodegradation range from 60 to 95% for different crude oils, so fresh spills of crude oils are readily treated by bioremediation (7). Refined products, such as gasoline, diesel, jet fuels, and heating oils, are usually more biodegradable than typical whole oils, but the various heavy fractions of crudes, such as the asphalts, are far less biodegradable and are not such attractive targets for bioremediation. Some crude oils have already been extensively biodegraded in their reservoirs, and these are also poor targets for bioremediation. An example is Orimulsion, a heavy oil in water emulsion (70% bitumen) stabilized by low levels of surfactants, used as a fuel for electricity generation. Similarly, old spills may have already undergone significant biodegradation and the residue may be relatively biologically inert. It is thus important to run laboratory studies to ensure that the contaminant is sufficiently biodegradable and that cleanup targets can be met. On the other hand, even very heavy fuels contain some biodegradable compounds, and a case can be made that stimulating the biodegradation of this fraction will minimize the environmental impact of these compounds, even if it will not have a dramatic effect on the total amount of oil in the environment.

HALOGENATED ALIPHATIC COMPOUNDS

Constituents. Halogenated organic compounds are widespread in nature, and some, such as dichloromethane, are produced on an enormous scale (by fungi) and serve as carbon and energy sources for diverse microbes (33). Synthetic chlorinated solvents, especially chloroalkanes and chloroalkenes, have become widely used in industrial processes in the second half of the twentieth century, and some representative examples are shown in Figure 8. These solvents have been used for more than 50 years,

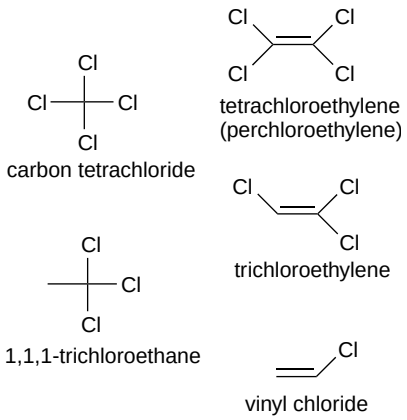

Figure 8. Some halogenated solvents.

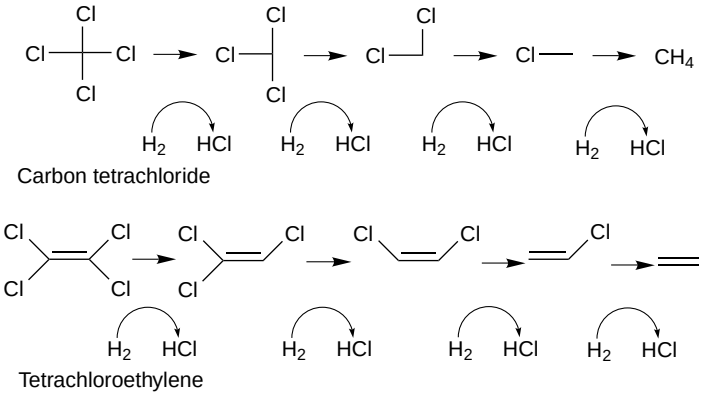

Figure 9. Sequential dehalogenation of carbon tetrachloride and tetrachloroethylene under anaerobic conditions.

and unfortunately they are now fairly widespread contaminants. Unlike the hydrocarbons, which usually float on water, the halogenated solvents typically have densities greater than one, and generally sink to the bottom of any groundwater and float on the bedrock. For this reason, they are sometimes known as DNAPLs (dense nonaqueous phase liquids).

Biodegradation

Halogenated solvents are degraded under aerobic and anaerobic conditions. The anaerobic process is typically a reductive dechlorination that progressively removes one halide at a time (Fig. 9). For example, carbon tetrachloride is sequentially dechlorinated to chloroform, dichloromethane, methyl chloride, and methane, and trichloroethylene is sequentially reduced to ethylene (34). The discovery of reductive dechlorination has led to halorespiration-based remediation technologies in which carbon sources are added to contaminated sites. Chloromethane and dichloromethane have been shown to be the sole carbon source for several anaerobic organisms (35), and it seems that we have much to learn about the microbial diversity of anaerobic microorganisms capable of dechlorinating solvents.

The simplest chlorinated alkanes, alkenes, and alcohols (e.g., chloromethane, dichloromethane, chloroethane, 1,2-dichloroethane, vinyl chloride, and 2-chloroethanol) serve as substrates for aerobic growth for some bacteria, but the majority of halogenated solvents do not seem to be able to support growth. Nevertheless, these compounds can be mineralized under aerobic conditions, albeit with no apparent benefit to the degrading organism. Indeed, the oxidation appears to be fortuitous, only occurring during the metabolism of a growth substrate. The phenomenon is therefore known as co-oxidation or cometabolism. Numerous bacteria are able to catalyze the oxidation of trichloroethylene; some use monooxygenases (e.g., methane and ammonia oxidizing species) while others contain dioxygenases (e.g., some toluene oxidizing species). The difference between these two classes of enzymes is the fate of the two atoms of molecular oxygen. Monooxygenases insert one oxygen atom into their substrate and reduce the other to water. Dioxygenases insert both atoms into their substrate (Fig. 10). In either case, biodegradation can proceed to complete mineralization.

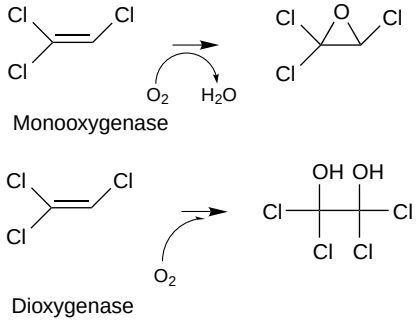

Figure 10. Comparison of the attack of monooxygenase and dioxygenase enzymes on trichloroethylene.

The biodegradation of trichloroethylene (trichloroethene) has been the most studied since this is probably the most widespread halogenated solvent contaminant. Several substrates drive trichlorethylene co-oxidation, including methane, propane, propylene, toluene, isopropylbenzene, and ammonia (36). The enzymes that metabolize these substrates have subtly different selectivities with regard to the halogenated solvents, and to date, none are capable of co-oxidizing carbon tetrachloride or tetrachloroethylene. Complete mineralization of these compounds can, however, be achieved by sequential anaerobic and aerobic processes.

Bioremediation

Air. Biofilters are an effective way of dealing with air from industrial processes that use halogenated solvents such as chloromethane, dichloromethane, chloroethane, 1,2-dichloroethane, and vinyl chloride, and that support aerobic growth (37). Both compost-based "dry" systems and trickling filter "wet" systems are in use. Similar filters could be incorporated into "pump and treat" operations.

Groundwater and soil. Soils and groundwater throughout the industrialized world have been contaminated with halogenated solvents, and remediation has a high priority. Since the solvents are so dense, they are typically found on the bedrock underlying aquifers. Pumping out the liquid phase is an obvious first step if the contaminant is likely to be mobile, but in situ bioremediation is a promising option (38). For example, the U.S. Department

of Energy has used anaerobic in situ degradation of carbon tetrachloride to treat an aquifer some 76 m below the Hanford, WA, site, with nitrate as electron acceptor and acetate as electron donor (39). Trichloroethylene is the most frequent target of remediation, and as discussed above, this only seems to be metabolized cometabolically. Remediation operations thus incorporate the addition of cometabolized substrate. Methane was used successfully at the U.S. Department of Energy site at Savannah River, near Aiken, South Carolina (40). This operation had both an air stripping and a biological component. Horizontal wells were used to pump methane and air below the contaminant, and an upper horizontal well in the vadose zone was used to withdraw these gases through the contaminated zone. Optimum biodegradation performance seemed to come from alternating injection of air and methane in air and the inclusion of nitrous oxide and triethylphosphate, both gases, to give a C : N : P ratio of 100 : 10 : 1. Success has also been achieved with a bioaugmentation strategy, using a toluene monooxygenase containing *Burkholderia cepacia* (and no cosubstrate) (41).

"Pump and treat" operations can also incorporate bioremediation; methane has been used as cosubstrate in aerobic bioreactors for halohydrocarbons including chlorofluorocarbons (42) and a sequential methanogenic-denitrifying bioreactor system has been developed (43).

Adding a slow release source of reductant to drive the reductive dechlorination of solvents in groundwater has also proved to be effective (26). One proprietary product is a polylactate ester that slowly hydrolyzes to release lactate, which in turn is metabolized anaerobically to release hydrogen. This in turn serves as the reductant of the chlorinated contaminants. A slow-release form of oxygen, magnesium peroxide, has also proved effective at stimulating the aerobic biodegradation of partially chlorinated species (26). Reactive barrier technologies, including biological barriers that exploit reductive dechlorination (22), are widely used for halogenated contaminants.

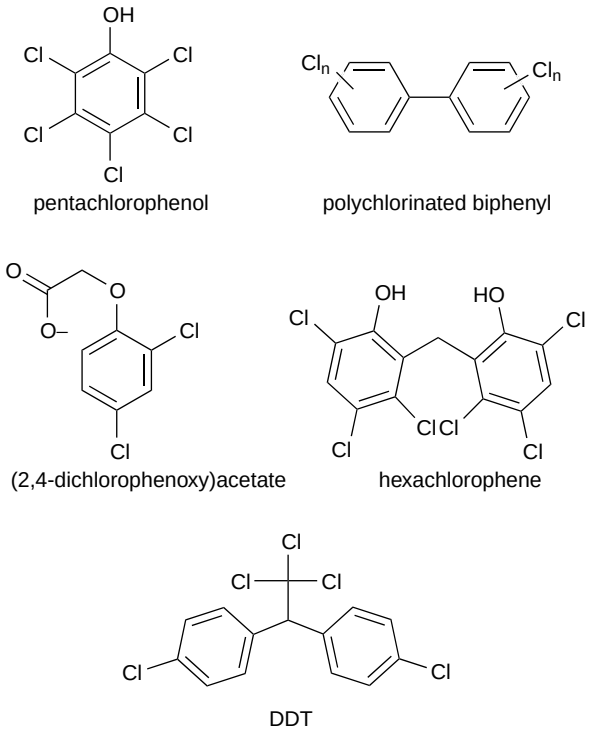

Figure 11. Some halogenated aromatic hydrocarbons.

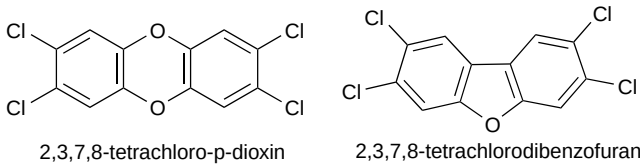

Figure 12. Dioxin and dibenzofuran.

HALOGENATED AROMATIC COMPOUNDS

Constituents.

Complex halogenated organic compounds have been widely used in commerce during the second half of the twentieth century. A few representative examples are shown in Figure 11; pentachlorophenol has been widely used as a wood preservative and also for termite control. (2,4-dichlorophenoxy) acetate (2,4-D) is widely used as a broadleaf herbicide, DDT is widely used as an insecticide, and hexachlorophene is widely used as a germicide. Polychlorinated biphenyls (PCBs) were sold with varying levels of chlorination for a range of purposes. They ranged from light oily fluids (with 2–4 chlorines) through viscous oils (5 chlorines) to greases and waxes (6 or more chlorines) and their names indicated the level of chlorination. Thus, Aroclor 1242 (Monsanto, U.S.A.), Kanechlor 300 (Kanegafuchi Chemical Industries, Japan), and Clophen A30 (Farbenfabriken Bayer AG, Germany) contained 42% chlorine by weight and an average of 3 chlorines per biphenyl. An important property that led to their broad use is their relative inertness, especially to biodegradation, so at first glance they may not seem a good target for bioremediation. Indeed, complex halogenated organic compounds were widely thought to be almost exclusively anthropogenic in origin so that there would have been little time for biodegradation pathways to evolve. This view is being corrected, for in fact a variety of organisms, particularly marine algae and some fungi, produce significant quantities of these compounds (44). Furthermore, it is now well established that polychlorinated dibenzo-*p*-dioxins and dibenzofurans (Fig. 12) are produced when biomass (or municipal waste) is burnt (45). There is thus good reason to expect that halogenated organic degrading organisms can be found in the biosphere, and this has been borne out in practice.

Biodegradation

Adriens presented a thorough description of the microbiology and technology of the bioremediation of chlorinated aromatic compounds in this volume. An important characteristic of degradation is the cleavage of carbon-chlorine bonds, and the enzymes that catalyze these reactions, the

dehalogenases, are being characterized (46). The reductive dechlorination seen with aliphatic chlorides (Fig. 9) seems to be a general phenomenon, and even compounds as persistent as DDT and the polychlorinated biphenyls are reductively dechlorinated under some conditions, particularly under methanogenic ones. Some compounds, such as pentachlorophenol, can be completely mineralized under anaerobic conditions, but the more recalcitrant ones require aerobic degradation after reductive dehalogenation.

Pentachlorophenol can be mineralized aerobically by bacteria (47) and fungi (48) and anaerobically by bacteria (49), and several bacterial isolates are able to grow aerobically using pentachlorophenol as the sole source of carbon and energy. Many of these grow rather well when supplemented with a more nutritious substrate, but unfortunately, in many cases it seems that the more vigorous growth with these substrates does not enhance the biodegradation of pentachlorophenol.

(2,4-dichlorophenoxy)acetate (2,4-D) has been one of the world's most popular herbicides, and although it is somewhat resistant to biodegradation, it is biodegraded by several bacterial isolates. It is a general truism that the more halogens on a molecule, the slower its biodegradation, and this is borne out with the related herbicide 2,4,5-T ((2,4,5-trichlorophenoxy)acetate). Nevertheless, bacterial degradation has been seen under both aerobic and anaerobic conditions, the latter involving reductive dechlorination via 2,4-D. Aerobic degradation removes acetate from (2,4-dichlorophenoxy)acetate to yield 2,4-dichlorophenol, which is subsequently hydroxylated to 3,5-dichlorocatechol, followed by ring cleavage and complete mineralization (50). There is good evidence that the genes for the degradation of 2,4-D have undergone interspecies transfer (51).

DDT (1,1,1-trichloro-2,2-bis(p-chlorophenyl)ethane) is a remarkably resistant molecule, which explains both its efficacy as an insecticide and its accumulation at the top of the food chain. Nevertheless, there are indications that it can be biodegraded, both anaerobically, with initial dechlorination (52), and aerobically, with initial ring hydroxylation (50). DDT and its partially degraded congeners are very hydrophobic and biodegradation seems to be stimulated by adding surfactants. White-rot fungi also degrade DDT under lignolytic conditions, although there is little mineralization to carbon dioxide (6).

The polychlorinated biphenyls are quite recalcitrant. Some lightly chlorinated biphenyls are readily mineralized under aerobic conditions (53), and indeed the structure of an enzyme that catalyzes the key ring-cleavage oxygenation has been determined by X-ray crystallography (54). More chlorinated congeners are resistant to aerobic degradation, but they are reductively dechlorinated under anaerobic conditions (55). Complete degradation of the commercial mixtures thus generally requires an anaerobic process, followed by an aerobic one. A major issue for the oxidative process is that biphenyl seems to be required for significant expression of the biodegradative system (53); the chlorinated compounds do not induce the enzymes that would degrade them. The biochemistry of the biodegradative process is only beginning to be unraveled, but already there are suggestions that there is considerable diversity in the enzyme systems able to degrade these compounds.

Bioremediation

Soil. Pentachlorophenol has been the target of bioremediation at a number of wood-treatment facilities, and good success has been achieved in several applications (56). It is rarely the sole contaminant and is often present with polynuclear hydrocarbons from creosote. In situ degradation has been stimulated by bioventing, wherein air is injected through some wells and extracted through others to both strip volatiles and provide oxygen to indigenous organisms (57).

The kinetics of such in situ degradation is rather slow, however, and more active bioremediation is usually attempted. For example, contaminated soil at the Champion Superfund site in Libby, MT, was placed into 1-acre land treatment units in 6-inch layers, and irrigated, tilled, and fertilized. Under these conditions, the half-lives of pentachlorophenol, pyrene, and several other polynuclear aromatic hydrocarbons, initially present at around 100 to 200 ppm, were on the order of 40 days (57). This success relied on the indigenous microbial populations in the soil, but many groups are focusing on the addition of organisms (58). Composting, and bioremediation focusing on the use of white-rot fungi, has also met with success at the pilot scale. Others have used fed-batch or fluidized-bed bioreactors to stimulate the biodegradation of pentachlorophenol. This allows significant optimization of the process and increases rates of degradation by 10-fold (57).

A major concern when remediating wood-treatment sites is that pentachlorophenol was often used in combination with metal salts, and these compounds, such as "chromated-copper-arsenate" (CCA), are potent inhibitors of at least some pentachlorophenol-degrading organisms (59). Sites with significant levels of such inorganics may not be suitable candidates for bioremediation.

The phenoxy-herbicide 2,4-D has been successfully bioremediated in soil contaminated with such a high level of the compound (710 ppm) that it was initially toxic to microorganisms (60). There were essentially no indigenous bacteria in the soil, and success relied on washing a significant fraction of the contaminant off the soil and adding bacteria enriched from a less contaminated site. Success was achieved in remediating both soil washwater and soil in a bioslurry reactor (60). 2,4-D is also effectively degraded in composting, with about half being completely mineralized, and the other half becoming incorporated in a nonextractable form in the residual soil organic matter (61).

The bioremediation of polychlorinated biphenyls in soils is receiving significant attention (53,56) because these compounds are quite widely distributed in the environment, either from leaking electrical transformers or because they were applied as part of road maintenance. In the latter case, the contamination usually includes petroleum hydrocarbons and unfortunately it seems that the two contaminants inhibit each other's degradation. Nevertheless, cultures are being found that

can degrade both polychlorinated biphenyls and petroleum hydrocarbons.

Groundwater. A successful groundwater bioremediation of pentachlorophenol is being carried out at the Libby Superfund site described earlier. A shallow aquifer is present at 5.5 to 21 m below the surface, and a contaminant plume is nearly 1.6 km in length. Nutrients and hydrogen peroxide were added at the source area and approximately half way along the plume, and pentachlorophenol concentrations decreased from 420 ppm to 3 ppm whenever oxygen concentrations were successfully raised. A membrane oxygen dissolution system was installed to replace the initial hydrogen peroxide additions, and costs were substantially lowered without an apparent decrease in remediation performance (62).

Pentachlorophenol is readily degraded in biofilm reactors (63), so bioremediation is a promising option for the treatment of contaminated groundwater brought to the surface as part of a "pump and treat" operation.

River and Pond Sediments. Much of the work on polychlorinated biphenyls has focused on the remediation of aquatic sediments, particularly from rivers, estuaries, and ponds (53). As noted earlier, a few of the most lightly chlorinated compounds are mineralized under aerobic conditions, but the more chlorinated species seem completely resistant to aerobic degradation, even by white-rot fungi. On the other hand, there is extensive dechlorination of highly chlorinated forms under anaerobic, particularly methanogenic, conditions. Bioremediation thus requires anaerobic and aerobic regimes. Intrinsic biodegradation of polychlorinated biphenyls can be recognized by the changing "fingerprint" of the individual isomers as biodegradation proceeds (53,64). The anaerobic dechlorination of the most recalcitrant congeners can apparently be "primed" by adding a readily dehalogenated congener, such as 2,5,3',4'-tetrachlorobiphenyl (65), but whether this is a realistic approach for in situ bioremediation remains to be seen. Harkness and coworkers (66) have successfully stimulated aerobic biodegradation in large caisons in the Hudson River by adding inorganic nutrients, biphenyl, and hydrogen peroxide, but found that repeated addition of a polychlorinated biphenyl degrading bacterium (*Alcaligenes eutrophus* H850) had no beneficial effect. Essentially no biodegradation occurred in the stirred control caissons, but losses on the order of 40% were seen in the caissons that received nutrients and peroxide, regardless of whether the stirring was aggressive or rather gentle. Whether this approach can be scaled-up for large scale use, with a net environmental benefit, remains to be seen.

NONCHLORINATED PESTICIDES AND HERBICIDES

Constituents. A vast number of herbicides, pesticides, fungicides, and so on, have been sold, and a few are shown in Figure 13. In order to be effective, they must have their effect before they are degraded in the environment, but on the other hand they must not be so resistant to degradation that they accumulate where they are used or in food chains. It is unusual for these compounds to become contaminants where they are applied correctly, but manufacturing facilities, storage depots, and rural airfields where "crop-dusters" are based have had spills that can lead to long-lasting contamination. Bioremediation is a promising technology to remediate such sites. There are also some locations where groundwater has become contaminated by these chemicals, and again, bioremediation may be a cost-effective remediation strategy.

Biodegradation

The majority of herbicides, pesticides, fungicides, and insecticides are biodegradable, although the intrinsic

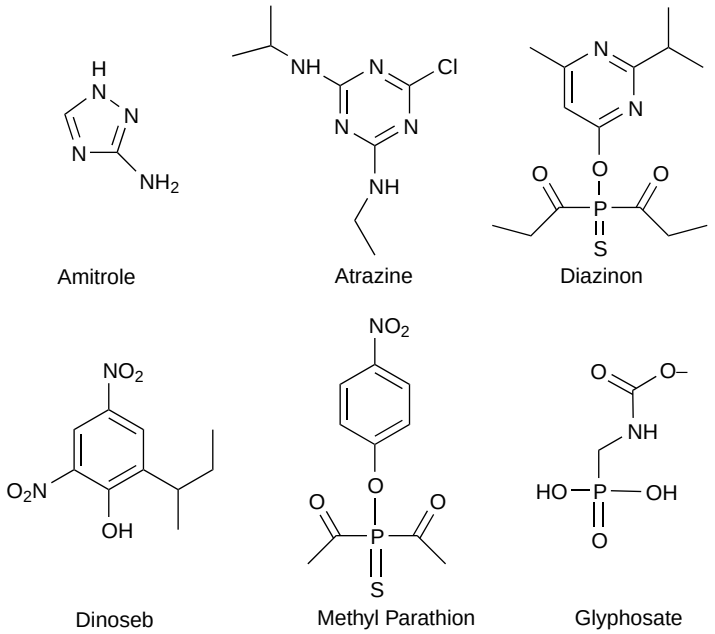

Figure 13. Some representative nitrogen-containing hydrocarbons.

biodegradability of individual compounds is one of the variables used in deciding which compound to use for a particular task. Some herbicides are acutely toxic to plants that absorb them, but are so readily degraded in soil that seeds can be planted at the same time as the herbicide application. Other herbicides are known to be effective at preventing plant growth for many months, and are used for long-term weed control. In some cases, the biodegradation of a pesticide is so rapid that it loses its efficacy, and pesticide rotation strategies must be used. Very few degradation pathways of these compounds have been worked out in detail, but some generalizations can be made.

Compounds with organophosphate moieties, such as diazinon, methyl-parathion, coumaphos, and glyphosate are usually hydrolyzed at the phosphorus atom (50,67). Indeed, several *Flavobacterium* isolates are able to grow using parathion and diazinon as sole sources of carbon.

Triazines pose rather more of a problem, probably because the carbons are in an effectively oxidized state so that little metabolic energy is obtained by their metabolism. Very few pure cultures of microorganisms are able to degrade triazines such as atrazine, although some Pseudomonads are able to use the compound as sole source of nitrogen in the presence of citrate or other simple carbon substrates. The initial reactions seem to be the removal of the ethyl or isopropyl substituents on the ring (50), followed by complete mineralization of the triazine ring. The nitrogen can be used as nitrogen source by some organisms (68), and as sole carbon and nitrogen source under anaerobic conditions (69).

Nitroaromatic compounds, such as dinoseb, are degraded under aerobic and anaerobic conditions (70). The nitro group may be cleaved from the molecule as nitrite or reduced to an amino group under either aerobic or anaerobic conditions. Alternatively, the ring may be the subject of reductive attack. Thus, while these molecules are sometimes quite long-lived in the environment, they can be completely mineralized under appropriate conditions (70). Alternatively, inert residues can be immobilized; for example, a *Clostridium bifermentans* anaerobically degrades dinoseb cometabolically in the presence of a fermentable substrate to below detectable levels, although only a small fraction is actually mineralized to carbon dioxide (71).

Carbamates such as aldicarb undergo degradation under both aerobic and anaerobic conditions. In fact, the oxidation of the sulfur moiety to the sulfoxide and sulfone is part of the activation of the compound to its most potent form. Subsequent aerobic metabolism can completely mineralize the compound, although this process is usually relatively slow so that it is an effective insecticide, acaricide, and nematocide. Anaerobically these compounds are hydrolyzed, and then mineralized by methanogens (72).

Bioremediation

Groundwater. Atrazine dominated the world herbicide market in the 1980s, and contamination of groundwater has been reported in locations worldwide. There are several reports that once in groundwater it is very recalcitrant, suggesting that atrazine-degrading organisms are not widespread. Nevertheless, successful biodegradation has been achieved with indigenous organisms in laboratory mesocosms after a lag phase, and activity remained once it was found (73). Interestingly, the degradation was somewhat slowed by the addition of low concentrations of readily assimilatable carbon, such as lactate, and it is not clear how biodegradation might be stimulated in the field. Nevertheless, it is clear that intrinsic remediation is likely to lead to the disappearance of atrazine from groundwaters once atrazine utilizers have become abundant, and perhaps inoculation with atrazine-metabolizing species will be effective.

If more active treatment is required, such as "pump and treat," it is possible that biological reactors will be a cost-effective replacement for activated carbon filters.

Soil. Herbicides and pesticides are of course metabolized in the soil to which they are applied, and there are many reports of isolating degrading organisms from such sites. Degradation activities are typically much higher at sites that have seen product application, indicating that natural enrichment processes occur. Much current effort is aimed at assessing the diversity of degradative pathways, and in many cases it seems that several different natural metabolic pathways can degrade individual pollutants. Little work has yet been presented in which the biodegradation of these compounds has been successfully stimulated, at field scale, by a bioremediation approach, but inoculation with active organisms may be a promising approach (74). The addition of genetically engineered organisms, albeit a killed recombinant *E. coli* that overexpresses atrazine chlorohydrolase, significantly increased atrazine degradation in a heavily contaminated soil (75).

MILITARY CHEMICALS

Constituents. The military use a range of chemicals as explosives and propellants, "energetic molecules," and by the nature of their use it is no surprise that there are now many areas in need of remediation. Generally speaking, modern explosives are cyclic, often heterocyclic compounds, composed of carbon, nitrogen, and oxygen. Perhaps the most well known is 2,4,6-trinitrotoluene (Fig. 14), but RDX (Royal Demolition explosive; hexahydro-1,3,5-trinitro-1,2,3-triazine, also known as cyclonite) and HMX (High Melting explosive; octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine) are even more powerful. N,N-dimethylhydrazine and perchlorate are used as solid rocket fuels. These compounds are sometimes present at quite high levels in soils and groundwater on military bases and production sites and need to be removed. One quite infamous problem at the latter is "pink water," a relatively undefined mixture of photodegradation products of TNT. Bioremediation is a promising technology for treating sites contaminated with such compounds.

Bioremediation may also be an appropriate tool for dealing with chemical agents such as the mustards and organophosphate neurotoxins (76,77), but little work on actual bioremediation has been published.

Biodegradation

Natural nitro-substituted organic compounds are quite unusual, and it was once thought that their degradation

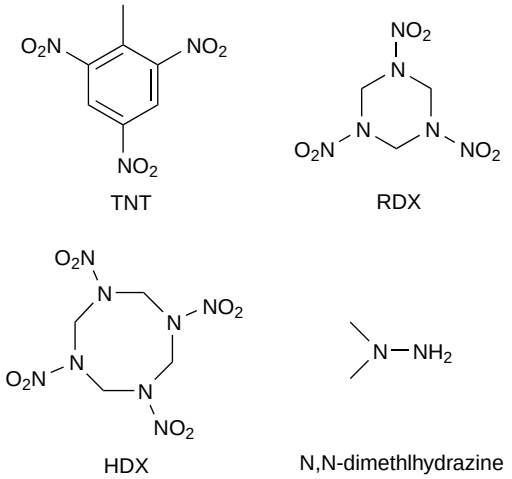

Figure 14. Some military chemicals.

was principally by abiotic processes. As we saw above in the case of dinoseb, however, nitro-substituted compounds are subject to a variety of degradative processes. The biodegradation of TNT is well established (78). Under anaerobic conditions it can be reduced to the corresponding aromatic amines and subsequently deaminated to toluene; the latter can be mineralized under anaerobic conditions, leading to the potentially complete mineralization of TNT in the absence of oxygen. Under aerobic conditions, a range of bacteria and fungi can mineralize TNT often cometabolically with the degradation of a more degradable substrate. However, there is also ample evidence that under some conditions the TNT is converted to insoluble large molecular weight compounds, probably by addition reactions to soil components such as humic and fulvic acids or cellular material in the case of plants. Lignolytic fungi also yield promising results for the degradation of both TNT and "pink water," particularly if the latter is pretreated with UV irradiation.

RDX and HMX are rather more recalcitrant, especially under aerobic conditions, but there are promising indications that biodegradation can occur under some conditions, especially composting (78). Several strains of bacteria able to use RDX (and triazine) as the sole source of nitrogen for growth have recently been isolated, and this is an area that is witnessing rapid progress.

Some work has been reported on the biodegradation of dimethylhydrazine (79), and there is a lot of current interest in perchlorate as a terminal electron acceptor for a range of heterotrophic bacteria (80). Perchlorate remediation is being achieved at the McGregor, Texas, Weapons plant site with a biological "reactive barrier technology" (81).

Bioremediation

Groundwater. Nitrotoluenes have been detected in groundwater in some areas, and intrinsic remediation seems to occur at some sites by anaerobic degradation. They are readily degraded in biological fluidized bed reactors (82), and research into whether this can be stimulated in situ with a net environmental benefit is proceeding. Rocket fuel-contaminated groundwater is also being treated at an experimental scale with bioremediation (83).

Soil. Optimum bioremediation of nitro compounds seems to require an anaerobic stage to encourage the reductive removal of the nitro groups, followed by an aerobic stage to encourage the mineralization of the carbon skeleton (78,56). Composting of soils contaminated by high explosives is being carried out at several U.S. Army Depot sites, including Umatilla in Oregon, Pueblo in Colorado, and Tooele in Utah (56). Bioslurry reactors are also in use (56).

OTHER ORGANIC COMPOUNDS

The majority of organic compounds in commerce are biodegradable, so bioremedation is a potential option for cleaning up after industrial and transportation accidents. For example, Flathman and coworkers (84) reported the successful bioremediation of 23,000 liters of vinyl acetate spilled from a railroad tank car in Albany, New York, at a cost approximately half that of excavation and disposal of the 1,100 m^3 of contaminated soil. They also report that in situ biological treatment has been used to remediate spills of other organics, including acrylonitrile, styrene, 2-butoxyethanol, and ethacrylate, at other railroad-accident sites. Bioremediation is thus already an important tool in remediating accidental spills of organic compounds.

Bioremediation is also an option when spills of such compounds contaminate groundwater. For example, bioremediation seems a feasible treatment for aquifers contaminated with phenol (85), alkylpyridines (86), sulfolane and diisopropanolamine (87). It has also been used to treat soils contaminated with the plasticizer bis(2-ethyl-hexyl)phthalate in a bioslurry reactor (88). "Biological plugs," actively aerated in-ground bioreactors, have been used to bioremediate a site contaminated with monoethanolamine (89).

INORGANIC CONTAMINANTS

Nitrogen Compounds

Constituents. Nitrogen-containing compounds are of concern for several reasons. Nitrate levels are regulated in groundwater because of concerns for human and animal health, while ammonia is regulated in streams and effluents as a potential fish toxicant, and any nitrogenous contaminant is a potential problem in water because of its stimulatory effect on the growth of algae. Other nitrogenous contaminants include cyanides in mine waters. Fortunately, all are amenable to biological treatment (90).

Biodegradation

The biological mineralization of fixed nitrogen is well studied; ammonia is oxidized to nitrite, and nitrite to nitrate, by autotrophic bacteria, and nitrate is reduced to nitrogen by anaerobic bacteria using nitrate as terminal

electron acceptor. Urea in sewage and industrial wastes is readily hydrolyzed to ammonia and carbon dioxide by many bacteria, and cyanides are used as sole sources of carbon and nitrogen by many aerobic organisms. Wastewater treatment facilities utilize these organisms in assuring that municipal and industrial effluents meet strict water quality standards.

Bioremediation

Surface Water. One example of exploiting biology to handle excess nitrogen in surface water arose at the USDoE Weldon Spring Site near St. Louis, MO. This site had been a uranium and thorium processing facility, and the processing involved nitric acid. The waste stream, known as raffinate, was discharged to surface impoundments and neutralized with lime to precipitate the metals. Two pits had nitrate levels that required treatment before discharge, but heavy rains in 1993 threatened to cause the pits to overflow. Bioremediation by the addition of calcium acetate as a carbon source successfully treated more than 19 million liters of water at a reasonable cost (91). The use of sulfur-based autotrophic denitrification ponds to remediate nitrate is also under investigation (92). Here the sulfur acts as electron donor to the nitrate, and competing sulfur oxidation by aerobes must be controlled by minimizing mixing and aeration.

Groundwater. One approach to minimizing the environmental impact of excess nitrogen in groundwater is to add a degradable substrate to the contaminated aquifer, in the absence of oxygen, to stimulate bacterial denitrification. Soluble compounds such as ethanol and acetate have been suggested (90), but insoluble substrates such as vegetable oil (93) or sawdust (94) seem to provide better control, especially for wells.

METALS AND METALLOIDS

A wide range of metallic and nonmetallic contaminants is present at industrial and agricultural sites throughout the world, both in ground and surface water and in soils. They pose quite a different problem from that of organic contaminants, since they cannot be degraded so that they "disappear." Some metal and metalloid elements have radically different bioavailabilities and toxicities depending on their redox state, so one option is stabilization by converting them to their least toxic form. This can be a very effective way of minimizing the environmental impact of a contaminant, but if the contaminant is not removed from the environment there is always the possibility that natural processes, biological or abiological, may reverse the process. Removing the contaminants from water phases is relatively straightforward, and the wastewater treatment industry practices this on an enormous scale. "Pump and treat" systems that mimic wastewater treatments are already being used for several contaminants and less complex systems involving biological mats are a promising solution for less demanding situations.

Immobilization and Toxicity Minimization

Adsorption. Biomass, often agricultural by-products but also including microbial products, have been widely used as adsorbents for metals and other contaminants in water (95), but they are outside the scope of this article.

Microbial Processes. Most elements display a range of solubilities and biological effects depending on their chemical form. For example, chromium, while it may be an essential micronutrient for many organisms, is known to be toxic at higher levels. Indeed, chromium has a range of available redox states that differ significantly in their environmental impact. Cr(VI) is generally more soluble than Cr(III), and more toxic, but a wide range of organisms, both bacteria and fungi, are able to reduce the former to the latter under both aerobic and anaerobic conditions, thereby reducing the environmental impact of the contaminant. Since Cr(III) precipitates as insoluble hydroxides under neutral and alkaline conditions, microbial reduction is a potential treatment for soils and waters (96).

Similarly, selenium is a micronutrient that is toxic at higher levels. It also has quite a different bioavailability in its different redox states, with the elemental form being the least biologically available. Many microorganisms, both bacteria and fungi, are able to reduce more oxidized species, especially selenite (Se(IV)), to the red elemental form, providing an appealing remediation option for this element (97). An alternative approach to remediating selenium contamination might be to encourage methylation to volatile dimethylselenide. Although the microbiology of this process is not yet very well understood, it seems to be the result of degradation of the selenium containing amino acid selenomethionine.

Arsenic is another element with different bioavailability in its different redox states. Arsenic is not known to be an essential nutrient for eukaryotes, but arsenate (As(V)) and arsenite (As(III)) are toxic, with the latter being rather more so, at least to mammals. Nevertheless, some microorganisms grow at the expense of reducing arsenate to arsenite (98), while others catalyze the reverse reaction (99). The element can be immobilized as an insoluble polymetallic sulfide by sulfate-reducing bacteria, presumably adventitiously because of the production of hydrogen sulfide (100). Indeed, many contaminant metal and metalloid ions can be immobilized as metal sulfides by sulfate-reducing bacteria. Sulfate-reducing bacteria can immobilize uranium quite effectively, but in this case it is precipitated as uraninite (UO_2) (101).

A rather more specific mechanism of microbial immobilization of metal ions is represented by the accumulation of uranium as an extracellular precipitate of hydrogen uranyl phosphate by a *Citrobacter* species (102). Staggering amounts of uranium can be precipitated — more than 900% of the bacterial dry weight! Indeed, even elements that do not readily form insoluble phosphates, such as nickel and neptunium, may be incorporated into the uranyl phosphate crystallites (103). The precipitation is driven by the production of phosphate ions at the cell surface by an external phosphatase, and while the process requires the addition of a phosphate donor, such as

glycerol-2-phosphate, it may be a valuable tool for cleaning water contaminated with radionuclides.

Microbial processes can also accumulate and immobilize mercury ions. *Escherichia coli* engineered to overexpress a Hg^{2+} transporter and metallothionein accumulate and immobilize mercury ions quite selectively (104). Alternatively, many microorganisms reduce mercury compounds to the elemental form, which is volatile (105). Although this certainly reduces the environmental impact of compounds such as methylmercury, such a bioprocess would have to include a mercury capture system (106) before it could be exploited on a large scale with public support.

Bioremediation

Water. Groundwater can be treated in anaerobic bioreactors that encourage the growth of sulfate-reducing bacteria, where the metals are reduced to insoluble sulfides and concentrated in the sludge. For example, such a system is in use to decontaminate a zinc smelter site in the Netherlands (107).

Bacterial remediation of selenium oxyanions in San Joaquin (CA) drainage water is under active investigation (108,109), but has not yet been commercialized. Agricultural drainage rich in selenium is also typically rich in nitrates, so bioremediation must also include conditions that stimulate denitrification (110).

Rhizofiltration and Other Forms of Phytoremediation. Rhizofiltration is the use of plant root systems to remove contaminating metal ions from water (111), and it now seems clear that microorganisms play an essential role on the roots (112). Nevertheless, little is known about the specific interactions of microbes with the plants, and this area is very much in its infancy.

Mine Drainage. Natural drainage waters that come into contact with active and abandoned metal and coal mines can become seriously contaminated with a range of heavy metal ions and/or often become quite acidic, with a pH near 2. While underground, the water is typically anoxic, and any iron is present as soluble ferrous species. When this mixes with aerobic surface water, the iron precipitates as bright orange ferric hydroxide, and this can have a serious environmental impact. In recent years, it has become clear that the environmental impact of acid mine drainage can be minimized by the construction of artificial wetlands that combine geochemistry and biological treatments. These systems are being designed for a range of wastewaters, most of which fall outside the scope of this section.

The precipitation of ferric hydroxide is typically biologically mediated, by iron-oxidizing bacteria, at acid pH, but is usually rather slow. Abiotic oxidation becomes more important at pH values above 5, and this is usually much faster than the biological process. Most constructed wetlands for treating acid mine waters thus start with a zone designed to raise the pH. A bed of crushed limestone often suffices to raise the pH significantly, and it is important that this be kept anoxic to prevent rust precipitation on the limestone, which would prevent further production of alkalinity. Once the pH is near neutral, the water is discharged into an aerobic wetland to encourage the precipitation of iron and aluminum oxides and the coprecipitation of arsenic, if this is present (113).

If heavy metals are present in mine water, the iron-free water can be made to flow into an anaerobic part of the constructed wetland, where organic material, such as compost, manure, or sawdust, provides reductants to sulfate-reducing bacteria that become established therein. These bacteria reduce sulfate to sulfide, which precipitates the heavy metal ions as insoluble sulfides. It is important that this part of the constructed wetland be kept anaerobic to prevent oxidation and remobilization of the precipitated metals. For this reason, this part of the wetland is typically kept flooded and free of aquatic plants that might introduce oxygen through their roots. (113). Finally, an aerobic algal mat can act as a polishing step to complete the removal of contaminants, particularly manganese (114). Mine drainage that is not acidic may not need such complicated systems, and individual parts of the treatment train described above may suffice in some situations.

Bacteria have been used to reduce Cr(VI) to Cr(III), thereby immobilizing it in soils and water (115). Reactive barrier technologies, including biological barriers (22), are being widely used for metal ion and metalloid contaminants.

CONCLUSION

Bioremediation is being successfully used to treat a wide range of contaminants in a broad range of environments. Contaminants amenable to bioremediation include crude oils and refined petroleum products, halogenated solvents, pesticides, herbicides, military chemicals, and mine waters, and they can be treated in air, soil, and water. In all cases it is clear that aiding and abetting natural selection is the key to success and that making small adjustments of the local environment to encourage the growth of remediating organisms may be all that is needed. For example, petroleum is biodegradable, but this degradation is typically nutrient limited; partially relieving this limitation can lead to stimulating the biodegradation severalfold with no adverse environmental impact. On the other hand, organisms growing on other substrates most effectively remove several halogenated solvents; adding these substrates, for example, methane, significantly increases the rate of removal of the contaminant.

The centrality of natural selection in designing a remediation strategy cannot be overestimated. One area where it sometimes seems to be ignored is the consideration of the need to add microbial inoculants to stimulate biodegradation (bioaugmentation). Some modern contaminants of concern (oil, many halogenated compounds) have been part of the biosphere for millennia, albeit usually at low levels. Microbes that can degrade them are probably ubiquitous, so adding organisms to stimulate biodegradation is unlikely to be cost-effective. If the environment is made hospitable for growth, the indigenous organisms are likely to prove sufficient for bioremediation. Perhaps the most startling demonstration of this was performed by the USEPA when testing potential inoculants for stimulating oil biodegradation

in Alaska following the Exxon Valdez oil spill (116). Eight products were tested in small laboratory reactors that allowed substantial degradation of a test oil by the indigenous organisms of Prince William Sound; all eight microbial inocula had a greater stimulatory effect on alkane degradation if they were sterilized by autoclaving prior to addition. This suggests that the indigenous organisms readily outcompeted the added products, but that autoclaving the products released some trace nutrient that was able to stimulate the growth of the endogenous organisms.

Of course, bioaugmentation may prove more effective with contaminants that have only recently entered the biosphere, such as methyl-*t*-butyl ether (11,12), or are toxic (58,60). It may also be effective if material is to be composted, where it is likely that composting organisms may take some time to become established. And modern molecular biology may offer opportunities for moving effective degradation pathways into organisms native to a contaminated site, improving biodegradation pathways by broadening the substrate range of degradative enzymes or by removing biochemical constraints to maximize degradative activities (75). There are, however, many technical and regulatory hurdles to be surmounted before this is likely to be widely used.

Another area where there is controversy is in the role of surfactants. Many contaminants of concern are hydrophobic and are adsorbed to soil material. Many bacteria, particularly those that degrade hydrocarbons, produce surfactants that are thought to help increase the bioavailability of the contaminant. Some release the surfactants into the medium, others incorporate them into their cell exterior, and there have been elegant experiments to show that inhibiting the production of these compounds inhibits the ability of the bacteria to degrade their substrates. Allen and coworkers (117) provide an example of how difficult it is to make broad generalizations; they examined the ability of a *Pseudomonas* and a *Sphingomonas* to degrade naphthalene and phenanthrene in the presence of a nonpolar, nondegradable (by these organisms) solvent (2,2,4,4,6,8,8-heptamethylnonane) or the nonionic surfactant Triton X-100. The heptamethylnonane increased the rate of degradation of both substrates for both microorganisms. The Triton X-100 increased the rate of degradation by the *Pseudomonas*, but inhibited that by the *Sphingomonas*. There have been many suggestions to add surfactants, either microbial or synthetic, to stimulate biodegradation. This seems to be beneficial in the case of some oil dispersants at sea (118), but the situation seems complicated in soils, and probably needs to be assessed on a case-by-case basis (119). Surfactants did not stimulate pentachlorophenol degradation in one recent study (120). Nevertheless, surfactants are clearly beneficial in the physical part of technologies such as bioslurping (18), so it will be important to ensure that, at least, they do not inhibit the biodegradation of residual contaminants.

BIOREMEDIATION: AQUATIC ECOSYSTEMS

K. H. Baker
Middletown, Pennsylvania

Contamination of aquatic environments, both freshwater and marine, with petroleum hydrocarbons and a variety of xenobiotic compounds is a commonplace occurrence in the modern world. Oceans and rivers remain major avenues of transportation and commerce with tankers and supertankers traversing the globe. While spectacular oil spills, resulting in the contamination of hundreds to thousands of square miles, have left the most vivid impact on the general public, scores of smaller releases and spills have resulted in extensive contamination of open waters, shores, and sediments. One of the technologies that has found widespread application in the remediation and restoration of aquatic ecosystems is bioremediation. This chapter will review the basic principles involved in the use of bioremediation in aquatic (freshwater and marine) ecosystems, provide an overview of examples of successful bioremediation projects, and examine several case studies in more depth to present a snapshot of the current state of the art. In addition to other chapters in this work, the reader is referred to numerous recent books and review articles for additional information (1–13).

OVERVIEW OF BIOREMEDIATION

Bioremediation relies on the abilities of microorganisms to degrade and detoxify organic and inorganic compounds. In its simplest form, bioremediation involves no intervention at all and simply allows natural processes to reduce the concentration of the contaminant in an environment. This is usually referred to as natural attenuation or intrinsic bioremediation. In most instances, alteration or manipulation of physical/chemical properties of the contaminant or factors in the environment is used to enhance the natural processes. This is referred to as *enhanced bioremediation*. Fundamentally, there are two approaches to

this enhanced bioremediation: (*1*) biostimulation, which depends primarily on the modification of the environment and (*2*) bioaugmentation, which uses the addition of microbial cultures to increase biodegredation. Frequently, these two approaches are combined and microorganisms are introduced in conjunction with such environmental modifications as nutrient supplementation.

Bacteria capable of at least some transformation of all but the most exotic of man-made chemicals are probably present in all aquatic environments (1,2,5,6,14–16). Isolation and characterization of organisms capable of degrading petroleum and related hydrocarbons (17–22), polyaromatic hydrocarbons (19,23–28), alkylbenzenes (29–31), chlorinated solvents (31,32), polychlorinated biphenyls, dioxins, and related compounds (33–36), and other organic contaminants (37,38) under either aerobic or anaerobic conditions is commonly reported in the microbiological literature. Kimura and coworkers (39) isolated 96 strains of bacteria from seawater that were capable of degrading normal alkanes, branched alkanes, cycloalkanes, and aromatic compounds. A marine bacterium, isolated from intertidal crude-oil contaminated sediments, showed enhanced growth in the presence of added petroleum hydrocarbons compared to growth in unsupplemented marine medium (40). Oil degrading bacteria were isolated from 96% of the sites examined in the vicinity of Zhejaing islands. The abundance of oil degrading microorganisms was correlated with the concentration of petroleum hydrocarbons in the water (41). Considering that most (90–99%) microbial species in natural communities cannot be detected using standard laboratory culture techniques, it is likely that these reports reflect the barest minimum of the biodegradation capabilities of microorganisms (42).

Chronic release of low levels of contaminants into aquatic environments usually results in an enrichment of the microbial community for organisms capable of degrading the contaminant. Under unfavorable environmental conditions or in the absence of prior exposure to the contaminant however, both the numbers and activity of specific microbial populations may be extremely low, accounting for 1% or less of the total bacterial community (43–45).

In many instances a lag or acclimation period is observed before active degradation of the compound takes place. Acclimation is a general term that may refer to several changes in microbial populations, including (*1*) growth of an initially small population of organisms capable of degrading the contaminant, (*2*) changes in metabolic regulation including induction and/or derepression of key enzymes in the necessary metabolic pathways, (*3*) genetic change in the indigenous populations, and (*4*) the preferential use of alternative substrates by the degrader populations (8,46–48). Leahy and coworkers (49) concluded that lack of adaptation by microbial communities accounted for low petroleum hydrocarbon degradation rates in sediment samples from the Gulf of Mexico. Siron and coworkers (50) assessed the adaptation of an indigenous cold seawater microbial community to petroleum hydrocarbons by monitoring the ratio of oil-degrading bacteria to total heterotrophs within the community. They reported a 10-fold increase in this ratio following exposure of the community to crude oil. Delille and Delille (51) studied enclosures on nine different sub-Antarctic intertidal beaches to which crude oil had been added. Despite the initially pristine condition of all of the sites, indigenous populations of oil-degrading microorganisms were present.

If environmental conditions prevent the natural development of microbial populations capable of degrading a particular compound, or if the development of such populations occurs at too slow a rate, it may be possible to enhance biodegradation through the addition of supplemental microorganisms (52,53). This process, termed *bioaugmentation*, may be accomplished using either microbial cultures selected from the contaminated site, grown under controlled conditions, and then re-added at much higher concentrations to the site or, alternatively, a variety of commercially prepared microbial products each designed for degradation of specific contaminants.

Effective bioremediation depends upon extensive site characterization with a particular emphasis on factors that control or enhance microbial activity. Although there are a large number of factors that influence microbial populations and activities, only a limited number of factors are amenable to modification from a technological and economic perspective.

All biological systems are influenced by ambient temperature. Microorganisms, which can be broadly categorized in terms of their temperature range, are no exception. Within the range of temperatures in which a microorganism can grow, biological activity generally increases with increasing temperature with maximum activity occurring at a temperature just below the maximum temperature the organism can tolerate. As a general rule of thumb, microbial activity doubles with each 10 °C increase in temperature. Seasonal differences in temperature, therefore, can have profound effects on the rate of biodegradation (43,54,55). Wyndiam and Costerton (56) reported a 40-fold reduction in the rate of naphthalene degradation in river sediment during the winter (0 to 4 °C) compared to the summer (8 to 21 °C).

Aquatic environments are frequently at temperatures in which microbial activity is low. Manipulation of the temperature of aquatic environments usually is not feasible and, therefore, temperature can be a significant constraint in the use of bioremediation. Low environmental temperature was a significant factor limiting the rate of bioremediation during cleanup of the *Exxon Valdez* spill in Prince William Sound, Alaska. In some instances in which contamination is primarily associated with sediments, ex situ treatment in bioreactors may allow for modification of temperature.

The optimal pH for microbial activity is generally between 5.5 and 8.5. Environmental pH is not a significant factor controlling bioremediation in open waters, such as rivers or oceans in which pH is usually controlled by natural buffering systems; however, pH may be outside the optimal range within sediments. Incubation of salt marsh sediments under slightly acidic conditions (pH 5.0 and 6.5) was found to decrease hydrocarbon mineralization relative to incubation at higher pH (8.0) (57). As with temperature,

manipulation of sediment pH is usually confined to the treatment of excavated/dredged material in bioreactors.

Microorganisms require a terminal electron acceptor as a sink for electrons generated during the metabolism of organic compounds. Under aerobic conditions, oxygen is used as the terminal electron acceptor being reduced to water. As many organic contaminants such as petroleum hydrocarbons are less dense than water they usually are found on the surface of open waters. Under these conditions, oxygen concentration is not a limiting factor. Degradation of organic compounds is generally, but not always, faster under aerobic rather than anaerobic conditions.

Contamination of aquatic environments is not limited to the surface of open waters. Numerous mechanisms are responsible for the transport of contaminants to sediments. Some contaminants such as chlorinated solvents are heavier than water and sink in aquatic systems. As oil weathers, the formation of droplets that are heavier than water may result in the transfer of these compounds to the sediments underlying open water. High molecular weight fractions of petroleum, including polyaromatic hydrocarbons such as benzo(a)pyrene tend to sorb to particles within the water column and hence accumulate within sediments (14,58). Thus, contaminants within aquatic environments can be transferred downward in the water column and under conditions of thermal (or in some estuaries salinity) stratification may enter anoxic/anaerobic environments or accumulate in sediments with reduced or depleted oxygen. Finally, wind and wave action can carry floating contaminants to shore areas such as beaches and wetlands where they can be deposited in sediments. Under conditions of oxygen limitation, some populations of microorganisms that can use alternative compounds, such as nitrate, sulfate, and carbonate as terminal electron acceptors may be able to degrade the contaminants, including petroleum hydrocarbons and polycyclic aromatic hydrocarbons (26,58–60). Microorganisms from the New York/New Jersey estuary, a site with a history of pollution, were able to degrade benzene, toluene, ethylbenzene, and xylenes components in the absence of molecular oxygen. Enrichment cultures from the sediments with this ability were established under denitrifying, sulfidogenic, methanogenic, and iron reducing conditions (61). In the case of anoxic/anaerobic sediments, electron acceptors (and redox potential) can be controlled in bioreactor systems for the remediation of excavated material.

Carbon, nitrogen, and phosphorus are essential for microbial maintenance and growth (1,2,5,62,63). During biodegradation of organic contaminants, the microbe's carbon requirements usually are met by the contaminant itself. Nitrogen and phosphorus, on the other hand, are present at extremely low concentrations in aquatic environments. Microbial growth, therefore, is limited by the low nutrient levels (1,5). Fuentes and coworkers (64) reported that ambient phosphorus concentrations were important in the survival of petroleum degrading isolates in tropical bays. In some cases, there are sufficient inputs of inorganic nitrogen and phosphorus to support extensive microbial activity (65–68). In these cases, intrinsic bioremediation, the use of natural microbial biodegradation without environmental modification to enhance microorganisms, may be sufficient to remediate a contaminated site (67,68).

When degradation is limited by the available concentrations of fixed forms of nitrogen and phosphorus, fertilizer addition can be effective in stimulating microbial activity and enhancing biodegradation of the contaminating petroleum (69). Care must be taken in determining the type and amount of fertilizer that should be added to the site. The amount of supplemental inorganic nutrients can be estimated on a stoichometric basis. Several standard textbooks on hazardous waste treatment and bioremediation outline the methods for making such an estimation (6,70). A more accurate appraisal of the optimum amount of inorganic nutrients to be added can be made using microcosm studies. A variety of techniques for conducting these types of studies have been described in the literature (1,71,72).

The amount of inorganic nutrients is not the only factor that needs to be considered in designing a biostimulation system. Equally important is the form of nutrients used (73,74). Water-soluble nutrients such as inorganic salts rapidly dissolve and are dispersed and diluted (75). For example, Foght and coworkers (76) found that the addition of supplemental nitrogen in the form of ammonium to a marine enrichment culture resulted in decreased degradation of aromatic compounds while the use of nitrate, as a source of nitrogen, enhanced biodegradation. Oleophilic nutrients dissolve slowly and so their use can result in sustained release of nutrients necessary to support bacterial growth and activity. Santos and coworkers (77) compared two different oleophilic fertilizers for use in enhanced bioremediation. Both of the products increased the biodegradation of Iranian crude oil. Neither formulation was found to be clearly superior to the other; rather, each had its own advantage (faster biodegradation of alkenes versus quicker disappearance of the oil slick) and the authors concluded that a mixture of the two fertilizers would offer the best treatment option.

Microorganisms are unable to efficiently metabolize compounds that are not dissolved in water. The availability of a compound is influenced by both its solubility and its partitioning between the aqueous and organic phases (78,79). Sorption of organic compounds by sediments can have profound effects on the bioavailability of the compounds. Generally, these materials are less bioavailable than dissolved compounds. In addition, sorption to sediment particles may result in the transport of the sorbed compounds to environments not conducive to biodegradation. Microorganisms are known to produce surface-active compounds — bioemulsifiers or biosurfactants — that increase the solubility and availability of organic compounds (80). In addition, man-made emulsifiers can be used to enhance bioavailability (5,6).

Biosurfactants can increase the bioavailability of nonaqueous phase liquids, such as hydrocarbons by either increasing the aqueous solubility of the hydrocarbons or by increasing the hydrophobicity of the bacterial cell surface. Rosenberg and Ron (81) have recently reviewed the structure, biosynthesis, and possible uses of biosurfactants. Rhamnolipids produced by two strains of *Pseudomonas*

aeruginosa grown on glucose and hexadecane were found to cause release of LPS from the outer membrane of the organisms resulting in lower cell surface hydrophobicity even at concentrations of the biosurfactant below the critical micelle concentration (82). *Acinetobacter radioresistans* KA53, on the other hand produces a high molecular weight complex of polysaccharide and protein named *Alasan* that functions as a bioemulsifier (83). Passeri and coworkers (84) isolated a glycolipid biosurfactant from a marine bacterial isolate (MM1) that increased solubility of normal alkanes in water.

Effective bioremediation depends upon containment of the contaminant within a defined area in which environmental conditions can be modified and controlled to enhance microbial growth and metabolism. This is not possible within open waters. While a few studies have been conducted in open water, the effectiveness of bioremediation remains unproven. In contrast, bioremediation in coastal regions and sediments has been shown to be effective in the treatment of contaminating organic compounds (1,9,11,12,85).

AQUATIC ENVIRONMENTS

Marine environments — oceans, estuaries, shorelines, and tidal marshes — are the most extensive environments in the world. Oceans alone occupy a volume of 1.46×10^9 km^3, approximately 71% of the Earth's surface. They are highly diverse in terms of their chemical, physical, and biological characteristics. Marine water is characterized by salinity between 3.3 and 3.7%. If brackish waters are included within this definition, salinity ranges from 1.0 to 3.7% are possible. In addition to the variability in chemical composition, marine environments are subject to considerable physical mixing. Winds, waves, tides, and currents all interact to result in a constantly changing environment. Nor is the variability limited to surface waters. Vertical stratification of water layers results in the presence of multiple habitats that differ in terms of salinity, light, temperature, pressure, and other factors even within limited geographic areas. Finally, different marine environments show profound differences in the biological communities present. Open ocean waters have extremely low biological productivity analogous to terrestrial deserts, while estuaries and tidal marshes have some of the highest productivity in the world. Heterotrophic bacterial populations in open oceans are typically highest at the surface (neuston) and decrease rapidly with depth. Thus, while numbers of 10^7 to 10^8 cells/mL are commonly found in upper ocean waters, this number may decrease by as much as an order of magnitude with each 100 m of depth (86). In oligotrophic areas, microbial numbers within the water column may reach as low as 10^0 organisms/mL. In addition to the differences in microbial numbers within the water column, there are also differences in the typical number of microorganisms between coastal and open water areas. In general, coastal waters have higher concentrations of microorganisms than open waters (87,88). This difference primarily reflects the different nutrient status of the two habitats with coastal areas benefiting from the input of nutrients from the surrounding terrestrial systems.

In terms of the global water budget, freshwater environments make a miniscule contribution. In terms of human society, freshwater environments have an unparalleled importance. The limited global freshwater reserves serve as a medium for transportation, support agriculture and industrial processes, function as a repository for waste products, provide recreational opportunities, and sustain human life by providing potable water. Because of the necessity of water for human existence, much research has been devoted to developing treatment systems and other means to safeguard freshwater environments.

Freshwater environments are as diverse as marine environments. Fundamentally, a distinction can be made between standing (lentic) water bodies such as lakes and ponds and flowing (lotic) systems such as rivers and streams.

In contrast to marine environments, freshwater environments are scarce, accounting for less than 1/10,000 of the total water available on the earth. While sharing many characteristics with marine and estuarine environments, there are several key points to consider in addressing bioremediation of freshwater environments. First, because of their small size compared to marine environments, freshwater environments are less constant, less stable in terms of physical and chemical characteristics. Temperature fluctuation, diurnal cycles of dissolved oxygen, and sudden changes in silt and sediment load owing to storm water are among the variables significantly influencing the biota of lakes, streams, and wetlands. In addition, because of the drastically reduced ratio of water to sediments, benthic processes assume a more important role in freshwater environments than in marine systems. Sediments rather than becoming a geologic sink for materials as happens in the profoundal depths of the ocean, become a temporary repository with a constant exchange of materials occurring between the sediments and the water. This means that sediments can serve as a source of extended contamination to the surrounding water and biota by the slow desorption of organic contaminants. Furthermore, as benthic/detrital food chains dominate in freshwater environments, the transfer and subsequent accumulation of lipophilic organic compounds into upper levels of the food chain are likely.

BIOREMEDIATION OF PETROLEUM HYDROCARBONS IN AQUATIC ENVIRONMENTS

Contamination of aquatic environments is the result of both natural processes and human activities. The variety of compounds impacting marine environments is enormous; bioremediation of one category of contaminants — petroleum hydrocarbons — will be considered here. Oil spills from off-shore drilling, tanker accidents and lightings, accidental releases associated with maritime activity, industrial releases, atmospheric transport and deposition of products of incomplete combustion, runoff from surrounding land, and natural oil seeps are major sources of petroleum hydrocarbons into the marine environment (Table 1; 89–95). While oil spills such as the

Table 1. Global Input of Oil to Marine Environments

Source	Amount (estimated 1990) (thousand tons/year)	Percentage of Total
Offshore oil production	47	2
Natural seeps	259	11
Atmospheric deposition	306	13
Oil transportation and shipping	564	24
Urban runoff and discharge	1,175	50

Source: Ref. 89.

1989 *Exxon Valdez* spill into Prince William Sound are spectacular and immediately grab media attention, they are not the major source of oil pollution in the marine environment. Soclo and coworkers (91) documented the importance of waste oils from mechanics shops in contaminating sediments in coastal regions of Benin while petroleum discharges from tankers and other wastes associated with petroleum delivery and processing dominated in sediments in Aquitaine (France). Zakaria and coworkers (92) reported that runoff of lubricating oils from roadways was a major source of contamination in sediments in the Straits of Malacca (Malaysia).

Upon release into the environment, a variety of physical and chemical processes result in the transformation and dispersion of the oil. Weathering causes the spilled oil to break down and become heavier than water. At the same time, the action of wind, waves, and currents may result in dispersion of the oil spill (96–100). In addition, the turbulence resulting from wind and waves can result in the formation of oil droplets that can be further dispersed throughout the water, forming secondary slicks or sinking within the water column (98). The turbulence can also result in emulsification of the oil. Two types of emulsions are possible: (*1*) water-in-oil emulsions and (*2*) oil-in-water emulsions. Water-in-oil emulsions, frequently called *chocolate mousse*, are associated with strong turbulence, which forcefully mixes the spill with the surrounding water resulting in a product in which water becomes trapped within oil droplets. Chocolate mousse floats on the water surface and can be dispersed large distances from the original spill. It is highly resistant to degradation and may persist in the environment for months to even years after the spill has occurred. Unlike water-in-oil emulsions, oil-in-water emulsions are heavier than water and so sink to the bottom contaminating sediments.

Lighter substances (short-chain alkanes and monoaromatic compounds) within the oil may evaporate from the surface of the spill leaving the heavier oil components behind (101). In temperate climates, the majority of the light hydrocarbons can evaporate from a spill within 1 or 2 days. Photooxidation of compounds present in oil transform aromatic compounds into products associated with the polar and resin fractions of petroleum while aliphatic sulfur compounds are oxidized to sufoxides, sulfones, sulfonates, and sulfates (102). Partial oxidation of components of the oil, occurring primarily at the edges of the spill in which oil, water, and air interface, may result in the formation of tar balls, which sink to the bottom contaminating sediments. Finally, significant transformation of petroleum hydrocarbons results from the metabolic activity of indigenous organisms (1,5,8,9,11,12,102–105).

Dispersive forces frequently result in the transport of petroleum from open water to the shoreline. Because of the importance of coastal, shoreline environments to human activities, remediation of these areas has been the focus of most marine bioremediation. Coastal environments vary considerably depending upon climate, topography, and other local and regional factors.

Most experiments to evaluate the efficacy of bioremediation in the treatment of oil spills have been conducted either in laboratory micro- or mesocosms or in small in situ enclosures (1,8,11,12,106,107). While such experiments provide understanding of the physiology and ecology of microbial populations involved in the degradation of petroleum hydrocarbons, they are difficult to extrapolate to real-world situations. Field studies on bioremediation could provide the information needed. Unfortunately, field studies are technically difficult, expensive, and usually constrained by regulatory restrictions. Ideally, field studies would involve the controlled release of petroleum hydrocarbons into either open oceans or adjacent to shorelines. In reality, the vast majority is conducted during response to actual oil spills and lacks the control of planned studies. Despite these limitations, both laboratory studies and studies conducted coincidentally with oil spills have provided useful insight into bioremediation under field conditions. Because of the low nutrient concentrations and low microbial populations typical of open ocean environments, studies in this type of environment have focused on biostimulation (the addition of nutrients) and bioaugmentation (the addition of microbial cultures).

Bioaugmentation has been shown to have variable and often disappointing results when applied to marine oil spills. Tagger and coworkers (107) found that supplemental bacterial cultures rapidly declined when added to oiled seawater. There was no enhancement of hydrocarbon removal in the presence of the supplemental microorganisms compared to natural conditions. Fayad and coworkers (74) noted that many of the commercial bioaugmentation products proposed for use in the aftermath of the Persian Gulf War had no convincing evidence of increased petroleum removal. They concluded that testing of products in laboratory microcosms using conditions simulating in situ conditions is necessary before these products are used. Lin and coworkers (108) compared fertilizer addition with the use of bioaugmentation for the remediation of salt marsh sediments contaminated with oil. While fertilizer addition increased both microbial respiration and removal of normal and aromatic hydrocarbons, no such enhancement was found with bioaugmentation. Supplemental organisms, derived from both the indigenous microbial community and nonindigenous strains, were found to be unable to survive when inoculated into river sediments without the addition of supplemental carbon

sources to which the organisms were adapted (109). Even under these conditions, only some of the inoculated strains were able to persist. Neralla and Weaver (110) evaluated the efficacy of 10 commercial bioremediation products (bioaugmentation) in the treatment of crude oil contaminated marshes. The products did not increase the number of oil degrading microorganisms significantly, but did enhance numbers of total heterotrophic bacteria present. No product increased degradation of petroleum hydrocarbons compared to a fertilized control. On the other hand, Mochalona and Antonova (111) found the use of combined surfactants and supplemental bacterial cultures enhanced degradation of oil in aquatic environments.

Biostimulation through the addition of inorganic nutrients has generally been found to enhance removal of petroleum hydrocarbons from open seas. Much research has been devoted to developing an appropriate and efficient delivery system for inorganic nutrients because the direct application of these compounds in water-soluble form results in rapid dilution and dissipation of the added nutrients; the use of oleophilic nutrients octyl phosphate and paraffinized urea (112) and paraffin-supported $MgNH_4PO_4$ (113) increased biodegradation. Despite these encouraging results, other researchers have reported no increased biodegradation using supplemental nutrients (114).

Considerably more research has examined the influence of supplemental inorganic nutrients on remediation of contaminated shorelines. The application of a commercial fertilizer to shoreline contaminated with unweathered Forcados crude oil resulted in an initial increase in the rate of biodegradation compared to a control plot that did not receive fertilizer. The effect, however, appeared to be transient because there were no differences between the treated and control plots four years after the spill (115,116).

Bioremediation has been evaluated, albeit under less than ideal experimental conditions, during remediation of several recent oil spills. While the lack of appropriate controls and sufficient independent replicates preclude firm conclusions, the results of these studies indicate that bioremediation, primarily via biostimulation, is a worthwhile technology for oil spill *cleanup*s.

The best-designed and most extensive studies under actual spill conditions are those associated with the *Exxon Valdez* Spill in Prince William Sound, Alaska. The *Exxon Valdez* spill on March 24, 1989 released approximately 41,000 m^3 (11 million gallons; 258,000 barrels) of Alaskan North Slope crude oil into Prince William Sound, resulting ultimately, in the contamination of about 2,090 km of coastline. Initial response to the spill was hindered by a storm on March 26, 1989 that spread the oil to the west of Blight Reef where the tanker ran aground. Over the next several weeks, the oil continued to spread, eventually impacting approximately 15% of the shoreline in Prince William Sound and the Gulf of Alaska (117).

The contaminated shoreline was dominated by rocky areas (72% rock face, 24% mixed boulder and cobble, 3.5% mixed cobble and pebble, and 0.5% fine grain sand/mud or marsh) (10). Initial cleanup focused on removal of the heaviest concentrations of oil using physical methods (cold- and warm-water washing, steam cleaning, and manual oil recovery). Bioremediation was not employed as a remediation technique until after shoreline oiling had been significantly reduced by a combination of weather, natural processes, and physical remediation techniques (118–120). Therefore, evaluation of bioremediation focused on the use of this process as a final cleanup and polishing tool rather than as a first response technology.

Initial studies involved intense site characterization. While the distribution of petroleum hydrocarbons as well as chemical characterization of the changes in the oil owing to weathering and other natural processes was well established in conjunction with ongoing remediation efforts, several additional studies focusing on biological parameters were needed to evaluate the feasibility of bioremediation. Pritchard and coworkers (121) compared the number of oil-degrading bacteria on impacted beaches to unaffected controls and reported that the number of hydrocarbon-degrading microorganisms was as much as 10,000-fold higher than the controls. Other researchers conducted microcosm studies to determine if any easily modified environmental factors were limiting microbial numbers and activity (122–125). Because of the high probability that biodegradation was limited by the supply of inorganic nutrients, special attention was given to the effect of supplemental nitrogen and phosphorus. These laboratory feasibility studies demonstrated that the addition of inorganic nitrogen to the microcosms increased mineralization of weathered Alaskan Slope crude oil. Based upon these studies, biostimulation was proposed as a remedial option and two field scale trials were initiated, at Snug Harbor and Passage Cove.

The field studies tended to support the usefulness of bioremediation for the cleanup of oil beaches. As with open ocean tests, the heterogeneity of the samples coupled with the virtual impossibility of establishing true controls precluded drawing firm conclusions.

Both of these studies compared microbial and chemicals parameters for samples obtained from plots established within the study area. Although the plots were in close proximity to each other and were set-up to reflect comparable environments, difficulties in interpreting the data arose from both interactions between the study areas and unrealized differences between the plots. For example, in the Snug Island studies, analysis of beach sediment demonstrated the presence of significant amounts of inorganic nitrogen (ammonia and nitrate) and phosphorous (phosphate) in both the treated and the control plots at the end of the experiment. Because there were no preexisting data on nutrients in the beach sediments, it was impossible to determine if the increased nutrient levels were the result of leaching from the treated plots or if they reflected normal seasonal changes in beach sediment chemistry (123). In the Passage Cove studies, high within site variability coupled with the initial choice of an inappropriate marker of biodegradation (pristane and phytane) made it impossible to demonstrate statistically significant differences between treated and control sites (121,126). In both of these studies, the most consistent result was a visible clearing of the oiled beach

surface in plots with added nutrients (Inepol EAP 22). Based on the encouraging, but not definitive, results in the Snug Harbor and Passage Cove studies, additional field studies were conducted in 1990 on Knight Island. With the additional time to plan these studies, modifications in experimental design were made that addressed some of the limitations of the previous studies. Specifically, by sampling paired treated and control beaches in three different areas, the researchers were able to obtain data that could be analyzed statistically. In addition, monitoring of pore water nutrient levels allowed the movement of added nutrients to be determined.

The treated beaches received two types of nutrient supplement — Inepol EAP 22 and Customblen. Microbial numbers (heterotrophs and oil-degraders), ability of the microbial communities to use hexadecane and phenanthrene, and levels of petroleum hydrocarbons in sediments were monitored at each sampling. In addition, interstitial (pore) water samples collected at the same time were analyzed for dissolved oxygen, salinity, pH, temperature, and nutrient levels. There was an increase in microbial numbers in both treated and control beaches over the duration of the study; however, no statistically significant differences between the two were found. Neither were there statistically significant differences in the numbers of oil degraders between the treated and control beaches. The lack of sustained effect of the nutrient amendments on microbial numbers could have been the result of two factors: (*1*) the heterogeneity of the sediment that resulted in large within plot variability or (*2*) the rapid removal of the nutrients from the site of application. This possibility was supported by pore water nutrient measurement that indicated removal of the nutrients in 10 to 20 days from application.

Despite the lack of increase in microbial numbers in the treated beaches, the researchers found a significant increase in mineralization of hexadecane and phenanthrene in the treated sediments compared to the control (127). The increased mineralization of petroleum compounds provided clear support for the use of biostimulation as a remediation technology.

The apparent disagreement between the response of the microbial community to supplemental nutrients in terms of microbial numbers compared to overall mineralization, in part, reflect the heterogeneity of the study area. Actual changes in microbial numbers within the sample plots may have been masked by overall variability. More importantly, the conflicting results highlight the possibility that increased mineralization of the contaminants may have been the result of increased activity at the level of individual microorganisms rather than increased microbial numbers (10). This possibility is important to remember in evaluating the feasibility of bioremediation in other situations.

Results from the chemical analysis of the sediments, while not as clear cut, did supply evidence supporting the efficacy of bioremediation. The chemical analysis suggested that the polar content of the petroleum was a significant factor influencing biodegradation (122,128). Other important factors were the ratio of nitrogen to oil, the elapsed time since nutrient addition, and the extent of natural biodegradation. A multivariate regression analysis incorporating these factors was developed, which showed good correlation with removal of the oil.

The final two field studies associated with the *Exxon Valdez* oil spill were conducted on Elrington and Disk Islands in the summer of 1990 (129). These studies evaluated different types of aqueous nutrient additions for biostimulation and also separately evaluated bioaugmentation using commercially available inocula of oil-degrading microorganisms. Sample heterogeneity in these studies was further reduced compared to previous studies by mixing and sieving fine sediment material and placing it in mesh baskets prior to the start of the study, thereby reducing within plot variability. Two different nutrient application regimes, single application and multiple applications, were evaluated in the Elrington Island studies. In both cases there was a statistically significant decrease in the weight of oil present in the treated plots compared to the control plots (129). In both treatments, removal of oil followed a linear trend. Removal of oil was higher in the plots receiving a single addition of nutrients. In contrast, when biodegradation was measured in terms of alkane removal, the plots receiving multiple nutrient additions showed a greater decrease in C18 to C27 alkanes. This difference suggests that biodegradation was not the only process responsible for the removal of oil; although the researchers did not determine what other processes, such as production of biosurfactants, were involved. In agreement with the prior studies on Knight Island, there was no consistent effect of nutrient addition on the numbers of oil-degrading bacteria present, although microbial activity was increased.

Finally, the use of commercially available inocula for bioaugmentation was tested on Disk Island (42,130). Using a randomized block design, comparisons were made between control, nutrient addition, and two different inocula plus nutrient treatment plots. There were no significant differences found between the different treatments. While these results do not support the use of bioaugmentation they do not unequivocally rule it out either. In this study, nutrient addition alone did not result in increased biodegradation; however, prior studies at other locations within Prince William Sound indicated that biostimulation could enhance removal and degradation of oil. The investigators conducting the study proposed several possible reasons, in addition to the within treatment plot variability, which might account for the apparent failure of bioaugmentation. Most important among the possible reasons was the age of the spill and associated highly weathered condition of the oil and the short duration of the study.

Taken as a whole, the field studies following the *Exxon Valdez* oil spill indicated that bioremediation could enhance oil removal and thus shorten cleanup time in at least some field situations. More importantly, the results of the studies indicated several factors that should be considered in designing and implementing oil spill bioremediation. Specifically, the importance of nutrient delivery systems that ensured elevated nutrient levels in pore water was highlighted. Furthermore, the negative

impact of long lag periods between the spill and the implementation of bioremediation was reflected in the poorer results at sites in which the oil had been highly weathered and biodegraded before studies were initiated.

In the summer of 1994, the Environmental Protection Agency conducted a field study (The Delaware Bay Study) to evaluate bioremediation. Unlike all other field studies performed, the 1994 study, which took place on a shoreline beach of the Delaware Bay, involved a planned release of light crude oil. Therefore, adequate considerations of experimental design allowing for statistical analysis of the results were incorporated into the study. As much of the environmental variability and the lack of adequate controls that hampers the interpretation of field studies of accidental spills could be avoided, much stronger conclusions regarding the use and limitations of bioremediation could be drawn.

The Delaware Bay Study was designed to compare oil removal under unamended (background) conditions to removal using biostimulation and bioaugmentation (131). Five separate area blocks on the beach were studied using a randomized block design with four treatment plots per block. The treatments were: (*1*) no treatment, no oil control; (*2*) oil, no treatment; (*3*) oil, addition of inorganic nutrients (biostimulation); and (*4*) oil, addition of inorganic nutrients plus a commercial inoculum (bioaugmentation). Sand samples from the plots were obtained at 14-day intervals. The samples were analyzed for a variety of microbiological, toxicological, and chemical parameters. The results of the Delaware Bay Study confirmed many of the general observations and conclusions of the spill field studies. Hopane (a nonbiodegradable component of oil) was used as a marker compound so the loss of oil from the plots to be divided into physical and biological components. Loss of hopane from all of the oiled plots occurred at the same rate indicating that physical removal mechanisms, such as wave action, had the same impact on all of the plots. Degradation was significantly faster in both the biostimulation and the bioaugmentation plots compared to the oiled control. Interestingly, there was no difference between the two types of treatments indicating that the microbial inoculum did not have a significant effect in enhancing biodegradation. This observation is in agreement with the results of the Prince William Sound study in which the use of a commercial inoculum was not found to significantly enhance biodegradation. The data also indicated a rapid increase in the indigenous microorganisms in response to the added oil. This increase reflected the high background nutrient levels on the beach that allowed the microorganisms to rapidly use additional sources of carbon and energy when they became available. Subsequent evaluation of the microbial community structure in samples from each of the plots using molecular techniques showed that the inoculum was rapidly eliminated from the plots, indicating that the inoculated microorganisms may not have been able to compete with the indigenous microbiota (131). As with the studies in Prince William Sound, the results of the Delaware Bay Study indicated that differences in the microbial communities present and not a simple increase in the total number of bacteria account for the enhanced removal of oil with biostimulation. In addition, both sets of studies indicated that bioaugmentation is of little value in the remediation of shorelines.

Bioremediation of open waters and oil-impacted shoreline surfaces is best implemented as in situ bioremediation. Not only has this technology been demonstrated to be useful in the remediation of petroleum hydrocarbons, the use of in situ technology minimizes environmental disruption and the possible transport of contaminants associated with ex situ technologies. In some environments, however, in situ approaches are not feasible. This is particularly true for the remediation of sediments in which ex situ treatment has found a limited, but promising niche.

Dredging of sediments is a routine operation required for the maintenance of navigation channels. As a result of dredging operations, contaminated sediments are often removed from aquatic environments. These materials must be treated before they can be disposed of or reused.

The use of bioreactors in conventional waste treatment plants is a well-established procedure. Their use in the treatment of contaminated sediments (slurry reactors, primarily) is in its infancy. Applications of bioreactor technology have focused on anoxic and anaerobic systems (132–136) in which bench and pilot scale studies indicate that the technology should be applicable to remediation of pesticides, chlorinated compounds, and other recalcitrant molecules. Recently, a patent was filed for a bioreactor design for treating sediment and soil slurries that can be used for either anaerobic or aerobic treatment (137).

A pilot-scale bioreactor system has been applied in the remediation of petroleum hydrocarbon contaminated sediments in the Netherlands (138,139). Contaminated sediment was removed from the Petroleum Harbor in Amsterdam. The sediment was transported to a treatment site in which it was fractionated by hydrocyclone separation and froth flotation. These processes separate the silt fraction into which the PAH has been concentrated. The silt fraction was subsequently treated in a continuous-feed bioreactor. Using this treatment, both the concentration and associated toxicity of the PAHs in the sediment was significantly reduced.

CONCLUSION

Bioremediation at sea, on shorelines, and in sediments is an emerging technology that holds great promise. By enhancing the activity of microorganisms, degradation of a wide variety of contaminants in the environment should be possible. While there is extensive information concerning the metabolic activities of specific strains of microorganisms, additional information, particularly information on microbial communities and activity in real world environments, is needed before bioremediation can be used to its fullest. In addition to the research needs in microbiology, additional research into the fate and transport of contaminants in the environment and into the design of innovative methods to control and modify the environment are needed. Hopefully, future engineering developments addressing control of spill dispersion and

methods of nutrients addition will lead to enhanced use of this technology.

Bioremediation of soil involves decontamination by biological means. This process can be difficult to achieve because three main components must be in balance — the environment, contaminants, and microorganism(s). The environment must be able to support biological activity by having a suitable temperature, moisture content, pH, nutrient supply, and electron acceptors such as oxygen for aerobic microorganisms or redox potential for anaerobic microorganisms. The soil type is also important. The soil contaminant(s) must also have characteristics necessary for bioremediation. It must not be too toxic for the microorganism(s), in a concentration low enough that it does not inhibit microbial activity and is high enough to be bioavailable to the microorganism(s). The contaminant(s) must be available on the soil matrices and soluble enough in water so that it can enter the microorganism's aqueous environment. A microorganism must be metabolically capable of degrading the contaminant(s) and be present in sufficient numbers as either indigenous or added genetically engineered microorganisms (Fig. 1). This article discusses these major influences on bioremediation in detail. In addition, phytoremediation is presented to expand the ideas of bioremediation. This article is a general overview of bioremediation, and more specific details can be found elsewhere (1–8).

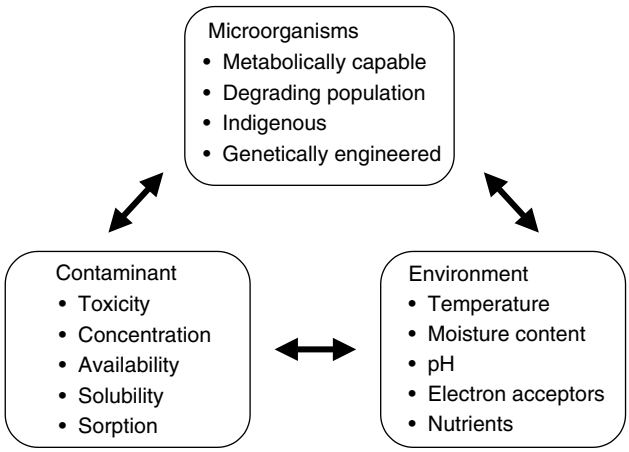

Figure 1. Three main interrelated components involved in bioremediation.

WHY BIOREMEDIATION?

Since the industrial revolution, human activities have resulted in large quantities of chemicals being eventually released into the environment, either deliberately for agricultural and industrial purposes or accidentally by mishandling of chemicals. It is estimated that there are about 50,000 contaminated sites in the United States alone, and the projected cost for cleaning these polluted areas in the next three to five decades using conventional physical or chemical methods (7,9,10) is estimated to be $1.7 trillion U.S. For a list of physical or chemical methods see Reference 7.

It is known that microorganisms are present in almost every environment on Earth and that they are capable of degrading and mineralizing a wide range of organic compounds. In general, biodegradation refers to a natural process that microorganisms use to break down organic compounds into less complex chemicals. When organic compounds of carbon, nitrogen, sulfur, and phosphorous are completely metabolized to inorganic compounds (e.g., pentachlorophenol degraded to carbon dioxide, water, and chloride ions), the process is referred to as mineralization (11). In most microorganisms energy is obtained from these processes. Typical microorganisms involved in biodegradation include aerobic bacteria, actinomycetes, cyanobacteria, anaerobic bacteria, fungi, and algae (7). Biodegradation is a natural process and costs associated with remediation technologies are less expensive than physical or chemical methods. In addition, bioremediation is more environment friendly and ecologically sound and has the potential to be more socially acceptable when compared to physical or chemical processes such as thermal treatment, incineration, soil washing, chemical treatment or extraction processes, supercritical fluid oxidation, and volatilization technologies (7).

NATURAL ATTENUATION

As a first step in determining if bioremediation is possible one should examine the efficacy of natural attenuation. Natural attenuation is defined as naturally occurring processes in the environment that act without human intervention to reduce the mass, toxicity, mobility, volume, or concentration of contaminants in those media (8). In some cases the reduction in contaminant concentration may not be biologically mediated. Reduction may be due to contaminant movement that includes dilution, dispersion, sorption, and volatilization, or because of abiotic transformation. Some of the advantages of natural attenuation are that the contaminant is normally transformed into less toxic by-products, the process is nonintrusive to the environment, there is no waste accumulation after excavating, the contaminant is not transported from its location, the process is less costly than conventional remediation strategies, and there is no need for specialized equipment. Some of the disadvantages associated with natural attenuation are that the time frames required for remediation are normally longer, someone must be responsible for monitoring the remediation process over the longer time frame, and natural and anthropogenic changes in the environment (i.e., hydrogeologic changes, reduction in electron acceptor concentrations, production in toxic biodegradation metabolites) may occur (8).

ENVIRONMENTAL CONSTRAINTS TO SOIL BIOREMEDIATION

One of the most important and fundamental factor in soil bioremediation is the condition of the environment. Temperature, moisture content, pH, nutrient supply, soil type, and electron acceptor or redox potential are all factors that contribute to providing a good environment for microbial growth, activity, and survival.

Temperature

Temperature is important for contaminant degradation because the rates of microbial enzyme reactions are temperature-dependent. An enzyme catalyzes a reaction at a specific temperature optimum; any temperature above or below that optimum decreases the reaction rate. Microbial degradation of hydrocarbons, for example, can occur at temperatures ranging from -2 to $70\,^{\circ}C$. Most microorganisms, however, are mesophiles and grow optimally between 25 and $35\,^{\circ}C$ (7). Temperature can also affect the properties of the contaminant. At higher temperatures, adsorption of the contaminant to soil particles is decreased; this in turn makes the contaminant more bioavailable. In conjunction with higher temperatures, however, shorter chain and lower molecular weight contaminants can evaporate and produce toxic effects to the microbial cell membranes and produce noxious odors from the soil site. Conversely, lower temperatures increase adsorption of the contaminant to the soil particles and therefore reduce the availability of the contaminant for microbial degradation (7).

Moisture Content

Moisture content is also an important factor in soil bioremediation. In general, bacteria must live in an aqueous environment. They depend on water for motility, gas exchange, transport of nutrients and wastes to and from the cell, and temperature regulation. In soil, water is held in different fractions of the soil — the saturated zone, and the vadose zone. In the saturated zone, soil particles are completely filled with water. In the vadose zone, soil particles are partly filled with water and partly filled with air (6). The amount of air and water in the vadose zone depends on the climate, soil composition, distribution of pore sizes, and depth of the groundwater and vegetation (6). At the soil–atmosphere interface, the soil gas and atmospheric air are relatively the same. As the groundwater is approached, the soil atmosphere changes due to microorganisms consuming oxygen and producing carbon dioxide. As the soil becomes more saturated with water, the gas exchange between the atmosphere and soil is reduced and the soil can become more anaerobic. Again there is a balance; if the moisture content is too low microbial activity is hindered, if too high a

suitable electron acceptor such as oxygen is decreased in concentration.

The ability of the soil to hold water is also important. Soil contains both mineral and organic fractions. The mineral fraction is classified according to the grain size of the mineral. In general, the larger the mineral the greater the permeability and aeration, whereas the smaller the mineral the lower the permeability and aeration. Therefore, clay (<2 μm) or silt (2–63 μm) particles will have a lower permeability than sand (63–2,000 μm) or gravel (2–63 μm). The organic fraction is composed of the living biomass (e.g., microorganisms, insects, worms, nematodes, arthropods, and plant material) and dead organic matter or humus. The dead organic matter is made up of dead microbial, plant, and animal cells that are not completely degraded. The humus content of soil can be as high as 20% in the case of peat soils and as low as 0 to 1% for poor sandy soils. The higher the organic content the higher the water holding capacity (WHC) of the soil (50–70% for aerobic soils and greater for anaerobic soils) (6,7).

pH

Microbial growth and activity is greatly affected by soil pH. Most soil bacteria have a pH range optimum between 6.5 and 8.5. If the soil is acidic, bacteria are poor competitors against acid tolerant fungi (7). The pH can also affect the solubility and availability of macro- and micronutrients, the mobility of toxic materials, and the reactivity of minerals (7). Toxic heavy metals are predominantly in an insoluble form near neutral pH. Toxic metals become mobile at lower pH values.

The surface charge on the soil colloidal particles is also affected by pH. For example, clays have a permanent negative charge but the charge of the organic or amorphous coatings around the clay material can change (7). A drop in pH can decrease the net negative charge and cause a greater adsorption of anionic material and vice-versa.

A common remedy to poor soil pH is liming to increase the pH or ferrous sulfate to decrease the pH. Liming involves the addition of any calcium- or magnesium-containing compound capable of reducing pH (e.g., calcium hydroxide, calcium carbonate, calcium magnesium carbonate, and calcium silicate) (7).

Electron Acceptors

Most electron acceptors are oxidized inorganic compounds, such as O_2, NO_3^{2-}, Mn^{4+}, Fe^{3+}, So_4^{2-}, and CO_2 (6). Many contaminants are degraded by aerobic pathways and therefore require oxygen. Aerobic reactions also yield the greatest amount of energy for microorganisms. In addition to its use as an electron acceptor, oxygen can be used as a substrate in oxygenase-catalyzed reactions (12). Thus, a well-aerated soil is important. As mentioned earlier, moisture content and oxygen diffusion in soil are closely related. The higher the soil moisture content, the lesser the oxygen diffusion from the atmosphere and therefore lesser the oxygen in the soil. In this situation the oxygen is consumed faster than it is replaced and the soil becomes anaerobic. Under anaerobic conditions, facultative and strict anaerobic microorganisms degrade the contaminants under denitrifying, methanogenic, sulfate-reducing, and iron-reducing conditions (12).

Nutrients

The three main nutrients, in addition to carbon (often the contaminant is a carbon source), required for microbial metabolism of soil contaminants are nitrogen, phosphorus, and potassium (7). When these are in limited supply, the ability of microorganisms to degrade the contaminant is reduced. Calculations on the bacterial cell indicate that there is a carbon, nitrogen, phosphorus ratio of 100 : 15 : 3. Other nutrients required in smaller amounts are zinc, calcium, manganese, iron, sodium, and sulfur (7). Many of the nutrients can be purchased from commercial suppliers.

CONTAMINANT VARIABLES THAT AFFECT THEIR DEGRADABILITY IN SOIL

The nature of the contaminant is another variable in the success or failure of bioremediation. If a contaminant is not biodegradable (i.e., recalcitrant), then any change in environmental or microbial factors will not help the remediation process. Other factors that one must be aware of are its toxicity, concentration, availability, solubility, and sorption of the contaminant to solid surfaces.

Toxicity

The toxicity of the contaminant to the microbial community in soil is a critical parameter. If the chemical is toxic toward the degrading microorganism then bioremediation will be inhibited. In some cases the toxicity of specific chemicals can be predicted based on chemical structure, substitution types and positions, solubility, and volatility (7). A problem with most contaminated sites, however, is that contaminants are usually present as chemical mixtures. Within a mixture, some of the chemicals may be more toxic to the microorganisms than others and therefore it can be difficult to predict what outcome the mixture will have on the degrading microbial population. In addition, degradation of the contaminant(s) can lead to products that are more toxic than the parent compound. Therefore, it is important to use toxicity tests during bioremediation to determine if biodegradation of targeted contaminant(s) and their intermediates have significantly decreased the toxicity of the treated soils. If the bioremediation program has been successful, a significant reduction in toxicity should ensue. A worst-case scenario is that no biodegradation occurs after treatment and either no reduction in toxicity or an increase in toxicity is observed. The possibility exists that the bioremediation program was successful in removing the targeted contaminant(s), yet the remediated soil remains as toxic or more toxic than before bioremediation. If this occurs, then the bioremediation program cannot be judged to have been successful.

Because reduction in toxicity is an important and desirable component of a bioremediation program, the problem arises as to what toxicity tests are suitable for use with soil samples that are heterogeneous by nature and

contain a multitude of inorganic and organic compounds as well as living prokaryotic and eukaryotic organisms that may produce toxic metabolites or extracellular products (i.e., proteases, nucleases, extracellular products or toxins, and capsular slime). The ideal test for a heterogeneous chemical mixture does not exist. Therefore, new tests need to be developed and existing testing protocols require modifications. It is likely that some tests suitable for certain soil types are not suitable with other types of soils (e.g., highly organic peat soil versus sandy soils).

From scientific and regulatory points of view, the ideal toxicological test should be simple, rapid, reproducible, inexpensive, amendable to standardization, highly sensitive, predictive, ecologically relevant, satisfy regulatory standards, and discriminating. However, neither does the ideal test that satisfies all the mentioned features exist at this time nor is one likely to be developed in the near future. Instead, for in vitro evaluation, it is necessary to use a battery of tests to ensure that the scientific and regulatory decisions are the best available at any point in time.

Toxicological tests that have been used to assess chemically contaminated soil include: Solid-Phase Microtox (13), Toxi-Chromotest (14), SOS-Chromopad test (14), Seed Germination Test using *Lathyris sativa* (modification of Greene and coworkers, 15), Earthworm Toxicity Test using *E. foetida* (modification of Goats and Edwards, 16), and Red Blood Cell Lysis assay (modification of Negrete and coworkers (17)).

With respect to soils, numerous toxicity studies have been undertaken to assess the effects of pesticides and other agrochemicals on microbial processes, population changes and numbers, bioaccumulation of pollutants by plants, and biodegradation of selected compounds added to soil as a result of industrial and/or agricultural practices (18,19). However, little information exists on the toxicity of soil before, during, and after bioremediation. Properly decommissioned soil sites may be used for numerous human activities and it is imperative that regulatory guidelines are established so as to eliminate significant risks from the site to humans or animals. The regulatory decisions will, therefore, be based on the best possible scientific knowledge available.

Concentration of Contaminant(s)

Contaminant concentration can affect the biodegradability and toxicity to the degrading microorganism(s). Higher molecular weight compounds appear to be more recalcitrant to degradation than lower molecular weight compounds, which may be related to the water solubility of the compounds (7). Once in contact with the degrading microorganism, concentration becomes a factor. In general, high concentrations inhibit microbial activity, however, the inhibitory concentration is dependent on the chemical. Some chemicals can be inhibitory at microgram concentrations per gram dry weight soil, whereas others may inhibit at gram quantities.

There also appears to be a lower concentration threshold for biodegradation. Microbial populations are unable to degrade chemicals at low concentrations. One reason may be the presence of microorganisms unable to grow or produce a sufficient population to degrade the contaminant (7). In some cases the only way to degrade a compound at a low concentration is to add a cosubstrate that is easily metabolized. Another reason could be that the chemical is unavailable for microbial degradation because of the adsorption to soil particles.

Availability

The bioavailability of the contaminant depends on the soil structure and the contaminant under study. Pollutants can be distributed among the solid, liquid, and gas phases of the soil. Many of the organic contaminants that enter soil are hydrophobic and therefore predominantly sorb onto the solid mineral and organic fractions. The longer the contaminant is in contact with the soil matrix the less accessible it becomes to the microorganisms (20). In most cases the rate of biodegradation is controlled by desorption of the contaminant from the soil matrix and not by microbial activity. Therefore, increasing desorption of the contaminant by use of surface-active agents (surfactants) can make the contaminant more available for biodegradation. Surfactants work by lowering the surface tension of the liquid.

Solubility

Chemical contaminants can differ significantly in their aqueous solubility. Polar compounds such as methanol are very soluble, whereas nonpolar compounds such as polychlorinated biphenyls (PCBs) have very limited solubilities. The greater the solubility of the chemical, the more available the chemical is to the microorganism and the greater the chance of biodegradation. Lower soluble chemicals do exhibit a mass transfer from the solid phase to the liquid phase, thereby supplying a limited concentration in the aqueous phase. Under these conditions it is the mass transfer rate that limits microbial growth and biodegradation rate (7). As mentioned in the previous section, surfactants can be used to increase the solubility and hence the bioavailability of the contaminant.

Sorption

Sorption of chemical contaminants to solid soil matrices affects the solubility and availability of the contaminant to the microbial population. Sorption includes both adsorption and absorption. Adsorption occurs on surfaces, whereas absorption describes uptake of the contaminant by the solid matrix beyond the surface (12). Adsorption may involve physical or van der waals forces, hydrogen bonding, chemisorption, or ion exchange (7). Cationic compounds are generally sorbed to cationic-exchange sites on clay minerals or humic surfaces, whereas anionic and nonionic compounds sorb to organic matter. The sorption of the contaminant to solid surfaces can depend on the concentration of the contaminant, type and quantity of the clay minerals, amount of organic matter in the soil, pH, temperature, and type of contaminant (7). The sorption of the contaminant to soil particles may not only make the contaminant unavailable for biodegradation but also make surfactant or chemical extraction difficult.

MICROBIOLOGICAL FACTORS

If the environment is optimum for microbial growth, activity, and survival and the contaminant is biodegradable, the last factor to consider is the population of catabolic microorganisms. Are there microorganisms or groups of microorganisms capable of degrading the contaminant? Is there a sufficient population present of indigenous, reintroduced or genetically engineered microorganisms (GEMs) to degrade the contaminant?

Metabolism of Soil Contaminants

The degradation potential of a contaminated site can be determined in the laboratory. Soil microcosms can be set up using the contaminated soil and the degradation or mineralization of the contaminant monitored over time. As this is performed in small scale and under optimum laboratory conditions (e.g., temperature, moisture content, pH, proper electron acceptor and nutrients) one would expect degradation to occur. If no degradation is observed, additional microbial metabolic barriers may need to be addressed. The first barrier to metabolism could be that the contaminant is structurally not amenable to biodegradation by the microbial population present in the soil (12). The halogen substitution pattern on many contaminants is usually the limiting factor for biodegradation. For example, there are 209 congeners of polychlorinated biphenyls (PCBs) ranging from one chlorine per biphenyl to 10 chlorines per biphenyl. Under aerobic conditions, bacteria have been shown to degrade various chlorine substitution patterns up to six chlorines per biphenyl. Under anaerobic conditions, reduction of higher chlorinated biphenyl molecules occurs, thus removing the inhibitory chlorine substitutions to enable further aerobic degradation to proceed (21).

Another metabolic barrier could be that the degrading microorganism requires a cometabolic substrate (12). Cometabolism is the transformation of a nongrowth substrate in the obligate presence of a growth substrate or other transformable compounds (22). In some cases the cometabolite may also induce production of catabolic enzymes necessary for degradation of the contaminant. For a more detailed review on cometabolism see Janke and Fritsche (23).

In some cases an alternate carbon source may be available in the soil that may limit the response of the degrading microorganisms to the contaminant. If an alternate carbon source is more easily degraded and provides microorganisms with sufficient carbon and energy, the microorganisms may preferentially utilize the alternate carbon source. For example, addition of easily degradable amino acids or glucose inhibits the aerobic mineralization of ethylene dibromide, *p*-nitrophenol, phenol, and toluene in subsurface soil samples (24).

Other factors that can inhibit biodegradation include toxicity of the contaminant or its metabolite to the microorganisms (as mentioned in the previous section on contaminant toxicity), protozoan predation, and genetic exchange. Predation by protozoa may not seem significant enough to hinder biodegradation of soil contaminants by bacteria, but documented evidence shows that it can occur (25). Genetic exchange between bacteria in the soil has been reviewed by Boyle (26) and Seech and Trevors (27). Evidence has shown that plasmid transfer can occur in nonsterile and sterile soil and the frequency of transfer depends on the population size and ratio of donor and recipient cells, along with several other factors.

Quantification of Degrading Microorganisms

Aside from metabolic constraints, the next question is whether there are contaminant degrading microorganisms in the soil and if the population is significant to effect bioremediation. Fertile soils contain approximately 1×10^9 bacteria per gram dry weight of soil. Isolation and quantification of contaminant degrading microorganisms from the soil microbial community by using classical microbiological techniques can be difficult. The best method is to enrichment for the contaminant degrading microorganism(s) from the natural soil community (7,11). Enrichment often requires that the specific target contaminant is present during the isolation. Soil is normally suspended in a minimal medium or agar plate containing the contaminant of interest. After an incubation period the culture is analyzed for growth and possibly contaminant loss. If microbial growth or loss of the contaminant is found, an aliquot of culture is removed and added to fresh minimal medium containing the contaminant. This process is repeated several times until a pure culture is obtained. This method does have its drawbacks because it only selects those microorganisms that can use the contaminant as a sole energy and carbon source. All other cometabolic isolates would not be found using this method (7). In addition, degradation of some complex pollutants may require a consortium of microorganisms and this creates difficulties in isolating individual microorganisms. Also, because an artificial environment is used when enriching the microorganisms, it could be possible that a specific nutrient required by the contaminant-degrading microorganism is missing. For example, various attempts to isolate polychlorinated biphenyl (PCB) dechlorinating strains from PCB contaminated sediment samples have been unsuccessful (28). One problem is that PCB dechlorination has not been obtained in a defined medium, implying a specific nutrient(s) in the sediment is necessary for the growth of the PCB-dechlorinating microorganisms.

Once a microorganism is known to degrade the contaminant it can be identified by several methods. Cellular morphology and gram-staining is often the first step. The second step can involve biochemical tests, cellular fatty acid profiles, or ribosomal ribonucleic acid (rRNA) analysis. Biochemical test kits such as the commercially available Biolog® System (biolog, Inc.) contain a series of carbon sources and a tetrazolium dye that changes colour when oxidized by the microorganism. The pattern of substrate utilization that results is representative of a specific species. Fatty acids present in the membrane of microorganisms work in the same way as a fingerprint. Fatty acids are extracted from the microorganism, methylated, and analyzed. The pattern that results is characteristic of the species. Using the same

fingerprint analogy, rRNA works in the same manner. The rRNA sequences 5S, 16S, 18S, and 23S can be used to identify microorganisms. Unique to rRNA is that the microorganism does not need to be isolated to be identified within a community of microorganisms (7,29).

Quantification of Contaminant Degrading Soil Bacteria by Most Probable Number (MPN)/Polymerase Chain Reaction (PCR)

Before the methods are discussed a brief description of PCR is necessary. PCR is an in vitro method for the amplification of defined DNA sequences. Via a repetitive series of cycles of template denaturation, primer annealing, and extension by DNA polymerase, PCR results in the exponential accumulation of an initial target DNA fragment. The essential components of a PCR mixture are the template DNA, primers, DNA polymerase, dNTPs, and buffer (30). The sensitivity of PCR has been theoretically stated to be as low as only one target DNA sequence per extractable soil sample for detection of a specific target sequence (31). For monitoring a contaminant-degrading bacterial strain, one needs to identify a unique DNA sequence for PCR amplification. This may be a partial sequence from a unique catabolic gene or in the case of genetically engineered microorganisms (GEMs), it may also be an artificial sequence not normally found in nature. Increasingly, PCR is being used to detect indigenous and introduced bacterial strains and their DNA from soil and water (32–39). DNA extraction protocols for environmental samples such as soil and water are becoming more rapid and efficient (32–34,40–42). Despite this, adsorption of bacterial cells and DNA to soil particles and interference by contaminants such as humic acids (43) during PCR often have a negative effect on the detection limit in soil samples. Although PCR detects the presence of specific genes, it does not indicate if cells are viable or if the gene is being expressed. To monitor expression one needs to use reverse transcription-PCR (RT-PCR). RT-PCR happens when reverse transcription of messenger RNA (mRNA) is combined with PCR to make complementary DNA from RNA, which is suitable for PCR. This method is very sensitive, highly specific, and efficient.

In addition to the classical method of viable plate counting, two major approaches have been used to quantify microbial subpopulations in soil using PCR. First, specific soil microbial subpopulations can be quantified by a most probable number (MPN)/PCR protocol. With this approach, Picard and coworkers (44) detected *Agrobacterium tumefaciens* ranging from 10^4 to 10^8 cells/g of soil. Recently, the authors modified and improved the sensitivity of the MPN/PCR method. With a week's enrichment of the Mpn-soil dilution samples prior to DNA extraction and PCR, the detection limit for a pentachlorophenol degrading *Pseudomonas* sp. UG30 was improved to 4 CFU/g dry weight of soil. This allowed for a unique study of the dynamics of a pentachlorophenol degrading bacterial species in a bioremediation process. The second approach is to quantify a target gene (or subpopulations of microorganisms) based on the quantity of the PCR products. To compensate for any differences that may affect the efficiency of PCR, a known amount of an internal standard DNA (i.e., DNA fragment amplified by the same primers of the target DNA) can be coamplified with the target DNA. As both the target and internal standard DNA are amplified with the same efficiency, the quantity of the target DNA can be calculated based on the amount of the amplified target and standard DNA. Automated quantitative PCR systems developed commercially are based on the principles of the competitive PCR protocol.

MONITORING BACTERIA INTRODUCED INTO SOIL

Once it is established that there is a degrading population in the soil the organism(s) can be introduced back into the soil in larger numbers or genetically modified to improve the catabolic capabilities and environmental fitness of the microorganism. If there were not a degrading population in the soil, nonindigenous microorganisms known to degrade the contaminant would need to be added. The above addition of microorganisms to soil is known as bioaugmentation. For bioaugmentation processes it is important to monitor the survival and persistence of the microorganisms.

Reporter Systems and Tracking Contaminant Degrading Soil Bacteria

Approximately 1% of the bacterial species observed and counted under a microscope from environmental samples can be recovered by conventional culture techniques (45). For example, contaminant-degrading bacteria expressing resistance to an antibiotic can be selected by plating on media containing the antibiotic. Antibiotic resistance can be and has been used as a reporter system; however, increasing occurrences of antibiotic resistant bacteria in the environment have raised serious concerns over introducing antibiotic-resistant genes into the environmental gene pool (46,47). These concerns have led to the construction of novel reporter systems.

Reporter systems are special genes that are either encoded on circular extrachromosomal DNA (plasmid) and then inserted into a microorganism or are inserted into the chromosome of a microorganism via a transposon. A transposon is a small piece of DNA that has the ability to jump from its source, usually a plasmid, to a recipient piece of DNA by a random event. When the reporter gene is on the plasmid, there is the possibility that the plasmid is lost when the cell divides. It can also be lost when the microorganisms are introduced into soil and the cells are no longer under selective pressure to maintain the plasmid. Some examples of reporter systems include the genes *xyle* (48), *lac*Zy (49), *lux* (50), and *gfp* (51). The *xyle* and *lac*Zy reporter genes are referred to as chromogenic markers because their gene products produce a color change in the bacterial colonies and this can be detected using selective or nonselective media. The *lux* and *gfp* gene products produce light and are therefore referred to as bioluminescent and fluorescent markers, respectively.

***xylE* Reporter Gene.** The *xyLE* gene codes for catechol 2,3-dioxygenase (C23O). Bacterial strains marked with

this gene can be detected and enumerated by incubating at 37 °C or 42 °C to enable expression of the enzyme C23O and then spraying plates with catechol. The enzyme converts colorless catechol to hydroxymuconic semialdehyde, a yellow product, causing the bacterial colonies to take on a yellow coloration that can be visually detected (47).

***lac*ZY Reporter Gene.** The *lac*Z gene codes for the enzyme β-galactosidase that cleaves lactose to produce D-galactose and D-glucose (49,52,53). The *lac*Y gene codes for lactose permease that transports lactose into the bacterial cell. In addition to cleaving lactose, β-galactosidase cleaves the chromogenic dye X-Gal (5-chloro-4-bromo-3-indolyl-β-D-galactopyranoside). Bacterial colonies expressing the *lac*ZY genes turn blue-green in color when exposed to X-Gal. Typical pseudomonad colonies are yellow-white in color and are lac^-, thus the *lac*ZY marker is very useful for pseudomonads.

***lux* Reporter Gene.** Bioluminescence is a phenotypic marker that is based on the introduction of genes for light emission. Originally cloned from *Vibrio fischeri* and *V. harveyi*, the *lux* operon includes *luxAB* coding for the luciferase enzyme, *luxCD* coding for reductase and transferase polypeptides of the fatty acid reductase, and *luxE* which codes for synthetase (50). The light-emitting reaction involves the oxidation of reduced flavin mononucleotide ($FMNH_2$) and a long-chain fatty aldehyde with the emission of blue-green light (50). Bacterial strains can also contain only the *luxAB* genes, and the long chain fatty aldehyde (e.g., *n*-tetradecyl aldehyde, dodecanal or decanal) can be added exogenously. Luminescence may be measured using a luminometer, scintillation counter, or photomultiplier. It may also be imaged directly using photographic or X-ray films and charge-coupled devices (32,47). *Pseudomonas* sp. UG14, a phenanthrene degrader was isolated from a creosote contaminated soil sample (54) and marked with *luxAB* genes (55). The background level of bioluminescence in soil was zero. One benefit of bioluminescent techniques for environmental application is the ability to measure light in real time without prior extraction of cells from the environment. Three disadvantages of using the *lux* reporter genes are the requirement for an aldehyde substrate such as *n*-decanal if the bacterium contains the *luxAB* genes only, the cost of a luminometer or photon imaging device, and the inability to obtain a specific activity. The requirement for an exogenous substrate can be overcome by cloning the *luxCDE* genes along with *luxAB* into the host (47). Although photographic or X-ray films may be used to image light-emitting colonies, colony resolution is reduced. Despite these drawbacks, bioluminescence is a versatile and reliable marker for monitoring bioremediating microorganisms.

***gfp* Reporter Gene.** A recent development in phenotypic markers is a fluorescent genetic tag called the green fluorescent protein (*gfp*) (51,56,57). The *gfp* genes were isolated from the jellyfish *Aequorea victoria* and when inserted behind a promoter they can be made to emit green light by exciting it with blue light. The chromophore responsible for *gfp* fluorescence is *p*-hydroxybenzylideneimidazolidinone, which is completely contained within the coding sequence of the protein and does not require any unusual cofactors. *gfp* also enables in vivo visualization of differential gene expression and protein localization when the *gfp* genes are fused directly to the genes encoding the protein of interest (51,56).

The *gfp* genes have been incorporated into several bacterial chromosomes, including *Pseudomonas* sp. UG14Gr (58) and *Moraxella* sp. strains G21 and G25 (59). *Pseudomonas* sp. UG14Gr was added to creosote-contaminated soil and was detected in the soil for up to 13 months after inoculation. In comparison, a non-*gfp* marked *Pseudomonas* strain was only detected up to 25 days, using antibiotic resistance as a selection marker (58). In the *gfp*-labeled *Moraxella* sp., insertion of *gfp* did not affect its biodegradative activity.

GFP is both advantageous and disadvantageous in environmental applications. Advantages include ease of detection, no requirement for an exogenous substrate, the possibility to observe single cells in real time, no requirement for fixing or staining of samples, the fact that GFP expression has no effect on the organism, absence of green fluorescent background in indigenous particles or bacteria, and its use in combination with other marker systems. The disadvantages are that there is variable GFP expression in different species, plasmids containing GFP may be unstable (chromosomal inserts are recommended), environmental influences are unknown, GFP may not work under anaerobic conditions, and GFP continues to fluoresce once the cell is dead or is lysed (60). The last problem has recently been solved by the production of unstable GFP mutants. The mutants contain a C-terminal oligopeptide extension that renders the *gfp* protein susceptible to degradation by intracellular tail-specific proteases (61). These *gfp* mutants can be used as transcriptional gene fusion products with other degradative genes to facilitate studies of real-time gene expression assays.

Nucleic Acid Probes and Immunological Techniques in Bioremediation

DNA hybridization technology is commonly used to detect the fate of introduced DNA sequences and avoid dependency on phenotypic expression of introduced genes. The technology is based on the formation of double-stranded DNA from complementary single-stranded DNA sequences. A homologous complementary labeled probe is applied to a targeted denatured nucleotide sequence bound to a filter. Probe labels may be radioactive or nonradioactive. Nonradioactive labels are preferred because radioactive probes have short half-lives, are hazardous, and require special waste disposal. Excess probe DNA is washed from the filter and the presence of the probe DNA is visualized using X-ray film or by chemical color production (62).

Using the appropriate probes, specific DNA sequences, such as the nitrogen fixation genes (*nif*), nodulation genes (*nod*), and mercury resistance genes (*mer*), can be detected in culturable cells using colony hybridization. The cells are recovered by viable plating and lysed directly on to a filter.

A most probable number-DNA hybridization method, originally described by Fredrickson and coworkers (63), can also be used and may provide higher sensitivity. For nonculturable cells, total community DNA extraction and analysis using dot or slot-blot hybridization or Southern hybridization can be employed. The sensitivity of gene probe assays can be greatly improved with the use of PCR.

Introduced microorganisms can also be monitored using immunological techniques (64). Immunological techniques involve the use of the microbial cell surface as a source of antigens for the preparation of serum containing antibodies, called antiserum. Microbial cells are injected into an animal whose immune system responds by producing antibodies to many different proteins present on the microbial cell surface. These heterogeneous antibodies are termed polyclonal. Monoclonal antibodies, specific to a single protein on the target bacterial cell, can also be produced by the hybridoma technique (65). This procedure involves the fusion of myeloma cells and B-lymphocyte cells. B-cells are responsible for the production of the antibody of interest. The myeloma cell has unlimited divisional properties and the B-lymphocyte cell produces the antibody. Fusion of the two nuclei forms a hybrid. Clones of the hybrid cells are referred to as hybridomas. The antibodies are labeled so that the microorganism of interest can be detected. Antibody labels include fluorescent dyes, radioisotopes, and enzymes (65). Monoclonal antibodies are more useful than polyclonal antibodies for monitoring specific introduced microorganisms because of the production of a single antibody specific to a single antigen. A newer technology using recombinant antibodies produced by bacteria is still in the early stages of development. However, this method has the potential to yield antibodies with greater specificity and affinity than either polyclonal or monoclonal antibody technologies. There is one limitation to immunological techniques, that is, the protein or antigen of interest must be expressed before the method can be employed.

ENHANCING BACTERIAL DEGRADING GENES THROUGH MOLECULAR BIOLOGY

Improving the degradative capabilities of microorganisms by altering bacterial degradation genes is important for developing efficient and quick bioremediation techniques. Genetic engineering, which is the use of *in vitro* techniques for the isolation, manipulation, recombination, and expression of a microorganism's DNA, is used to alter the genes. Ultimately, the changes incorporated into the DNA of a microorganism may be expressed in the proteins produced by it. Functional changes to a protein can be observed as alteration of its structure, rate of enzymatic activity, and/or an enzyme's affinity for its substrate in either a positive or a negative manner. Changes made to a DNA sequence often result in no observable change in enzyme activity. These types of neutral changes arise from the redundancy of the genetic code, that is, more than one codon code for the same amino acid, and/or from the incorporation of an amino acid with properties similar to the original one. Various techniques, including site-directed mutagenesis and DNA shuffling, have been developed to aid in the alteration of genes.

A common type of gene modification is in vitro oligonucleotide-directed (site-directed) mutagenesis. This method involves making specific base changes to a DNA sequence resulting in a known amino acid change in the resulting protein (66,67). The changes in DNA can be made through the use of mutagenic primers that contain the desired site-specific base change(s). Random mutagenesis involves the random incorporation of mutations using error prone PCR (68,69). The resulting amplified gene products will contain base changes with unknown effects on the resulting protein. The gene products are then screened for any differences in activity such as improved metabolism of xenobiotic compounds for the development of bioremediation techniques.

Although gene modification techniques have been in use for many years, they have some disadvantages. Oligonucleotide-directed mutagenesis requires some knowledge of where to make the specific changes in gene sequences. This means that some knowledge of the protein's structure-function relationship is essential. However, for the majority of enzymes, this knowledge is not available. As for random mutagenesis, it is an inefficient method, resulting in many nonfunctional mutations. The development of DNA shuffling, a relatively new technique described by Stemmer (70,71), has changed the way in which gene enhancements can be made. DNA shuffling is regarded as sexual recombination at the molecular level. Briefly, one or several homologous genes are digested with DNase I to yield a pool of random fragments. The fragments are reassembled using DNA polymerase, whereby homologous fragments recombine and prime one another until the gene is reassembled (70). The resulting products are screened for the desired functional properties. Individual proteins as well as entire pathways have been mutated using this technique to significantly improve their activity manyfold (Table 1).

Table 1. Some Selected Examples of Improvements of Proteins by DNA Shuffling

Example	Property to Be Modified	Increased Activity	Reference
β-lactamase gene	Antibiotic activity/enzyme activity	32,000 fold	71
Green fluorescent protein	Fluorescence	45 fold	72
β-galactosidase	Specific activity	66 fold	70
Arsenate Pathway	Arsenate detoxification	40 fold	73

One of the major problems associated with gene expression is determining which promoter will function in the environment and whether it will express the genes of choice (74). If a protein's affinity for a substrate is improved by oligonucleotide-directed mutagenesis and the promoter is left the same, regulation of the pathway would remain unchanged. Transcriptional regulation could then still be controlled by such mechanisms as substrate concentration inhibition or metabolite feedback inhibition. A solution would be to introduce the catabolic genes under a promoter that is unrelated to the contaminant but native to the environment. For example, place the catabolic genes under the regulation of a carbon source produced in a plant's root exudates (74).

ENCAPSULATION OF MICROBIAL CELLS FOR USE IN SOIL BIOREMEDIATION

The use of encapsulated microbial cells (i.e., cells distributed throughout a porous biopolymer) is being tested for bioremediation effectiveness in situ. Encapsulation may be a way for microorganisms to survive and maintain metabolic activity in a more controlled microenvironment within the heterogeneity of the soil environment. Biodegradable, nontoxic algal biopolymers such as alginate or κ-carrageenan may be the most practical and effective for environmental use (75). The encapsulation process is mild, and microbial cell viability is maintained for a wide range of microorganisms, including GEMs. Amendments such as nutrient sources or protective compounds can be added to the formulation, offering increased flexibility for diverse conditions that are found at different contaminated sites.

The ability of a microbial inoculum of either free or encapsulated cells to bioremediate contaminated soil has been investigated. Encapsulated microbial cells have been used effectively in bioreactors to detoxify or remediate liquid suspensions of toxic substances. Experiments with encapsulated cells in broth have demonstrated a significant increase (doubling) in tolerance to toxic compounds such as pentachlorophenol (76) and a significant increase in the ability to mineralize pentachlorophenol (75). Examples of similar results with other compounds have been reviewed (75).

Encapsulation of bacterial cells has been observed to significantly increase cell survival in soil compared to free cells (77,78). Encapsulated bacterial cells have demonstrated significantly increased survival through extremes in environmental abiotic conditions such as wet or dry cycles (77) and freeze or thaw cycles (79) when compared with free cells. Protection from potential biotic stresses such as predation has been demonstrated with bacteriophages (80) and protection from other predators is likely (75). Investigations of contaminant degradation in soil have shown that metabolic activity lasts longer in encapsulated cells than free cells (81), and significantly increased rates of degradation are possible using encapsulated bacterial cells. Cell movement through soil is shown to be reduced with the use of encapsulated cells (82,83); the cells remain within the bead in the soil matrix, whereas free cells move with vertical water flow around aggregates and through pores.

Dry encapsulated microbial cells may be easier to store, transport, and apply than liquid suspensions. The formulation also reduces the possibility of contamination during storage and transportation and reduces bioaerosol formation during application. Encapsulated cells have been kept in storage in the dark for up to one year at 4 °C without losing cell viability (84), and recent results have demonstrated encapsulated *Pseudomonas* sp. UG2Lr cells still maintaining viability after three years.

The application of microbial immobilization technology in bioremediation is still in its infancy but promises to offer enhanced effectiveness of microbial inoculum in environmental applications. Although there are limitations that need further exploration, including possible oxygen limitations, morphological alterations of cells inside beads (smaller cells), and effects of contaminant availability, the use of microbial inoculation on its own or in conjunction with other bioremediation strategies may prove to be more effective with this technique.

MONITORING OF BIODEGRADATION RATES

Gas Chromatography and High Performance Liquid Chromatography Analysis vs. Mineralization Studies

In laboratory experiments, two approaches have been used to determine the biodegradability of organic contaminants in soil: (*1*) loss of the parent compound as analyzed by either gas chromatography (GC) or high performance liquid chromatography (HPLC) and (*2*) mineralization experiments in which the ^{14}C-labeled parent compound is recovered as $^{14}CO_2$ (85). In the first method, the loss of a peak on a chromatogram makes it difficult to decide whether the parent compound is being partly degraded, mineralized, adsorbed to microbial biomass, or bound to soil particles or glassware. Even when experiments with killed-cell and abiotic controls are performed, the extraction efficiency and standard error can make data difficult to interpret (85). Conversely, recovery of significant amounts of $^{14}CO_2$ from a microcosm incubated with a ^{14}C-labeled substrate provides definitive proof of mineralization (85,86). Mineralization studies are generally simple to set up, and it is easy to collect samples that can be analyzed over a short period of time. In addition, information obtained from mineralization studies in microcosms can be used to predict trends on a larger scale field operation. The disadvantages of using ^{14}C-labeled compounds are that the compounds are expensive or may not be readily available from commercial sources, that studies can only be performed in laboratory soil microcosms, that the addition of the radiolabeled compound may not be a good indicator of the behaviour of a contaminant in aged soil, and the potential hazards of working with a radioactive material. Also, in soils with a mixture of contaminants, the radioactive compound would only be representative of a mixture and could not indicate the behavior of all compounds present. It is generally recommended that mineralization studies be accompanied by other analytical methods such as GC or HPLC (85).

METALS AND RADIONUCLIDES

The focus thus far has been on the biological remediation of organic contaminated sites, however, some mention should be made of metals and radionuclide contamination. Most of the metal contaminated sites are a result of industrial practices such as mining, nuclear processing, and manufacturing of batteries, electrical components, metal alloys, paints, preservatives, and insecticides (87). Toxic metals typically associated with contaminated sites include lead, mercury, arsenic, beryllium, boron, cadmium, chromium, copper, nickel, manganese, selenium, silver, tin, and zinc (87). Waste from nuclear power plants includes uranium (^{235}U), thorium (^{230}Th), and radium (^{226}R) (87,88). In comparison to the bioremediation of organic contaminated sites, metals and radionuclides are not degraded. Therefore, unless they are removed by human intervention, they will persist indefinitely. Thus, bioremediation in the case of metals and radionuclides predominantly involves immbolization to prevent further spread of the contaminant.

Immobilization of metals by microorganisms can occur due to changes in pH and redox potential and by complexation mechanisms. As mentioned in the pH section, pH has an effect on the mobilization metals. At an alkaline pH the metals form insoluble mineral carbonates or phosphates, whereas at a lower pH the metals exist as free ionic species or as soluble organometals (87). An example of a microbial environment in which the pH is dramatically decreased is in the case of acid mine drainage. The oxidation of iron sulfide ores by *Thiobacillus ferrooxidans* results in the formation of sulfuric acid. Although this organism would be useful in leaching of metals in the mining industry, its presence in a metal contaminated site would increase the mobilization of metals to groundwater.

The redox potential also plays an important role. This normally is controlled by the moisture content of the soil (see Moisture Content). Under a reduced or anaerobic environment (negative E_h), metals precipitate due to the presence of carbonates, ferrous ions, and sulfides (87). Metals become more soluble under oxidizing conditions (positive E_h) such as the situation with *Thiobacillus ferrooxidans* described in the previous paragraph.

Complexation of metals by microorganisms is a natural process. For example, microorganisms obtain metals that are essential for their viability, including sodium, potassium, copper, iron, and manganese. Unwanted or toxic metals may also be complexed to prevent them from affecting cellular processes. Essential metals such as sodium and potassium are important for the production of membrane potentials, whereas copper, iron, and manganese are used for metalloenzymes (87). Complexation of toxic metals can occur using extracellular polymers binding to cell surfaces, or they may be taken up intracellularly. Binding of metals to extracellular polymers and cell surfaces depends on the organism, metal, and pH (89). For example, algal cell walls are typically made up of a fibrillar layer and an amorphous layer. The fibrillar layer can be made of cellulose, mannan, or xylan, whereas the amorphous layer can contain alginic acid, fucoidan, agar, carrageenan, porphyran, or sulfated complex heteropolysacharides such as galactose, arabinose, xylose, rhamnose, and glucuronic acid (89). All of these compounds contain carboxyl sulfonated groups that are excellent in binding various metals. Bacteria on the other hand have a thick cell wall layer of peptidoglycan containing teichoic and teichuronic acids (gram-positive bacteria) or an outer cell membrane layer containing lipopolysaccharides and phospholipids (gram-negative bacteria) (89). The negative charges from the carboxyl and phosphonate groups are responsible for metal binding. Fungi have a cell wall composed mainly of chitin or cellulose (89). In addition, they have an outer amorphous layer containing α-glucans, mannan, galactans, chitosan, or glycogen (89). Like bacteria and algae, the phosphate and carboxyl groups are responsible for the negative charge, however unique to the fungi, a positive charge is produced by the amine groups in the chitosan (89). Therefore, depending on whether the metal is anionic or cationic, it will bind to the positive or negative charged groups, respectively, of the cell wall structures. pH of the environment also has an affect; at a lower pH cationic metal binding is reduced, whereas anionic binding is increased. For example, the anions chromate (CrO_4^{2-}) and selenate (SeO_4^{2-}) bind better at a lower pH. Intracellular uptake can take place either by passive diffusion or active transport. Once taken up some bacteria are known to sequester the metals using a cysteine-rich protein called a metallothionein. The metal can then be transported out of the cell or remain as an intracellular granule.

Radioactive waste is treated in the same manner as nonradioactive metals. An additional factor, however, is that radiation can cause lethal mutations in the DNA of microorganisms. For this reason biological products are most often sought, including tannins, melanins, bacterial chelating agents, microbial polysaccharides, metallothioneins, chitin, and whole cells (87). For an excellent review on the bioremediation of radionuclide-containing waste, see Lloyd and Macaskie (88).

PHYTOREMEDIATION

Phytoremediation has been defined as the in situ use of plants to stabilize, remediate, and reduce or restore contaminated soil, sediment, and surface or groundwaters (90,91). The prefix *phyto* means plant and *remediation* means to correct (92). Phytoremediation is an attractive remediation technology because it is cost-effective, causes minimal environmental disturbance, is suitable for a broad range of contaminants including metals, radionuclides, and organics, is aesthetically pleasing, has long-term applicability, and organic contaminants such as petroleum and pesticides can be completely degraded through mineralization (93–95). It relies on the plant's ability to act as "a solar-driven pumping and filtering system" and enhances or stimulates the natural tendency of ecosystem to restore itself (96).

There are limitations to phytoremediation and each site must be assessed individually to determine if phytoremediation is a feasible remediation option. If

the contaminant poses a direct hazard to humans or to the environment, phytoremediation is probably not the best remediation option because the clean-up time is longer than that for other remediation technologies. Other limitations of phytoremediation include the rate of plant development and depth of root systems. The contaminant must be in contact with the root and it follows that the contaminant concentration could be toxic to the plant or the microorganisms associated with the plant, there is a potential for entry into the food chain if appropriate control measures are not implemented, and the success of phytoremediation can be limited by soil and environmental conditions such as moisture and temperature (93–95).

Phytoremediation can be divided into six main categories: enhanced rhizosphere degradation, phytodegradation, phytoextraction, rhizofiltration, phytovolatilization, and Phytostabilization (Fig. 2). The two main contaminant degradation categories are enhanced rhizosphere degradation and phytodegradation. The former uses the bacteria in the root rhizosphere to degrade the contaminant, whereas the latter involves the plant degrading the contaminant by itself. All other phytoremediation techniques involve stabiliztin or extracting the contaminant from the environmental media that is then sequestered in the plant tissue or is transformed and/or volatilized. To keep with the theme of this encyclopedia only the enhanced rhizosphere degradation method is discussed later. For all other methods the reader is referred to Table 2.

Enhanced rhizosphere degradation is also referred to as plant assisted bioremediation and phytostimulation. It involves the stimulation by the plant through the release of exudates of the microbial community that is associated with the rhizosphere or root zone. It is the bacterial and fungal communities that are primarily responsible for degrading the contaminant rather than the plant itself. The interactions between the plant and the rhizosphere community are complex and not well understood.

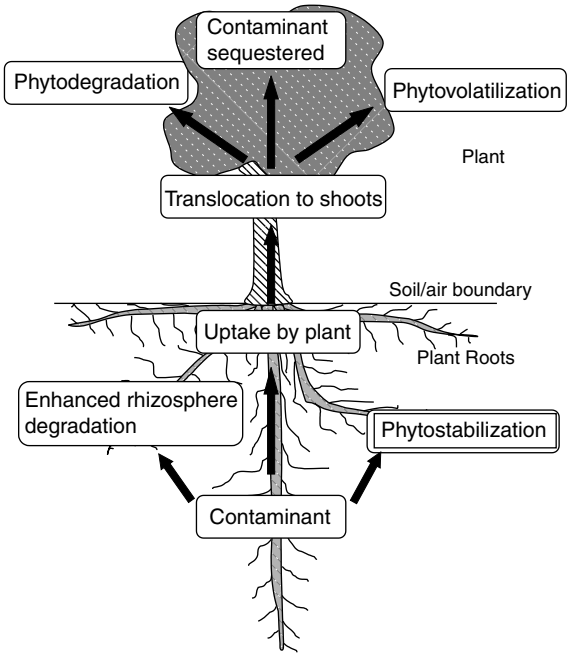

Figure 2. Schematic diagram showing the types of phytoremediation and where they occur in the plant.

Table 2. Types of Phytoremediation Available

Phytoremediation Categories	Technology	Media	Suitable Plants Tested	References
Enhanced Rhizosphere Degradation	Degradation of the contaminant by plant rhizosphere microorganisms	Mainly soil, sediment, and sludge, but also surface and ground water	Grasses, hybrid poplars, red-mulberry, alfalfa, cattails	93,97,98,99,100
Phytodegradation	The degradation of a compound through plant metabolism or through the release of enzymes by the plant	Soil, sediment, sludge, ground and surface water	Algae, stonewart, hybrid poplars, cattails, and rice	93,101
Phytoextraction	Plants accumulate metals and radionuclides and translocate them to harvestable plant parts	Soil, sediment, and sludge	Indian mustard, alpine pennycress, sunflowers, poplars	93,102–105
Rhizofiltration	Plants absorb or precipitate metals and radionuclides from aqueous solutions around the roots, therefore immobilizing the metals or radionuclides	Surface or groundwater	Sunflowers, Indian mustard, and water hyacinth	93,106–108
Phytovolatilization	The uptake and possible transformation of a compound by the plant and subsequent release into the atmosphere	Groundwater, soil, sediment, and sludge	Poplar, alfalfa, black locust and Indian mustard	93,109
Phytostabilization	Stabilization of the metal contaminated soil by plant roots reducing the movement off-site	Soil	Indian mustard, grasses, and hybrid poplars	93,102

Curl and Truelove (110) defined the rhizosphere as the soil subjected to the influence of living roots. It contains a diverse community consisting of microbiota, (bacteria, fungi, and algae) and micro and mesofauna (such as nematodes, insects, mites) (111). There are numerous factors that influence the composition and activity of this community, including plant species and age, root type, soil type, environmental conditions (carbon dioxide, light, pH, temperature, moisture, and nutrients) and exposure to historical contamination (97,98). Generally, the bacterial population is dominated by gram-negative, nonsporulating bacilli, with a small proportion of gram-positive bacilli, cocci, pleomorphic rods, and aerobic nonspore forming bacteria (111).

The rhizosphere has been studied extensively over the years, primarily for agricultural reasons (96). Attempts have been made to understand the interactions occurring in the hope of controlling plant pathogens, increasing crop yield, and optimizing symbiotic relationships such as *Rhizobium* and mycorrhizal fungi. Only recently has it been realized that the rhizosphere can be important in increasing the degradation of environmental contaminants (112–116).

Plants release compounds (exudates) into the rhizosphere (called rhizodeposition), which act as nutrient sources for microorganisms. Roots and root associated fungal hyphae provide surfaces for microbial colonization (96,117,118). Plants also alter the soil's physicochemical properties, making the soil environment more hospitable for microorganisms (112,118).

Exudates may be organic or inorganic and can result from active exudation, passive leaking, production of mucilage, or dead or sloughing off plant cells (119). Exudates can be up to 30–40% of the photosynthetically fixed carbon and include simple sugars, amino acids, organic acids, fatty acids, sterols, growth factors, nucleotides, flavanones, and enzymes (96,120). Some exudates are structural analogs to xenobiotics, so the rhizosphere community may already be enriched to degrade certain environmental contaminants. (121,122). Monomeric components of lignin are structural analogs to chlorinated aromatic acids (121), *p*-coumaric acid is structurally similar to benzenes (115), morin is similar to polycyclic aromatic hydrocarbons (PAH) (115), and biphenyl actually induces enzymes required for PCB degradation and acts as a growth substrate for cometabolism (115,123). Plants support a microbial community with densities of an order of magnitude that matches or is higher than that of bulk soil (97). This is termed the rhizosphere effect and is defined as the ratio of the number of microorganisms in the rhizosphere to that in the nonrhizosphere soil (R/S ratio) (96). R/S values typically range from 5 to 20 but can be as high as 100 or more (96).

Siciliano and Germida (114) reported three possible mechanisms that plants could enhance the degradation of soil contaminants: (*1*) the plant nonspecifically enhances the microbial community, that is, increases the R/S ratio (*2*) enhancement of microbial activity that protects the plant from the contaminant, and (*3*) the development of microbial communities that specifically degrade the contaminants.

The plant provides a niche that can support a wide diversity of microorganisms. Often, it is not a single strain responsible for the complete degradation of a contaminant, but rather the concerted effort of a community of organisms, each responsible for a sequential step in the degradation (122). By simply hosting a wide diversity of organisms, it is thought that the plant increases the probability of completing each step in the degradation process. Also, the release of exudates is thought to provide an environment conducive to cometabolism (96). Cometabolism is when one compound is degraded by an organism but is not used as an energy source by that organism. The organism must also degrade another compound at the same time that is used as a substrate and as an energy source. The rhizosphere also provides an environment favorable for gene transfer, including plasmids encoding degradative genes (122).

The second mechanism of the plant's role in phytoremediation is to enhance microbial communities that protect the plant. Interactions in the rhizosphere are complex and have often evolved to benefit both the plant and the microbial community. Walton and coworkers (111) proposed that plants exposed to contaminants alter their exudation patterns, thereby sending signals to microorganisms to detoxify the contaminant. The plant provides nourishment and oxygen in exchange for protection and/or detoxification. Siciliano and Germida (124) inoculated Daurian wild rye with two pseudomonads species. These inoculants enabled the plant to establish and survive in the contaminated soil, thereby reducing phytotoxicity. However, contaminant levels were not reduced. Increased microbial numbers and activity in the rhizosphere do not always correlate with increased degradation. Microorganisms may reduce the phytotoxicity of a compound by immobilizing the xenobiotic through humification or sequestration (97). Humification is the incorportation of organic compounds into soil organic matter. Humic material may also act as electron acceptors during low-oxygen conditions, thereby aiding in the degradation or transformation of organic substances when oxygen is limited (97).

The third possible role of plants is that they enrich a degrading microbial community. Vegetation has been shown to enhance degradation rates in a variety of environmental conditions of a wide range of organic contaminants such as total petroleum hydrocarbons (TPH), PAH, PCBs, pesticides, organic solvents, and surfactants (117,122,123). Nichols and coworkers (125) found an increase in microbes capable of degrading a mixture of organic contaminants, with the greatest increase in the rhizosphere. Microorganisms will typically adapt to a contaminant by selective enrichment of those capable of tolerating or degrading the contaminant. The plant provides further selection pressure, stimulates cometabolism, provides a niche for long-term survival of degradative plasmids and provides an environment conducive to gene transfer.

It is very difficult to develop a consistently effective plant-microbe system for phytoremediation because of the many possible plant–microbe–contaminant interactions and because of our limited understanding of the factors influencing rhizosphere population dynamics. It has been

shown, however, that inoculating or seeding a phytoremediation system with microbial degraders or plant growth promoting bacteria can be effective (114,115,121,126,127). Inoculation in bioremediation often fails because the introduced microorganisms fail to compete with indigenous soil organisms. It is thought that the plant provides a niche for the introduced bacteria, allowing them to compete with indigenous organisms. Also, the plant provides additional nutrients, increased moisture exposure through transpiration, and a surface area for colonization, and the roots provide a mechanism of delivering the organisms to the contaminants. In addition, land plants are often colonized by mycorrhizal fungi whose hyphal network acts as extensions of roots, exploiting a greater volume of soil. Hyphae also release photosynthetically fixed plant carbon into the mycorrhizosphere and provide extensive surface areas for colonization. Heinonsalo and coworkers (118) found the highest density of bacteria in the mycorrhizosphere of a contaminated soil.

Although phytoremediation is still in its infancy, it does hold considerable promise for the remediation of organic and inorganic contaminated soils, sediments, and water.

CONCLUSION

Bioremediation is increasingly being recognized as a promising environmental technology. It is possible to demonstrate bioremediation of chemically contaminated soils in relatively small-scale soil microcosms. Similar results may or may not be achieved in the open soil environment or in a bioreactor. Environmental conditions are often difficult to control in the open environment and the rate and extent of bioremediation of targeted chemicals may proceed slower than in the laboratory setting or possibly not at all.

Natural attenuation has been presented in this article followed by factors that are necessary for soil bioremediation to proceed. The first task is to determine what happens if the contaminant is left alone for a period of time (natural attenuation). Does intervention actually help in remediating the contaminated site or is spreading the contamination when disturbing the soil just exacerbating the problem? Once it is established that human intervention is necessary, then it must be determined if the environment, contaminant, and the degrading microorganisms are in balance or are present. If the environment is not optimum for microbial growth, activity, and survival, biodegradation of the contaminant is limited. Conversely, if the environment is optimum but the contaminant is toxic or not bioavailable, biodegradation and bioremediation is unsuccessful. The last important factor that must be present and active is the contaminant-degrading microorganism. Case studies of bioremediation taking into account the above variables are presented in Table 3.

Research on isolating, monitoring, and genetically engineering microorganisms has improved the prospects of using bioremediation as an alternative to chemical or physical remediation strategies. In addition, new technologies such as microbial encapsulation and

Table 3. Case Studies in Bioremediation

Case Study 1. Bioremediation of PCBs in the Hudson River
General Electric Corporation, Schenectady, New York, sponsored a bioremediation test site for the in situ bioremediation of PCBs (2,128). Six cylinders were placed in a shallow section of the Hudson River where sediment was contaminated with PCBs. Five cylinders received different treatments including oxygen, nutrient, and biphenyl amendment and the addition of laboratory PCB degrading bacteria. Over a 10-week test period, over one- third of the PCBs were destroyed. The loss of degradable PCBs and the presence of key microbially produced PCB intermediates indicated that microorganisms were responsible for the degradation. The bioaugmented cylinders did not have an additional effect on degradation.
Case Study 2. Bioremediation of Wood Preservatives
Grace Bioremediation Technologies, Ontario, Canada, used bioremediation technology to treat a sandy loam soil contaminated with polyaromatic hydrocarbons, petroleum hydrocarbons, and chlorophenols (129). Four treatment plots were constructed. Plot 1 was a control, whereas Plots 2–4 were tilled and irrigated to 70% water holding capacity twice a month, nitrogen and phosphorus were added to plots 3 and 4 to achieve a C : N : P ratio of 100 : 5 : 1, and plot 4 received additional amendment composed of agricultural crop residues. After 526 days, over 83% of each of the contaminants were degraded in plots 3 and 4, whereas less than 50% and 75% were lost in plots 1 and 2, respectively. The consensus between six toxicity tests (seed germination, earthworm survival, SOS Chromotest, solid-phase Microtox, and red blood cell haemolysis assay) revealed that the toxicity of the soil was reduced over the bioremediation period.
Case Study 3. Bioremediation of Soil Contaminated with Radionuclides
Agricultural land in Vromos Bay, southeastern Bulgaria, is contaminated with radionuclides (uranium, radium) and toxic heavy metals (copper, cadmium, lead) because of mining and mineral processing practices. Groudev and coworkers (130) set up a 400 m^2 test site to determine if the indigenous microflora could be used to bioremediate the soil. The soil was characterized to have a slight alkaline pH. To increase aeration in the upper soil horizon, the soil was ploughed periodically. Leach solutions containing carbonate ions plus dissolved organic compounds were used to help in the dissolution of the contaminants from the upper soil horizon (horizon A) to the lower soil horizons. In addition, water containing ammonium phosphate and organic compounds was injected into the lower soil horizons (horizon B_2, 55 cm) using vertical pipes to stimulate the sulfate reducing bacteria (SRB). Between 52 and 70% of the total radionuclides and toxic metals were removed from the upper soil horizon. The dissolution of these metals was predominantly attributed to the activity of the heterotrophic and chemolithotrophic aerobic microorganisms in the upper soil horizon. In the lower soil horizon the radium was found bound to clay particles, whereas uranium was precipitated as uraninite (UO_2). The metals were found as insoluble sulfides. The activity was attributed to SRBs.

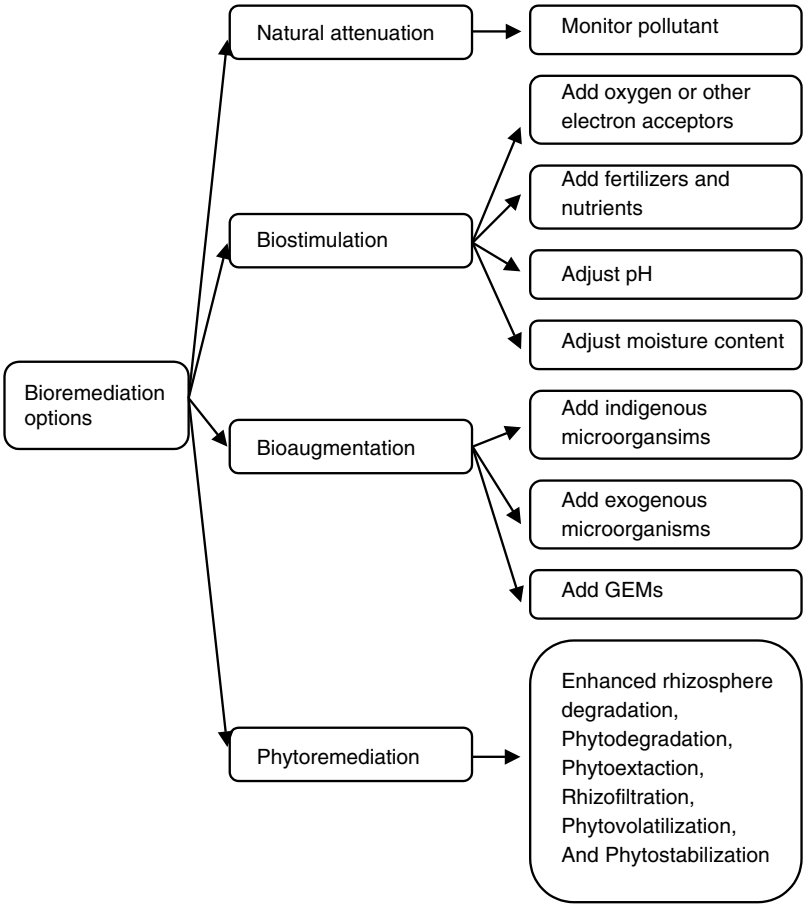

Figure 3. Bioremediation options.

phytoremediation have provided novel approaches to help existing bioremediation processes.

There is no standard protocol that can be uniformly applied to all sites as each bioremediation site is different. Each situation requires a careful examination of all options available for bioremediation (Fig. 3). In addition, each site needs to be assessed separately with all of the factors involved, including the environment, the contaminant and the degrading microorganism(s) considered as a whole.

BIOSOLIDS: ANAEROBIC DIGESTION OF

W. T. M. SANDERS
G. ZEEMAN
A. J. M. STAMS
Wageningen University
Wageningen, The Netherlands

The activated sludge process was developed in England in 1914 by Ardern and Lockett and was so named because it involved the production of an activated mass of microorganisms capable of stabilizing a waste aerobically (1). The activated sludge process is the most widely applied method for sewage treatment. Many versions of the process are in use, but fundamentally, they are all similar. The system shown in Figure 1 is a completely mixed activated sludge system, in which wastewater containing organic waste is first brought into a settling tank in which the solids are allowed to settle. Then the pre-settled wastewater is led into the aeration tank in which an aerobic suspended culture is maintained in suspension by the use of diffused or mechanical aeration. In the aeration tank the bacterial biomass carries out the conversions given in Equation (1) (1). In the aeration tank new biomass not only is formed but also is degraded through endogenous respiration Equation (2) (1). After a specific period the mixed liquor in the aeration tank is led to a settling tank in which the cells (or activated sludge) are separated from the treated wastewater. A portion of the activated sludge is recycled to the aeration tank to maintain the desired level of bacteria in the reactor. The remainder waste is called the secondary or waste activated sludge (WAS). Before WAS can be disposed off, it has to be stabilized to reduce pathogens, eliminate offensive odors, eliminate the potential for putrefaction, and improve the dewatering characteristics. The methods that can be applied to stabilize sludge can be divided into four categories. (*1*) biological reduction of the volatile content, (*2*) chemical oxidation of the volatile content, (*3*) addition of chemicals to render it unsuitable for the survival of microorganisms, and (*4*) application of heat to disinfect or sterilize the sludge (1).

The biological methods include composting, aerobic stabilization, and anaerobic stabilization. The latter is discussed in this article. Anaerobic digestion takes place under anaerobic conditions in an airtight reactor. Sludge, introduced continuously or intermittently, is retained in the reactor for a period of time, during which microorganisms, under anaerobic conditions, convert the volatile solids in the sludge to a variety of end products including methane (CH_4) and carbon dioxide (CO_2) (1).

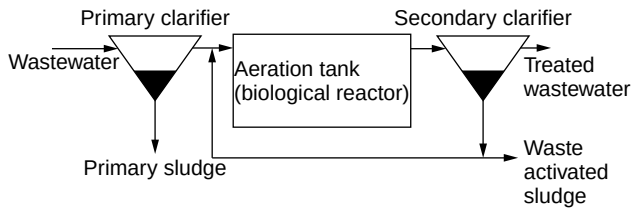

Figure 1. Schematic drawing of a completely mixed activated sludge system.

Table 1. Results of the Mesophilic Sludge Digesters of the WWTP Elburg, The Netherlands

Parameter	Primary Sludge Digester	Activated Sludge Digester
TSS reduction (%)	41	19
VSS reduction (%)	56	28
HRT (days)	27	23
Gas production (m^3/kg TSin)	0.25–0.65	0.10–0.16

In most wastewater treatment plants, the WAS and primary sludge are mixed and digested together in one reactor. However, when the amount of WAS in the reactor feed increases above 40% of the total amount of sludge, the performance of the digester decreases quickly (2). Moreover, when the primary and WAS are digested separately the production of methane and the reduction of volatile solids from WAS is much lower than compared to the primary sludge (Table 1). Apparently the volatile solids in the WAS are more difficult to degrade than those present in primary sludge.

$$\underset{\text{(organic waste)}}{\text{COHNS}} + O_2 + \text{nutrients} + \text{bacteria} \rightarrow CO_2 + NH_3 + \underset{\text{(new biomass)}}{C_5H_7NO_2} + \text{other end products} \quad (1)$$

Endogenous respiration:

$$\underset{\text{(biomass)}}{C_5H_7NO_2} + 5O_2 + \text{bacteria} \rightarrow 2H_2O + NH_3 + \text{energy} \quad (2)$$

THE STRUCTURE OF ACTIVATED SLUDGE

The structure/composition of the activated sludge is important for its biodegradability. In this section, information on the structure and composition of the activated sludge is presented.

A typical activated sludge floc is 80 to 120 m in diameter and consists of five components, namely, bacteria, water, organic fibers, inorganic particles, and extracellular polymeric compounds (ACTIVATED SLUDGE — THE FLOC). These substances arise from the wastewater or from the bacteria themselves (3–5). The backbone of the sludge is formed by the extracellular polymeric compounds, which are linked together by divalent cations (mainly Ca^{2+}), thus forming a gel-like structure in which all other components are embedded.

The bacteria in activated sludge comprise a viable and a nonviable fraction. A viable cell can be defined as a cell with an intact encapsulating structure that shows some kind of metabolism, that is, is capable of either metabolizing a substrate or reproduction, or both.

Owing to the complex structure of AS, the measurement of the number of viable cells is not as easy as it is for pure cultures. Many microorganisms are linked together in sludge flocs so that some kind of treatment to separate the

bacteria into individual reproductive units is necessary for counting procedures, such as plate counting or direct microscopic counting, possibly after staining. Staining procedures that are used are acridine orange, DAPI, and FITC staining (6). Respiring bacteria can be counted by INT staining, which is sensitive to a dehydrogenase enzyme in the electron transport system. A drawback of the plate counting techniques is that the actual number of microorganisms present can be easily underestimated as no single medium will support growth of all different kinds of viable bacteria present (7).

Microbial biomass consists of a variety of biopolymers. Stouthamer (8) determined that the dry weight of microbial cells is composed of protein (52.4%), polysaccharides (16.6%), lipid (9.4%), RNA (15.7%), and DNA (3.2%). It is important to note that the mentioned biopolymers contribute more than 95% of the total dry weight of microbial cells. However, the relative composition of the biomass is largely dependent on the types of microorganisms present in the sludge and the conditions under which the biomass has been grown. For example, under nitrogen, phosphorous, or iron limitation, microorganisms may produce and accumulate large amounts of polysaccharides or other biopolymers as storage compounds. This influences the relative polymer composition of the biomass. DNA concentrations are maintained in relatively constant proportions within microorganisms (9). Therefore, determination of the amount of DNA in the activated sludge is another method of determining the amount of viable cells. However, as DNA can also be detected in the extracellular polymeric components of the WAS, this method will lead to an overestimation of the number of viable bacteria in the WAS.

Several authors have tried to establish the viable biomass fraction in activated sludge. Weddle and Jenkins (10) derived activated sludge from laboratory reactors that were fed with autoclaved primary sewage. AS viability was determined by standard plate counting procedures on sonically dispersed sludge using activated sludge extract agar. The specific viability varied between 1.5 and 2.0×10^8 cells/mg VSS for net growth rates between 0.026 day^{-1} and 0.33 day^{-1}. Assuming an average VSS mass per viable microorganism of 1.0×10^{-12} gram, the viable fraction amounted to 15 to 20%.

Frolund (11) worked with sludge from two WWTPs with a sludge age of 7 to 9 days and 30 to 35 days, with (partly) chemical phosphate removal. They counted about 5×10^8 cells/mg VS in WAS with acridine orange (AO) staining in WAS from the high SRT plant. Only 10% of these cells appeared to be actively respiring as measured with CTC staining. From the average cell size measured from microscopic observations and a density conversion factor, the viable fraction was estimated at 10% of VS. They extracted a maximum of 16 mg DNA per gram VS from both the high SRT sludge and the low SRT sludge. Their sludge had a low VS content — 57% of TS. Taking a DNA content of 3.1% of dry weight for an average *Entamoeba coli* B/r cell (9) or $0.9 \times 3.1 = 2.8\%$ of VS, the viable fraction can be estimated at $160/2.8 = 57\%$.

The number of viable cells in the activated sludge depends, among others, on the sludge-loading rate of the activated sludge plant. This can be illustrated by simulation of a simple wastewater treatment plant (WWTP) consisting of one aeration tank and a secondary clarifier at different sludge-loading rates (12). The simulation of the WWTP was done with the activated sludge model no. 1 (13). This model has been widely accepted for the description of the activated sludge process. Inert particulate material plays an essential role in the process, which determines the fraction of viable microorganisms. This inert particulate material may be present in the influent but it is also formed in the death-regeneration cycle, because upon lysis of microorganisms, only part of the released material is biodegradable. In ASM 1 the inert particulate material becomes part of the sludge floc. Because the number of death-regeneration cycles increases with sludge age, the amount of inert particulate material also increases. This results in a lower viable fraction at higher sludge ages. In the model, therefore, the fraction viable particulate material, that is, viable microorganisms, depends on both the concentration of inert particulate materials in the influent and the sludge age.

In the simulation experiment the influent composition and oxygen concentration in the aeration tank was kept constant. Only the flow rate of the WWTP was varied in order to vary the sludge load. Each simulation was conducted over 40 days, which was amply sufficient to reach a steady state. Table 2 shows the viable fraction f_{bio}, depending on the organic loading rate (OLR) and solids retention time (SRT). The fraction of heterotrophic active biomass is seen to increase with increasing sludge-loading rate and decreasing SRT.

To reduce the growth of algae in surface water, many wastewater treatment plants (WWTP) have to meet very strict effluent standards for total phosphate and nitrogen. The removal of nitrogen in a conventional activated sludge plant requires a long sludge residence time to allow growth of the slow-growing nitrifying bacteria, *Nitrosomonas*, and *Nitrobacter*. Therefore, an ever-increasing amount of waste-activated sludge of a long sludge age is produced.

The exopolymeric compounds should be considered as the third major sludge component after water and bacteria (14). As aforementioned, these polymers are interconnected by divalent ions, mainly Ca^{2+} (15), through which a matrix that can be considered as the backbone of the activated sludge is formed. Two types

Table 2. Effect of the Organic Loading Rate (OLR) of a WWTP on the Fraction Viable Biomass (f_{bio}) in the Activated Sludge. Results were Obtained by Simulation of a WWTP with ASM 1 (12)

$Q_{influent}$ [m^3/day]	OLR [g COD/g TSS/day]	SRT [days]	f_{bio} [% of total solids]
120	0.167	25.8	27.9
240	0.298	12.2	42.4
480	0.499	6.2	55.1
960	0.857	3.1	64.6
1,920	1.522	1.6	70.8
3,840	2.789	0.8	73.5

of exopolymers are distinguished slime polymers and capsular polymers, respectively. The slime polymers are only loosely attached to the biomass and can be extracted by mild extraction methods. The slime contains all types of biopolymers, which are believed to be mainly autolysis products from the bacteria. The capsular polymers, on the other hand, are very strongly attached to the bacteria. Capsular polymers require much more rigid extraction methods than slime polymers. Capsular polymers are thought to play an important role in the dewatering of sludge, although publications on this subject are not unequivocal. This is probably because many different extraction methods are used and the reproducibility of most methods is low. Especially when using techniques for extraction of capsular polymers, lysis of biomass occurs often. This causes overestimation of the amount of extracted polymer. In Table 3 an overview is given of the methods used to extract slime and/or capsular polymers. The amount of slime and capsular polymers that were found in several investigations are listed in Table 4.

In summary, it can be seen that the composition of the volatile solids in activated sludge comprises more than 80% inactive biomass, less than 4% exopolymers and 7 to 19% active biomass.

The water is activated sludge can be divided into four fractions (23):

- free water
- interstitial water
- vicinal water
- water of hydration water

The free water is not bound to the sludge and can be removed by means of conventional techniques for dewatering such as thickening, centrifugation, and vacuum filtration. The interstitial water is situated in the floc structure and can only be removed when the floc is destroyed. If surface-active polymers are used in mechanical dewatering techniques it is possible to remove some interstitial water. The vicinal water is bound to the surface of the sludge and can only be removed by drying at 105EC. The water of hydration is water that is chemically bound to the particle. Removal of this water requires thermochemical destruction of the particles (24,25).

THE MICROBIOLOGY OF METHANOGENIC PRODUCTION

Anaerobic decomposition is initiated by hydrolysis of biopolymers by extracellular enzymes, which are formed

Table 3. Extraction Methods Reported to be Used for Extraction of Exopolymers. Division of the Methods Has Been Made on the Basis of the Type of Extracted Polymers

	Slime	Capsular	Both
Method 1			
Extraction of polymers:			
The polymers are extracted by centrifugation at 2,000 to 10,000 g. The supernatant contains the polymers and the pellet is discarded.	T		
Analysis of the polymers:			
The amount of polymers in the supernatant is determined by one of the following methods:			
— Extraction of polymers from the supernatant with, for instance, ethanol. The total amount of polymer is determined gravimatically after drying the extract or chemically after resuspension in water.			
— Direct measurement of the amount of protein, carbohydrate, DNA, RNA, and/or humic substances.			
Method 2			
Washing of the sludge			
Centrifugation at 2,000 to 10,000 g. The supernatant is discarded and the pellet is resuspended in a buffer solution.			
Extraction of polymers:		T	
The polymers are extracted by one of the following methods:			
— centrifugation at >10, 000 g			
— addition of ion exchange resin such as Dowex or XA			
— boiling upto one hour			
Analysis of the polymer:			
see method 1			
Method 3			
The same method as in method 2 are used. However the washing procedure is skipped.			T

Table 4. Composition of the Exopolymers Extracted from Fresh Activated Sludge. The Division Between Slime and Capsular Polymers Has Been Made based on the Extraction Method as Depicted in Table 3

Only Slime Polymers Extracted	Both Slime and Capsular Polymers Extracted	Only Capsular Polymers Extracted
1. 52 mg total slime polymers/g VS		
2.	212 mg protein/g VS 40 mg carbohydrates/g VS 101 mg humic substances/g VS 16 mg DNA/g VS	
3.	68 to 100 mg protein/g VS 71 to 127 mg carbohydrates/g VS 35 to 54 mg RNA/g VS 28 to 41 mg DNA/g VS	
4. 25 to 90 mg total polymers/g TSS		
5. 21 to 35 mg total polymers/g TSS		
6. 0.52 to 29.1 mg total polymers/g TSS		13.1 to 23.8 mg total polymers/g TSS
7.	9 to 90 mg carbohydrates/g TSS	

Note: References and extraction method:
1. centrifugation, 20 minutes, 2,000 g (16).
2. extraction with Dowex from unwashed sludge (method 3) (17).
3. centrifugation of washed sludge 15 minutes at 32,500 g (method 2) (18).
4. centrifugation (19).
5. centrifugation (20).
6. centrifugation 15 minutes, 13,200 g with and without addition of K_2HPO_4 (21).
7. settled sludge, washed with water subsequently boiled for one hour (22).

and excreted by fermentative microorganisms. Polysaccharides yield monomeric and oligomeric C6 and C5 sugars, while proteins are converted to single amino acids and small peptides. Proteins are composed of about 20 amino acids with different chemical structure. RNA and DNA are transformed to C5 sugars and nucleic bases purines (adenine and guanine) and pyrimidines (cytosine, thymine, and uracil). Lipids are degraded to glycerol and long-chain fatty acids. The general pattern of anaerobic mineralization of complex organic matter is that fermentative bacteria metabolize easily with degradable compounds such as sugars, amino acids, purines, pyrimidines, and glycerol to a variety of fatty acids, bicarbonate, formate, and hydrogen. Acetogenic bacteria degrade higher fatty acids to acetate, carbon dioxide, hydrogen, and formate. These compounds are the substrates for methanogens (26). All these processes, fermentation, acetogenesis, and methanogenesis (Fig. 2), will take place at the same time, but often, because of the different growth rates and activities of the different microorganisms, these processes are partially uncoupled. The whole sequence of anaerobic biodegradation is very dynamic in the sense that methanogens strongly influence the metabolism of fermentative and acetogenic bacteria by means of interspecies hydrogen transfer (27,28).

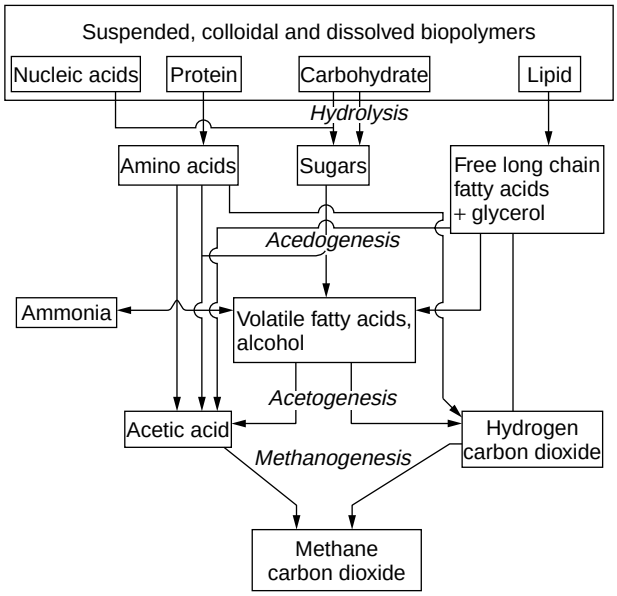

Figure 2. General scheme of the anaerobic digestion process.

Mineralization of Sugars

Sugars are substrates, which can be fermented by a variety of different microorganisms via different pathways leading to typical end products (29). Generally C6 sugars are degraded by glycolysis or the Entner-Doudoroff pathway to pyruvate, while C5 sugars are converted via a combined pentose pathway and the glycolytic or the Entner-Doudoroff pathway to pyruvate. Conversion of sugars to pyruvate is an oxidative process, which intracellularly results in the formation of NADH. The further metabolism of pyruvate depends on the organisms involved, and reflects the biochemical mechanisms, which the sugar-fermenting microorganisms use to dispose off reducing equivalents. Facultative aerobic microorganisms that are abundantly present in the sludge may perform a so-called mixed acid fermentation, in which a variety of reduced organic products are formed, including ethanol, lactate, succinate, formate, and butanediol. More specific fermentations by specialized microorganisms will occur as well. Alcoholic fermentation, lactic acid fermentation, homoacetogenic fermentation, and propionic acid and butyric acid fermentation are examples of

specific fermentations carried out by anaerobic microorganisms. The combined occurrence of all these individual fermentations will yield a variety of and products such as ethanol, lactate, acetate, propionate, butyrate, lactate, hydrogen, and bicarbonate. Other reduced organic compounds such as butanol, acetone, and butanediol may be formed, but are quantitatively of little importance. Except for butyrate, propionate, and acetate, the reduced compounds may be fermented further by specific microorganisms. For example, lactate and ethanol ($+CO_2$) will be fermented to acetate and propionate by *Desulfobulbus propionicus* and *Pelobacter propionicus* (30,31), *Clostridium kluyveri* can ferment ethanol (+acetate) to butyrate, while lactate and ethanol can also be fermented by the homacetogens to solely acetate. Succinate can be decarboxylated to propionate by *Propionigenium modestum* (32). However, propionate, butyrate, and long-chain fatty acids cannot be fermented. Propionate is oxidized to acetate, CO_2 and hydrogen formate, while butyrate and long-chain fatty acids are oxidized to acetate and hydrogen (see later). Instead of hydrogen, acetogens may also dispose off reducing equivalents as formate. The relative importance of hydrogen and formate is not clear (28). Acetate, $H_2 + CO_2$ and formate are finally converted by the methanogens to $CH_4 + CO_2$, CH_4 and $CH_4 + CO_2$, respectively. Physiologically, methanogens are very specialized. *Methanosaeta* species are only able to grow on acetate while *Methanobrevibacter* species can only use H_2 and CO_2 and *Methanospirillum* and *Methanobacterium* species use both $H_2 + CO_2$ and formate for growth. *Methanosarcina* species are most versatile; they can use $H_2 + CO_2$, acetate, methanol, and other methylated compounds for growth (33–35).

In methanogenic environments the utilization of hydrogen by methanogens affects the metabolism of those sugar-fermenting microorganisms that have the ability to use protons as electron sinks. A typical example is the fermentation of glucose by *Ruminococcus albus* (36). In pure culture this organism forms acetate, CO_2, hydrogen, and ethanol as end products, while in coculture, ethanol is not formed (Fig. 3). *Ruminococcus albus* degrades glucose via the glycolytic pathway. This results in the formation of NADH (glyceraldehyde-3-phosphate dehydrogenase) and reduced ferredoxin (pyruvate:ferredoxin oxidoreductase). The redox couples of $Fd_{(ox)}/Fd_{(red)}$ and AND/NADH are -398 and -320 mV, respectively, whereas the redox couple H^+/H_2 is -414 mV (37). The Gibbs free energy changes ($\Delta G^{0'}$ values) of the redox reactions can be calculated using $\Delta G^{0'} = -n.F.\Delta E^{0'}$, where n is the number of electrons transferred, F is the Faraday constant, and $\Delta E^{0'}$ is the difference between the redox couples:
