TABLE OF CONTENTS

A

Acetylene Reduction Assay
Acid Mine Drainage
Acidophiles
Actinomycetes, Airborne
Actinomycetes in Activated Sludge
Actinomycetes in Soils
Actinomycetes: Role in Foaming of Activated Sludge
Actinorhizal Symbiosis
Activated Carbon
Activated Sludge, Filamentous Bacteria in
Activated Sludge — Foaming
Activated Sludge, Methodology
Activated Sludge — Microbiology of Nitrogen Removal
Activated Sludge Models: Microbiological Basis
Activated Sludge — Molecular Techniques for Determining Community Composition
Activated Sludge — Sequencing Batch Reactors
Activated Sludge — The Floc
Activated Sludge — The "G-Bacteria"
Activated Sludge — The Microbial Community
Activated Sludge — The Process
Activated Sludge: Use of Molecular Tools
Activity and Carbon Transformations in Biofilms
Adenoviruses
Adhesion, Immobilization and Retention of Microorganisms on Solid Substrata
Adhesion (primary) of Microorganisms onto Surfaces
Adhesion to Surfaces
Adsorption of Microorganisms to Surfaces
Adsorption of Viruses to Surfaces
Aerobic Alkaliphiles
Aerobic Endospores
Aerobic Respiration, Principles of
Aggregates and Consortia, Microbial
Agroterrorism
Air Pollution Control
Air Sampling
Air-Water Interface
Airborne Bacterial Pathogens
Airborne Fungi
Airborne Microorganisms
Airborne Toxigenic Molds
Algae
Algae Biotechnology
Algae, Blue-Green
Algae: Eutrophication
Algae, Polar
Algae: Streams
Algae: Toxicity Testing
Algae, Use as Biological Indicators in Paleolimnology
Algae: Waste Stabilization Ponds
Algal Blooms
Algal Blooms — Impact on Treatment, Taste, and Odor Problems
Algal Pigments as Indicators
Algal Turf Scrubbing: Potential Use for Wastewater Treatment
Alkaline Enzymes
Alkaliphiles
Alkaliphiles: Alkaline Enzymes and Their Applications
Alkalithermophiles (Anaerobic)
Allergens, Fungal
Ammonification
Amoeboid Protozoa
Anaerobic Digestion of Biosolids
Anaerobic Granules
Anaerobic Granules and Granulation Processes
Anammox
Anhydrobiosis
Anthrax
Antibiotic Resistance
Anydrobiosis
Aquifers, Atlantic Coastal Plain
Arbuscular Mycorrhizae
Archaea, Detection of
Archaea: Detection Methods
Archaea in Biotechnology
Archaea in Marine Environments
Archaea in Soil Habitats
Archaea in Soils
Archaea, Thermophilic
Assessing Microbial Proteomes in the Environment
Assimilable Organic Carbon (AOC) in Drinking Water
Assimilable Organic Carbon (AOC) in Treated Water: Determination and Significance
Astroviruses
Attachment of Microorganisms

B

Bacteria: Streams
Bacterial Cell Structure
Bacterial Contaminants in Residential Environments
Bacterial Pathogens in Waste Stabilization Ponds
Bacterial Phytostimulators in the Rhizosphere
Bacterioneuston
Bacteriophage as Indicators
Bacteriophage: Biology and Genetics
Bacteriophage Detection Methodologies
Bacteriophage of Enteric Bacteria: Occurrence and Persistance in the Environment
Bacterioplankton
Benthic Algae
Benthic-Associated Primary Productivity
Bioaerosol Sampling and Analysis
Bioaerosols in Agricultural and Outdoor Settings
Bioaerosols in Industrial Settings
Bioaerosols: Modeling
Bioaerosols: Transport and Fate
Bioaerosols, Virus
Bioaerosols: Wastewater Treatment Plants
Bioaugmentation
Bioaugmentation: Cold-Adapted Microbes

Bioavailability of Organic Substrates
Biochip-Based Devices and Methods in Microbial Community Ribotyping
Biocontrol, Microbial Agents in Soil
Biocorrosion: Role of Sulfate Reducing Bacteria
Biodegradability: Methods for Assessing Biodegradability Under Laboratory and Field Condition
Biodegradable Dissolved Organic Carbon (BDOC)
Biodegradable Dissolved Organic Carbon in Drinking Water
Biodegradation: Composts
Biodegradation: Fuel Oxygenates
Biodegradation, Halogenated Aromatics
Biodegradation: Landfills
Biodegradation: Oxygenase Enzymes
Biodegradation: Reductive Dehalogenation and Metabolism of Chlorinated Organics by Anaerobes
Biodegradation: Wetlands
Biodeterioration
Biodeterioration of Mineral Materials
Biodiversity in Soils: Use of Molecular Methods for its Characterization
Bioemulsifiers
Biofilm Detachment
Biofilms, Activity in
Biofilms, Algal Biofilms
Biofilms: Bacterial-Fungal Biofilms
Biofilms, Carbon Transformations in
Biofilms, Conditioning Films
Biofilms: Extracellular Enzymes
Biofilms, Extracellular Polymeric Substance
Biofilms, Formation Rate in Water Distribution Systems
Biofilms, Growth Kinetics of Microbes in
Biofilms in Natural and Drinking Water Systems

TABLE OF CONTENTS

B

Biofilms in the Food Industry
Biofilms, Methodology
Biofilms, Modeling of
Biofilms, Pathogens in
Biofilms, Sorption Properties of
Biofilms: Suspended Biofilms
Biofiltration
Biofiltration and Bioodors
Biofouling: Chemical Control of Biofouling in Water Systems
Biofouling in the Marine Environment
Biofouling of Industrial Systems
Biogenic Trace Gases
Biogeochemical Cycles
Biohydrometallurgy
Bioleaching
Bioleaching of Metals
Biological Control, Use of Biosurfactants in
Biological Warfare
Biology of Cryptosporidium
Bioluminescence, Methodology
Biomarkers, Lipid
Biomass, Algal
Biomass, Bacterioplankton
Biomass: Soil Microbial Biomass
Biomineralization by Bacteria
Biomining
Biomining Using Archaea
Bioodors Control in Waste Treatment Facilities
Biopesticides
Bioplastics
Bioremediation: An Overview of How Microbiological Processes Can Be Applied to the Cleanup of Organic and Inorganic Environmental Pollutants
Bioremediation: Aquatic Ecosystems
Bioremediation, Aquifers
Bioremediation, Biosurfactants Use in
Bioremediation, Cold-Adapted Microorganisms in
Bioremediation, Methanotrophs in
Bioremediation of Hot Desert Soils
Bioremediation of Soils
Bioremediation, Pesticides in Soils
Bioremediation, PLFA Analysis
Bioreporters
Biosolids: Anaerobic Digestion of
Biosolids, Bioaerosols from
Biosolids, Granules in
Biosorbents for Metals
Biostability of Drinking Water
Biostimulation, Aquatic Ecosystems
Biostimulation, Aquifers
Biostimulation: Cold-Adapted Microbes
Biostimulation, Hot Desert Soils
Biosurfactants: Types, Screening Methods, and Applications
Biotechnological Applications of Biosurfactants and Bioemulsifiers
Biotechnology, Fungi in
Biotechnology, Methanotrophs in
Bioterrorism
Biotoxins
Biotrickling Filters for Air Pollution Control
Blue-Green Algae
Borreliosis, Lyme
Bottled Water
Bottled Water, Microbiology of
Brown Rot Fungi
Brown Tide
Bulking Control
Bulking in Activated Sludge
Bulking of Activated Sludge

C

Caliciviruses
Campylobacter jejuni and Other Enteric *Campylobacter*
Capillary Electrophoresis in Genetic Analysis and Ribotyping of Microbiota in the Environment
Carbon Monoxide
Caves and Mines Microbiological Sampling
Caves and Other Low-Light Environments: Aerophitic Photoautotrophic Microorganisms
Cell Viability, Methodology for
Chaperone and Chaperonins
Chemical Weapons, Biodegradation of
Chemolithoautotrophy
Cholera
Chrysophytes
Ciliated Protozoa
Ciliates in Freshwater Ecosystems
Cisterns
Climate Change, Use of Chrysophytes as Indicators of
Cloning
Clostridium
Coagulation in Water Treatment Plants: Pathogen Removal
Cold-Active Enzymes
Cold-Adapted Microorganisms: Adaptation Strategies and Biotechnological Potential
Cold Deserts
Cold-Induced Proteins
Cold Shock
Cold-Shock Proteins
Coliform Bacteria as Indicators of Water Quality
Coliform Bacteria—Control in Drinking Water Distribution Systems
Coliform Regrowth in Water Distribution Systems
Coliphage: Detection Methodologies
Cometabolism
Commercial Use of Microorganisms, Regulation of
Compost: Biodegradation of Toxic Organic Compounds
Conditioning Films in Aquatic Environments
Confocal Laser Scanning Microscopy (CLSM)

Consortia, Microbial
Controlling the Microbial Quality of Drinking Water in Distribution Systems
Corrosion
Cosmetics, Use of Biosurfactants in
Crude Oil, Biodegradation of
Crude Oil Spills
Culturable Subsurface Microbial Communities
Cyanobacteria
Cyanobacteria in Soils
Cyanobacteria-Toxins in Drinking Water
Cyanobacterial Mats
Cyanobacterial Mats and Nitrogenen Fixation
Cyanophages
Cyclospora: Basic Biology, Occurrence Fate and Methodologies

D

Data Analysis and Modeling
Dehalogenation of Haloorganics
Denaturing Gradient Gel Electrophoresis (DGGE)
Denitrification
Denitrification in Activated Sludge
Denitrification in the Marine Environment
Desert Environments
Desert Environments: Biological Soil Crusts
Desert Environments — Soil Microbial Communities in Cold Deserts
Desiccation, Adaptation of Microorganisms to
Desiccation by Exposure to Space Vacuum or Extremely Dry Deserts: Effect on Microorganisms
Desiccation of Microorganisms
Desulfurization of Fossil Fuels
Detection of Airborne Microorganisms
Detection of Enteroviruses
Diatoms in Biofilms
Diazotrophs
Dinitrogenase
Dinoflagellates, Toxic
Dioxygenases
Disinfection: Chlorine, Monochloramine, and Chlorine Dioxide
Disinfection, Effect on Viruses
Disinfection of Legionellae
Disinfection of Protozoan Parasites
Disinfection, Ultraviolet (UV)
Dna Chips
Domestic Microbiology
Drinking Water Biofilms
Drinking Water, Cyanobacteria in
Drinking Water Distribution Systems, Invertebrates and Protozoa in
Drinking Water Distribution Systems, Pathogens in
Drinking Water, Nitrifying Bacteria in
Drinking Water, Sulfur Bacteria in
Drinking Water, Viruses in

E

Ecological Significance of Subsurface Microorganisms
Ecology of Marine Microbial Biofilms
Ecology, Pathogenicity, and Systematics of *Aeromonas* in the Environment
Ectomycorrhizal Fungi
Electrophoresis
Emergency Water Supplies
Endolithic Microorganisms in Arid Regions
Endosymbiosis in Ecology and Evolution
Endosymbiosis Involving Amebas
Endosymbiosis Involving Cyanobacteria
Endotoxins in Bottled Water
Enhanced Biological Phosphorus Removal (EBPR) in Activated Sludge
Enhanced Detection of Airborne Microbial Contaminants
Entamoeba histolytica / Entamoeba dispar
Enteric Adenoviruses
Enterococci, Fecal
Enterohemorrhagic E. Coli (EHEC)
Enteroinvasive E. Coli
Enteropathogenic E. Coli (EPEC)
Enterotoxigenic E. Coli (ETEC)
Enteroviruses: basic Biology and Diseases
Enteroviruses in Water: Concentration and Detection

TABLE OF CONTENTS

E

Enteroviruses: Occurrence and Persistence in the Environment
Entomopathogens (Bacteria, Fungi, Prototozoa, Viruses)
Environmental Genomics
Environmental Release of Microorganisms
Enzymatic Toxicity Tests
Enzyme Inhibition
Enzyme Kinetics
Enzymes, Archaeal
Enzymes: Biotechnological Applications
Enzymes, Cold-Active
Enzymes, Industrial
Enzymes in Soils
Enzymes: Oxygenases
Epifluorescence Microscopy
Epilithic Microorganisms
EPS
Eutrophication and Algae
Evolution of Metabolic Pathways for Degradation of Environmental Pollutants
Exobiology
Extracellular Enzymes in Biofilms
Extracellular Polymeric Substances (EPS)
Extracellular Polymeric Substances (EPS): Structural, Ecological and Technical Aspects
Extremophiles: Life in Extreme Environments

F

Fate and Microbial Degradation of Halogenated Aromatics
Fate of Viruses and Protozoan Parasites in Aquatic Sediments
Fecal Contamination, Sources of
Fecal Streptococci/Enterococci in Aquatic Environments
Field Release of Genetically Engineered Microorganisms (GEM)
Filamentous Bacteria in Activated Sludge: Current Taxonomic Status and Ecology
Filamentous Bulking in Activated Sludge, Control of
Filtration (High-Rate): Removal of Pathogenic Microorganisms
Filtration: Occurrence of Protozoa in Spent Filter Backwash Water
Fingerprinting Techniques
Flagellated Protozoa
Flocs, Microbial
Flooded Soils
Fluorescence Microscopy
Fluorescent in situ Hybridization (Fish)
Fluorescent in situ Hybridization (Fish): Use in Activated Sludge
Fluorescent Probes for in situ Analyses of Microbial Communities
Fluorochromes
Foaming in Activated Sludge
Food Contamination
Food Industry
Food Preservation
Food Processing and Bioaerosols
Fossil Fuels Desulfurization
Free-Living Amebas Present in the Environment Can Cause Meningoencephalitis in Humans and Other Animals
Freeze-Drying
Freeze Drying: Preservations of Microorganisms by Freeze-Drying
Fuel Additives, Biodegradation of
Fumonisins
Fungal Allergy and Allergens
Fungal Biofilms
Fungal Contaminants
Fungi
Fungi and Indoor Air
Fungi and Pollutant Biodegradation
Fungi, Culture Media for
Fungi, for Biotechnology
Fungi in Freshwater Ecosystems
Fungi in Marine/Estuarine Waters
Fungi in Soils
Fungi in Streams

G

G-Bacteria in Activated Sludge
Gallionella ferruginea: An Iron-Oxidizing and Stalk-Forming Groundwater Bacterium
Gases, Trace
Gene Chips
Gene Exchange in Biofilms
Gene Probes
Gene Transfer in Biofilms
Genetic Ecology of Soil
Genetic Manipulation of Fungi
Genetically Engineered Microorganisms (GEMs)
Genetically Engineered Microorganisms for Biodegradation of Recalcitrant Compounds
Genetically Modified Microorganisms (GMM) in Soil Environments
Genomics, Environmental
Geochemical and Geological Significance of Subsurface Microbiology
Geochemical Aspects of Subsurface Microbiology
Geostatistics for Determining the Distribution of Soil Microorganisms
Giardia: Basic Biology, Genetics and Epidemiology
Giardia: Detection and Occurrence of in the Environment
Granular Activated Carbon, Bacteriology of
Granular High-Rate Filtration: Removal of Pathogenic Microorganisms
Granular Sludge
Green Fluorescent Protein (GFP)
Greenhouse Effect, Role of Microorganisms
Groundwater, Protistan Communities in

Groundwater Sampling
Groundwater, Sulfur Bacteria in
Groundwater, Viruses in
Growth, Diauxic
Growth, on Mixed Substrates

H

Haber-Bosch Process
Halogenated Compounds, Bioremediation of
Halogenated Hydrocarbon (Gases)
Haloorganics Dehalogenation
Halophiles
Halophiles: Aerobic Halophilic Microorganisms
Halophiles: Anaerobic Prokaryotes from Hypersaline Environments
Halophilic Archaea
Halophilic Microorganisms
Halotolerant Bacteria
Harmful Algal Blooms (HAB)
Heat-Shock Genes
Heat-Shock Proteins
Heavy Metal Toxicity
Helicobacter pylori
Hepatitis Viruses (HAV-HEV)
Heterotrophic Bacteria as Indicators of Water Quality
High Hydrostatic Pressure: Microbial Inactivation and Food Preservation
Home Treatment Devices — Microbiology of Point of Use and Point of Entry Devices
Hot Desert Soil Microbial Communities
Hot Tubs Microbiology
Human Caliciviruses: Basic Virology and Epidemiology
Humic Substances in Aquatic Environments
Hydrocarbon Biodegradation in Cold Environments
Hydrocarbons, Biodegradation of
Hydrocarbons, Bioremediation of
Hydrodesulfurization
Hydrophobicity of Microorganisms: Methodology
Hydrothermal Vents: Biodiversity in Deep-Sea Hydrothermal Vents
Hydrothermal Vents: Prokaryotes in Deep-Sea Hydrothermal Vents
Hyperthermophiles

I

Ice Environments
Ice Microbial Communities
Identification of Airborne Fungi
Igneous Rock Aquifers Microbial Communities
Image Analysis of Microorganisms
Imaging
Immobilization of Microorganisms on Solid Substrata
Indicators of Water Quality: Aerobic Spores
Indicators of Water Quality: Bacteriophage
Indicators of Water Quality: Clostridium
Indicators of Water Quality: Coliforms
Indicators of Water Quality: Fecal Streptococci/Enterococci
Indicators of Water Quality: Source Water Protection
Indoor Exposure to Fungi
Indoor Health
Industrial Enzymes
Industrial Settings, Bioaerosols in
Infectious Airborne Bacteria
Inorganic Nutrient Use by Marine Microorganisms
Insecticides, Microbial
Invertebrate-Associated Microorganisms in Deep-Sea Hydrothermal Vents
Invertebrates and Protozoa (Free-Living) in Drinking Water Distribution Systems
Ion Exhange in Water Treatment Plants: Pathogen Removal
Ionizing Radiation, Effect on Microorganisms
Iron Cycling
Iron Oxidation
Iron-Reducing Microbes in Petroleum Reservoirs
Isospora
Isotopic Fractionation

K

Kinetics (Microbial): Theory and Applications
Kinetics of Microbial Processes and Population Growth in Soil

TABLE OF CONTENTS

L

Labelling of Microbial Cells (Enzymatic, Fluorescent, Immunological, Phylogenetic, and Physiological Labels)
Lakes, Periphyton in
Landfilling of Municipal Solid Wastes: Microbiological Processes and Environmental Impacts
Laser Scanning Microscopy in Combination With Fluorescence Techniques for Biofilm Study
Leaf Decomposition By Fungi in Freshwater Ecosystems
Legionellae
Legionella in the Environment: Persistence, Evolution, and Pathogenicity
Legume Inoculation
Leptospirosis
Lipid Biomarkers in Environmental Microbiology
Lipids, Archaeal
Lithotrophic Microbial Ecosystems in the Subsurface
Low Light Environments
Luciferase and Green Fluorescent Protein as Bioreporters in Microbial Systems
Lyme Borreliosis

M

Machining and Bioaerosols
Macrophyte Colonization by Fungi
Magnetotactic Bacteria
Manganese Cycling
Manganese Oxidation
Marine Biotechnology
Marine Methanogens
Mats, Microbial
Membrane Filter Procedure for Heterotrophic Bacteria
Mercury Cycling
Meroplankton
Messenger RNA-Targeted Probes
Metabolic Pathways
Metabolism of Mixtures of Organic Pollutants
Metals
Metals, Bioremediation of
Metals in Soils
Metals: Interaction with Biofilms
Metals, Microbe Resistance to
Metals: Microbial Processes Affecting Metals
Metal Stressed Environments, Bacteria in
Metal Transformations
Metal (U,Fe,Mn,Hg) Cycling
Methane
Methanogenesis
Methanogenesis in the Marine Environment
Methanogens
Methanogens: Biotechnological Applications
Methanogens in Petroleum Reservoirs
Methanogens in Soils
Methanotrophic Bacteria
Methanotrophic Bacteria: Use in Bioremediation
Methanotrophs
Methods for Flow Cytometry and Cell Sorting
Methods for the Identification of Microbial Isolates
Methylation of Metals
Microarrays
Microarrays: Applications in Environmental Microbiology
Microbial Degradation of Explosives
Microbial Degradation of Fuel Oxygenates
Microbial Enhanced Oil Recovery (MEOR), Use of and Biosurfactants in
Microbial Flocs Suspended Biofilms
Microbially-Influenced Corrosion (MIC)
Microbial Removal by Pretreatment, coagulation and Ion Exchange
Microbial Starvation Survival in Subsurface Environments
Microbial Toxicity Tests
Microbiology of Atlantic Coastal Plain Aquifers and Other Unconsolidated Subsurface Sediments
Microbiology of Cretaceous Shales and Sandstones of the Southwestern United States
Microbiology of Deep High Temperature Sedimentary Environments
Microchips
Microgravity Effects on Microorganisms
Microorganisms in Soil: Factors Influencing Their Activity
Microspheres as Tracers in Groundwater
Microsporidia: Basic Biology
Microsporidia: Occurrence, Fate and Methodologies
Mine Tailings
Mines
Mixotrophs
Modeling of Biofilms
Modeling of Virus Transport and Removal in the Subsurface
Modeling the Transport of Bioaerosols
Modeling
Models, Activated Sludge
Models: Role of Protozoa
Molecular Methods for Soils
Monooxygenases
Mustard Gas, Biodegradation of
Mycobacterium avium Complex
Mycorrhizae
Mycorrhizae: Arbuscular Mycorrhizae
Mycorrhizae: Ectomycorrhizal Fungi
Mycotoxins

N

Natural Organic Matter (NOM) in Aquatic Environments;
Neural Networks
Neuston Microbiology: Life at the Air–Water Interface
Nitrification
Nitrification in Activated Sludge
Nitrification in Aquatic Systems
Nitrification in Soils

Nitrification in The Marine Environment
Nitrifiers Typing using Microchips
Nitrifying Bacteria in Drinking Water
Nitogen Cycle
Nitrogen Cycle in Aquatic Systems
Nitrogen Cycle in Soils
Nitrogen Cycle in the Marine Environment
Nitogen Fixation
Nitrogen Fixation in Methanotrophs
Nitrogen Fixation in Soils — Free-Living Microbes
Nitrogen Fixation in Soils (Symbiotic)
Nitrogen Fixation in the Marine Environment
Nitrogen Fixation Measurement
Nitrogen Gases
Nitrogen in Marine Microorganisms
Nitrogen Removal in Activated Sludge
Norwalk-Like Viruses: Detection Methodologies and Environmental Fate
Norwalk-Like Viruses (NLVS)
Nosocomial Infections
Nuclear Waste Respository in Yucca Mountain: Microbiological Aspects
Nucleic Acids Extraction from Soils
Nutrient Cycling: Role of Bacterioplankton
Nutrients Use By Marine Microorganisms

O

Occurrence of Protozoa in Spent Filter Backwash Water
Ochratoxins
Oil Reservoirs
Oligotrophic Bacteria
Opportunistic Pathogens
Organic Matter in Water
Organic Matter Removal in Water Treatment
Organic Substances: Interaction with Biofilms
Organophosphorus Nerve Agents, Biodegradation of
Osmoprotection of Microorganisms
Oxygen: Effect on Marine Microbial Communities
Oxygenase Enzymes: Role in Biodegradation

P

Paleoecology
Paleoenvironmental Reconstruction
Paleolimonology
Paleolimnology: Subfossil Algae Other than Diatoms and Chrysophytes
Paleolimnology: Use of Algal Pigments as Indicators
Paleolimnology: Use of Siliceous Structures of Chrysophytes as Biological Indicators in Freshwater Systems
Panspermia Thesis
Paralytic Shellfish Poisoning
Parasitic Protozoa: Fate in Wastewater Treatment Plants
Pathogen, Bacterial
Pathogenic *Escherichia coli*
Pathogens, Bacterial
Pathogens (Bacterial) in Waste Stabilization Ponds
Pathogens in Environmental Biofilms

TABLE OF CONTENTS

P

Pathogen Survival in Aquatic Environmnents
Periphyton
Permafrost
Pesticide Degradation in Soils
Pesticides, Bioremediation of
Pest Mangement
Petroleum and Other Hydrocarbons, Biodegradation of
Petroleum Reservoirs, Influence, Activity and Growth of Subsurface Microflora in
Petroleum Reservoirs, Microbial Diversity in
Pfiesteria: The Toxic Pfiesteria Complex
Phage: Detection Methodologies
Phosphorus Cycling in Aquatic Environments: Role of Bacteria
Phosphorus in Marine Microorganisms
Photosynthetic Bacteria
Photosynthetic Bacteria in Caves
Photosynthetic Bacteria in Drinking Water
Photosynthetic Bacteria in Soils
Photosynthetic Bacteria in Waste Stabilization Ponds
Photosynthetic Pigments in Marine Algae and Bacteria
Phototrophic Purple and Green Bacteria in Marine and Hypersaline Environments
Phycotoxins
Phyllosphere
Phylogenetically Based Methods in Microbial Ecology
Phylogenetics, Archaea
Phylogeny
Phylogeny of Aquifer Communities
Phytoneuston
Phytoplankton
Phytoplankton, Polar
Phytostimulators, Bacterial
Pigments of Algae as Paleolimnological Indicators
Planktonic Algae
Planktonic Algae in the Marine Environment
Planktonic Microorganisms: Bacterioplankton
Plant–Microbe Interactions in the Marine Environment
Plfa Analysis
Point-of-Use Treatment Devices for Drinking Water
Polar Marine Phytoplankton
Polymerase Chain Reaction (PCR)
Polymers in Activated Sludge
Population Growth in Soils, Kinetics of
Preservation of Algae for Toxicity Testing
Pretreatment in Water Treatment Plants: Pathogen Removal
Primary Productivity
Primary Productivity in the Marine Environment
Probes
Probes: Rrna-Targeted Probes for Activated Sludge
Processing of Subsurface Samples
Prochlorococcus
Productivity, Bacterioplankton
Protection of Source Water
Protistan Communities in Groundwater
Protozoa (Free-Living) in Drinking Water Distribution Systems
Protozoa in Activated Sludge
Protozoa in Marine and Estuarine Waters
Protozoa in Streams
Protozoan Ciliates in Freshwater Ecosystems
Protozoan Parasites
Protozoan Parasites, Disinfection of
Protozoan Parasites in Food
Protozoan Parasites in Sediments
Pseudomonas
Psychrophiles
Psychrophilic Bacteria
Psychrophilic Bacteria: Isolation and Characterization
Psychrophilic Microorganisms
Psychrotolerant Microorganisms
Psychrotrophic Bacteria
Psychrotrophic Microorganisms
Pulp and Paper Industry: Microbiological Aspects of

Q

Quality Assurance/Quality Control in Subsurface Sampling and Processing
Quality, Soil Quality
Quantification of Microbial Biomass
Quorum Sensing in Biofilms

R

Radiation Effect on Bacteria
Radiation Effects on Microorganisms
Radioactive Waste Disposal, Geomicrobiology of
Rainwater Roof Catchment Systems, Microbial Quality of
Red Tides and Other Harmful Algal Blooms
Reedbeds for Wastewater Treatment
Regrowth of Bacteria in Water Distribution Systems
Regulation of Bottled Water
Regulation of the Commercial Uses of Microorganisms
Regulations for Drinking Water
Removal of Pathogenic Microbes by Granular High-Rate Filtration
RESIDENTIAL ENVIRONMENTS Retention of Microorganisms on Solid Substrata
Rhizosphere
Rhizosphere, Archaea in
Rhizosphere Microbiology
Rhizospheric Effect
Ribosomal RNA-Targeted Probes.
Ribotyping
Ribotyping Methods for Assessment of in situ Microbial Community Structure
Ribotyping of Microbial Communities
Rice Agriculture
Rice Soils
Risk Assessment
Risk Assessment of Environmental Exposure to Viruses

Riverine Biofilms
Rivers, Periphyton in
Root Exudates
Root Secretions
Rotaviruses
Rural Water Supplies

S

Salinity Effects on the Physiology of Soil Microorganisms
Salinity Tolerance
Salmonella in Aquatic Environments
Salt Production
Salt Production, Involvement of Microorganisms in
Sampling in Subsurface Environments
Sampling of Bioaerosols
Sampling Techniques for Environmental Microbiology
Screening Chemical Toxicity in Soils
Seagrasses Communities
Sea Ice Microorganisms
Sediments
Sediment Sampling
Sediments and PLFA Analysis
Sediments, Archaea in
Sediments, Bioremediation of
Sediments: Nitrification in
Sediments, Nitrogen Fixation in
Sediments: Sulfate Reduction in Marine Sediments
S Gases
S-Layer, Archaeal
Septic Tank Systems
Sequencing Batch Biofilm Reactor (SBBR)
Sequencing Batch Reactor (SBR) Technology
Shelf Storage of Bottled Water
Shellfish, Salmonella in
Shigella
Siderophores
Siderophores in Marine Bacteria
Siliceous Structures of Chrysophytes
Silicon in Marine Microorganisms
Sludge
Sludge, Granules in
Snow and Ice Environments
Soil Archaea
Soil Bacteria
Soil Bioremediation (Pesticides)
Soilborne Diseases, Biocontrol of
Soil Crusts, Biological
Soil Distribution of Microorganisms
Soil Enzymes
Soil Formation, Role of Microorganisms
Soil Fungi: Nature's Nutritional Network
Soil Genetic Ecology
Soil Microbial Biomass
Soil and Soil Microorganisms
Soil Nitrogen Cycle
Soil Quality
Soil Quality: The Role of Microorganisms
Soil Sampling
Soil Slurry Sequencing Batch Reactor (Ss-Sbr)
Soils, Biodegradation in
Soils, Biodiversity in
Soils, Distribution of Microorganisms in
Soils, Kinetics of Microbial Processes
Soil Toxicity Tests
Soils, Virus Survival in
Solar Power: Disinfection of Cistern Water
Solid Wastes
Solid Wastes Microbiology
Solvents, Effects on Microorganisms
Solvent-Tolerant Bacteria
Sorption Properties of Biofilms
Sorting of Microbial Cells.
Source Water Protection: Microbiology of Source Water
Sources of Fecal Contamination
Spa and Hot Tub Microbiology

TABLE OF CONTENTS

S

Space Microbiology: Effects of Ionizing Radiation on Microorganisms in Space
Space Microbiology: Microgravity and Microorganisms
Space: Survival in Space
Space Vacuum
Spatial Distribution of Microorganisms in Soils
Spores As Indicators
Stalk-Forming Bacteria
Starvation of Microorganisms in Subsurface Sediments
Statistical Analysis
Storage of Environmental Samples
Storage Polymers: Role in the Ecology of Activated Sludge
Stream Microbiology
Streams, Periphyton in
Streptococci, Fecal
Stress
Stress Genes
Stress Proteins
Stress Response in Archaea
Stress Response in Bacteria
Stress Response in Bacteria: Heat Shock
Stromatolites
Subaerial Communities
Subsurface Microbial Communities: Diversity of Culturable Microorganisms
Subsurface Microbiology
Subsurface Samples: Collection and Processing
Subsurface Sampling
Subsurface Sedimentary Environments
Subsurface Sediments
Sulfate Reducing Bacteria
Sulfate-Reducing Bacteria: Environmental and Technological Aspects
Sulfate Reducing Bacteria in Petroleum Reservoirs
Sulfate Reduction in Marine Sediments
Sulfur Bacteria in Drinking Water
Sulfur Cycle
Sulfur Cycle in Soils
Sulfur Oxidizing Bacteria
Surfaces
Suspended Biofilms
Sustainable Agriculture
Sustainable Agriculture: Role of Microorganisms
Sustainable Solid Waste Management
Symbiotic Nitrogen Fixation

T

Textile Industry and Bioaerosols
Thermophiles
Thermophiles: Anaerobic Alkalithermophiles
Thermophiles, Diversity of
Thermophilic Alkaliphiles
Tnt Biodegradation
Toxicity of Metals to Microorganisms
Toxicity of Organic Solvents to Microorganisms
Toxicity Testing in Soil, Use of Microbial and Enzymatic Tests
Toxicity Testing in Wastewater Treatment Plants Using Microorganisms
Toxigenic Molds
Toxins, Microbial
Toxoplasma gondii
Trace Elements in Marine Microorganisms
Trace Gases Soil
Tracers in Groundwater: Use of Microorganisms and Microspheres
Transport of Bacteria Through Soils
Transport of Pathogens in Surface Waters
Trophic State and Algal Community Structure

U

Unbalanced Growth Conditions
Uranium Cycling
Use of Cold-Adapted Microorganisms in Biotechnology
Use of Microscopic Algae in Toxicity Testing
UV Disinfection — Theory to Practice

V

Vadose Zone Microbiology
Viable But Not Culturable (Vbnc)
Viable But Not Culturable (VBNC) Microorganisms
Viable Counts in Environmental Samples
Viral Aerosols
Viral Diseases
Viral Disinfection
Virus Survival in Soils
Virus Transport in The Subsurface
Virus Transport Though Soils
Viruses and Protozoan Parasites in Food, Including Methodology
Viruses: Astroviruses
Viruses: Caliciviruses
Viruses, Concentration and Detection
Viruses: Enteroviruses
Viruses: Hepatitis Viruses
Viruses in Drinking Water and Groundwater
Viruses in Food
Viruses in the Marine Environment
Viruses in Waste Stabilization Ponds
Viruses: Rotaviruses
Volcanic Tuffs: Deep Subsurface Microbiology of

W

Wastewater and Biosolids as Sources of Airborne Microorganisms
Wastewater Stabilization Ponds
Wastewater Treatment and Bioaerosols
Wastewater Treatment and Giardia
Wastewater Treatment Microbiology

Wastewater Treatment, Microbiology of
Wastewater Treatment-Septic Tank Systems
Water Activity
Water Distribution Systems
Water Fungi as Decomposers in Freshwater Ecosystems
Water Sampling
Water Treatment Plants: Protozoa in Spent Filter Backwash Water
Weathering
Weathering, Microbiol
Weathering: Mineral Weathering and Microbial Metabolism
Wetlands
Wetlands and Readbeds for Wastewater Treatment
Wetlands: Biodegradation of Organic Pollutants
Wetlands, Fungal Activity in
Wetlands, Periphyton in
White Rot Fungi
White Rot Fungi in Bioremediation
Wood Decomposition By Fungi
Wood Degrading Fungi
Wood Processing and Bioaerosols

X

Xerotolerant Microorganisms

Z

Zoonotic Transmission of Parasites
Zoonotic Transmission of Pathogens

PREFACE

Environmental microbiology was born at the dawn of the "environmental era" at the beginning of the 1970s. Thirty years of maturation have led to an exciting and vibrant field that has attracted countless numbers of productive and enthusiastic scientists and students at universities, research centers and government agencies around the world. The wealth of environmental microbiology literature has made it imperative to make a pause at this time and summarize our knowledge in an encyclopedia format. For the sake of organization, we have identified 14 areas within environmental microbiology. These areas are discussed in more details in the introductory chapter.

The rising tide of molecular biology has led to the use and adaptation of modern molecular techniques along with sophisticated equipment to the study of microorganisms in their environments, especially extreme environments. The study of extremophiles has increased our knowledge on the limits and origin of life on our planet.

Over 420 authors from 25 countries contributed 320 entries to this encyclopedia. We have witnessed a small reduction in the planned coverage of topics, due to the inability of some authors to deliver their manuscripts. Despite this slight setback, some on-board authors have courageously agreed to "plug the holes" by expanding their own contribution to cover a missing topic or by authoring another entry. In addition to the print version, an expanded version of the encyclopedia will be available in the near future on-line to cover those missing topics. Cross-reference titles (orphan entries) or key words have been included in the encyclopedia to help readers retrieve a given topic, and an author index is also provided.

The *Encyclopedia of Environmental Microbiology* will serve as a quick reference work to be used by professors, undergraduate and graduate students, researchers in the public and private sectors, research organizations, environmental and patent lawyers, and government officials for a quick introduction to a given topic in this vast microbiology field.

The preparation and completion of this encyclopedia is a complex undertaking that involved the participation and cooperation of several individuals. The authors are the "soldiers" without whom this work would not have been possible. They contributed their expertise unselfishly despite their busy schedules. I am thankful and grateful to all of them for sharing their knowledge with anybody interested in this fascinating field. I am indebted to my colleagues and co-editors on the editorial board who have patiently and expertly helped me in orchestrating this major endeavor. They have helped tremendously in selecting suitable authors and in participating in the review of the manuscripts. Their names and affiliation appear on a separate list in this encyclopedia. I am grateful to my colleagues and my students at the Department of Environmental Engineering Sciences for their support and encouragement.

The quality of manuscripts is greatly enhanced by the participation of expert reviewers. I am indebted to the hundreds of reviewers who offered many useful suggestions for improving the manuscripts. Their names do not appear in this encyclopedia because many of them expressed the desire to remain anonymous. Thank you for a job well done.

This encyclopedia involved the participation and cooperation of several individuals at John Wiley and Sons. I would like to thank the team at the Encyclopedia Department who has worked tirelessly to see the successful completion of this work. I thank Glenn Collins who recruited me and convinced me that the job of editor-in-chief of the encyclopedia was a worthwhile endeavor. I extend special thanks to Laurie Claret, the assistant managing editor, for her expert assistance as she undertook this job without missing a beat, following the departure of Glenn Collins. I thank Surlan Murrel, editorial assistant, for her patience and, along with Laurie, for shielding me from the massive amount of correspondence and tedious record keeping. I thank them for graciously adapting to my academic lifestyle which sometimes consists of reviewing manuscripts in the Luxembourg Garden and sidewalk cafes in Paris.

I am grateful to Nancy, Julie and Natalie, and all my family and friends, for their love, good wishes, moral support, and patience with me.

GABRIEL BITTON

ABBREVIATIONS USED IN AN OVERVIEW OF IMAGING SCIENCE

Abs	absorption
AgX	silver halide
ATC	air traffic control
B	magnetic
β	beta particle (electron)
$\beta+$	positron
Bio.	biologists
BW	bandwidth
CCD	charge-coupled device
Chem	chemical
CID	charge-injected device
CP	charged particle
CRT	cathode-ray tube
CT	computed tomography
DIP	digital image processing
E	electric
e^-	electron
ECG	electrocardiogram
EE	electrical engineers
EEG	electroencephalogram
ESR	electron spin resonance
EMG	electromyogram
EMR	electromagnetic radiation
fMRI	functional magnetic resonance imaging
FT	Fourier transform
ϕ	phase
γ	gamma particle
HC	hard copy
θ, t	angle, time
$h\nu$	photon, radiation
Impe.	electrical impedance
Intel.	intelligent
IR	infrared
IS	intelligent system
LC	inductive capacitive
LCD	liquid crystal display
MEG	magnetoencephalography
MIS	multispectral image segmentation
MRA	magnetic resonance angiography
MRI	magnetic resonance imaging
MW	microwave
n	neutron
ν	frequency
NMR	nuclear magnetic resonance
obj.	objects
org.	organic
PET	positron emission tomography
PMT	photomultiplier tube
Polar	polarization
PIXIE	proton-induced X-ray emission
P	proton
RF	radio frequency
Refl	reflection
Scint.	scintillator
SIMS	secondary ion mass spectroscopy
SC	soft copy
Scat.	scattering
SQUID	superconducting quantum interference device
SSDA	solid-state detector array
Surf.	surface
Syst.	system
t	time
tan	tangent
Tomo.	tomographic
Tran.	transmission
T_2^*	inhomogeneous nuclear spin–spin relaxation time
UV	ultraviolet
x, y	two perpendicular spatial dimensions
2-D	two-dimensional

CONVERSION FACTORS, ABBREVIATIONS, AND UNIT SYMBOLS

SI UNITS (Adopted 1960)

The International System of Units (abbreviated SI), is being implemented throughout the world. This measurement system is a modernized version of the MKSA (meter, kilogram, second, ampere) system, and its details are published and controlled by an international treaty organization (The International Bureau of Weights and Measures) (1).

SI units are divided into three classes:

BASE UNITS

length	meter[†] (m)
mass	kilogram (kg)
time	second (s)
electric current	ampere (A)
thermodynamic temperature[‡]	kelvin (K)
amount of substance	mole (mol)
luminous intensity	candela (cd)

SUPPLEMENTARY UNITS

plane angle	radian (rad)
solid angle	steradian (sr)

DERIVED UNITS AND OTHER ACCEPTABLE UNITS

These units are formed by combining base units, supplementary units, and other derived units (2–4). Those derived units having special names and symbols are marked with an asterisk in the list below.

Quantity	Unit	Symbol	Acceptable equivalent
*absorbed dose	gray	Gy	J/kg
acceleration	meter per second squared	m/s^2	
*activity (of a radionuclide)	becquerel	Bq	1/s
area	square kilometer	km^2	
	square hectometer	hm^2	ha (hectare)
	square meter	m^2	
concentration (of amount of substance)	mole per cubic meter	mol/m^3	
current density	ampere per square meter	A/m^2	
density, mass density	kilogram per cubic meter	kg/m^3	g/L; mg/cm^3
dipole moment (quantity)	coulomb meter	C·m	
*dose equivalent	sievert	Sv	J/kg
*electric capacitance	farad	F	C/V
*electric charge, quantity of electricity	coulomb	C	A·s
electric charge density	coulomb per cubic meter	C/m^3	
*electric conductance	siemens	S	A/V
electric field strength	volt per meter	V/m	
electric flux density	coulomb per square meter	C/m^2	
*electric potential, potential difference, electromotive force	volt	V	W/A
*electric resistance	ohm	Ω	V/A
*energy, work, quantity of heat	megajoule	MJ	

Quantity Unit Symbol Acceptable equivalent

[†]The spellings "metre" and "litre" are preferred by ASTM; however, "-er" is used in the *Encyclopedia*.

[‡]Wide use is made of Celsius temperature (t) defined by

$$t = T - T_0$$

where T is the thermodynamic temperature, expressed in kelvin, and $T_0 = 273.15$ K by definition. A temperature interval may be expressed in degrees Celsius as well as in kelvin.

	kilojoule	kJ	
	joule	J	N·m
	electronvolt†	eV†	
	kilowatt-hour†	kW·h†	
energy density	joule per cubic meter	J/m^3	
*force	kilonewton	kN	
	newton	N	$kg·m/s^2$
*frequency	megahertz	MHz	
	hertz	Hz	1/s
heat capacity, entropy	joule per kelvin	J/K	
heat capacity (specific), specific entropy	joule per kilogram kelvin	J/(kg·K)	
heat-transfer coefficient	watt per square meter kelvin	$W/(m^2·K)$	
*illuminance	lux	lx	lm/m^2
*inductance	henry	H	Wb/A
linear density	kilogram per meter	kg/m	
luminance	candela per square meter	cd/m^2	
*luminous flux	lumen	lm	cd·sr
magnetic field strength	ampere per meter	A/m	
*magnetic flux	weber	Wb	V·s
*magnetic flux density	tesla	T	Wb/m^2
molar energy	joule per mole	J/mol	
molar entropy, molar heat capacity	joule per mole kelvin	J/(mol·K)	
moment of force, torque	newton meter	N·m	
momentum	kilogram meter per second	kg·m/s	
permeability	henry per meter	H/m	
permittivity	farad per meter	F/m	
*power, heat flow rate, radiant flux	kilowatt	kW	
	watt	W	J/s
power density, heat flux density, irradiance	watt per square meter	W/m^2	
*pressure, stress	megapascal	MPa	
	kilopascal	kPa	
	pascal	Pa	N/m^2
sound level	decibel	dB	
specific energy	joule per kilogram	J/kg	
specific volume	cubic meter per kilogram	m^3/kg	
surface tension	newton per meter	N/m	
thermal conductivity	watt per meter kelvin	W/(m·K)	
velocity	meter per second	m/s	
	kilometer per hour	km/h	
viscosity, dynamic	pascal second	Pa·s	
	millipascal second	mPa·s	
viscosity, kinematic	square meter per second	m^2/s	
	square millimeter per second	mm^2/s	
volume	cubic meter	m^3	
	cubic diameter	dm^3	L (liter) (5)
	cubic centimeter	cm^3	mL
wave number	1 per meter	m^{-1}	
	1 per centimeter	cm^{-1}	

†This non-SI unit is recognized by the CIPM as having to be retained because of practical importance or use in specialized fields (1).

In addition, there are 16 prefixes used to indicate order of magnitude, as follows:

Multiplication Factor	Prefix	Symbol	Note
10^{18}	exa	E	
10^{15}	peta	P	
10^{12}	tera	T	
10^{9}	giga	G	
10^{6}	mega	M	
10^{3}	kilo	k	
10^{2}	hecto	h[a]	[a]Although hecto, deka, deci, and centi are SI prefixes, their use should be avoided except for SI unit-multiples for area and volume and nontechnical use of centimeter, as for body and clothing measurement.
10	deka	da[a]	
10^{-1}	deci	d[a]	
10^{-2}	centi	c[a]	
10^{-3}	milli	m	
10^{-6}	micro	μ	
10^{-9}	nano	n	
10^{-12}	pico	p	
10^{-15}	femto	f	
10^{-18}	atto	a	

For a complete description of SI and its use the reader is referred to ASTM E380 (4) and the article UNITS AND CONVERSION FACTORS which appears in Vol. 24.

A representative list of conversion factors from non-SI to SI units is presented herewith. Factors are given to four significant figures. Exact relationships are followed by a dagger. A more complete list is given in the latest editions of ASTM E380 (4) and ANSI Z210.1 (6).

Conversion Factors to SI Units

To convert from	To	Multiply by
acre	square meter (m^2)	4.047×10^{3}

ABBREVIATIONS AND UNIT SYMBOLS

"When a new discipline such as imaging science evolves from several existing scientific and engineering disciplines, it is difficult to establish an agreed upon list of abbreviations and unit symbols that will be used by all the disciplines. Therefore, intead of presenting here a comprehensive list of abbreviations and unit symbols used in this encyclopedia, each encyclopedia entry has a list of abbreviations and unit sybols used in the entry. Included in this section are a set of rules for writing unit symbols."

Rules for Writing Unit Symbols (4):

1. Unit symbols are printed in upright letters (roman) regardless of the type style used in the surround text.
2. Unit symbols are unaltered in the plural.
3. Unit symbols are not followed by a period except when used at the end of a sentence.
4. Letter unit symbols are generally printed lower-case (for example, cd for candela) unless the unit name has been derived from a proper name, in which case the first letter of the symbol is capitalized (W, Pa). Prefixes and unit symbols retain their prescribed form regardless of the surrounding typography.
5. In the complete expression for a quantity, a space should be left between the numerical value and the unit symbol. For example, write 2.37 lm, *not* 2.37 lm, and 35 mm, *not* 35 mm. When the quantity is used in an adjectival sense, a hyphen is often used, for example, 35-mm film. *Exception*: No space is left between the numerical value and the symbols of degree, minute, and second of plane angle, degree Celsius, and the percent sign.
6. No space is used between the prefix and unit symbol (for example, kg).
7. Symbols, not abbreviations, should be used for units. For example, use "A," not "amp," for ampere.
8. When multiplying unit symbols, use a raised dot:

N·m for newton meter

In the case of W·h, the dot may be omitted, thus:

$$Wh$$

An exception to this practice is made for computer printouts, automatic typewrier work, etc, where the raised dot is not possible, and a dot on the line may be used.

9. When dividing unit symbols, use one of the following forms:

$$m/s \quad or \quad m \cdot s^{-1} \quad or \quad \frac{m}{s}$$

In no case should more than one slash be used in the same expression unless parentheses are inserted to avoid ambiguity. For example, write:

$$J/(mol \cdot k) \quad or \quad J \cdot mol^{-1} \cdot K^{-1} \quad or \quad (J/mol)/K$$

but *not*

$$J/mol/K$$

10. Do not mix symbols and unit names in the same expression. Write:

$$\text{joules per kilogram} \quad or \quad J/kg \quad or \quad J \cdot kg^{-1}$$

but *not*

$$\text{joules/kilogram} \quad nor \quad \text{joules/kg} \quad nor \quad \text{joules} \cdot kg^{-1}$$

INTRODUCTION

Environmental Microbiology encompasses numerous levels of organization ranging from microbial genes to microbial ecosystems. It is the study of the activity of indigenous microorganisms in their habitats and their interactions with other microorganisms or higher organisms. It is also the study of the fate of microbial pathogens and microscopic parasites outside their hosts in natural environments such water, sediments, soils, air, and engineered systems. Environmental microbiology also deals with the applied aspects of microbiology as regards the environment, agriculture, food and water quality, resource recovery, water and wastewater treatment, and human and animal health.

This Encyclopedia was designed to provide the most comprehensive coverage of the various fields within Environmental Microbiology. We have identified 14 areas within this discipline. These areas are illustrated in Figure 1 (the names of associate editors for each area are indicated in the figure).

IDENTIFIED AREAS IN ENVIRONMENTAL MICROBIOLOGY

Aeromicrobiology is the study of microorganisms found in the air and the public health implications of airborne microbes (fungi, bacteria, viruses), their metabolites (e.g., mycotoxins), and cell components. Several entries deal with the public health aspects (e.g., allergies) of airborne fungi, especially in indoor environments. Airborne microbes under agricultural and industrial settings are also covered. Other entries deal with models to predict the dispersion and fate of microorganisms in the airborne state. A current preoccupation of public health officials around the world is bioterrorism which concerns the intentional release of pathogenic microorganisms in the air (e.g., *Bacillus anthracis*) for harmful purposes.

The ***aquatic microbiology*** area covers various types of aquatic environments, including freshwater, estuarine and marine waters, groundwater, wetlands, and aquatic sediments. Some of these environments (freshwaters, marine waters) have long been studied by microbiologists and limnologists while others (groundwater, wetlands) have been investigated only during the past 20 years. This vast area necessitated the enlisting of three associate editors to tackle the task.

Freshwater microbiology entries included some on bacteria, cyanobacteria, fungi, algae and protozoa and their activities in lakes, rivers, streams and wetlands. Paleolimnology is also addressed through the use of paleolimnological indicators such as algal pigments and remains (e.g., diatoms) to reconstruct past environmental changes in aquatic environments.

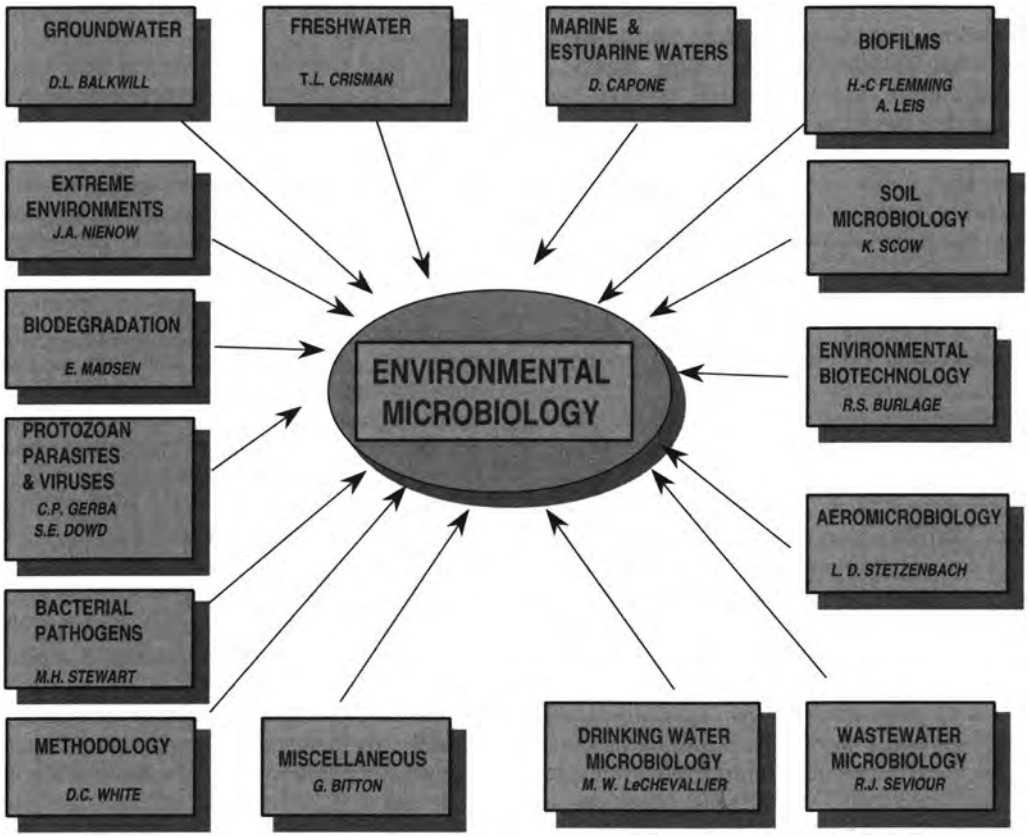

Figure 1.

Marine waters represent approximately 97% of the aquatic environment on planet Earth. This explains the attention given to this environment by marine microbiologists around the globe. Planktonic microorganisms in the oceans and seas serve as food for higher organisms and are the base of the food chain. The marine plankton includes algae, bacteria (eubacteria, cyanobacteria, photosynthetic bacteria), fungi, viruses and protozoa. Algae are responsible for primary productivity in the water column while bacteria play a crucial role in nutrient (N, P, S) and metal cycling in both the water column and the sediments. This encyclopedia also covers chapters on archae including methanogens, red tides and other harmful algae, plant-microorganisms interactions and seagrass microbial communities. The marine environment is the home of a wide range of microorganisms, many of which can be tapped for biotechnological applications which include pharmaceuticals, biomaterials, enzymes, nutritional supplements and other useful products.

The goal of **subsurface microbiology** is the study of the microbiology of subsurface sediments and formations as well as groundwater. Prior to the 1970s, research on this hidden resource was focused on groundwater supply. In the 1970s, researchers directed their attention to groundwater quality, leading to continuing studies on contamination of this precious resource by microbial pathogens and chemical contaminants. The 1980s saw the focus shifting to subsurface sediments with studies on characterization of subsurface microorganisms, their concentrations, and their activity. Cultivation techniques and molecular biology tools showed the existence of a wide range of bacterial types. The phylogenetic characteristics of culturable bacteria from diverse subsurface environments has been undertaken in the U.S., but only a small fraction of approximately 13,000 isolated strains has been characterized. We know now that microorganisms exist in subsurface environments extending to a depth of approximately two miles and possibly beyond this depth. Energy sources, both organic and inorganic, occur at relatively very low concentrations, enough to sustain the microorganisms in this oligotrophic environment. Subsurface microorganisms are stressed, starved, display very low metabolic activity and remain in a dormant state for very long periods of time (thousands to possibly millions of years).

Soil microbiology is one of the oldest subdiscipline within environmental microbiology. Soils play a key role in the life support system on planet Earth. A combination of physical, chemical and biological factors play a role in their formation. Soil microorganisms (bacteria, fungi, protozoa) interact with organic matter, mineral particles, water and gases, the major components of this complex ecosystem. They play a key role in nutrient cycling and affect soil quality by mineralizing plant nutrients, improving soil structure, processing plant residues into organic matter, and degrading toxic compounds in soils, particularly chemical pesticides used in modern agriculture. Rhizosphere microbial communities enter into symbiotic or mycorrhizal associations with plant roots, leading to promotion of plant growth. On the other hand, fungal and bacterial pathogens are the cause of plant diseases with the subsequent decrease in the yield of agricultural crops. Due to serious concerns for human and animal health and for the environment, attempts are being made to use microbial control agents or biopesticides in lieu of chemical pesticides to control plant diseases, nematodes or insects. The most successful biopesticide marketed for insect control is *Bacillus thuringiensis* which produces a toxin that is lethal to insect pests. Unfortunately, soils are becoming the receptacles of a wide range of toxicants, pathogens and parasites as a result of human activities which include agricultural practices, industrial and mining operations, and disposal of liquid and solid wastes. As regards soil contamination by hazardous wastes, current research is addressing soil bioremediation which consists of enhancing the biodegradation capacity of indigenous soil microorganisms or using genetically engineered microorganisms.

Advances in molecular genetics have helped launch the field of soil genetic ecology with the goal of studying gene exchange, microbial community fingerprinting, analysis of functional genes that code for key enzymes, and the phylogenetic diversity of microorganisms in soils. It is estimated that there are approximately 10,000 bacterial species in one gram of soils. Culture-based techniques yield only a very small fraction (<1%) of the total number of species uncovered by using molecular biology techniques such as amplified rDNA restriction analysis (ARDRA), polymerase chain reaction (PCR), denaturing gradient gel electrophoresis (DGGE) or terminal restriction fragment length polymorphism (T-RFLP). Soil genetic ecology may benefit from the use of microarrays (gene chips). All of these efforts may lead to some potential industrial applications.

Dr. Rick Cavicchioli, from the university of New South Wales, characterized the extremophiles as the *"bungi jumpers "* of the microbial world. There are 36 entries covering this theme in the Encyclopedia. These microorganisms are able to survive and grow in ***extreme environments*** with regard to environmental factors such as temperature (psychrophiles, hyperthermophiles), pH (acidophiles, alkaliphiles), salt concentration (halophiles), hydrostatic pressure (barophiles), water activity (xerotolerant microorganisms), microgravity, ionizing radiation, light (e.g., growth under low-light in caves), interfaces such as the air-water interface, nutrient concentration (oligotrophs), and in the presence of toxic chemicals (toxitolerant microorganisms). This area is important to environmental microbiologists who want to gain knowledge on the limits and the origin of life on Planet Earth and potentially in Space. Some of these extreme environments (e.g., permafrost) could serve as models for potential life in other planets and for attempting to answer the question of life preservation on Earth. An active research area concerns the biotechnological applications of these extremophiles and their products.

Research on ***biodegradation*** in water, soil, sediments, wastewater treatment plants is now receiving increased attention by microbiologists around the world. Microorganisms play a key role in biogeochemical cycles, particularly the carbon cycle. During the last few decades, an array of foreign compounds called xenobiotics (i.e.,

foreign to biological systems) was introduced into the environment. These compounds are generally resistant or recalcitrant to degradation by microbial action. The topics addressed in this area include the biodegradation of halogenated aromatics, petroleum and other hydrocarbons, reductive dehalogenation and metabolism of haloorganics, or fuel oxygenates, as well as the methodology to assess the biodegradability of these recalcitrant compounds. Some chemicals such as the halogenated organic compounds (halogenated hydrocarbons, halogenated aromatics, pesticides, PCBs; dioxin, polychlorinated dibenzofurans) are quite resistant to microbial action. Biotechnological applications of this research include mainly the bioremediation of soils and aquifers.

Public health microbiologists deal with the fate (transport and survival) of pathogenic microorganisms and parasites in the environment, and with the development of the appropriate methodology for their detection in environmental matrices. This information is useful for assessing the risk they pose to humans and animals, and for indicating preventive measures for avoiding or reducing human exposure to these harmful agents. During the past three decades we have witnessed dramatic advances in the methodology for detection of pathogenic microorganisms and parasites in environmental samples, including wastewater, drinking water, soils, biosolids, freshwaters, marine waters, sediments, and air. Three associate editors have been assigned to this vast subdiscipline in environmental microbiology. One editor dealt with bacterial pathogens and the two others dealt with viruses and protozoan parasites. Most of the "classical" bacterial pathogens are included (e.g., *Vibrio cholera*, *Salmonella*, *Shigella*, *E. coli*, *Pseudomonas*, *Mycobacterium avium* Complex, *Leptospira*, *Legionella*, *Campylobacter*) as well as emerging pathogens such as *Helicobacter pylori* for which there are indications that it may be transmitted via the waterborne or food-borne routes. The biology, methodology (concentration and assay), risk assessment, and fate in the environment of a wide range of pathogenic viruses are discussed in this encyclopedia. The list include enteroviruses, hepatitis viruses, human caliciviruses including the Norwark virus, rotaviruses, astroviruses, and adenoviruses. In recent years, research has focused on the epidemiology, methodology, fate in the environment, including food, and risk assessment of protozoan parasites which produce hardy cysts or oocysts which persist in the environment. Furthermore, they are not completely removed following passage though water and wastewater treatment plants and are generally resistant to disinfection. The list of parasites covered in this work include *Cryptosporidium*, *Giardia*, *Entamoeba histolytica*, *toxoplasma gondii*, *Isospora*, *Cyclospora*, microsporidia, and free-living amebas. The detection of bacterial and viral pathogens, and protozoan parasites discussed above requires costly and time-consuming methodology as well as well trained labor. The use of microbial indicators of fecal contamination is thus required. These indicators include total coliforms, fecal coliforms, *E. coli*, fecal streptococci/enterococci, *Clostridium perfringens* and bacterial phage.

Public health microbiologists, in collaboration with environmental engineers, must also work towards reducing the pathogen and parasite load in domestic wastewater, biosolids, and drinking water.

Drinking water *microbiologists* seek to understand the mechanisms behind the removal/inactivation of microbial pathogens and parasites, cyanobacterial toxins, algae, and microorganisms responsible for taste and odor problems, by various processes involved in water treatment plants. These processes include coagulation-flocculation, filtration (sand, activated carbon), water softening, disinfection (e.g., chlorination, ozonation, U.V irradiation) and, more recently, biological treatment of water. It is now realized that organic compounds, present at very low concentrations (μg/L levels) in water distribution systems, are responsible for the formation of trihalomethanes microbial regrowth in distribution pipes, and chlorine demand with the subsequent reduction of free available chlorine. Special topics such as home treatment devices, cistern water and bottled water are also covered in the encyclopedia.

The objectives of **wastewater treatment** are the reduction of organic compounds (i.e., BOD reduction) and suspended solids in wastewater, removal/reduction of nutrients (N, P) and toxic trace organics and metals to avoid or at least pollution of receiving waters,, and removal/inactivation of pathogenic microorganisms and parasites. Microorganisms (bacteria, fungi, protozoa) play a crucial role in the biological treatment of wastewater, particularly in BOD and nutrient removal. Several chapters in this encyclopedia are devoted to the microbiology of activated sludge, trickling filters, waste stabilization ponds, biofiltration, biosolids treatment and disposal, and to the use of wetlands, reed beds, algal turf scrubbers, septic tanks or landfills to treat domestic wastewater and municipal solid wastes. The activated sludge process is often prone to solid separation problems such as filamentous bulking and foaming. The physiology, growth kinetics, and control of filamentous bacteria are covered in a few chapters.

Biofilms develop on biological and non biological surfaces immersed in water and wastewater. They are ubiquitous in natural aquatic environments (e.g., stream beds) and in engineered systems (e.g., fixed-film bioreactors). While they are beneficial in fixed-film bioreactors (biological treatment of drinking waster and wastewater) or in groundwater (biodegradation of organic pollutants), their accumulation leads to problems in water distribution pipes, biofouling which adversely affect the performance of artificial structures, and to medical problems such as dental plaques or colonization of artificial implants, leading to increased infection in patients.

The colonization process starts with chemical conditioning of the surface, followed by microbial colonization and finally by macroorganisms. Bacteria, the first colonizing microorganisms, excrete extracellular polymeric substances that help "cement" the biofilm onto the surface. Eukaryotes (algae, fungi, protozoa) are also part of the biofilm microbial community. The members of this community display increased exchange of nutrients

and metabolites, facilitated gene exchange, protection from grazing, and increased resistance to toxic chemicals. Members use quorum sensing to communicate with one another. Signaling chemicals consist of homoserine lactones in gram-negative bacteria. Various techniques have been developed for studying biofilm microorganisms. Molecular techniques (e.g., rRNA-based methods, fingerprinting techniques) and other techniques such as laser scanning microscopy are now available for identification of biofilm microorganisms. Other methods are useful for determining the metabolic activity of these microorganisms. Specific biofilms covered in the encyclopedia include diatom and bacterial-fungal biofilms, and biofouling in industrial systems and its control. A few other important topics related to biofilms include biodeterioration of mineral surfaces, bioleaching, biocorrosion, microbial weathering, biofilms in natural and drinking water distribution pipes, and biofilms in the food industry.

Humans have exploited microbes and their products for thousands of years. Wine is the classical example of a biotechnological product, although the involvement of microscopic yeast cells in the process was not known until the pioneering work of Pasteur. Today, biotechnologists have developed a myriad of modern techniques and processes that use microorganisms and their products (e.g., enzymes, biosurfactants, compatible solutes, ice nucleating proteins) for the benefit of humans, animals and the environment. The microorganisms covered in this encyclopedia include archaea, bacteria (e.g., methanotrophs, sulfate reducing bacteria), algae, and fungi. The advances made in **biotechnology** are benefiting the fields of medicine, agriculture and environmental remediation. Much hope is now placed on marine microorganisms and extremophiles (especially those belonging to the archaea domain) for biotechnological breakthroughs. A wide range of useful products are now derived from hyperthermophiles, psychrophiles, halophiles, alkaliphiles and acidophiles, benefiting medicine, molecular biology, bioremediation, as well as the food, pharmaceutical, pulp and paper or the oil industries.

The encyclopedia also covers the biotechnological aspects of processes such as bioleaching of metals, desulfurization of coal, treatment of waste and air or bioremediation of contaminated soils and aquatic environments.

The achievements of researchers in all the areas of environmental microbiology discussed earlier would not have been possible without the development of adequate **methodology** to tackle the various tasks. This area is extremely important to our understanding of the role of microorganisms in their natural settings, including those inhabiting extreme environments. We have witnessed significant advances in our ability to determine the numbers, biomass, activity, injury, and death of microorganisms in environmental samples. The development of genetic probes, such as the 16S rRNA-targeted probes, has increased our knowledge of phylogenetics and microbial community structure in water, sediments, soils or biofilms, and has helped tremendously in the detection of microbial pathogens and parasites in complex environmental matrices. Methods covered detail in several entries of this encyclopedia, deal with the identification of microbial isolates, flow cytometry, biochip-based devices (i.e., microarrays) for microbial community ribotyping, image analysis, biophotonic imaging, bioreporters, fluorescent in situ rRNA probes, lipid biomarkers, phylogenetics, **ribotyping, capillary electrophoresis, and methods for specifically detecting microbes such as archaea or psychrophiles.**

It is hoped the information presented in this encyclopedia will be the catalyst for more exciting research on the role of microorganisms in the environment, the control of pathogenic and parasitic microorganisms by engineered treatment systems which serve as safeguards against disease occurrence in humans and animals, a better understanding of life at the edge, and the beneficial use of microorganisms for restoring the environment, and improving our quality of life.

Bendigo, Australia

One of the major solids separation problems in activated sludge plants is the occurrence of a thick stable viscous scum on the surface of aeration tanks or sedimentation tanks (Fig. 1). This scum, or foam, a result of overgrowth of certain microbes in the activated sludge, causes a number of operational problems (extra maintenance, reduction in oxygen transfer, poor effluent, foam in anaerobic digesters) and is a potential health hazard (spread of pathogens) as well. It occurs often in activated sludge plants [e.g., 50% of plants surveyed in Italy recently exhibited foaming (1)]. Some consider that foaming has become the most serious operational problem in activated sludge systems today (2). In this review, I will discuss the organisms that cause the problem, factors affecting foam formation, and methods currently used to control the problem. There is more emphasis on recent issues. For an examination of earlier studies on the microbiology and control of foaming, see References 3 and 4. Other types of foam are sometimes experienced due to nonbiodegradeable detergents and foaming at plant start-up, but these foams are not stable (5) and are not considered here.

WHAT IS FOAMING?

Foam formation has been described as a flotation process involving interaction among gas bubbles (produced by the aeration system), surfactants (these can be produced by many microbes in the plant and be present in the incoming waste), and hydrophobic particles, principally the "foam-forming" microorganisms (4). The foam is made stable through the presence of surfactants and hydrophobic particles. Nonfilamentous microbes may also contribute to foam formation, particularly through their emulsifying ability (6).

WHICH MICROBES CAUSE FOAMING?

The principal method used for identifying the causative organisms in activated sludge mixed liquor and foam have been the microscopic methods based on early work by Eikelboom (7,8). These have been published in a number of manuals (5,9,10). Although foam formation was originally attributed to an actinomycete called "*Nocardia*," surveys using these methods (11–14) have shown that the main foam-forming organisms belong to a number of different morphological types, including branched and unbranched filaments and nonfilamentous forms.

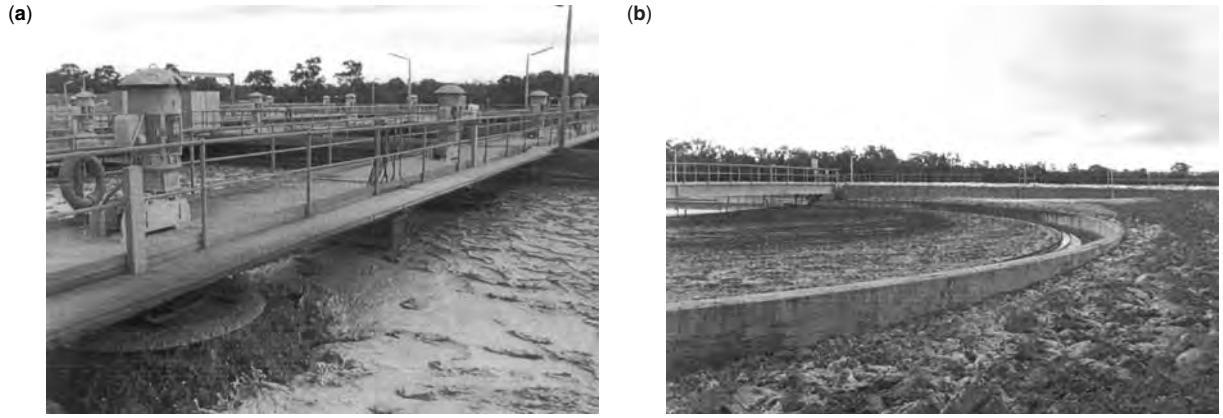

Figure 1. (**a**) Foam on surface of aeration tank, (**b**) major foam overflow. Photos: Wayne Murdoch, Coliban Water, Bendigo, Australia.

Microthrix parvicella

Microthrix parvicella is a long coiled unbranched gram-positive filamentous actinomycete (Fig. 2a). It has been the major cause of foaming in Europe (1,2,15), Australia (13,14), and South Africa (11,12), but less common in published reports from the United States. It appears to be more prominent in biological nutrient removal plants (12), and its appearance may be temperature related because it appears in larger numbers in cooler months in Europe

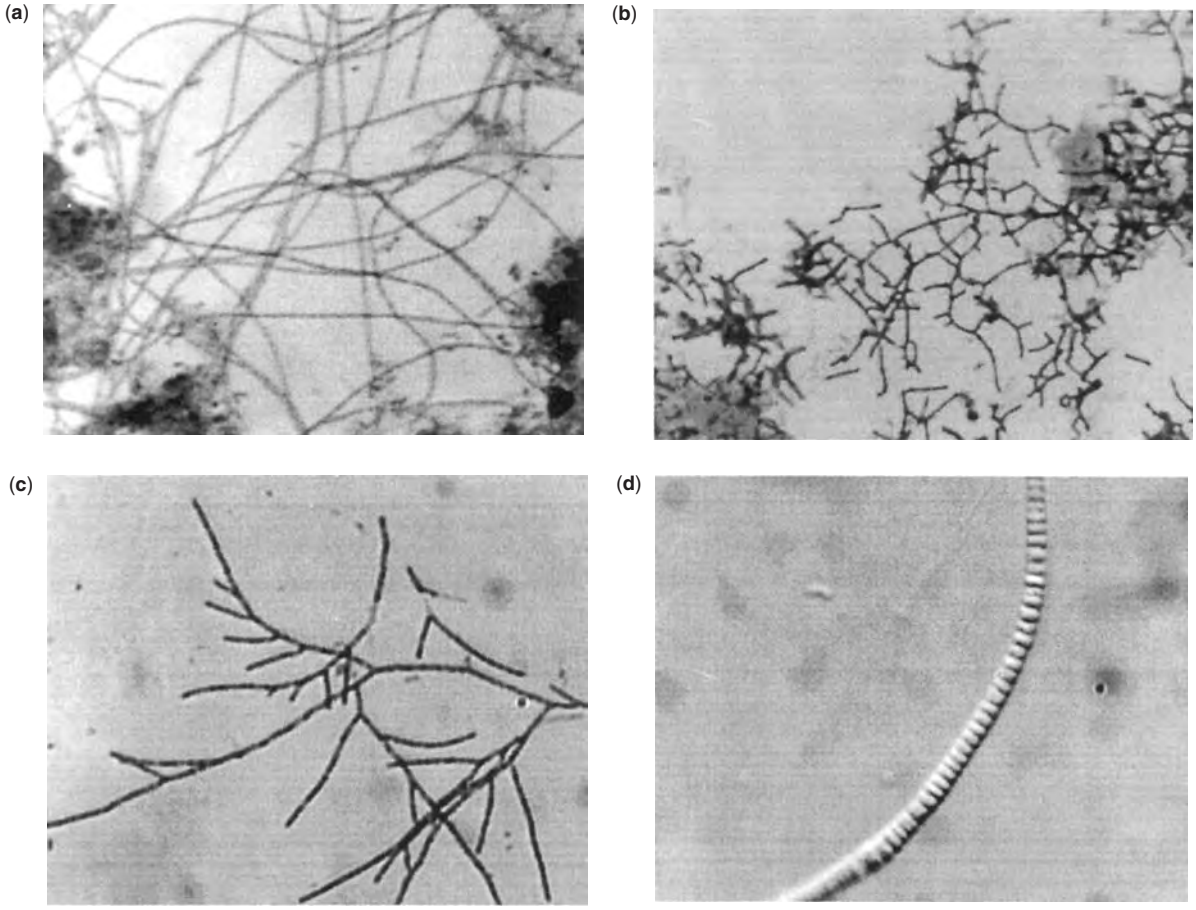

Figure 2. (**a**) Long coiled unbranched filaments of *M. parvicella*, (**b**) GALO (*Gordonia amarae*-like organism) or Nocardia showing typical right-angled branching, (**c**) *Skermania piniformis*, with its tree-like branching, (**d**) *Nostocoida limicola* II. Photos: Beth Seviour, Biotechnology Research Centre, Bendigo, Australia.

(15,16) and is more prominent in cooler regions of Australia (13). It is also responsible for bulking - another solids separation problem in activated sludge.

The taxonomy of *M. parvicella* has now been resolved despite difficulty with growing the organism in the laboratory (17) — it is a deep-branching member of high percentage molecular G + C group of actinomycetes closest to *Acidimicrobium ferrooxidans*. Organisms related to *M. parvicella* have been found in diverse environments, for example, a peat bog in Germany, geothermally heated soil in New Zealand, soil in Australia, and various marine environments in Japan and Finland. However, *M. parvicella* still has *Candidatus* status as it has not yet been fully characterized due to poor growth on conventional media (17).

Growth of *M. parvicella* occurs when aeration is intermittent, but is suppressed under continuous oxygen supply (18). This may be related to its requirement for reduced sulfur and nitrogen compounds, which may not be present in adequate quantities in fully aerated systems (18). It also explains why the organism is commonly found in biological nutrient plants (BNR), which have both anaerobic and anoxic stages.

Recent studies using microautoradiography (MAR) confirmed earlier studies by Slijkhuis, which showed that *M. parvicella* will only grow on long-chain fatty acids (or their Tween esters) but not on simpler substrates (19). However, another study contradicted these studies in finding some growth on acetate (20). The MAR studies (19) showed that uptake of long-chain fatty acids occurred under aerobic, anaerobic, and anoxic conditions, but there was no proof that they were actually metabolized under anoxic and anaerobic conditions (they may only have been incorporated as storage compounds). This rapid uptake of lipids probably explains the high lipid content of *M. parvicella*, which can approach 35% dry weight (21).

A property of the organism that has implications in foam control is its very high resistance to chlorination compared to other filamentous microbes found in activated sludge (22,23).

Although its significance is not known, there appears to be a link between dominance of sludge by *M. parvicella* and high levels of uronic acids produced in the extracellular polymers in the sludge (24).

Gordonia amarae-like Organisms (GALO)

These bacteria are shorter branched gram-positive filaments with branches at approximately 90° (Fig. 2b). They are commonly reported as *Nocardia*, but are sometimes called NALO (*Nocardia amarae*-like organism) because their morphology is similar to *N. amarae* (25) and because other mycolic acid–containing actinomycetes may also have similar morphology under certain conditions. Since *N. amarae* was reclassified as a *Gordonia* (26), our laboratory now uses the term *G. amarae*-like organisms or GALO to describe these morphotypes.

Although organisms such as *M. parvicella* and *S. piniformis* can be readily identified using microscopy, the morphotype described as GALO (*Nocardia*) represents many related organisms and hence cannot be identified to genus level by microscopic morphology alone. Recent advances in the taxonomy of these microorganisms have clarified that organisms with GALO morphology belong to a number of genera: *Nocardia*, *Gordonia*, *Tsukamurella*, *Rhodococcus*, and *Dietzia* (4). These are all actinomycetes, which contain mycolic acids in their cell walls (together with *S. piniformis*, but not *M. parvicella*). The following have been isolated in *pure culture* from foam, illustrating the diversity of mycolata found in activated sludge: *G. amarae*, *Gordonia terrae* and *Gordonia sputi*, *Nocardia asteroides Nocardia farcinica*, *Nocardia otitidiscaviarum*, *Rhodococcus coprophilus*, *Rhodococcus equi*, *Rhodococcus erythropolis*, *Rhodococcus globerulus*, *Rhodococcus rhodochrous*, *Rhodococcus ruber*, *Rhodococcus rubra*, *Tsukamurella paurometabola*, *Tsukamurella spumae*, and *Dietzia maris* (4). In addition, there are many new species belonging to most of these genera, and *Mycobacterium* (27–29) and maybe even new genera (29).

The mycolic acid containing actinomycetes are aerobic organisms and are stimulated by increased dissolved oxygen concentrations (30). Hence they can be controlled by biological selectors, which reduce dissolved oxygen. Although these organisms have traditionally been thought to occur in plants with long sludge age, some GALOs have particularly fast growth rates and may not be washed out by reducing sludge age.

Many wastes from food and chemical industries contain hydrophobic substrates such as vegetable oils, greases, and hydrocarbons, and these may cause problems in activated sludge plants (31). The mycolic acid–containing actinomycetes readily use such substrates, but with varying growth rates and affinities (29,32–34). The hydrophobic nature of foam-formers with GALO morphology allows them to attach to hydrophobic substrates rather than to grow in the aqueous phase. This may give them a means of competing with faster growing organisms present in the aqueous phase of activated sludge (34,35).

The mycolic acid–containing actinomycetes grow at a range of temperatures (36). Those growing at lower temperatures (5 °C) are principally rhodococci. Therefore, the so-called *Nocardia* foams at low temperatures are more likely to be caused by the *Rhodococcus* species. Some foam isolates can grow at 40 °C or higher, suggesting these are more likely to occur in plants treating warm wastewater, or possibly could grow in the foam itself when ambient air temperatures are high (36).

Skermania piniformis

Skermania piniformis is a branched filamentous actinomycete with a treelike appearance (Fig. 2c), and is the only *Nocardia* with morphology sufficiently different to allow identification in its own right (37,38). However, most surveys do not differentiate it from *Nocardia* or GALO. Hence its true incidence outside Australia, where most studies have been carried out, is unknown. It was originally called PTLO (pine treelike organism) because of its treelike branching morphology, but was then classified as *Nocardia pinensis* (39). More recently, these PTLOs were reclassified as a new genus, with only one member, *S. piniformis* (40). *Skermania piniformis* is usually associated with plants operating at sludge ages greater than 20 days (14), and grows over a relatively narrow

range of temperatures (15–30 °C), but this is still sufficient to cause problems in many plants (36). *Skermania piniformis* grows better on hydrophobic substrates such as olive oil and Tween 80 than on glucose (34) as well as other hydrophobic substrates (29).

Nostocoida limicola

Nostocoida limicola is an unusual filamentous bacterium containing chains of rounded cells (Fig. 2d). Recent European surveys suggest it appears in foam more commonly than previously thought (2,6,41). Although there are three morphotypes, these surveys did not differentiate among *N. limicola* types I, II, and III, which are now known to belong to separate, unrelated genera (42,43). The foam-former is probably *N. limicola* II, which is now recognized as Candidatus *N. limicola* II (44), belonging to the Intrasporangiaceae. It is phylogenetically closely related to and probably a member of the same genus as cocci in the genus *Tetrasphaera*, also isolated from activated sludge (45). *Nostocoida limicola* II is a low F : M organism (5). Increasing the F:M ratio causes it to lose its competitive advantage (30).

Others Filamentous Foam-Formers

Other filamentous microbes have also been associated with foam formation. Eikelboom Type 1863 is one of major causes of foam (after *Nocardia* and *Microthrix*) according to Jenkins and coworkers (5). Types 0675/0041 have a high incidence in some surveys, especially in biological nutrient removal plants (6,46). Other organisms such as Eikelboom Types 0092, 0041, 0803, 0413, 1851, 021N, 0914, 0581, 1701, *Haliscomenobacter hydrossis*, *Sphaerotilus* sp, and cyanobacteria have been reported as the dominant organism in foam, but their incidence is usually low (3,4).

Nonfilamentous Foam-Formers

Closely related taxonomically to the branching filaments are nonfilamentous forms of some of the mycolic acid–producing actinomycetes, called "actinomycetes," as revealed in one survey (14) to differentiate them from GALO and *S. piniformis*. These "actinomycetes" were defined as gram-positive rods (often slightly branched or not at all) without the distinctive branching patterns of GALO or *S. piniformis*. Other studies support their importance (6,47). These nonfilamentous foam-formers have possibly been overlooked in earlier studies of foam as they are less obvious than the branching organisms we call GALO or "*Nocardia*."

Cocci have also been reported in nonfilamentous foams in some plants. These include gram-positive cocci in Australian plants (13,48), which may also be mycolata, as some of these undergo a coccus stage in the so-called rod-coccus life cycle. The gram-negative coccobacillus *Acinetobacter* sp. have also been described as the dominant organism in the foam of a nutrient removal plant (49), but its more important contribution to foaming is probably through the emulsifiers it produces (6), hence encouraging the growth of organisms such as *G. amarae* (50).

The Need to Identify?

Although in some cases simple identification based on morphology is adequate for monitoring an activated sludge plant, there are occasions when more precise identification could be important: (a) To assist with foam control of GALOs: Since GALOs have different growth rates, correct identification may indicate whether manipulation of sludge age will be successful as a control measure. For example, some rhodococci grow relatively fast (38) and reduction of sludge age may not be sufficient to eliminate these, although it will eliminate slower growing rhodococci and other GALOs. (b) Some foam-formers are pathogens: Although *G. amarae*, *S. piniformis*, and *M. parvicella* are not known to be pathogens, others organisms isolated from foam (e.g., *N. asteroides*, *N. farcinica*, and *R. equi*) are potential pathogens. Since identification of pathogens is not possible on morphological grounds, identification using molecular probes is likely to become important.

USE OF MOLECULAR PROBES IN FOAM

While probes have made in situ identification possible without the need to isolate an organism, the wide range of mycolic acid producing organisms present in activated sludge means that probes will probably still remain a research tool rather than a routine quality assurance tool for a few years yet, as the number of different probes necessary to make a complete analysis is fairly large. However, microarray/biochip probe technology (51) may eventually simplify such an analysis.

To date, probe studies have not explored the range of mycolata likely to be present in activated sludge. Most studies have concentrated on *Gordonia*, especially *G. amarae* (52–54) and *Rhodococcus* (47). It was concluded that *G. amarae* makes up only a small proportion of gordoniae found in foam, strains previously identified as *G. amarae* may represent two different species of *Gordonia*, and that a *Rhodoccoccus* probe detects both branching organisms and short rods. The use of confocal laser scanning microscopy is recommended to improve detection of organisms within flocs (47,55).

A probe based on an Australia isolate of *M. parvicella* has also been designed and successfully detected *M. parvicella* in European studies (56). However, unless the *M. parvicella* probe detects some unusual morphotypes (not to date), it is less likely to be more useful than conventional microscopy, which readily identifies *M. parvicella*.

MONITORING FOAM

Quantification is a prerequisite for rational investigation of foaming in activated sludge (57) and various quantification techniques for monitoring the level of organisms in foam and mixed liquor have been reported. These include measuring the abundance of filaments (5), immunofluorescence (58,59), use of a selective medium containing n-octodecane and nalidixic acid (60) and quantitative in situ hybridization (57).

However, many of these methods have problems, and choosing a meaningful method is difficult. Levels of

foam-formers in the mixed liquor are only meaningful if foaming has not occurred. Once foaming occurs, it separates to varying degrees. The foam-forming organisms from the mixed liquor and the level in the mixed liquor is not necessarily then meaningful. Another problem with quantification is that the mycolic acid–containing actinomycetes may be present as short rods or cocci, and branching filaments, and some methods do not address this problem, counting only filaments. Lack of specificity can also be a problem with the immunofluorescent techniques described.

Foaming potential of a biomass can also be measured through foam production by aeration under laboratory conditions (61) and hydrophobicity measurements.

HYDROPHOBICITY AND FOAM

Mixed liquor biomass is more hydrophobic in foaming plants than in nonfoaming plants, and onset of foaming incidents is often correlated with increase in cell surface hydrophobicity (CSH) (62,63). Therefore, there is interest in the hydrophobic properties of foam-forming organisms and their role in foam formation, particularly the hydrophobic mycolic acids present in the cell walls of GALOs and *S. piniformis*.

Pure culture studies with foam isolates of mycolic acid–containing actinomycetes show that the CSH varies with culture age, nutrient sources, and temperature (64), but variations in the mycolic acid composition have little influence on their CSH or foaming ability (Stratton and coworkers, 1999). However, using cell-water contact angles as a measure of CSH, studies of *Corynebacterium*, *Rhodococcus*, *Gordonia*, and *Mycobacterium* revealed a tendency for CSH to increase with mycolic acid size. An exception was *Mycobacterium*, which was less hydrophobic than *Gordonia* (65). Possibly other cell wall or excreted components neutralize the hydrophobic nature of the mycolic acids (66). Thus, although foam-formers are hydrophobic, the relationship between CSH and mycolic acids is complex.

There is also some evidence that *M. parvicella*, which does not contain mycolic acids, is also strongly hydrophobic (21).

FOAM CONTROL

There are many inconsistencies and disagreement as to which methods are the best, and many are based on anecdotal data. The best methods to use may depend on which organisms are causing the foam, but this is not possible if microscopic examination is not carried out. Microscopic examination will easily identify *M. parvicella*, *S. piniformis*, and *N. limicola* II, and action can readily be instigated based on our knowledge of the physiology of these organisms. However, if the foam-former is identified as a GALO, identification to species is more difficult. Consequently, choosing the right course of action may be more difficult (4). The most common approaches to foam control are summarized as follows.

Manipulation of Loading Rate

Washout of foam-forming organisms by reduction of sludge age or increase in F:M (Food:Microorganisms) ratio is commonly practiced. Reduction of sludge age should wash out slowly growing organisms but this does not always work since different foam-formers have different growth rates (4). *Microthrix parvicella* and *S. piniformis* are slow-growers and can be controlled this way, but this may be at the expense of nitrification, which requires a long sludge age. However, organisms with the morphology of GALO may represent both fast- and slow-growing actinomycetes, and therefore reduction of sludge age may not successfully control the foam.

Use of Selectors

Selectors, also known as contact zones (67), are separate reaction vessels added to the system to allow kinetic and/or metabolic selection of certain groups of microbes before the waste enters the main treatment basin. They can be aerobic, anoxic, and anaerobic (4). However, these are less successful for foaming control than for bulking control (2). Anoxic selectors favor growth of floc formers at the expense of *Nocardia*, but are not useful for *M. parvicella* foams because *M. parvicella* grows well anoxically.

There has recently been interest in two-stage selectors. One method (68) involves a first stage, which is aerated, but the second stage is capable of variable aeration. When the second stage was subjected to an aeration period of between 9 and 12 hours, the population of *M. parvicella* was reduced sufficiently to prevent stable foam formation in the aeration tank, but had no effect on *N. limicola*. Another approach is to have separate "feasting" and "fasting" units (69), which capitalize on the sensitivity of filamentous bacteria to F : M ratio, with the combined effect of both units resulting in the suppression of the overgrowth of filamentous bacteria without adversely affecting the organic treatment efficiency of the modified process.

Physical Methods

Some feel that physical methods rather than biological methods are more successful in treating foaming problems (2), and emphasize the proper design and construction of secondary clarifiers to avoid the escape of floating biomass to the final effluent. A number of different physical approaches have been used. Water sprays are used to physically break down the foam, but with mixed results, probably because of the stability of the foam (3). Physical removal of scum as it accumulates is also practised. A variation on this is to use a so-called classifying selector (70) to encourage flotation so that foam-formers rise to surface more rapidly, and then remove them. This reduced *Nocardia* levels, particularly when nonionic detergent was added to the system. It is important not to recycle any trapped foam back into the activated sludge biomass — this recycles the organisms that cause the problem.

Chemical Additives

The addition of chemicals to control foaming is always a consideration, but is in most cases an emergency

control method rather than a fundamental solution (23). A number of approaches have been described, with various degrees of success.

Chlorination. This kills filaments protruding from flocs but does not kill flocs unless too much chlorine is applied. Chlorination is useful, but care must be taken not to over chlorinate. *Microthrix* is possibly more resistant to chlorine than "Nocardia" (22,23). However, *G. amarae* is more sensitive to chlorine than nonfoaming organisms such as *Pseudomonas aeruginosa* and *Escherichia coli* in pure culture and in a laboratory scale plant (71).

Ozonation. Like chlorine, ozone is a strong oxidizing agent. Recent studies suggest that it can be useful in suppressing scum without affecting the rest of the biomass (72,73) added it to aeration tank at slightly higher levels and found that it eliminated foaming in the aeration tank. Ozone also improves sludge settleability and accelerates nitrification (72).

Antifoam. The use of antifoams is not often successful (46,74), probably because the foams they were developed against are usually much less stable than those experienced in activated sludge plants (75). They are also very expensive.

Bioaugmentation. These are commercial mixtures of microbes, sometimes supplemented with enzymes. They are expensive and often do not work, or need to keep adding for continued effect (therefore, expensive). In both lab-scale and full-scale experiments such mixtures do not appear to affect foaming, although in some cases, they resulted in a change of bacteria involved (from "*Nocardia*" to *M. parvicella*) (76).

Iron Salts. The dosing of mixed liquor with iron salts has also been successful in some instances, but the response appears to be variable (77). Iron salts have been found to be useful for a Rhodococcus induced scum, but laboratory trials with different cultures of mycolic acid containing actinomycetes showed a variable response to iron (78).

Addition of Polymers. Addition of cationic polymer to the clarifier to combat poor settling activated sludge resulted in the elimination of "*Nocardia*" foam after three days (79), probably by neutralizing and precipitating the foam-stabilizing anionic surfactants present in the wastewater. Successful suppression of foaming by *M. parvicella* through the addition of quaternary ammonium-based antifilament polymer has also been reported (23).

Manipulation of Cell Surface Chemistry. Addition of clay compounds such as bentonite, talc, zeolite, and montmorillinite can remove foam-forming organisms (63,80).

Appropriate Design

It is thought that subsurface culture withdrawal encouraged the growth of dispersed (i.e., free floating) *G. amarae* filaments rather than filaments within flocs; and these dispersed filaments are more likely to produce stable foams (81). This is equivalent to the situation in vessels with foam-trapping, which tend to have dispersed growth of "Nocardia" (79). It is now possible to design plants to minimize scum formation by eliminating any chance of surface trapping of scum in a reactor. There should be a free-surface flow in the reactor, with the whole surface layer moving through the reactor with essentially the same retention time as the bulk of the mixed liquor. This ensures that solids trapped on the surface do not have retention periods in excess of the liquid retention period, particularly the sludge age (82).

FOAMING IN ANAEROBIC DIGESTERS

Recent investigations into foaming in anaerobic digesters suggest that this problem is related to that in activated sludge plants. Digesters fed with sludge containing GALO or *M. parvicella* end up with the same organisms dominating the digester foam (52,53,83–87).

The operating strategy to prevent foam in the anaerobic digesters at these plants is to control the growth of *M. parvicella* in the activated sludge tanks by increasing the sludge load. Top installed stirrers and the addition of polyaluminum salt have also been used to prevent foam formation (86).

Pilot scale studies show that heat pretreatment of excess activated sludge with a high content of *M. parvicella* (87) and "*Nocardia*" (84) reduces its foam potential, but chlorination increases its foaming potential (85) when placed in an anaerobic digester.

ACTIVATED SLUDGE — MICROBIOLOGY OF NITROGEN REMOVAL

Ingo Schmidt
Marc Strous
Mike M. S. Jetten
University Nijmegen
Toernooiveld, The Netherlands

The elimination of inorganic nitrogen compounds plays an important role in wastewater treatment, because these compounds contribute significantly to the eutrophication of aquatic environments and are toxic to fish. Ammonium occurs as the main nitrogen component of untreated wastewater. Organically bound nitrogen is also released as ammonium. Generally, ammonium nitrogen is removed by biological treatment such as activated sludge systems or trickling filters. Removal is also effected by several chemical and physical methods such as precipitation, stripping, or ion exchange. The first step of biological ammonium elimination is nitrification. The oxidation of ammonium to nitrite is catalyzed by the ammonia oxidizing bacteria. The subsequent oxidation of the nitrite to nitrate is catalyzed by the nitrite oxidizing bacteria. In the course of denitrification, the second step of biological nitrogen removal, nitrite and nitrate are reduced to gaseous N-compounds such as nitric oxide, nitrous oxide, or dinitrogen.

THE BIOLOGICAL NITROGEN CYCLE

Nitrogen (N) is an element with oxidation states from −III to +V (Table 1).

Nitrogen is an important element in proteins, genetic material, and further essential organic molecules. In the atmosphere, nitrogen mainly exists as dinitrogen gas (N_2), where it constitutes about 78% of the atmosphere. Nitrogen is fixed by bacteria in primary production and is liberated as ammonium in the biological food chain (N-cycle). Part of the ammonium is returned to primary production and the bacterial processes of nitrification and denitrification recycle the surplus to the atmosphere as N_2.

Table 1. Oxidation States of Nitrogen

Compound	Formula	Oxidation State
Ammonium	NH_4^+	−III
Hydrazine	N_2H_4	−II
Hydroxylamine	NH_2OH	−I
Dinitrogen	N_2	0
Nitrous oxide	N_2O	+I
Nitric oxide (Nitrogen monoxide)	NO	+II
Nitrite	NO_2^-	+III
Nitrate	NO_3^-	+V

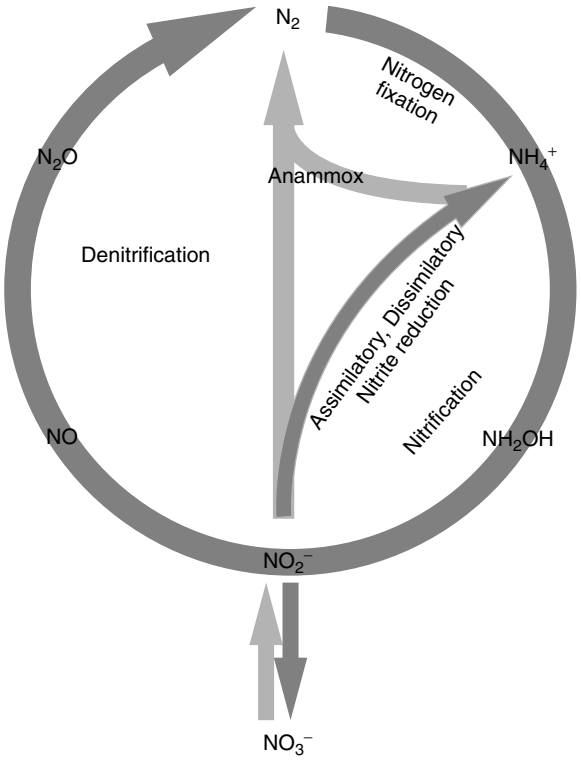

Figure 1. Biological nitrogen cycle.

The biological nitrogen cycle is shown in Figure 1. After fixation, nitrogen is available to other organisms in the form of ammonia/ammonium (NH_3/NH_4^+). It can subsequently be assimilated into biomass, or it can be used for energy generation by specialized bacteria in the process of nitrification.

Two groups of microorganisms are responsible for nitrification. Ammonia oxidizers catalyze the first step, the oxidation of ammonia to nitrite, and nitrite oxidizers catalyze the second step, the oxidation of nitrite to nitrate. Nitrate can be reduced to ammonia via nitrite. Further, nitrite and nitrate can be used as terminal electron acceptors during denitrification (anaerobic respiration) to form N_2. N_2O and NO may occur as intermediates in the process.

From a microbiological point of view, the nitrogen cycle (Table 2) is made up of four catabolic reactions (oxidation of ammonia, oxidation of nitrite, denitrification, and

dissimilatory nitrite reduction) and three anabolic reactions (ammonium assimilation, assimilatory nitrite reduction, and nitrogen fixation). Oxidation of ammonia can be divided into aerobic (O_2-dependent), anaerobic (NO_2-dependent), and anaerobic (nitrite-dependent, Anammox) oxidation of ammonia.

OXIDATION OF AMMONIA

Physiology of Ammonia Oxidation

The gram-negative ammonia oxidizers, for example, members of the genera *Nitrosomonas* and *Nitrosospira* (1) are lithoautotrophic organisms using carbon dioxide as the main carbon source. Species of the genera *Nitrosomonas* reveal extensive intracytoplasmic membrane (ICM) systems (Fig. 2). In *Nitrosococcus oceanus*, ICMs are arranged as a centrally located stack of parallel, flattered vesicles, and in other species, as flattened vesicles in the peripheral cytoplasm (e.g., *Nitrosomonas eutropha*). Recently, molecular tools that infer the presence of ammonia oxidizing bacteria in the environment have been supplemented by PCR primers for specific amplification of the ammonia monooxygenase structural genes *amoA*. Environmental 16S rRNA and *amoA* libraries extend the knowledge on the natural diversity of ammonia oxidizing bacteria. Comparative 16S rRNA sequence analyses revealed that members of this physiological group are confined to two monophyletic lineages within the *Proteobacteria*. *Nitrosococcus oceanus* is affiliated with the gamma-subclass of the *Proteobacteria*, whereas members of the genera *Nitrosomonas* and *Nitrosospira* form a closely related grouping within the beta-subclass of *Proteobacteria* (2).

Ammonia oxidizers are widespread in nature as well as in artificial ecosystems. Strains of different species have been isolated from fresh, brackish, and salt waters and soils. Some ammonia oxidizers are adapted to special, sometimes extreme environments. For example, strains of *Nitrosospira* have been isolated from acid tea soil at pH values of 4.6, *Nitrosomonas* strains from marine sediments with low temperatures, and from alkaline soda lakes with pH values above 10.0 (3).

Ammonia is oxidized in two steps. First, ammonia is oxidized to hydroxylamine by the ammonia monooxygenase (Eq. 1). This enzyme is unspecific and also oxidizes

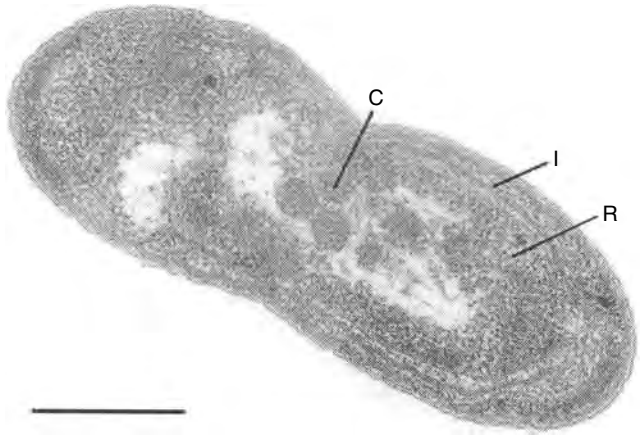

Figure 2. Electron micrograph of ultrathin sections of *N. eutropha*. C: carboxysome, Cy: cytoplasm with ribosomes (R), I: intracytoplasmic membranes. Bar: 0.5 μm.

several apolar compounds such as methane, carbon monoxide, or some aliphatic and aromatic hydrocarbons. These compounds can act as competitive inhibitors of ammonia oxidation. The second step (Eq. 2) in this metabolism is performed by the enzyme hydroxylamine oxidoreductase (HAO). This enzyme oxidizes hydroxylamine to nitrite. Two of the four electrons released from this reaction are required for the AMO-reaction and the remaining are used for the generation of a proton motive force in order to regenerate ATP and NADH.

$$NH_3 + O_2 + 2H^+ + 2e^- \rightarrow NH_2OH + H_2O \quad (1)$$

$$NH_2OH + H_2O \rightarrow HNO_2 + 4H^+ + 4e^- \quad (2)$$

$$NH_3 + O_2 \rightarrow HNO_2 + 2H^+ + 2e^- \quad (3)$$

ANOXIC METABOLISM (ANOXIC AMMONIA OXIDATION)

Recently, an anoxic metabolism (denitrification and oxidation of ammonia) in ammonia oxidizers (*Nitrosomonas*) was discovered (4,5). Furthermore, a new autotrophic

Table 2. Catabolic Reactions of the Nitrogen Cycle

Reaction		Equation
Ammonia oxidation	O_2-dependent	$NH_3 + O_2 \rightarrow HNO_2 + 2H^+ + 2e^-$
	NO_2-dependent	$NH_3 + N_2O_4 \rightarrow HNO_2 + 2NO + 2H^+ + 2e^-$
	Anammox	$NH_3 + 1.3HNO_2 \rightarrow 0.3HNO_3 + 1N_2 + 1.7H_2O + 0.6H^+ + 0.6e^-$
Nitrite oxidation		$HNO_2 + H_2O \rightarrow HNO_3 + 2H^+ + 2e^-$
Denitrification		$HNO_3 + 2H^+ + 2e^- \rightarrow HNO_2 + H_2O$
		$HNO_2 + H^+ + e^- \rightarrow NO + H_2O$
		$2NO + 2H^+ + 2e^- \rightarrow N_2O + H_2O$
		$N_2O + 2H^+ + 2e^- \rightarrow N_2 + H_2O$
Dissimilatory nitrite reduction		$HNO_2 + 6H^+ + 6e^- \rightarrow NH_3 + 2H_2O$

member of the order *Planctomycetales* was identified, oxidizing ammonia under anoxic conditions to N_2 with nitrite as electron acceptor via the intermediate hydrazine (6).

Denitrification by Ammonia Oxidizers

During oxic oxidation of ammonia by ammonia oxidizers, small amounts of nitric and nitrous oxide are released. Both gases are also produced in the course of aerobic denitrification by ammonia oxidizing bacteria. Additionally, the formation of dinitrogen is observed (5,7). In the absence of dissolved oxygen, *Nitrosomonas* is capable of anoxic denitrification (Fig. 3) with molecular hydrogen (4) or simple organic compounds serving as the electron donors, whereas nitrite is used as the electron acceptor. However, high aerobic denitrification activities were only obtained when the cells were grown under extremely oxygen-limited conditions. But under these conditions ammonia oxidation rates are low.

Anaerobic NO_2-Dependent Oxidation of Ammonia by *Nitrosomonas*

In the absence of dissolved oxygen, oxidation of ammonia has recently been observed in cultures of *N. eutropha* (5). These cells were able to replace molecular oxygen by nitrogen dioxide or dinitrogen tetroxide, respectively, in the course of ammonia monooxygenase reaction (Eqs. 4–6).

$$NH_3 + N_2O_4 + 2H^+ + 2e^- \rightarrow NH_2OH + H_2O + 2NO \quad (4)$$

$$NH_2OH + H_2O \rightarrow HNO_2 + 4H^+ + 4e^- \quad (5)$$

$$NH_3 + N_2O_4 \rightarrow HNO_2 + 2NO + 2H^+ + 2e^- \quad (6)$$

Hydroxylamine and nitric oxide were formed in this reaction. Although nitric oxide was not further metabolized, hydroxylamine was oxidized to nitrite, as shown, under oxic conditions. The nitrite produced was partly used as an electron acceptor, leading to the formation of dinitrogen (Eq. 7).

$$HNO_2 + 3H^+ + 3e^- \rightarrow N_2 \quad (7)$$

Equation 1 to 6 indicate that there are only a few differences between the anaerobic and the aerobic oxidation of ammonia by *N. eutropha*. Instead of O_2 in the course of aerobic oxidation of ammonia, N_2O_4 is used as electron acceptor and NO, an additional product, is released.

Effect of Nitrogenous Oxides on Oxidation of Ammonia

Ammonia oxidizing bacteria of the genus *Nitrosomonas* are inhibited when gaseous nitric oxide is removed from laboratory-scale cultures by means of intensive aeration. Nitrification starts again when nitric oxide is added to the gas inlet of the culture vessels (8). Using a laboratory-scale fermenter with complete biomass retention, it could be shown that nitrogenous oxides such as nitric oxide and especially nitrogen dioxide have a significant promoting effect on pure cultures of *N. eutropha* (9). Compared with cultures grown without these externally added nitrogenous oxides their addition resulted in a pronounced increase in nitrification rate, specific activity of ammonia oxidation, growth rate, maximum cell density, and aerobic denitrification capacity. Maximum cell numbers amounted to $2 \cdot 10^{10}$ *Nitrosomonas* cells per ml. Further, about 50% of the nitrite produced was aerobically denitrified to dinitrogen when nitrogen dioxide was present.

Recently, a new hypothetical model for oxidation of ammonia by *N. eutropha* was developed (10). A new complex role for nitrogen oxides in the metabolism of these organisms was proposed. Anaerobic oxidation of ammonia (Eqs. 4–6) is dependent on the presence of the oxidizing agent N_2O_4. NO is produced in stoichiometric amounts and released into the atmosphere. The situation is more complex under oxic conditions. In the presence of O_2, the produced NO can be oxidized to NO_2. According to the new model (Fig. 4), N_2O_4 is the oxidizing agent under oxic conditions. During the oxidation of ammonia,

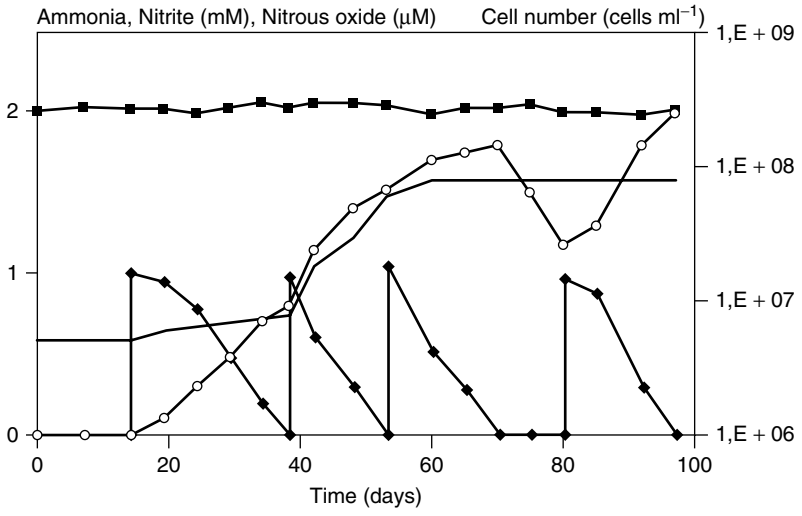

Figure 3. Denitrification and cell growth of *N. eutropha* in a hydrogen atmosphere with 20% carbon dioxide. Hydrogen, not ammonia, was used as electron donor indicated by decreasing the H_2 concentration (not shown), whereas the ammonia concentration remained unchanged. (■), ammonia; (♦), nitrite; (◯), N_2O; (−), cell number.

hydroxylamine and NO are produced as intermediates. Although hydroxylamine is further oxidized to nitrite, NO is (re)oxidized to NO_2 (N_2O_4).

The new hypothetical model is in agreement with the reaction described earlier for aerobic oxidation of ammonia. Although the total consumption rates (ammonia, oxygen) and production rates (hydroxylamine as intermediate) remain unchanged, the mechanism of the reaction is different.

ANAEROBIC AMMONIUM OXIDATION (ANAMMOX)

Engelbert Broda (1977) predicted the existence of chemolithoautotrophic bacteria capable of anaerobic ammonium oxidation (Anammox).

$$NH_4^+ + NO_2^- \rightarrow N_2 + 2H_2O \quad (8)$$

Only recently the experimental confirmation of Broda's prediction was described (6). The biological nature of the process was verified and nitrite was shown to be the preferred electron acceptor. Hydroxylamine and hydrazine were identified as intermediates. Bacteria were enriched in a mineral medium containing ammonia and nitrite, and bicarbonate was the only carbon source. The growth rate of the cultures was extremely low (doubling time three weeks), and reactor systems with very efficient biomass retention had to be used. The enrichments were dominated by a bacterium with a conspicuous distinctive morphology. The bacterium was physically purified from the enrichment by density gradient centrifugation (11). The purified cell suspension had high anammox activity and fixed carbon dioxide. The 16S rDNA gene of the bacterium was shown to branch very deep within the planctomycete lineage of descent. The anaerobic ammonium oxidizing *planctomycete*-like bacterium was named "*Candidatus* Brocadia anammoxidans." The 16S rDNA sequence information was used to design specific oligonucleotide probes for application in fluorescence in situ hybridization (FISH), and these probes were used to survey the presence of *B. anammoxidans* and related bacteria in several wastewater treatment systems with a very high nitrogen load and limited air supply. Indeed "*Candidatus* Brocadia anammoxidans" and the closely related "*Candidatus* Kuenenia stuttgartiensis" could be detected in many of these systems throughout the world (12).

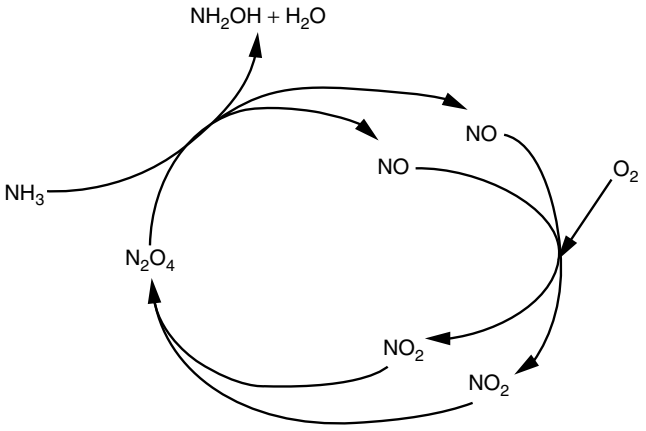

Figure 4. NO_x-cycle: New hypothetical model of ammonia oxidation by *Nitrosomonas*. According to this model, N_2O_4 is the oxidant for oxidation of ammonia. Under oxic conditions oxygen will be used to reoxidize NO to NO_2 (N_2O_4). Hydroxylamine will be oxidized to nitrite.

For the application of the Anammox process, it is important to know how *B. anammoxidans* coped with oxygen. Batch experiments showed that oxygen as low as 2 μM completely, but reversibly, inhibited the anammox activity. The obligately anaerobic nature of *B. anammoxidans* is in sharp contrast with the more versatile aerobic *Nitrosomonas*-like ammonium oxidizers.

As a result of this inhibition by oxygen, it seems likely that the aerobic ammonium oxidizing bacteria and *B. anammoxidans* are only able to coexist under oxygen limiting conditions. The ammonia oxidizers would oxidize ammonia to nitrite and keep the oxygen concentration low, and *B. anammoxidans* would convert the toxic nitrite and the remaining ammonium to nitrogen gas. By gradually supplying more and more air into an anammox sequencing batch reactor, it was indeed possible to establish such a cooperation. In the reactor, *Nitrosomonas*-like bacteria consumed the oxygen effectively, so that the actual oxygen concentration remained below the detection limit of 2 μM. Nitrite concentrations never exceeded 1 mM, indicating that *B. anammoxidans* was active as well. After five months wastewater with an ammonia concentration of 30 mM was converted into dinitrogen gas and some nitrate, according to Equation 9 (13).

$$2.5NH_4^+ + 2.1O_2 \rightarrow 0.2NO_3^- + 1.15N_2 + 3.6H_2O + 2.8H^+ \quad (9)$$

The microbial composition of the biomass in this reactor was analyzed with FISH, using *B. anammoxidans* (Amx820) and *Nitrosomonas* (Neu653) specific probes. Initially *B. anammoxidans* dominated (70%) but over time more and more *Nitrosomonas*-like bacteria were detected. Aerobic nitrite oxidizers (*Nitrobacter* or *Nitrospira*) were never detected, consistent with the absence of nitrite oxidizing activity in oxic batch tests.

The symbiosis of aerobic and anaerobic ammonium oxidizing bacteria is relevant for wastewater treatment. The experiments showed that ammonium can be removed in a simple, single oxygen-limited step. The process was named CANON (completely autotrophic N-removal over nitrite). Figure 5 shows images of CANON biomass after hybridization with labeled probes.

The introduction of anammox to N-removal would lead to a substantial reduction of operational costs. The process would be suitable to treat waters that contain high ammonium and little organic COD. The Anammox process would replace the conventional denitrification step completely and would also save half of the nitrification aeration costs.

The feasibility of anammox to treat sludge liquor was investigated in combination with the SHARON (single reactor system for high ammonium removal over nitrite)

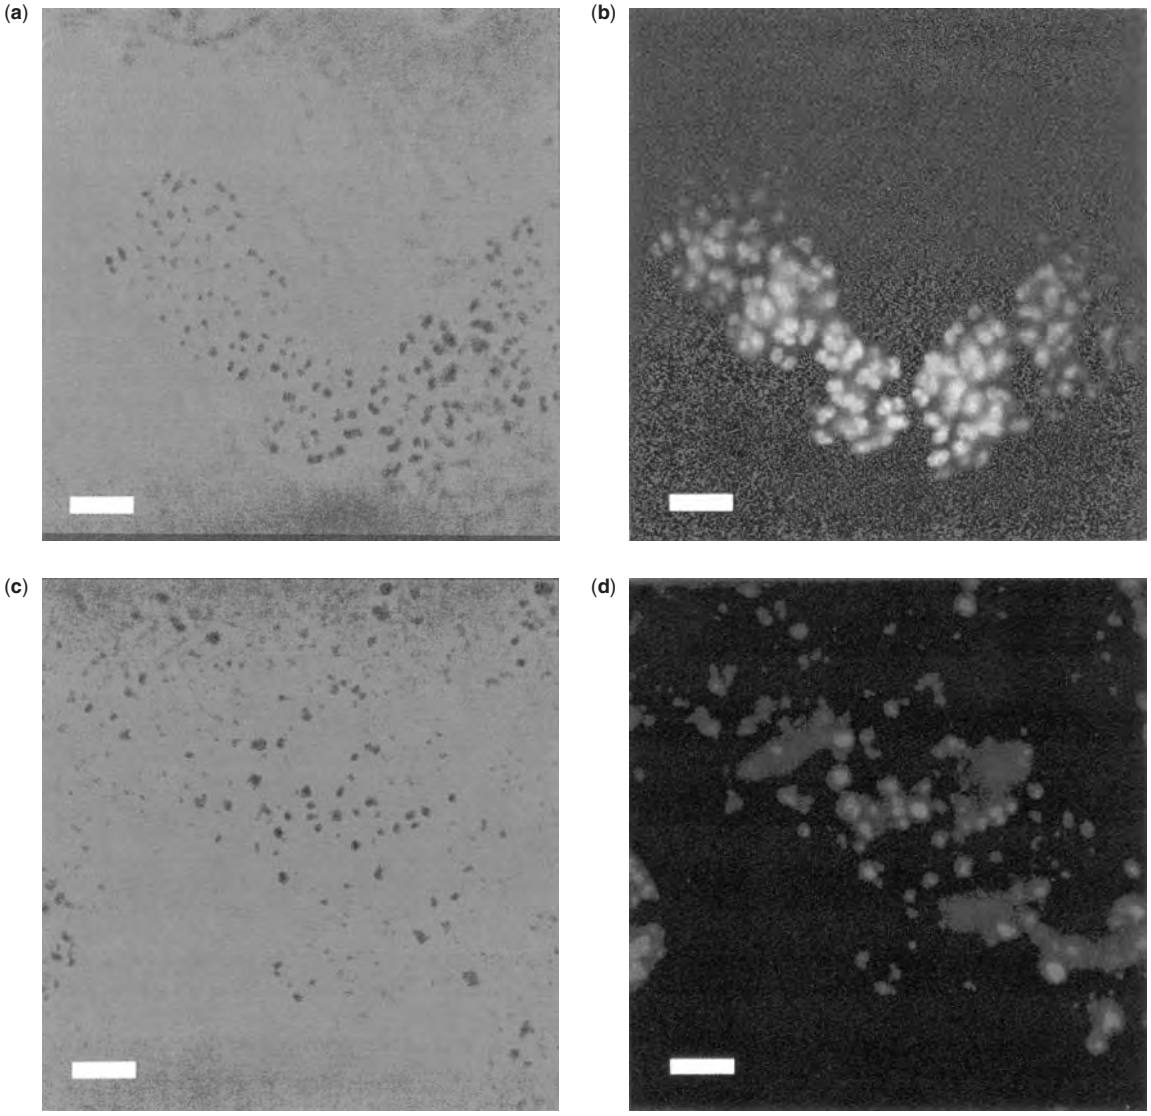

Figure 5. Phase contrast (a,c) and epifluorescence (b,d) images of biofilm aggregates from a CANON reactor after hybridization with Cy-3 labeled probes PLA46 (b, specific for planctomycetes) and BET42 (d, specific for beta proteobacteria, mainly nitrifiers in this case). The figure shows that both aerobic and anaerobic ammonium oxidizers are present in this reactor system for nitrogen removal from wastewater. Bar equals 5 micrometer. See color insert.

process. SHARON was developed recently for the removal of ammonium via the so-called nitrite route (14). It was tested for two years in the laboratory and successfully scaled-up to full scale (1,800 m^3) (15). Anammox needs ammonium and nitrite in a ratio of about one to one. This ratio can be achieved without control using the SHARON process as a prenitrification step. When half of the ammonium is converted, the alkalinity of the sludge liquor is depleted, leading to a pH drop and preventing further nitrification (Eq. 10).

$$NH_4^+ + HCO_3^- + 0.75O_2 \rightarrow 0.5NH_4^+ + 0.5NO_2^- + CO_2 + 1.5H_2O \qquad (10)$$

The feasibility of SHARON for the production of ammonium and nitrite (1 : 1) was demonstrated in a 20-L laboratory system (16). The ammonium was oxidized for 53% to nitrite at 1.2 kg N m^{-3} per day without pH control. The effluent of the SHARON reactor was fed directly to an anammox reactor system. This reactor removed all nitrite, and left some ammonium. During the test period the nitrogen load was 0.75 kg N m^{-3} per day. The specific activity of the anammox biomass was very high: 0.8 kg N (kg dry weight)$^{-1}$ per day.

The combined SHARON-Anammox process is presently evaluated for full-scale implementation. On the basis of the design of the combined SHARON-Anammox process, a cost estimate of 0.75 Euro kg^{-1} N was calculated. This is

very low compared with the 2 to 5 Euro kg^{-1} N estimated for other processes that have been tested on a pilot plant scale for N-removal from sludge liquors.

HETEROTROPHIC AMMONIA OXIDATION

The oxidation of ammonia, hydroxylamine, or organic nitrogen compounds, for example, oximes, to nitrite by various chemoorganotrophic microorganisms is called heterotrophic nitrification. The latter is a cometabolism, which is assumed not to be coupled to energy conservation. Heterotrophic nitrifiers are found among algae, fungi, and bacteria. Compared with those of autotrophic nitrifiers, nitrification rates of heterotrophic nitrifiers are low. Therefore, heterotrophic nitrification was thought to occur preferentially under conditions that are not favorable for autotrophic nitrification, for example, acidic environments. However, recent research has revealed that heterotrophic nitrification only contributes to a minor extent to overall nitrate production, even in acid soils. Recently, heterotrophic nitrification has received some attention, because it frequently occurs while accompanied by aerobic denitrification. In principle, this combination could lead to the elimination of dissolved nitrogen compounds in a single-step reactor system.

OXIDATION OF NITRITE

Physiology of Nitrite Oxidation

The second step in nitrification, the oxidation of nitrite to nitrate, is performed by nitrite oxidizing bacteria, for example, members of the genera *Nitrobacter*, *Nitrospira*, or *Nitrococcus*. Several strains of *Nitrobacter* and one strain of *Nitrospira* are the only nitrite oxidizers that are not restricted to marine environments (17).

The key enzyme of nitrite oxidizing bacteria is the membrane bound nitrite oxidoreductase, which oxidizes nitrite with water as the source of oxygen to form nitrate. The electrons released from this reaction are transferred via a- and c-type cytochromes to a cytochrome oxidase of the aa_3-type. However, the mechanism for energy conservation in nitrite oxidizers is still unclear. No electron transport chain linked to proton translocation could be found, a factor that is necessary to maintain a proton motive force for ATP regeneration. Thus, NADH is thought to be produced as the first step of energy conservation. The overall process deserves further research for complete elucidation.

Growth Characteristics of Nitrite Oxidizers

Nitrite oxidizers are generally lithoautotrophic organisms. Carbon dioxide is fixed as the main carbon source using RuBisCO, which is in part carboxysome-bound. Higher growth rates are obtained when the cells are maintained mixotrophically. In contrast to ammonia oxidizing bacteria, several strains of *Nitrobacter* are capable of heterotrophic growth under oxic as well as anoxic conditions. Heterotrophic growth is significantly slower than lithoautotrophic, although, 10- to 50-fold higher cell densities are obtained.

Oxidation of nitrite occurs under obligately oxic conditions. The involved organisms are much more sensitive to oxygen limitation than ammonia oxidizers are. At dissolved oxygen concentrations of about 0.5 mg l^{-1}, oxidation of nitrite is inhibited. Additionally, *Nitrobacter* is inhibited at high oxygen concentrations. Thus, the oxygen content of a nitrite oxidizing nitrification tank has to be maintained carefully to avoid accumulation of nitrite. With sufficient oxygen supply oxidation of nitrite proceeds at a faster rate than conversion of ammonia to nitrite. Therefore, high nitrite concentrations are rarely found in either natural environments or in wastewater treatment plants.

Denitrification by Nitrite Oxidizers

Some strains of *Nitrobacter* have been shown to be denitrifying organisms as well. Nitrate can be used as an acceptor for electrons derived from organic compounds to promote anoxic growth. Because the oxidation of nitrite is a reversible process, the nitrite oxidoreductase can reduce nitrate to nitrite in the absence of oxygen. Further, the nitrite oxidoreductase was purified together with a nitrite reductase, which reduces nitrite to nitric oxide. Evidence is given that the subsequent oxidation of nitric oxide to nitrite is involved in NAD-reduction in *Nitrobacter hamburgensis*. However, because denitrifying cells of *Nitrobacter* grow very slowly, it seems improbable that denitrification by nitrite oxidizers might have any significance in the treatment of wastewater.

DENITRIFICATION

General Aspects of Denitrification

Denitrification is the reduction of oxidized nitrogen compounds such as nitrite or nitrate to gaseous nitrogen compounds. This process is performed by various chemoorganotrophic, lithoautotrophic, and phototrophic bacteria and some fungi, especially under oxygen-reduced or anoxic conditions. Denitrification can be described as anoxic respiration. Electrons originated from, for example, organic matter, reduced sulfur compounds, or molecular hydrogen are transferred to reduce nitrogen compounds instead of oxygen in order to establish a proton motive force usable for ATP regeneration. Enzymes involved are nitrate reductase, nitrite reductase, nitric oxide reductase, and finally nitrous oxide reductase. Dinitrogen is the main end product of denitrification, whereas the nitrogenous gases nitric oxide and nitrous oxide can occur as intermediates at low concentrations (18). However, these gases are also released as end products when denitrification enzymes are not completely expressed, for example, when the concentration of dissolved oxygen is too high.

Substrate Requirements of Denitrifiers

The common denitrifiers in municipal wastewater treatment plants are chemoorganotrophic bacteria, for example, *Paracoccus denitrificans* or *Alcaligenes eutrophus*, which require an electron donor of an organic

nature. Hence, complete denitrification requires a sufficient supply of organic matter. In detail, a specific C : N ratio is required to provide an adequate amount of electron donors for the reduction of a distinct amount of nitrogen oxides. Wastewater with an inadequate COD loading should therefore be supplemented with an external organic electron donor–like acetate or methanol to avoid exceeding outlet concentrations of nitrate or nitrite. Recently, denitrification activity could be demonstrated in pure cultures of ammonia oxidizers such as *N. eutropha* (4). Under anoxic conditions *N. eutropha* is able to denitrify with molecular hydrogen as electron donor and nitrite as the only electron acceptor in a sulfide-reduced medium producing nitrous oxide and dinitrogen. Cell growth is directly coupled to nitrite reduction.

Aerobic Denitrification

Denitrification also occurs in the presence of oxygen. The range of oxygen concentration permitting aerobic denitrification is broad and differs from one organism to another (19). The onset of aerobic denitrification does not depend on the oxygen sensitivity of the corresponding enzymes but rather on regulation of oxygen- or redox-sensing factors involved in the regulation on a transcriptional level. This is further indicated by denitrifying enzymes expressed under anoxic conditions that remain active in the presence of oxygen (20). Generally, the ability to denitrify under oxic conditions seems to be the rule rather than the exception among denitrifiers. However, in the treatment of wastewater denitrification commonly proceeds under anoxic and not under oxic conditions because in the presence of oxygen large amounts of organic matter would be "wasted "on respiration and biomass production. Hence, denitrification would cease or run incompletely as a result of a lack of electron donors.

ACTIVATED SLUDGE MODELS: MICROBIOLOGICAL BASIS

MINO TAKASHI
The University of Tokyo
Tokyo, Japan

The activated sludge (AS) process is the most common wastewater treatment process. It was primarily designed for the removal of organic material or carbon (C) (see ACTIVATED SLUDGE — THE PROCESS), but has been modified to remove nitrogen (N) and phosphorus (P) as well. From an engineering point of view, it is necessary to model the behavior of the process mathematically and to predict, for example, the effluent water quality or the amount of excess sludge produced. The main mechanism for the substrate removal is biological. Therefore, mechanistic and structured mathematical models are needed for describing the major biological events occurring within the system or the behavior of the microorganisms responsible for the treatment. Among the mechanistic mathematical models available, the IWA (International Water Association) AS models (1) have been recognized as the worldwide standard. In the present article, the fundamental concepts and the underlying microbiological bases of the IWA models are critically discussed.

HISTORY OF IWA AS MODELS

A pioneer work on AS modeling was carried out in the late 1970s to early 1980s by the group of G. v. R. Marais from University of Cape Town, South Africa. They proposed basic ideas for general structures of AS models (2), chemical oxygen demand (COD) fractionation for modeling purpose (2), application of oxygen uptake rate measurements for determination of model parameters (3), and so on. Their work has been the basis for the development of the IWA AS models.

In 1983, a task group was organized within the International Association on Water Pollution Research and Control (IAWPRC, later renamed as the International

Association on Water Quality [IAWQ] and then as the IWA) to formulate general mathematical tools for describing the behavior of the AS process. In 1987 they published a mechanistic mathematical model called the *IAWPRC Activated Sludge Model No. 1 (ASM 1)* that incorporated carbon and nitrogen removal (4). This model became very popular and was adopted as the standard AS model worldwide. In the present article, ASM 1 will not be discussed in detail because newer models have since been developed. In 1991, the IAWQ task group was reorganized, and they attempted to formulate an updated model that included enhanced biological phosphorus removal (EBPR) as well as removal of carbon and nitrogen. Thus, ASM 2, describing carbon, nitrogen, and phosphorus removal, was published in 1995 (5). In 1999, two additional models were proposed: ASM 2d (6) was a partial extension of ASM 2, and ASM 3 (7) was developed to overcome many defects in ASM 1, 2, and 2d and was designed as the core model that formed the basis for further extension. As IAWPRC or IAWQ has been now changed to IWA, all these models presented by the task group are hereafter called the "IWA" models. The main characteristics of these IWA AS models are summarized in Table 1.

Apart from the IWA AS models, a new approach was proposed by the group of van Loosdrecht and Heijnen from Delft University of Technology, the Netherlands (8–10) for modeling the EBPR processes. They developed a structured metabolic model for the EBPR processes based on bioenergetics and stoichiometry of known metabolic reactions. All relevant metabolic reactions underlying the EBPR metabolism were described, and their reaction rates were correlated with each other by applying stoichiometry-based linear relations between these reaction rates. This approach allowed for significant reduction in the number of kinetic or stoichiometric parameters to be determined: it was possible to reasonably describe the dynamic behavior of EBPR processes with a set of 14 parameters. On the other hand, the apparent complexity of the model increased and much biochemical knowledge is required to understand the behaviors of the model. This Delft model is too complicated to be used for practical purposes. However, as this Delft model describes more detailed biochemical structures of the EBPR metabolism in a scientific way, it is considered to be a promising research tool.

Currently, commercial software for running AS models are available in the market, and many attempts have been made to use AS models for either practical or scientific purposes (11,12). In such modeling practices, the IWA AS models are recognized as benchmark models.

BASIC CONCEPTS OF IWA AS MODELS

Mechanistic Models

There are several essential objectives of AS modeling. These include: (*1*) prediction of effluent water quality in terms of key water quality indexes, such as COD, nitrogen, and phosphorus species; (*2*) estimation of excess sludge production; (*3*) estimation of oxygen consumption in the system; and (*4*) prediction of the behavior of concerned microbes in the system. Recently, the importance of mechanistic mathematical models is increasing significantly because of the progress of computer technology. Huge computations can be performed within a short period of time, which allows these AS models to be complex, without limitations of computation time, and to be applicable not only for academic or educational purpose but also for more practical uses such as design, process control, and operation support. Increasing demand for nitrogen and phosphorus removal (see ACTIVATED SLUDGE — THE PROCESS, ACTIVATED SLUDGE — MICROBIOLOGY OF NITROGEN REMOVAL, ACTIVATED SLUDGE — MOLECULAR TECHNIQUES FOR DETERMINING COMMUNITY COMPOSITION) has facilitated the increased application of such mechanistic AS models in process control. Precise process control is not necessarily needed for carbon removal, but it is extremely important for nitrogen and phosphorus removal.

The AS process is a biological process in which carbon removal is carried out by heterotrophic organisms, nitrogen removal is achieved through biological nitrification and denitrification, and EBPR is made possible because a group of bacteria are able to accumulate intracellular polyphosphate (poly-P) (13). The more these biological processes have been understood, the more complex, but more generally applicable, the models developed have become. The use of AS mathematical models allows wastewater engineers to test many different possible designs or operational strategies by simulation, without carrying out expensive and time-consuming pilot plant studies. Therefore, once conceptual understanding of the AS process had expanded sufficiently, attempts were made to incorporate microbiological and biochemical information of relevant biological processes into AS models. Mechanistic and structured mathematical models have thus been formulated that can describe in general terms the major events occurring within the system or the behavior of the microorganisms responsible for the treatment. The IWA models are the most commonly accepted models of such kind.

Processes and Components

In AS systems, different groups of microorganisms perform various biological reactions, such as carbon oxidation, nitrification, denitrification, and poly-P accumulation. These biological reactions actually determine the concentrations of different system components. In AS modeling, the term "process" is used to define an event that occurs independently in the system (4) and is concerned with the transformation or conversion of one or more system components such as the microorganisms, COD, and ammonia. So, the identification of important processes affecting the system behavior and the selection of key components relevant to the identified processes are two major tasks required for AS modeling. From a modeling point of view, microorganisms are classified into a few groups, each of which should reasonably represent a functional microbial group and be responsible for at least one process (4). The system components and the processes in the model must

Table 1. Characteristics of IWA AS Models

Abbreviation	Year Published	Target Pollutant	No. of Processes	No. of Components		Microbial Groups Described	Characteristics, Advantages, and Constraints of Model
				Soluble	Particulate		
ASM 1	1986	C, N	8	7	6	Heterotrophs, nitrifiers	The first model proposed by the IAWPRC Task Group, which became a standard AS model and the common basis for further research A structured/mechanistic model simulating carbon and nitrogen removal Peterson's matrix format is adopted for the presentation of the model, offering the best opportunity to the users to trace all the interactions of the system components Heterotrophs are assumed to perform not only the aerobic growth with the oxidation of organic substrates, but also denitrification It is assumed that hydrolysis of high-molecular compounds is done only by heterotrophs As a general rule, the Monod type kinetic expression is used
ASM 2	1995	C, N, P	19	9	10	Heterotrophs, nitrifiers, PAOs	Biological phosphorus removal is modeled in addition to carbon and nitrogen removal, thus PAOs are introduces as bacteria responsible for EBPR Cell internal storage components, PHA, and polyphosphate, are introduced to describe the behavior of PAOs The COD fraction is assumed to carry a defined amount of nitrogen and phosphorus. The ammonification of organic nitrogen, which is adopted in ASM 1, is replaced by hydrolysis of nitrogen-containing COD The hydrolysis process eventually involves not only true hydrolysis of complex molecules but many other processes such as degradation of stored substrates and predation by higher animals
ASM2d	1998	C, N, P	21	9	10	Heterotrophs, nitrifiers, PAOs	An extension of ASM 2: denitrifying capability is given to PAOs so that anoxic phosphorus uptake can be realized in the model Basic structure is the same as that of ASM 2
ASM 3	1998	C, N	12	7	6	Heterotrophs, nitrifiers	An extension of ASM 1: phosphorus removal not included, and only carbon and nitrogen removal modeled Developed by revising some defects in ASM 1 and 2, and designed as the core model for further extension The concept of biomass decay in ASM 1 and 2 is replaced by the endogenous respiration concept All heterotrophs are assumed to be able to store cell internal storage compounds

Note: PAO–polyphosphate accumulating organisms, EBPR–enhanced biological phosphate removal.

be defined as simple as possible, but should be complex enough to describe the system behavior in such a way as to fit the model user's purpose (4). The components in the model do not always represent something identifiable in reality. In the IWA models, there are several variables clearly defined on the basis of certain modeling concepts that are neither measured by chemical analyses nor separated by physical means. Similarly, the processes in the model may not always reflect the corresponding reactions in reality. For example, "hydrolysis" in the IWA models should not only mean true hydrolytic biochemical reactions but may also include other processes such as predation by higher animals and utilization of intracellular storage polymers (see details a later section). The processes and microbial groups adopted in ASM 2, 2d, and 3 are listed in Table 2.

Stoichiometry and Kinetics

Then, the stoichiometry (quantitative relationship between components in a chemical reaction) and the kinetics (dependency of process rate on the concentrations of relevant components) should be defined for each process. When the stoichiometry of a process is determined, the continuity of the process must be strictly maintained. Continuity is a term that carries the mathematical equivalence to the principle that in chemical reactions, elements, electrons (or COD), and net electrical charges may neither be created nor be destroyed (4,5). For the

Table 2. Biological Processes in ASM 2, 2d, and 3

Model	Microorganisms Responsible for the Process	Biological Processes
ASM 2	Heterotrophs	Aerobic hydrolysis
		Anoxic hydrolysis
		Anaerobic hydrolysis

		Aerobic endogenous respiration of nitrifiers
		Anoxic endogenous respiration of nitrifiers

kinetics, the Monod model (14) is generally adopted as the rate expression for the biological growth process in the IWA models:

$$\text{Process Rate} = \frac{\upsilon XS}{(S + K)}$$

where υ is the rate coefficient for the process, X the concentration of biomass that performs the process, S the limiting substrate concentration, and K the saturation coefficient.

The Monod model is generally used, not because it may either best fit the experimental data or have a definite microbiological basis. Generally speaking, the growth rate of an organism is dependent on the limiting substrate concentration in relatively low substrate concentration ranges, whereas its growth rate is not affected by substrate concentration at higher concentrations. The Monod model can express this general dependency of the process rate on the substrate concentration reasonably well in simple terms. Only for a few specific processes other types of kinetic expressions are adopted, because of several specific reasons; for example, a kinetic model for a surface-limited reaction is used for hydrolysis processes (4) and a saturation equation is used for poly-P storage (5).

After both the stoichiometry and the kinetics of the concerned system are defined, the mass balance for each component may be created for a given system boundary (e.g., a completely mixed AS reactor). Various processes can affect the concentration of a specific component, and all the processes affecting the concentration of that particular component are taken into account in the mass balance. From the mass balance, the concentration of each system component can be calculated and the system behavior can then be simulated (4). In order to simulate carbon oxidation, nitrogen, and phosphorus removal, COD (measured using potassium dichromate as the oxidizing reagent), nitrogen and phosphorus are selected as the basis for mass balance in the IWA models (4,5). Instead of COD, carbon itself can be used for the mass balance for organic substances (7). The advantage of using COD (or actually the oxygen equivalent in the oxidation-reduction reaction) for the mass balance is that the oxygen balance can be calculated and thus used to predict the oxygen requirement in the system (4). Because the AS process is an oxygen-dependent system, it is extremely useful, in practice, that the simulation model can predict reasonably the oxygen concentration in the system and its oxygen requirement.

ESSENTIAL PROCESSES IN IWA MODELS

General

Processes mainly adopted in ASM 2 are discussed in this section. For modeling purposes, microorganisms in the AS are usually classified into several functional groups. In ASM 2, only three groups of microorganisms are recognized and represent a broad range of different microbial populations. These three groups are: heterotrophs (microorganisms that live on organic substrates as carbon and energy sources), nitrifiers (autotrophs that oxidize ammonia to nitrite and nitrate), and phosphorus accumulating organisms (PAOs, microorganisms that have a capability to accumulate poly-P and are responsible for EBPR). Functions of these three biomass fractions in ASM 2 are schematically shown in Figures 1 to 3.

Heterotrophs are modeled as "almighty" microorganisms that can grow aerobically, denitrify, hydrolyze complex organic compounds and carry out fermentations. Nitrifiers are autotrophs and do not contribute to organic carbon removal. They are involved in the oxidative part of biological nitrogen removal. PAOs are a group of heterotrophs, but they are considered as a separate group when EBPR is modeled. The present classification of microorganisms is too simple, in some cases, to describe the complicated and poorly understood behavior of AS processes. However, it is sufficient to simulate major events that actually affect fundamental system design or control strategy of the AS process.

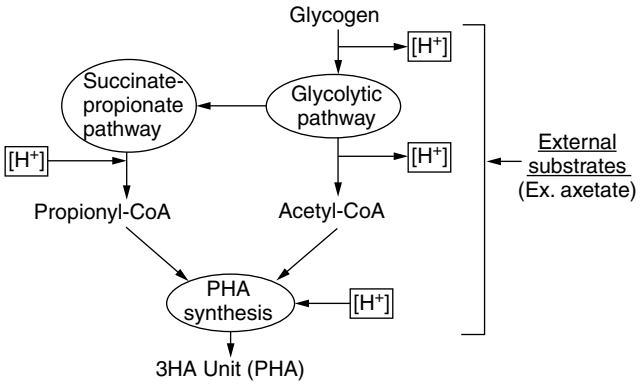

Figure 3. Anaerobic carbon metabolism of PAOs for enhanced biological phosphate removal. Glycogen functions as regulator of redox balance in the cell.

Aerobic Growth of Heterotrophs and Carbon Removal

The major mechanism of carbon removal in the AS process is by the growth of heterotrophs on organic substrates. These heterotrophs include diverse phylogenetic, taxonomic, and functional groups (15), but all, except for PAOs as discussed later, are assumed to be one functional group of microorganisms in ASM 2. Their common nature is that they all utilize organic substrates as the carbon and energy sources for growth.

In heterotrophic growth, organic substrates are used in two ways: one for the energy-generating metabolism (adenosine triphophosphate [ATP] production) and the other for assimilative metabolism (biosynthesis of the cell). Some substrates in the wastewater are oxidized completely to carbon dioxide and utilized for energy (ATP) generation. This is an oxidation process and requires a terminal electron acceptor. The AS reactors are usually aerated and kept aerobic so that oxygen serves as the electron acceptor. The rest of the substrates are used for the synthesis of biomass and withdrawn from the AS system as excess sludge. The ratio of this carbon distribution is represented by the yield (Y, the ratio of mass of produced biomass to mass of the substrate utilized) in the AS models (16). This yield is assumed to be a constant, an assumption that is generally acceptable for wastewaters with similar compositions.

Wastewaters may contain a large variety of organic compounds that are utilized by microorganisms at different rates. Therefore, an important question to be asked when heterotrophic growth is modeled is: how many fractions of organic substrates should be defined in the model to satisfactorily describe the substrate removal profiles in the AS system? In the IWA models, the organic substrates are principally divided into two fractions, namely, *slowly biodegradable substrate* (SB-COD, denoted as X_S) and *readily biodegradable substrate* (RB-COD, denoted as S_S). This is because the oxygen uptake rate (OUR) during aerobic substrate removal from a municipal wastewater showed (3) a two-stage response, which implies that organic substrates present in municipal wastewaters can be divided into two fractions with two different OURs. It is instructive to think that SB-COD represents the high-molecular or particulate fraction and that RB-COD represents the low-molecular or soluble fraction (4,5).

From a modeling point of view, SB-COD is defined as the COD fraction that is hydrolyzed to smaller molecules before being utilized, and RB-COD is defined as the COD fraction that can be directly utilized by heterotrophs with no prior hydrolysis (4). In other words, SB-COD need to be first hydrolyzed to RB-COD and only then is utilized for heterotrophic growth. The conversion of SB-COD to RB-COD is referred to as "hydrolysis" in the IWA models (5). The two observed rates in the profile can be interpreted as the hydrolysis rate and the aerobic growth rate of heterotrophs. However, the distinction between SB- and RB-COD is not always done clearly in practice. Some soluble COD fractions may contain rather complex molecules that cannot be utilized directly by heterotrophs and should be classified as SB-COD even though they are soluble (5). The present COD fractionation is simple enough for practical use and complex enough to reasonably describe the behavior of AS systems under most situations.

In ASM 2, the RB-COD faction is further divided into two fractions, "fermentation products (S_A)" and "fermentable readily biodegradable substrate (S_F)." Thus,

$$S_S = S_F + S_A$$

The process of conversion from S_A to S_F is defined as fermentation. This fractionation as well as the process of fermentation are necessary when EBPR is modeled, as discussed later. The transformation of organic substrates by heterotrophs, including the fermentation step, is shown graphically in Figure 1.

In the real world, many wastewaters do not show the typical two-stage response in the OUR test. For example, OUR profiles of some municipal wastewaters show a gradual decreasing trend along with time when organic substrates are removed in a batch test (17). Such results imply that a wastewater may contain many compounds with different utilization rates. However, it is not recommended to increase the number of COD fractions, because determination of each COD fraction as well as the parameters associated with it becomes increasingly difficult as the numbers increase. On the other hand, the composition of industrial wastewaters depends totally on the type of industry and the industrial processes used, and a few major organic components can be often identified from the raw materials or from the processes. Then, each major organic component can represent a COD fraction that has a single process rate. Specialist microorganisms can also be defined, which thrive on certain particular components. When the wastewater composition is defined clearly enough and the process rates for the identified components are measurable, it is possible to assign a process rate to each relevant component and, in more limited cases, a specialist microorganism that utilizes it.

Denitrification and Nitrification

Biological nitrogen removal is achieved by the combination of autotrophic nitrification and heterotrophic denitrification (see ACTIVATED SLUDGE — MICROBIOLOGY OF NITROGEN

Removal). The nitrogen conversion processes modeled in ASM 2 are shown graphically in Figure 2.

Under anoxic conditions (i.e., where oxygen is not available but nitrate or nitrite is), nitrate or nitrite can be used as electron acceptors in heterotrophic growth (15). This anoxic growth is referred to as denitrification. Denitrifying heterotrophs that grow anoxically usually grow aerobically utilizing oxygen as electron acceptor. Thus, denitrifiers should be a part of aerobic heterotrophs. In ASM 2, heterotrophs are defined as one biomass fraction and modeled in such a way that all heterotrophs can denitrify. But, this is not true in reality.

Aerobic and the anoxic growth of heterotrophs are very similar to each other in terms of stoichiometry and kinetics, but differ in that the observed specific growth rates of heterotrophs are usually lower under anoxic conditions than under aerobic conditions (18). A factor (the reduction factor for denitrification) is introduced to allow for this reduced growth rate under anoxic conditions (4,5). This factor is defined as the ratio of the specific growth rate under anoxic conditions to that under aerobic conditions, which actually implies the portion of denitrifiers within the total heterotrophic biomass (5). An advantage of the introduction of this factor is that most actual situations can then be simulated without increasing the number of processes. However, this factor may not be a universal constant but a parameter that should be calibrated for each specific system or situation, because the ratio of denitrifiers may vary according to different environmental conditions. It is of course possible to create a model that involves two heterotrophic biomass fractions, one with and the other without denitrification capability. The dual-heterotroph model may describe denitrification behavior of systems more sensitively than the IWA models. However, the complexity of the model will increase and the identification of stoichiometric or kinetic parameters will become more difficult.

Nitrification (19) is a process in which ammonia is biologically oxidized to nitrite and nitrate in the presence of oxygen as the terminal electron acceptor. Nitrifiers are autotrophic bacteria and use inorganic carbon (carbon dioxide) as the carbon source. Nitrification involves two steps: oxidation of ammonia to nitrite, and further oxidation of nitrite to nitrate (see Activated Sludge — Microbiology of Nitrogen Removal). These two steps are carried out by phylogenetically different groups of bacteria. The ammonia oxidizers include *Nitrosomonas* and *Nitrosospira* and nitrite oxidizers, including *Nitrobacter* and *Nitrospira* (20). However, the IWA models do not distinguish between these two groups of nitrifiers, but only one biomass fraction is used for all bacteria that carry out complete nitrification. There are two major reasons for this. First, the growth rate of nitrite oxidizers is usually higher than that of ammonia oxidizers. Therefore, nitrite does not accumulate in the system, but is consumed by nitrite oxidizers immediately after its production by ammonia oxidizers (21). So, in most cases, nitrification takes place as if it were a single process. Secondly, nitrite can be produced not only as an intermediate product in nitrification but sometimes as a by-product of denitrification (22). Production of nitrite through nitrification has been studied in detail, but there is very little kinetic information available about the nitrite production through denitrification (5). This means that the nitrite concentration is not satisfactorily predictable.

Nitrous oxide (N_2O) is a nitrogenous species that can be produced both in nitrification and denitrification and should not be neglected in constructing mass balance of nitrogen (22). N_2O is of concern these days from an environmental point of view, because it is a greenhouse gas that may contribute to global warming (23). However, N_2O production is not taken into account in the IWA models. The mechanism and the conditions for N_2O production are still poorly understood. In practice, it is almost impossible to determine satisfactorily all the kinetic parameters involved in these complex processes affecting its behavior.

EBPR

Phosphorus is an essential element for biomass growth, and the sludge produced as excess sludge will contain a certain amount of phosphorus. Thus, phosphorus can be removed from wastewater by withdrawing the excess sludge from the AS system. However, municipal wastewaters usually contain more phosphorus than is required for the biomass growth, so phosphorus in the influent may not be completely removed only by normal microbial growth equivalent. On the other hand, the phosphorus content of the sludge may increase up to 5 to 6% or even more than 10% in extreme cases, whereas the phosphorus content of a typical AS may be only about 1.5 to 2% of phosphorus (on dry weight basis) (13). Such high phosphorus content is caused by an excess accumulation of poly-P in the sludge and may lead to much higher phosphorus removal efficiency than usual (see Activated Sludge — Molecular Techniques for Determining Community Composition). This high phosphorus removal by biological means is referred to as EBPR. The bacteria that can achieve the high phosphorus content through the accumulation of poly-P and are thus responsible for EBPR are called PAOs. It is necessary to describe the behavior of PAOs in mathematical terms to incorporate EBPR into the AS model.

A high phosphorus content of the sludge from EBPR can be achieved by introducing an anaerobic phase into the influent end of the AS process, followed by conventional aerobic phase (see Activated Sludge — The Process; 24). In such EBPR processes, the AS passes through anaerobic and aerobic conditions alternately, and the influent wastewater (or actually the organic substrates) is introduced into the anaerobic phase. In practice, this anaerobic-aerobic alternation can be achieved either by spatial configuration of anaerobic and aerobic zones in series with sludge recycle in continuous flow reactors or by temporal arrangement of anaerobic and aerobic periods in sequence batch reactors (see Activated Sludge — Sequencing Batch Reactors). Such EBPR processes are called anaerobic-aerobic or anaerobic-oxic processes. By exposing the sludge to these alternative anaerobic and aerobic conditions, PAOs are selected and grow to become dominant in the process. To achieve high and stable EBPR performance, it is essential to maintain PAOs in the system (25,26).

The mechanism of proliferation of PAOs in the EBPR process has been described as follows (25–27; also see another contribution of this Encyclopedia, ACTIVATED SLUDGE — MOLECULAR TECHNIQUES FOR DETERMINING COMMUNITY COMPOSITION). Because the AS is mixed with the influent wastewater in the anaerobic phase, organisms that can utilize organic substrates more rapidly in an anaerobic environment have an advantage. PAOs are the organisms that utilize the energy generated by the hydrolysis of polyphosphate for the uptake of the carbon substrates in the anaerobic phase of the EBPR process and can proliferate over other microorganisms under such conditions. The carbon substrates taken up by PAOs in the anaerobic phase are converted to polyhydroxyalkanoates (PHA) and stored inside the cell (28). Because PHA is a reduced polymer, its synthesis requires a source of reducing power, which is obtained by partial oxidation of intracellularly stored glycogen to carbon dioxide (29). The glycogen is partially converted via acetyl coenzyme A (CoA) to polyhydroxybutyrate (PHB). Thus, uptake of organic substrates and concomitant PHA synthesis by the sludge, degradation of stored poly-P and the consequent release of orthophosphate to the bulk solution, and utilization of stored glycogen are typical metabolic characteristics of the anaerobic phase of EBPR processes (25). In the subsequent aerobic phase, PAOs grow aerobically, recover the glycogen level, and assimilate orthophosphate to resynthesize poly-P, by using the stored PHA as their carbon and energy sources. Such typical EBPR metabolism is shown graphically in Figure 3.

Anaerobic metabolism of PAOs may involve glycogen being metabolized via propionyl-CoA to 3-hydroxyvalerate-rich PHA (the propionate-succinate pathway). This conversion does not lead to carbon dioxide production and consumes reducing power. This means that glycogen can either produce reducing power if metabolized through acetyl CoA, or consume reducing power if metabolized through propionyl-CoA. Glycogen stored in the cell should function as a regulator of the redox balance in the cell (25). The generation of reducing power should occur when more oxidative substrates are available, whereas its consumption should occur when more reductive substrates are utilized (30). It is essential for PAOs to take up carbon substrates at a faster rate than the other bacteria in the anaerobic stage, no matter what kinds of substrates are available in the influent wastewater. The mechanism described earlier can provide PAOs with a capability to assimilate different kinds of both reduced and oxidized organic substrates in the anaerobic phase without disturbing the redox balance in the cell. Glycogen storage appears to be the key strategy for PAOs to maintain the redox balance in the anaerobic uptake of various organic substrates, and hence to emerge dominant in the face of the selective pressures existing in EBPR processes (25).

This EBPR mechanism is partially adopted in ASM 2. Conceptual structures of the PAO metabolism adopted in ASM 2 are schematically shown in Figure 4. A prominent difference between this model structure and the generally accepted scientific mechanism is that glycogen is not introduced in the model, whereas glycogen probably plays an essential role in the real world. Only one

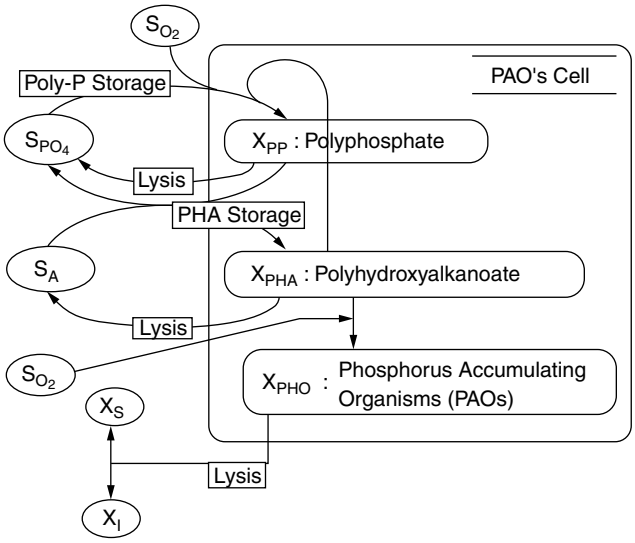

Figure 4. Metabolism of PAOs in ASM 2. S_{PO_4}: orthophosphate, S_{O_2}: dissolved oxygen, S_A: fermentation products, X_S: slowly biodegradable substrates, X_{PAO}: phosphorus accumulating organisms, X_{PP}: polyphosphate associated with XPAO, X_{PHA}: polyhydroxyalkaonates associated with XPAO, X_I: inert organics.

component, X_{PHA} (cell internal storage product of PAOs) is defined as carbon storage material in the model. This simplification is made in ASM 2 because the actual metabolism of the PAO is so unfamiliar to practitioners that they may have difficulty in understanding the model behavior fully. Glycogen and poly-P are the two key storage polymers that enable PAOs to take up organic substrates under anaerobic conditions. The former either supplies or consumes reducing power to maintain the redox balance in the cell and the latter generates energy necessary for the uptake of organic substrates and for their storage in the form of PHA under anaerobic conditions. Both are essential factors for PAOs to survive in the anaerobic-aerobic process. If glycogen is excluded from the model, situations in which glycogen, as the limiting factor, determines the system behavior may not be simulated properly. However, the relative size of the glycogen pool is usually almost the same as that of the poly-P pool (31). This means that most of the real situations in the operation of the EBPR processes, in practice, can be described with only one of the two parameters: either glycogen or poly-P. In ASM 2, poly-P is selected as a model component, and glycogen, which is not familiar to practitioners, is not adopted.

From the viewpoint of reaction stoichiometry, the component X_{PHA} in the model should represent all carbon storage materials in PAOs, including PHA and glycogen. Therefore, the model implies that the substrates anaerobically taken up by PAOs are converted to PHA without any loss or supply of carbon. However, a part of PHA is actually synthesized from glycogen that has already accumulated in PAOs (32,33). This argument should lead to an important warning: X_{PHA} in the model does not necessarily represent the analytically measured PHA.

It is believed that some organic substrates are selectively utilized by PAOs. As short-chain fatty acid such as acetate are favored as the carbon source for EBPR (34), the fraction of RB-COD that can be utilized by PAOs is defined as S_A in ASM 2. The fraction of RB-COD that can be utilized by heterotrophs other than PAOs but not by PAOs is defined as S_F. For the growth of heterotrophs, S_F and S_A have no difference: both are utilized by heterotrophs exactly in the same way in terms of stoichiometry and kinetics. In the modeling context the term "fermentation" is defined as the process in which S_F is transformed to S_A and is introduced to describe the possible selective preference of PAOs for certain substrates. Fermentation in ASM 2 does not exactly imply its microbiological meaning, as discussed later.

ASM 2d (6) is an extended version of ASM 2. It has been shown that some PAOs have denitrification capability (35). In other words, some PAOs can utilize nitrate or nitrite as the electron acceptor, and so they take up orthophosphate with a consumption of nitrate or nitrite under oxygen-free conditions. To describe this anoxic uptake of orthophosphate, this denitrification capability is attributed to PAOs in ASM 2d ("d" stands for "denitrification") (6). PAOs with denitrification capability (DN-PAOs) are very common in EBPR systems (35,36), so without the introduction of DN-PAOs, the EBPR processes incorporating recycling of nitrified liquid cannot be modeled properly. When nitrification is significant in the system, ASM 2d not ASM 2 should be used for its simulation. An anoxic reduction factor (the factor expressing the ratio of the anoxic growth rate to that of the aerobic) is again introduced to account for the reduced growth rate under the anoxic conditions (6).

Hydrolysis

Hydrolysis in the IWA models is defined as the process in which complex molecules not metabolized by microorganisms (SB-COD) are degraded to relatively simple molecules that can then be assimilated and metabolized directly by heterotrophic bacteria (RB-COD) (4,5). Hydrolysis is not an oxidation-reduction reaction and theoretically should not involve any electron transfer. However, the hydrolysis process in the model may include not only the real "biochemical" hydrolysis caused by hydrolytic exoenzymes, but also processes such as predation by higher animals or any other processes contributing to breakdown of polymers to low-molecular compounds. In addition, carbon storage may be strongly correlated with the hydrolysis process. As modeled in ASM 3, external substrates can be polymerized and stored inside the cell when they are utilized by microorganisms. Subsequent breakdown of these internal storage products to smaller metabolic intermediates cannot be distinguished from the extracellular hydrolysis of SB-COD in the oxygen balance–based models, because neither upsets the oxygen balance.

In ASM 2, the hydrolysis rate is considered to be greatest under aerobic conditions, medium under anoxic (denitrifying) conditions, and lowest under anaerobic conditions (5). If the same hydrolysis rate is applied under anaerobic, anoxic, and aerobic conditions, too much S_S is supplied through hydrolysis and too much denitrification (under anoxic conditions) or phosphate release (anaerobic conditions) emerges from the model compared with that actually observed in the AS systems. Differences in the hydrolysis rates under different electron acceptor conditions are allowed for by introducing anoxic and anaerobic hydrolysis reduction factors. As true hydrolysis is not an oxidative or reductive process, the availability of electron acceptors should not affect the process rate. However, several possible factors may contribute to the apparent reduced hydrolysis rates under anoxic or anaerobic conditions in the model as follows:

1. The activity of predators (protozoa and higher animals) may be less under anaerobic and anoxic conditions than under aerobic conditions.
2. Carbon storage may take place under any of these conditions, but the utilization of the storage products should be more under aerobic and anoxic conditions than under anaerobic conditions.

These may lead to an underestimation of the hydrolysis rate in the model. The hydrolysis rate in ASM 2 is one of the most difficult parameters to estimate. This problem has now partly been solved by the introduction of the storage process in ASM 3, where this anoxic or anaerobic hydrolysis reduction factor is no longer used (7).

Municipal wastewaters usually contain organic nitrogen compounds. After their hydrolysis, ammonia nitrogen is released. In the ASM models, it is assumed that SB-COD should include a nitrogen fraction and that ammonia is released when SB-COD is hydrolyzed to RB-COD. This approach is extended to other COD fractions. Once the nitrogen content of each COD fraction is determined experimentally, the model describes the behavior of organic nitrogen compounds quite well. The same philosophy is also applied to describe the behavior of phosphorus bound to organic matters, namely, each COD fraction include a phosphorus fraction.

Fermentation

The process "fermentation" was introduced in ASM 2 to describe EBPR metabolism, and is different from fermentation in the microbiological sense. In ASM 2, a fraction of RB-COD utilized by PAOs (S_A) is distinguished from the rest of RB-COD that cannot be directly taken up by PAOs (S_F). The conversion of the latter to the former is defined as fermentation. The process is called fermentation, because compounds that are likely to be classified as S_A include fermentation products such as acetate and other short-chain fatty acids.

In a microbiological context, fermentation is a growth generating process. However, fermentation in ASM 2 is not modeled as such, but it is assumed to be a conversion process in which S_F is simply converted to S_A without any production of biomass. There are two major reasons for this assumption. First, the biomass yield in fermentative growth processes is small. Second, two yield values for the same heterotrophs (X_H), one for aerobic and anoxic growth processes and the other for fermentation processes, are confusing in the modeling context.

Decay, Lysis, and Endogenous Respiration

When microorganisms are put into an environment in which no substrates are available, a gradual decrease in biomass level will occur. Several possible mechanisms can be proposed to account for this biomass reduction. They include decay or lysis and endogenous respiration (37). Conceptual schemes of decay and endogenous respiration are given in Figure 5.

The term "decay" may be used to describe degradation of biomass in general, in which the biomass is degraded and converted either to substrates that are then reutilized by heterotrophic biomass or to inert organic substances that are biologically inactive. Decay may occur partly because of activities of lytic enzymes produced by the biomass and partly because of external factors such as mechanical or physical stress, chemical attack, or predation activities (37). The indigenous enzymatic decay is often called lysis. When the biomass reduction is modeled allowing for this decay, the decay rate does not correspond to the biomass reduction rate, because some biomass is regenerated by the secondary substrates produced by the decay process itself. The first two IWA models (ASM 1 and 2) adopt this approach. However, the complex nature of this decay-regeneration model structure often leads to difficulties in evaluating relevant kinetic parameters. Therefore, ASM 3 adopts a different approach by incorporating endogenous respiration. In this approach, it is assumed that the biomass is continuously oxidized to carbon dioxide under aerobic or anoxic conditions, thus generating the necessary energy for endogenous metabolism or for cell maintenance. The essential advantage of this endogenous respiration approach is its simplicity. No regeneration of substrate is considered and the endogenous respiration rate then directly expresses the biomass reduction rate. On the other hand, biomass reduction under anaerobic conditions cannot be described by this approach because no inorganic electron acceptors are available under anaerobic conditions. In reality, the decay rate seems to be very small and can be usually neglected under anaerobic conditions. However, hydrolytic decay can theoretically occur even under anaerobic conditions and its significance in actual wastewater treatment processes still remains unclear.

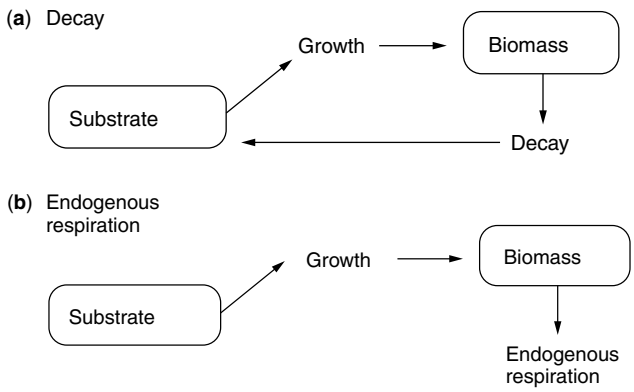

Figure 5. Conceptual scheme of decay and endogenous respiration.

Carbon Storage

It has been pointed out that the carbon storage capability of microorganisms plays a key role in the ecological selection in biological wastewater treatment (38). Microorganisms in AS are exposed to carbon-rich and -deficient conditions alternatively. For example, either spatial or temporal gradients of substrate concentration are formed in many AS reactors, such as sequence batch reactors, plug flow reactors, systems with selector, and contact-stabilization processes (39). Also, carbon loadings from influent wastewater tend to fluctuate dynamically from time to time. These dynamic conditions, in terms of the availability of carbon sources, will create highly competitive environments, in which substrate uptake rates during the carbon-rich periods will actually determine the survival and proliferation of certain microorganisms (39,40). So, some microorganisms adopt a strategy to store carbon sources in the cell under carbon-rich conditions by achieving a high substrate uptake rate. They use this stored carbon sources under carbon-deficient conditions. In fact, PAOs have the capability to store PHA under anaerobic conditions, and this explains their dominance in anaerobic-aerobic EBPR systems (25). This strategy for carbon storage seems to be adopted by aerobic or anoxic heterotrophs as well, because storage seems to be an essential capability of microorganisms to outcompete others for substrates under dynamic conditions (39). Therefore, the process of carbon storage is introduced in ASM 3 (7).

In ASM 3, a single heterotrophic biomass (X_H) is defined as being responsible for carbon and nitrogen removal, and this X_H stores RB-COD (S_S) in the form of cell internal storage products (X_{STO}). It is assumed in the stoichiometry of ASM 3 that X_{STO} is exclusively PHB. PHA, including PHB, are also likely to be major storage products, and possibly other polymers, such as lipids, glycogen, and polypeptides, exist (16). At present, little information is available about the presence, importance, and characteristics of these carbon storage products in AS. The storage process is modeled as an energy-requiring process, and the ratio of utilized S_S to stored X_{STO} is defined as the yield for the storage process. This yield should be much higher than yields of growth processes, because the energy requirement for storage is much smaller than that for growth (41). Storage occurs both under aerobic and anoxic conditions (36), and anoxic storage is identical to aerobic storage, but denitrification rather than aerobic respiration provides the energy required. As more energy is produced in aerobic respiration than in denitrification, a higher yield is applied to aerobic storage than to anoxic storage.

An assumption that may not be true in the real world but is incorporated into the models, is that all S_S taken up by X_H is first converted to and stored as X_{STO}, which is then utilized by X_H as the substrate for growth. This means that X_H accumulate and utilize X_{STO} at the same time during their growth. Heterotrophs utilize external substrates not necessarily via storage products but directly for growth. However, it is not wise, during modeling, to provide two heterotrophic growth processes (one on S_S and the other on X_{STO}), because more kinetic parameters

must then be identified. To avoid such a complexity in the model structure, the foregoing assumption is made in ASM 3.

LIMITATIONS AND FUTURE PERSPECTIVES OF AS MODELS

It is important to note that microbiological information is not always incorporated into these AS models. There are many processes that are known to microbiologists but that have not yet been introduced to IWA models for several reasons. It is assumed by the AS models that processes with engineering significance should be modeled. In other words, only those processes that affect the concentrations of system components relevant to practical objectives should be considered. Thus, the activities of absolute anaerobic bacteria, for example, are neglected in the IWA models, despite the fact that various strict anaerobic bacteria, such as sulfate-reducing bacteria, can be detected even in fully aerobic AS processes (42). However, their activities are usually considered to be negligible in terms of the COD balance and they are not introduced in the AS models. As their metabolisms are well understood, it would be relatively simple to model them if necessary.

As far as nitrogen removal is concerned, the model structures are far behind the microbiological information, and so the following are not considered in ASM 2 or other IWA models, as discussed previously.

1. Nitrite production, either through nitrification or denitrification, is not taken into account. Nitrite accumulation and its inhibitory effects on microbial activities are not predicted.
2. N_2O production is not considered. It is known that under certain conditions part of nitrogen can be released to the air as N_2O in the courses of both nitrification and denitrification (22). This leads to additional loss of nitrogen from the system, and to an incomplete mass balance of nitrogen, unless it is taken into account.
3. There are several other nitrogen-related metabolic reactions, such as those involved in anaerobic ammonia oxidation known as ANAMMOX (43), in which ammonia is oxidized by nitrite to produce nitrogen gas, autotrophic denitrification (44) (denitrification by inorganic compounds as electron donor), and so on. They will disturb the nitrogen balance, but are not considered at all in the IWA models, because it is considered unlikely that these metabolisms are significantly active in the AS systems.

Nitrite production during nitrification is more common than that in denitrification, and more microbiological and kinetic information is available about the former than the latter. Therefore, nitrite production during nitrification can be modeled satisfactorily and such models may be applied to situations in which nitrite production through denitrification is not significant.

Bulking is a situation in which AS does not settle in the secondary clarifier because of excessive growth of filamentous organism (45). This is a serious and critical problem in the operation of the AS process, because solutions to it have not yet been established in practice. From a practical point of view, there is a high demand for models to describe the bulking phenomena, but widely accepted bulking models have not been established yet. The main reason is that the mechanism of bulking is not clearly understood. Many different filamentous organisms can cause bulking and each of them may have different microbiological and kinetic natures (46). It is also very difficult to quantify filamentous biomass reliably. The conditions responsible for bulking are not always known. All these difficulties lead to lack of definite information about the mechanism of bulking, and thus to lack of acceptable bulking models. It is essential to obtain more detailed microbiological and kinetic information on different causative filaments to establish reliable bulking models.

Predation by protozoa or higher animals commonly occurs in the AS process (see PROTOZOA IN ACTIVATED SLUDGE). Predation is not included in the IWA models but may contribute to decay and hydrolysis in the modeling context. Several different types of predators are present in the AS, and some of their characteristics have been studied. They can be modeled relatively easily from a structural point of view. However, predator populations cannot be quantified easily, and thus identification of related parameters may be difficult.

Soluble microbial products (SMP) are often considered as important COD fraction in wastewater treatment systems (47). When decay or lysis of the whole cell or a part of the cell occurs, secondary substrates will be released into the bulk solution. This process is modeled as decay or lysis process in ASM 1 and 2. It is assumed in ASM 1 and 2 that the biomass is degraded to SB-COD and inert COD. This means that the secondary substrates produced through decay or lysis are exactly the same as other SB-COD fractions from a modeling perspective. This is not likely: secondary substrates produced by the biomass will almost certainly have different kinetic characteristics. Therefore, SMP should be defined as a separate component representing the secondary substrates produced by the lytic activities of the cells. Contribution of the SMP to the COD balance is more significant in biofilm systems than in AS systems, and SMP is sometimes introduced in the modeling of the biofilm process (47).

It is easy to allow a model to become more complex based on microbiological information. For example, we have only one heterotrophic biomass in ASM 1 and 3, but this can be divided into many different heterotrophic groups, including those with and without denitrifying capability or with and without storage capability. One may think that such a multiple heterotroph model should have a higher capability to describe more comprehensive situations, but this is not always true. Parameter identification becomes more difficult as the complexity of the model increases, and the predictability of models may decrease. As stated before, it is evident that cell internal glycogen plays an essential role in the EBPR metabolism, but glycogen is not incorporated into ASM 2 so that the structure of the model may not be too complicated for practitioners. In the practical application of the AS model, most of the PAO

behavior can be described with only one of the two storage polymers: poly-P or glycogen. It is reasonable, therefore, that poly-P, which can be easily understood by wastewater engineers, is adopted in ASM 2 to reduce its complexity. However, glycogen in PAOs is sometimes essential and critical if the AS models are to be used for scientific purposes. In fact, several AS models with glycogen have been proposed (48).

The concentration of hydrogen ion (H^+) or pH is not considered as a state variable in the IWA models. This is simply because pH is not exactly predictable. To describe the behavior of pH (H^+), it is necessary to be able to model the acid-base equilibrium. However, many chemical species can affect this in wastewater or in the AS systems in general. It is impossible to include all these species into the model. On the other hand, the acid-base equilibrium is well understood theoretically and it is easy to create a pH prediction model once the species that are involved in the this equilibrium are identified. For example, the carbonate equilibrium can be introduced into the AS model to predict pH. In oligotrophic water environments, the carbonate equilibrium actually determines the pH in the system. So, a carbonate-based pH prediction module of the AS model can be developed as a first step. For this purpose, ASM 3c (49), an adapted version of ASM 3, where organic components are expressed in terms of organic carbon rather than COD, may be useful. If carbon is used as the basis for mass balance, carbon dioxide should be accounted for in this balance and the pH prediction model based on the carbonate equilibrium will become realistic. Because pH is a very important factor affecting microbiological activities, the development of AS models containing the effect of pH will be useful both from a scientific and a practical point of view.

CONCLUSION

In the present article, various microbiological issues associated with the IWA AS models are discussed in terms of modeling. The IWA models have been developed on the basis of evidence accepted by the majority of microbiologically oriented wastewater engineers. Therefore, the IWA models are not the most advanced AS models, but rather give a fundamental and common basis for the further development of revised, detailed, or innovative models. Extension and improvement of the present models will surely be made according to practical demands in the future.

ACTIVATED SLUDGE — MOLECULAR TECHNIQUES FOR DETERMINING COMMUNITY COMPOSITION

ALEXANDER LOY
HOLGER DAIMS
MICHAEL WAGNER
Technische Universität München
Freising, Germany

Wastewater treatment is one of the most important biotechnological processes that is used worldwide to treat polluted sewage and to ameliorate anthropogenically induced damage to the environment. Depending on the treatment goals, different types of sewage treatment plants are used (see ACTIVATED SLUDGE — THE PROCESS). This article focuses on the microbiology of the activated sludge process, which is most commonly used and in which the microbial biomass is aerated and kept in suspension during the treatment process. In addition, we also cover activated sludge and biofilm nutrient removal plants in which anaerobic and aerobic treatments are combined to allow for complete nitrogen and/or biologically enhanced phosphorus removal (EBPR). It is common knowledge that in all types of wastewater treatment plants (wwtps), prokaryotic microorganisms dominate and represent the "causative agent" responsible for the observed conversions. On the other hand, certain microorganisms cause the most frequently encountered problems in wastewater treatment (see FILAMENTOUS BACTERIA IN ACTIVATED SLUDGE: CURRENT TAXONOMIC STATUS AND ECOLOGY). Thus, the efficiency and robustness of a wastewater treatment plant mainly depend on the composition and activity of the microbial communities present in its different stages (see ACTIVATED SLUDGE — THE MICROBIAL COMMUNITY). Although biological wastewater treatment has been intentionally used for more than a century, because of methodological limitations, knowledge on the microbiology of this process was scarce until a decade ago. Consequently, these microbial communities were considered as a "black box," and progress in the design and control of plants was derived mainly from empirical research in civil and process engineering. Only after the introduction of molecular techniques in microbial ecology, it has become possible to determine the composition and dynamics of microbial communities in these systems and to identify the microbial key players for the different process types. It is the aim of this article to review these new insights and to provide some guidance on how this knowledge could be extended by implementing newly developed methods and be used for future improvement in wastewater treatment.

METHODS FOR MICROBIAL DIVERSITY ANALYSIS IN WASTEWATER TREATMENT PLANTS (WWTPS)

This article briefly summarizes established methods for microbial community analysis. It is not the goal to provide an encompassing overview on technical details of each method but rather to discuss the advantages and limitations of each approach for its use in wastewater treatment microbiology.

Light Microscopy and Cultivation

Traditionally, two approaches to investigate the microorganisms in wwtps were applied. Most frequently, obtained samples were analyzed by standard light microscopy to obtain an overview of the abundance of floc-forming and filamentous bacteria. Because of the importance of the latter group of organisms for sludge bulking and foaming (Activated sludge — bulking; Activated sludge — foaming), keys were developed for a provisional identification of filamentous bacteria using (*1*) their reaction to gram- and Neisser-staining and (*2*) morphological characteristics (1,2). However, recent molecular approaches revealed that microorganisms affiliated with different bacterial domains are identified as the same filament type using these keys (see FILAMENTOUS BACTERIA IN ACTIVATED SLUDGE: CURRENT TAXONOMIC STATUS AND ECOLOGY). Furthermore, polymorphism of certain filaments has been described (3), which further complicates morphology-based identification.

The second approach is based on cultivation and isolation of bacteria from wwtps. The number of active bacteria can be estimated by most probable number (MPN) techniques and/or total plate counts. After isolation, bacteria are identified using either physiological parameters or chemotaxonomic markers such as cellular fatty acids or respiratory quinone profiles. The latter two biomarkers can also be used directly for profiling activated sludge microbial communities (4–6) but provide only relatively low-resolution information. Numerous bacteria were isolated and identified using cultivation-based techniques, leading to the perception that, for example, pseudomonads, enterobacteriaceae, and acinetobacters are key components of the microbiota of these systems (see ACTIVATED SLUDGE — THE MICROBIAL COMMUNITY). After the introduction of molecular techniques for community analyses it became obvious that only less than 16% of the microorganisms can be isolated from activated sludge by standard cultivation and that those bacteria forming colonies on the respective media are generally of minor numerical importance in situ (7–10). Therefore, cultivation offers a very biased and incomplete view of the bacterial diversity there. On the other hand, directed cultivation of in situ important microorganisms is still a prerequisite for their encompassing physiological and genetical analysis.

Immunofluorescence

A more direct identification and quantification of bacteria is offered by the use of fluorescent antibodies (FA). However, the production of these antibodies, generally, still requires the prior isolation of the target organism, restricting the method to culturable bacteria. Once available, the FA technique can be used to identify and quantify defined microorganisms within activated sludge or biofilms. For example, *Sphaerotilus natans*, *Acinetobacter* sp. (11), and *Thiothrix* sp. have been detected by this technique (12). The specificity of antibodies cannot be adjusted and is usually below the species level. This is an advantage if, for example, the fate of specific strains should be monitored. On the other hand, the high serological diversity of many bacterial genera and even species (13,14) would require the simultaneous use of a huge number of FA for their detection, thus rendering the method cumbersome. Furthermore, FA are relatively large molecules and thus do not easily penetrate through dense extracellular polymeric substances of flocs and biofilms, although this problem can be avoided if the FA technique is applied to cryosections. Another difficulty of the FA technique is that it often suffers from a high background fluorescence caused by unspecific binding of the FA to, for example, detritus (14,15) and filament sheaths. In addition, the expression of the detected epitopes on the cell surface can vary with changing environmental conditions, a fact that can cause false-negative results. Despite these limitations, the FA technique has the unique advantage that detection does not require the killing of the cells. Thus, antibodies can be used to enrich target cells, for example, via flow cytometry, coated microtiter plates, or magnetic beads for subsequent cultivation.

The 16S rDNA Approach

The comparative sequence analysis of environmentally retrieved 16S rDNA sequences has become the gold standard for cultivation-independent assessment of bacterial diversity in natural and engineered systems (16). Current 16S rDNA databases contain more than 20,000 entries (17) and thus provide a high-resolution framework for the assignment of those sequences obtained in 16S rDNA libraries from environmental diversity surveys (18). The approach consists of DNA extraction, subsequent PCR amplification of (a fragment of) the 16S rDNA gene using primers targeting regions conserved in the bacterial domain, cloning, and sequencing. The obtained sequences are analyzed together with adequate reference sequences to infer their phylogenetic affiliation. A meaningful phylogenetic analysis requires the use of almost full-length 16S rDNA sequences and of different treeing methods applied to different data sets (19).

As a result of the development of premanufactured kits (e.g., for cloning) and automated sequencers, the analyses of relatively high clone numbers per library has become possible. It is however important, but rarely done in published studies, to determine whether the number of analyzed clones does sufficiently well represent the diversity in the established library. For this purpose, the clones should be grouped into operational taxonomic units (OTUs) according to their 16S rDNA similarities with each other. We recommend to use a 97% similarity threshold for OTU assignment, because it has been demonstrated that two organisms with a lower 16S rDNA similarity also have DNA-DNA similarities below 70% and thus represent different genospecies (20,21). However, organisms with highly similar or even identical 16S rDNA sequence might nevertheless represent two different species (20), and thus the OTU concept leads to underestimation of the actual species richness. Once the clones have been assigned to OTUs, rarefaction analyses (22,23) or coverage estimates (24) should be performed to determine whether the analyzed number of clones represents a sufficient sample size. Figure 1 shows rarefaction analyses of 16S rDNA surveys of wwtps, the respective coverage estimates are depicted in Table 1.

The rarefaction analyses and coverage estimates show that most studies did not adequately harvest the diversity of their 16S rDNA libraries. This is understandable, because the number of identical or highly similar clone sequences increases with the number of sequenced clones and thus extensive clone sequencing creates highly redundant information. Therefore, screening of the 16S rDNA clones with fingerprinting techniques (discussed later) for selection of different clones for sequence analyses is recommended.

However, it is important to realize that even if the complete diversity of an environmental 16S rDNA clone library is harvested, the obtained species inventory might not represent the naturally occurring diversity. In other words, not all, and sometimes even not all, numerically important bacterial populations of an environmental sample will be found in a respective 16S rDNA library. This failure might be caused by (*1*) inefficient DNA extraction (27) (e.g., certain gram-positive bacteria are difficult to lyse), (*2*) inadequate coverage of the selected PCR primers, (*3*) kinetic and stochastic biases introduced by the PCR amplification (28–30), and (*4*) cloning biases. For example, the high coverage but low overall OTU number obtained in the 16S rDNA library analysis of activated sludge from a municipal high-load wastewater treatment basin (31) does not necessarily reflect low species richness but was probably caused by the omission of a dedicated DNA-extraction protocol before PCR amplification.

For establishing a most representative 16S rDNA library, one might consider to (*1*) use different DNA-extraction techniques and to combine the isolated nucleic acids before PCR amplification, (*2*) to use more than one primer set for amplification, and (*3*) to use different vectors for cloning. Regarding the PCR conditions best suited for a general diversity survey, extremely stringent annealing conditions should be avoided to allow binding of the primers to organisms with nucleotide exchanges in the target position. This procedure might lead to the amplification of undesired PCR products and the necessity to purify the expected PCR amplificate by agarose gel electrophoresis and band excision before cloning. Furthermore, the PCR cycle number has a profound

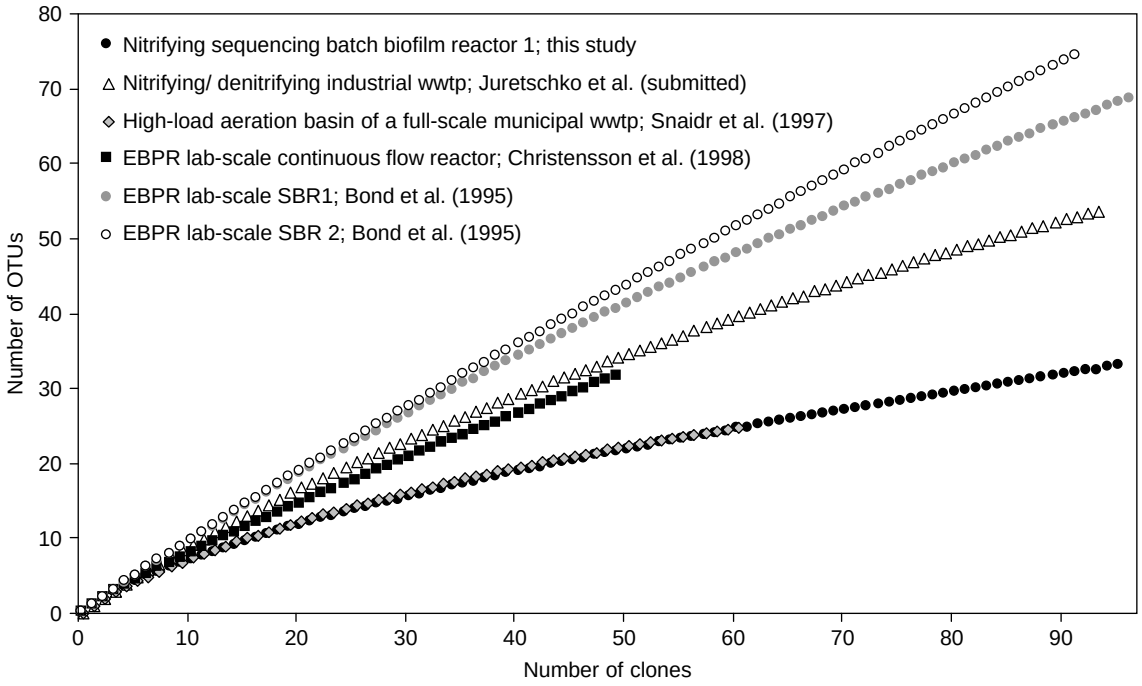

Figure 1. Rarefaction analyses of 16S rDNA inventories of different wwtps. A 97% similarity threshold was used for assignment to an operational taxonomic unit (OTU). The studies of Liu and coworkers (25) and Dabert and coworkers (26) were not considered because only one sequence per OTU has been deposited in public databases.

influence on the composition of the PCR amplificate if complex template mixtures are used (29). If high cycle numbers are used, highly abundant and less abundant organisms are more likely to be represented in comparable numbers in the PCR product, an effect caused by template reannealing at high concentrations (29). In contrast, the 16S rDNA composition of PCR products generated with low cycle numbers more accurately represents the composition of the 16S rDNA sequences in the isolated nucleic acids.

Additionally, the 16S rDNA approach can also indicate or even create artificial diversity. Small sequence differences among multiple rRNA operons of a single bacterium, the so-called microheterogeneities (32), might be interpreted after amplification and cloning as microdiversity, which, however, does not exist at the organism level. Furthermore, the formation of chimeric sequences via in vitro recombinations (33,34) and the introduction of point mutations via the thermostable DNA polymerase (35,36) leads to the retrieval of sequences that differ from their natural counterparts. Although chimeric sequences composed of distantly related sequence fragments can be recognized easily by standard software tools (37) or comparative phylogenetic analyses of different sequence regions (27), it is virtually impossible to identify chimeras among closely related organisms. Polymerase-induced mutations can only be detected with a certain probability in highly conserved sequence regions by database comparison.

In essence, the 16S rDNA approach described earlier is an essential tool for microbial diversity analyses in wwtps. However, because of the numerous biases inherent to this approach quantitative data on the microbial community composition can only be obtained if it is combined with quantitative dot blot or in situ hybridization techniques, which are described later.

16S rDNA-Based Fingerprinting Techniques

16S rDNA-based fingerprinting techniques nicely amend the 16S rDNA approach described earlier. The common principle of these methods is to separate PCR products of the same length but different sequence to visualize the diversity within the amplificate by a banding pattern. Many of these techniques were invented to analyze mutations in medical research and were later adapted to environmental microbiology. The most frequently applied fingerprinting technique in wastewater microbiology is the denaturing gradient gel electrophoresis (DGGE) (6,38–40), but also terminal restriction fragment length polymorphism (T-RFLP) (41), gelretardation (42), and single strand conformation polymorphism (SSCP) (43,44) have been used. The main advantage of the fingerprinting techniques is that high sample numbers can be processed in a relatively short time to gain an overview of the dynamics of complex microbial communities in wwtps. DGGE and gelretardation bands of interest can be excised, cloned, and sequenced for subsequent identification. DGGE offers a higher resolution compared with gelretardation but is, in contrast to the latter method, limited to fragments smaller than 500 nucleotides that are not well-suited for phylogenetic analyses. The organism represented by a T-RFLP or SSCP band can only be identified if a 16S rDNA clone library is also established, and if the obtained clones are sequenced

for identification and are used also as references in the respective fingerprinting protocol. In general, fingerprinting techniques are affected by the same DNA-extraction and PCR-amplification biases as the 16S rDNA approach and thus cannot provide quantitative data.

Hybridization Techniques Using rRNA-Targeted Probes

Dot blot and in situ hybridization techniques using rRNA-targeted oligonucleotide probes allow us, in contrast to all other methods discussed in this article, to quantitatively determine the composition of complex microbial communities. The specificity of the probes can be adjusted to different phylogenetic levels. Specialized software tools have been developed to assist in probe design and evaluation (17). After design, for each probe optimal hybridization conditions have to be carefully determined using target and nontarget microorganisms. This evaluation requires different procedures for the dot blot (45) and in situ format (46,47). Today a considerable number of ready-to-use domain-, division-, genus-, and species-specific probes are available for identification of the respective target microorganisms within their natural habitat (for a review see Amann and coworkers (16,48)). For high-resolution analyses of a certain environmental sample, additional probes must be designed against cloned sequences obtained with the 16S rDNA approach. Application of these probes in the dot blot or in situ format allows the detection and quantification of the corresponding microorganisms within the habitat for which the 16S rDNA library was established. The complete procedure including the 16S rDNA gene library analysis, clone-specific probe design, and quantitative hybridization experiments is referred to as the *full-cycle rRNA approach* (16).

In the dot blot format, total RNA is extracted from the environment and is immobilized on a membrane together with dilution series of RNA of reference species. Reference rRNA of uncultured microorganisms can be obtained by in vitro transcription of the respective cloned 16S rDNA sequences. Subsequently, the membrane is hybridized with a radioactively labeled probe, and after a stringent wash step the amount of target rRNA is quantified with a Phospho-Imager. Results are expressed as ng of target rRNA per weight or volume of the environmental sample. Alternatively, the membrane can be rehybridized with a bacterial or universal probe, and the amount of population-specific rRNA detected with the specific probe is expressed as fraction of the total (bacterial) rRNA. For details of the method the reader is referred to Raskin and coworkers (49). Quantitative dot blot hybridization measures the abundance of the target population via its rRNA content. Because the rRNA content of a microbial cell varies with its activity and physiological history (50), and prevailing environmental conditions, the obtained data cannot be translated to cell numbers. Furthermore, the method might be biased by a varying efficiency of RNA-extraction from different microbial populations and degradation of the rRNA (which might affect different probe target sites in a different way) during the procedure. Quantitative dot blot analyses have been used in wastewater microbiology (45,51–53) but are more widely applied on environments such as soil and microbial mats (54,55), which because of their high background fluorescence are not well-suited for fluorescence in situ hybridization (FISH).

In situ hybridization with fluorescently labeled, rRNA-targeted oligonucleotide probes is perfectly suited to identify the target organisms within activated sludge flocs or biofilms by specific staining. For this purpose, samples are pretreated with chemical fixatives to kill the cells, to preserve their morphology, and to make them accessible to oligonucleotide probes. For gram-negative bacteria, a paraformaldehyde-based fixative fulfills these requirements and allows storage of the samples at $-20\,^{\circ}C$ for several years (16). However, a fixation protocol permeabilizing all gram-positive bacteria still has to be developed. Many, but not all, gram-positive bacteria can be permeabilized efficiently for FISH by addition of 50% EtOH (56). Others, for example, the mycolata containing mycolic acids in their cell walls, require additional or alternative pretreatments including the use of cell wall lytic enzymes (57–59). Fixed samples are hybridized with probes labeled with fluorescent dyes. For environmental studies, the dyes FLUOS 5 (6)-carboxyfluorescein-N-hydroxysuccimide ester: green fluorescence), Cy3 (orange fluorescence), or Cy5 (infrared fluorescence) are well-suited and permit the specific detection of the target cells with up to three simultaneously applied probes (60). If more than one probe is used in a hybridization experiment and if the probes require different conditions to ensure specificity, subsequent hybridization reactions from high to low stringency have to be performed (3). In contrast to dot blot hybridization, simultaneous binding of multiple probes to the same target cells can be proven by FISH through microscopic observation of the hybridized cells and the use of different probe labels. Therefore, sets of probes with hierarchical or identical specificity can be used to increase the reliability of the identification.

For many years, quantitative FISH data on the bacterial community structure of activated sludge or biofilms required microscopic counting of stained cells, a time-consuming procedure that is relatively inaccurate in samples containing densely clustered cells. Generally, the abundance of a certain population of interest is expressed as the percentage of all cells that can be stained with either bacterial probes (7,47) or a DNA-binding dye such as DAPI (61). The combination of FISH and confocal laser scanning microscopy (62) not only dramatically improved the image quality by exclusion of blurring out-of-focus fluorescence, but also allowed the development of semiautomatic quantification protocols by use of digital image analyses (42,63). These methods measure the specifically stained biovolume of a target population and refer it to the volume of those microorganisms stained by the bacterial probe set or a DNA-binding dye. Although using the manual technique only a few hundred or thousand cells are counted, the semiautomated protocols detect more than 100,000 cells per measurement and thus are much more reliable and reproducible.

However, it is important to realize that numbers obtained by this technique or its manual counterpart cannot be used directly to compare the abundance of detected bacterial populations among different samples, because differences in biomass among the samples are not considered. Thus, for intersample comparison, the respective numbers need to be normalized by taking into account biomass differences estimated, for example, via volatile suspended solids (VSS) determinations (64) or total DAPI counts per sample volume on a membrane filter (8).

Confocal laser scanning microscopic analyses of FISH results may also be used to investigate the spatial distribution of microorganisms in activated sludge flocs and biofilms and to study colocalization of microbial populations (27,62,65). However, such analysis can only be performed with high accuracy, if the architecture of the flocs or biofilms is preserved by embedding (for embedding protocols see (66) or cryosectioning (65,67)) and is thus not destroyed during fixation and hybridization.

One potential disadvantage of FISH is its relatively high detection limit of approximately 10^3 to 10^4 target cells ml^{-1}. Furthermore, only cells with a ribosome content of more than about 1,000 copies can be detected by probes without additional signal amplification (68). Because microorganisms with a low cellular ribosome content are probably not active, this requirement does not hamper the in situ analysis of physiologically active cells in wwtps. This is also reflected by the fact that about 90% of all DAPI-positive cells can be detected with the bacterial probe set in a typical plant (47). On the other hand, it is frequently assumed that a high cellular ribosome content of a microbial cell leading to a bright FISH signal is an indicator of its physiological activity at the time of sampling. This interpretation can be misleading because nitrifying bacteria, for example, maintain high ribosome levels even after complete

inhibition for several days (14) or starvation for a month (69). More direct in situ analyses of the activity may be achieved by the use of oligonucleotide probes targeting the 16S/23S intergenic spacer region as demonstrated for *Acinetobacter* sp. (70) and the anaerobic ammonium-oxidizer *Candidatus* "Kuenenia stuttgartiensis" (71).

In summary, a variety of molecular methods is available for investigating microbial diversity in wastewater treatment plants. In particular, the full-cycle rRNA approach allows to precisely measure the composition and dynamics of microbial communities in these systems. The following section provides an overview on the current status of knowledge that has been accumulated by application of these research approaches in wastewater microbiology.

GENERAL MICROBIAL DIVERSITY IN WASTEWATER TREATMENT PLANTS

FISH with Group-Specific Probes

Group-specific rRNA-targeted probes (Table 2) have been widely applied in the so-called top-to-bottom approach for the investigation of activated sludge to obtain a fast but relatively low-resolution analysis of the respective microbial communities (7,8,10,25,72). These studies showed the dominance of *Proteobacteria* and revealed that the β-subclass is the most abundant subclass in these systems. α- and γ-subclass *Proteobacteria* are found in lower but generally still considerable numbers. Subsequently, the widespread distribution of members of the *Cytophagales* (8,73), the *Planctomycetales* (74), and the high-G+C gram-positive bacteria (8,25) in activated sludge was demonstrated. In addition, application of group- and genus-specific probes showed that the numerically important bacterial groups in activated sludge are dramatically underrepresented after cultivation and that certain bacterial groups with a low in situ abundance are best adapted to laboratory cultivation and thus are isolated most frequently. For example, γ-subclass *Proteobacteria* generally occur in relatively low numbers in activated sludge but clearly dominate the heterotrophic flora obtainable on nutrient rich agar plates (7–9).

16S rDNA-Based Diversity Surveys

The most detailed knowledge on species richness of microbial communities in wastewater treatment plants can be obtained by phylogenetic inventories via 16S rDNA clone libraries established using bacterial or universal primers. However, probably because of the tediousness of the method, such surveys have only been published for six treatment systems, including five laboratory scale reactors (25,26,75,76), and one high-load basin of a full-scale municipal wastewater treatment plant (31). Results of these surveys are summarized in Table 1. In addition to published results, we have included in this table two studies from our laboratory dealing with a pilot-scale nitrifying, sequencing batch biofilm reactor (partially published by Daims and coworkers (77)) and an intermittently aerated nitrifying/denitrifying industrial activated sludge plant connected to a rendering plant (78). It is obvious that the number of plants for which 16S rDNA libraries have been established is too low to provide an encompassing overview of the entire microbial diversity of such systems. Although several SBRs with enhanced biological phosphorus removal have been investigated, for the other plant types only single surveys were performed. Nevertheless, some general conclusions can be drawn already. Of the 36 divisions recognized for the bacterial domain (18), members of 13 divisions were detected in the surveys, indicating considerable microbial diversity in wastewater treatment plants. Consistent with the FISH results mentioned earlier, *Proteobacteria* are abundant in each library and represent more than 50% of the clones in five of the eight surveys. With one exception, β-*Proteobacteria* are the most frequently retrieved members of this division. Apart from the *Proteobacteria*, the *Cytophagales*, the Green-nonsulfur bacteria and the *Planctomycetes* were detected in significant numbers. One library of a plant designed for enhanced biological phosphorus removal in a continuous flow system is dominated by high-G+C gram-positive bacteria, consistent with the proposed importance of this group for phosphorus removal (discussed later) (8).

Fluorescence In Situ Hybridization and the Full-Cycle rRNA Approach

So far the microbial community structures of activated sludges from only two wastewater treatment plants have been investigated using the full-cycle rRNA approach. Snaidr and coworkers analyzed a high-load aeration basin of a large municipal wastewater treatment plant (31,60), whereas Juretschko and coworkers studied an intermittently aerated industrial wastewater treatment plant designed for simultaneous nitrification and denitrification (27,78). The results from the respective 16S rDNA clone libraries are depicted in Table 1. Snaidr and coworkers designed probes for a few selected clones and showed that a high microdiversity of bacteria of the beta-1 group of the β-subclass of *Proteobacteria* was present in the municipal activated sludge. Furthermore, *Sphingomonas*- and *Arcobacter*-related populations were detected with a relative abundance of 3 and 4% of all cells, respectively.

The composition of the microbial community in the industrial plant was investigated in more detail using semiautomatic quantitative FISH. Hybridization with group-specific probes demonstrated that the β-subclass of *Proteobacteria* made up almost half of the total biovolume of those bacteria detectable with the bacterial probe set (Fig. 2a). Other in situ important groups were the α-subclass of *Proteobacteria*, the *Nitrospira*-phylum, the *Planctomycetes*, and the green nonsulfur bacteria. Figure 2a also depicts differences between the in situ abundance of the groups and their representation in the clone library.

The composition of the β-subclass of *Proteobacteria*, the numerically most important group within this system, was further analyzed using OTU-specific probes for quantitative FISH (Fig. 2b). Bacteria related to *Zoogloea*

ramigera and the *Azoarcus/Thauera* cluster were the most abundant members of this subclass in situ, and accounted for 36% and 34% of the biovolume of the *β-Proteobacteria*. In addition, significant numbers of the ammonia-oxidizer *Nitrosococcus mobilis* (which was not present in the clone library), *Alcaligenes latus*-like bacteria, and *Brachymonas denitrificans*-related microorganisms were recorded. In total, only 6.5% of the bacteria of the *β-Proteobacteria* detectable in situ could not be assigned to a specific genus.

FUNCTIONAL GROUPS OF MICROORGANISMS IN TREATMENT PLANTS

From an applied perspective, identification and characterization of those bacteria responsible for specific

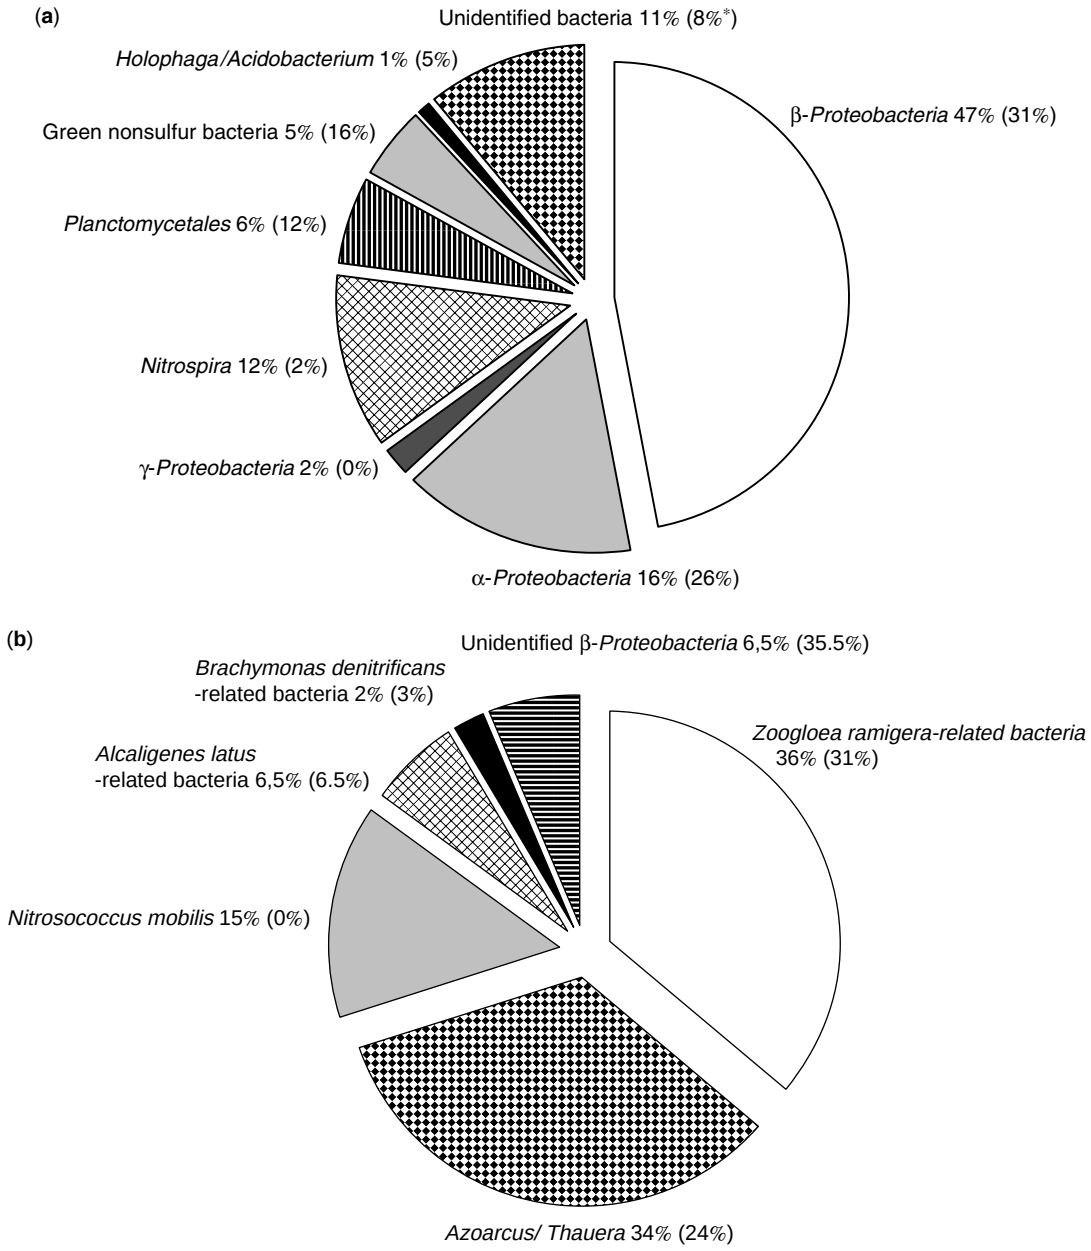

Figure 2. Microbial community structure of an industrial nitrifying/denitrifying activated sludge analyzed by FISH using group-specific (panel a) or β-subclass OTU-specific (panel b) probes. The biovolume of the specifically stained cells was determined using confocal laser scanning microscopy and digital image analyses and expressed as percentage of the biovolume of those cells detectable by in situ hybridization with the bacterial probe set. For panel B the biovolume of the β-subclass *Proteobacteria* was set to 100% and the other groups shown in this panel were scaled accordingly. Numbers in brackets show the abundance of the respective target organisms in the 16S rDNA clone library established for the same sample. ∗sequences not affiliated with the depicted groups.

transformations of sewage compounds are of primary importance. In particular, the organisms responsible for nitrogen and phosphorus removal are of interest. However, 16S rDNA sequence-based identification of a microorganism generally does not allow to infer its functional properties. Phylogenetically closely related microorganisms may possess different metabolic potentials. For example, certain obviously nonphotosynthetic bacteria that have been implicated with enhanced biological phosphorus removal (EBPR) are closely related to the phototrophic β-subclass proteobacterium *Rhodocyclus purpureus* ((89); mentioned later also), which is not capable of performing the required phosphorus transformations. On the other hand, several physiological traits important for wwtps, for example, denitrification, are found dispersed in many different phylogenetic lineages. Only for a few physiological

groups does an unambiguous linkage between phylogeny and physiology exist. One example is the lithoautotrophic ammonia oxidizers that form two monophyletic clusters in the β- and γ-subclasses of *Proteobacteria*, respectively (90). All known organisms affiliated with these clusters gain their energy by oxidation of ammonia to nitrite.

One way to identify microorganisms capable of performing a certain function in a wwtp is to use lab-scale reactors inoculated with activated sludge or biofilm material, which select for the respective functional microbial group. Using this approach, enrichments of yet uncultured nitrite oxidizers (91), anaerobic ammonium oxidizers (92), and bacteria catalyzing EBPR (89,93) were obtained. Although these studies provided important new insights, enrichment in reactors might favor the growth of organisms not important in a full-scale wwtp by inducing biases comparable to those caused by cultivation approaches. This effect is probably pronounced, in particular, if the reactor is fed with artificial sewage or if the sewage is amended with nutrients such as acetate. Therefore, the identification of organisms catalyzing a certain function in a reactor enrichment always has to be complemented with investigations on the in situ abundance and function of these bacteria in full-scale wwtps.

A major current research challenge is the development and validation of techniques for in situ analyses of the function of microorganisms within their environment. For example, selected genes coding for key enzymes of certain metabolic pathways (often referred to as *functional genes*) can be used both as phylogenetic and functional markers for the respective organisms. Using this approach, specific primers are used for PCR amplification of a fragment of the respective gene from a wwtp sample. After cloning and sequencing, the affiliation of the environmental gene fragments is determined by comparative sequence analyses with reference cultures. Although this approach also suffers from DNA extraction, PCR- and cloning-biases (discussed earlier), it combines, in contrast to the 16S rDNA approach, identification with assignment of a metabolic potential. In wastewater microbiology, the *dsrAB* genes coding for the dissimilatory sulfite reductase of sulfate-reducers (94) and the *amoA* gene encoding the active-site subunit of the ammonia-monooxygenase of ammonia-oxidizers (95,96) have been used to investigate the diversity of both functional groups (90,97). However, the mere detection of a functional gene does not prove that this gene was transcribed, translated, and functionally active in the respective organism.

Another way to link in situ identification of microorganisms in wwtps with a specific function is to combine FISH and microelectrodes (98). For example, zones of nitrification or denitrification in a biofilm can be determined using the appropriate microelectrodes. Equipped with this information, the bacteria living in the respective zones can be identified using FISH (65,67,99,100). If quantitative FISH data are available, this sophisticated approach can even be used to estimate substrate conversion rates per cell and K_S values (65). Nevertheless, the combination of FISH and microelectrodes has several limitations. Microelectrodes are not available for all important substances (e.g., a microelectrode suitable for phosphate determinations has not yet been developed), and those that exist do not function under all environmental conditions. Microelectrode measurements are one-dimensional and thus are heavily influenced by spatial heterogeneity of the sample. This is particularly important because it is currently not possible to detect the injection channel of the microelectrode in a subsequent FISH analysis in order to investigate the microbial communities surrounding this site. Therefore, FISH-microelectrode measurements are much easier to interpret in biofilms with a layered distribution of microorganisms than in heterogeneous and structurally dynamic activated sludge flocs. Furthermore, the spatial resolution of microelectrodes of 10 to 50 μm is clearly above the single-cell level and does not allow to directly investigate the function of single microbial cells in an environment.

The in situ physiology of microorganisms in wwtps can be investigated using a combination of FISH and microautoradiography (101,102). A small volume of the native sample is incubated with radioactively labeled substrates under suitable environmental conditions. After incubation the samples are fixed, and substrate not incorporated by the cells is removed by a series of wash steps. Subsequently, samples are cryosectioned and transferred to a cover slip for FISH analyses. Finally, the samples are covered with an autoradiographic emulsion, developed, and viewed with an inverse confocal laser scanning microscope. Cells are identified by their probe-conferred fluorescence, and silver grain formation on top of the cells (in the emulsion) indicates physiological activity and substrate uptake under the selected environmental conditions. If combined with an appropriate study design, most functionally important groups of microorganisms can be identified and quantified using the combination of FISH and microautoradiography (101). It should be stressed that radioactive labeling of cells in the FISH-microautoradiography procedure is unlikely to be caused by simple substrate uptake because the cells are permeabilized for oligonucleotide penetration and therefore unbound substrate is removed during the multiple wash steps. Consequently, microautoradiographic detection requires incorporation of the substrate into a macromolecule by the enzymatic apparatus of the cell. The major disadvantages of FISH-microautoradiography are that it is relatively expensive and time-consuming, and that radioactive derivatives of many substances are not easily available. Furthermore, the spatial resolution of microautoradiography depends on the isotope used for substrate labeling. Although tritium-labeled substrates often allow single cell resolution in cryosections, lower resolution on a cell cluster level is achieved using ^{14}C- or ^{33}P-labeled substrates.

In the following sections, the current knowledge on the diversity of important physiological groups of bacteria in wwtps is reviewed.

Nitrifying Bacteria

The nitrifying bacteria encompass two groups of microorganisms, the ammonia- and the nitrite-oxidizing bacteria, which catalyze the oxidation of ammonia to nitrite and of nitrite to nitrate, respectively. Because most of the

nitrogen in the influent of a wwtp is present either in form of urea (which is hydrolyzed to ammonia) or ammonium/ammonia, the nitrifying bacteria play a central role in nitrogen removal in wwtps. It is important to lower the ammonia concentrations in the effluent of wwtps because this compound is toxic to aquatic life and promotes eutrophication in the receiving water. Nitrifying bacteria are extremely slow-growing microorganisms and are recalcitrant to cultivation attempts. Because of the sensitivity of nitrifying bacteria to disturbances such as pH and temperature shifts, breakdown of the nitrification process is frequently reported from municipal and especially industrial wwtps.

According to microbiology and civil engineering textbooks, the model ammonia-oxidizer is *Nitrosomonas europaea*. However, FISH analyses in nitrifying activated sludge and biofilms showed that other ammonia-oxidizers are more important. In an industrial nitrifying/denitrifying plant, the dominant ammonia-oxidizer was *N. mobilis*, a bacterium that was previously considered to occur in brackish water only (27). Subsequently, *N. mobilis* was also detected in significant numbers in a nitrifying sequencing batch biofilm reactor (77). In contrast, *Nitrosospira*-related ammonia-oxidizers were found to be dominant in situ in a laboratory scale-fluidized bed reactor (103). Although *Nitrosospira* was also reported in a PCR-based study as important ammonia-oxidizer genus in wwtps (104), this finding could not be confirmed by FISH analyses of various wwtps and by a large *amoA*-based ammonia-oxidizer diversity survey in wwtps (90). Today it is generally accepted that nitrosomonads (including *N. mobilis*), and not nitrosospiras (encompassing the genera *Nitrosospira*, *Nitrosolobus*, and *Nitrosovibrio*), are important for ammonia oxidation in wwtps. This perception is also reflected in Figure 3 that shows the affiliation of 178 *amoA* clones retrieved from various nitrifying wwtps. Only 10 *amoA* clones from these systems cluster with the nitrosospiras, whereas the remaining 168 clones are affiliated with the nitrosomonads. Figure 3 also shows that almost all recognized lineages of β-subclass ammonia-oxidizers can be found in wwtps. Numerically, the *N. europaea/Nitrosomonas eutropha*-lineage, the *N. mobilis*-lineage, and the *Nitrosomonas marina/Nitrosomonas oligotropha/Nitrosomonas urea* cluster are most frequently detected.

In conclusion, wwtps harbor a diversity of ammonia oxidizers of the β-subclass of *Proteobacteria*, which was enormously underestimated previously. Most of these ammonia-oxidizers are, on the basis of comparative *amoA* sequence analyses, relatively close relatives of described ammonia-oxidizer species. Interestingly, quantitative FISH results indicate that some nitrifying wwtps are dominated by a single ammonia-oxidizer species (27), whereas other plants harbor at least five different coexisting ammonia-oxidizer populations that are present in significant numbers (77).

Traditionally, members of the genera *Nitrobacter* were considered as the most important nitrite-oxidizers in wwtps (105). Therefore, the finding that *Nitrobacter* could not be detected by FISH with specific 16S rRNA-targeted probes in various nitrifying wwtps came as a surprise (106). Using the full-cycle rRNA approach, the occurrence of novel, yet uncultured, *Nitrospira*-like nitrite-oxidizing bacteria in nitrifying wwtps could be demonstrated (27,77,100,107,108). The importance of these microorganisms for nitrite oxidation in wwtps was also confirmed by reactor enrichment studies (91). Today four different phylogenetic lineages, two of them containing 16S rDNA clones of wwtps, within the genus *Nitrospira* have been recognized (Fig. 4) and phylum- and genus-specific probes suitable for FISH are available (109). Combination of FISH and microautoradiography showed that the *Nitrospira*-like nitrite-oxidizers in activated sludge fix carbon dioxide and can also grow mixotrophically using pyruvate but not acetate, butyrate, and propionate (109).

It has been postulated that the predominance of *Nitrospira*-like bacteria over *Nitrobacter* in most wwtps is a reflection of their different survival strategies. Although *Nitrospira*-like nitrite oxidizers are, according to data extracted from microelectrode-FISH analyses, K-strategists and thus may possess a low μ_{max}, but they are well-adapted to low nitrite and oxygen concentrations; *Nitrobacter* was postulated to be a relatively fast-growing r-strategist with low affinities to nitrite and oxygen (65). Because nitrite concentrations in most reactors from wwtps are low, *Nitrospiras* will outcompete *Nitrobacter* in these systems. In plants with temporally or spatially elevated nitrite concentrations, for example, in nitrifying sequencing batch reactors, both nitrite-oxidizers should be able to coexist. Consistent with this hypothesis, co-occurrence of *Nitrobacter* and *Nitrospira*-like bacteria has been observed by FISH in a nitrifying sequencing batch biofilm reactor (109).

Denitrifying Bacteria

Denitrification, the anaerobic respiration with nitrite or nitrate as electron acceptor, is used in wastewater to convert the product(s) of nitrification into gaseous nitrogen compounds (mainly dinitrogen), and thus to remove them from the sewage. Most attempts to identify and enumerate denitrifiers in activated sludge were based on cultivation-dependent approaches. Members of the genera *Alcaligenes*, *Pseudomonas*, *Methylobacterium*, *Bacillus*, *Paracoccus*, and *Hyphomicrobium* were isolated as part of the denitrifying microbial flora from wwtps (110–114). The latter genus was also detected microscopically by its typical cell morphology in denitrifying activated sludge (115,116). However, little is known about whether the aforementioned listed bacterial genera are representative for the in situ active denitrifiers in wwtps. Neef and coworkers, using specific FISH probes, detected significant numbers of *Paracoccus* spp. and *Hyphomicrobium* spp. in a denitrifying sand filter supplemented with methanol as reduced carbon compound for nitrate reduction. But both genera were present in numbers below 0.1% of the total cell counts in a nondenitrifying sand filter run in parallel without addition of methanol, indirectly suggesting an active participation of both genera in the denitrification process (74). Molecular studies of the community composition of denitrifying bacteria are difficult to perform because the denitrifying phenotype cannot be inferred from the

Figure 3. Diversity of *amoA* clones retrieved from different nitrifying wwtps. A schematic AmoA–based phylogenetic classification of the β-subclass ammonia oxidizing bacteria is shown. Multifurcations connect branches for which a relative order could not be unambiguously determined by applying different treeing methods. The cluster designations were adopted from those of Purkhold and coworkers (90). The height of each tetragon indicates the number of sequences in the cluster. γ-subclass ammonia oxidizers are not included because they currently have not been detected by FISH nor by *amoA*-analyses in nitrifying wwtps.

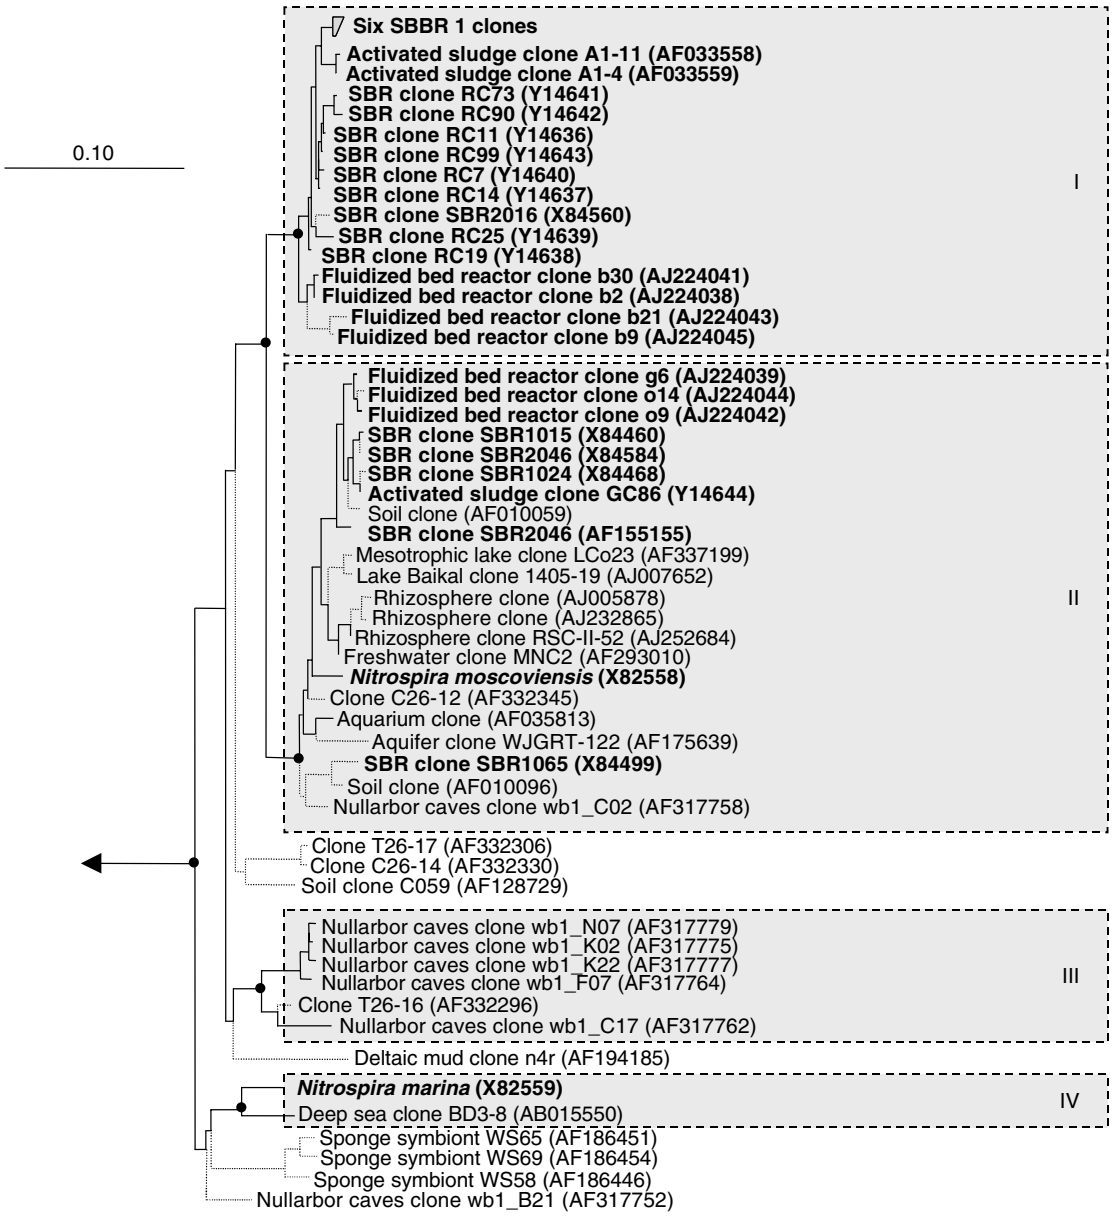

Figure 4. Phylogenetic tree of the genus *Nitrospira* based on comparative analysis of 16S rRNA sequences. The basic tree topology was determined by maximum-likelihood analysis of all sequences longer than 1,300 nucleotides. Shorter sequences were successively added without changing the overall tree topology. Branches leading to sequences shorter than 1,000 nucleotides are dotted to point out that the exact affiliation of these sequences cannot be determined. Black spots on tree nodes symbolize high parsimony bootstrap support, above 90%, based on 100 iterations. The scale bar indicates 0.1 estimated changes per nucleotide. Clones from wwtps and reactors and sequences that belong to isolated strains are depicted in bold. The four sublineages of the genus *Nitrospira* are boxed in gray and marked by the numbers I to IV. Figure modified from Daims and coworkers (109).

phylogeny of a microorganism. The capability to denitrify is found in many bacterial divisions and is not confined to defined phylogenetic clusters within these divisions. However, the combination of FISH and microautoradiography (101) allows to identify denitrifiers in situ. For this purpose, two types of experiments need to be performed. In the first experiment, the wwtp sample is incubated under anaerobic condition in absence of nitrate or nitrite with radioactively labeled substrates that are typically used as electron donors for denitrification. In the second experiment, the sample is incubated with the same labeled substrates under anaerobic conditions but in the presence of nitrate or nitrite. Bacterial species, identified by FISH, that take up substrate under anaerobic conditions exclusively in the presence of nitrate or nitrite are most likely denitrifiers. The use of this technique in combination with

the full-cycle rRNA approach revealed that novel, still uncultured *Azoarcus*-related bacteria are important denitrifiers in an industrial nitrifying/denitrifying wwtp (117).

Anaerobic Ammonium Oxidizing Bacteria

Unexpected nitrogen losses are frequently observed in wastewater treatment plants. In these plants, ammonia was obviously converted to gaseous nitrogen compounds in the absence of organic electron donors excluding the activity of conventional denitrifiers. Using the full-cycle rRNA approach, we could demonstrate that novel planctomycetes distantly related to the recently described anaerobic ammonium oxidizer *Candidatus* "Brocadia anammoxidans" (92,118) did occur in high numbers in these systems (42,118) and were thus probably responsible for the nitrogen removal. Consequently, the new candidatus genus "Kuenenia stuttgartiensis" was proposed (42). Using specific 16S and 23S rRNA-targeting probes for both anaerobic ammonium oxidizers (42,71), a predominance of *Candidatus* "*Kuenenia stuttgartiensis*" over *Candidatus* "Brocadia anammoxidans" in wwtps was observed.

The anaerobic ammonium oxidizers are a perfect example that completely unexpected organisms are hidden in wwtps. Both anaerobic ammonium oxidizers form a monophyletic deep-branching lineage within the *Planctomycetales* (Fig. 5) and oxidize ammonium anaerobically with nitrite to dinitrogen gas (42,92,119). Anaerobic ammonium oxidation in contrast to classical nitrification and denitrification allows to remove ammonium in a one-step process saving space, energy, and money because no aeration or addition of organic carbon for denitrification are required. Anaerobic ammonium oxidation is a very promising method for the treatment of sewage with a high ammonium and low organic carbon content. However, this process needs a mixture of ammonium and nitrite and thus must be coupled to partial nitrification for nitrite production (42,118,120). Furthermore, establishment of anaerobic ammonium oxidizing activity in a wwtp takes a very long time, and once established the process is sensitive to perturbation.

Bacteria Important for Enhanced Biological Phosphorus Removal

Phosphorus removal from wastewater is important to prevent eutrophication, and is therefore an integral part of modern municipal and industrial nutrient removal wwtps. Phosphorus can be precipitated by the addition of iron or aluminum salts and subsequently be removed with the excess sludge. Chemical precipitation is a very reliable method for phosphorus removal but increases significantly the sludge production and thus creates additional costs. Furthermore, the use of chemical precipitants often introduces heavy metal contamination into the sewage and increases the salt concentration of the effluent. Alternatively, phosphorus removal can be achieved by microbiological mechanisms in a process called *enhanced biological phosphorus removal* (EBPR) (121–124). This process is characterized by cycling the activated sludge through alternating anaerobic and aerobic conditions. In the anaerobic stage, the bacteria responsible for EBPR are supposed to gain energy from polyphosphate hydrolysis accompanied by subsequent P_i release for uptake of short-chain fatty acids and their storage in the form of polyhydroxyalkanoates (PHA). Two different models were postulated for the production of the reducing equivalents for this anaerobic metabolism (125,126). In the subsequent aerobic stage, the polyphosphate accumulating organisms (PAOs) possess a selective advantage compared with other microorganisms that were not able to take up fatty acids under the preceding anaerobic conditions by using the stored PHA in an otherwise carbon-poor environment. In parallel, PAOs restore their polyphosphate pools by aerobic uptake of available phosphate from the wastewater. After sedimentation in the secondary clarifier, a part of the biomass is recycled to the anerobic stage and mixed with new wastewater, whereas the excess sludge containing the intracellular polyphosphates is removed from the system.

In contrast to chemical precipitation, EBPR plants have been frequently reported to fail. This raised interest in the microbiology of the process. Traditionally, on the basis of cultivation experiments γ-subclass *Proteobacteria* of the genus *Acinetobacter* were believed to be the only PAOs (127–129). However, today it has become apparent that *Acinetobacter* can accumulate polyphosphate but does not possess the earlier-described PAO metabolism (122). Furthermore, cultivation-independent methods such as fluorescent antibody staining (11), respiratory quinone profiles (4), and FISH with a genus-specific probe (8,9) demonstrated that the relative abundance of *Acinetobacter* in EBPR systems was dramatically overestimated because of cultivation biases, further confirming that *Acinetobacter* is not of importance for EBPR.

Several other bacteria isolated from EBPR reactors have been suggested as PAO candidates. *Microlunatus phosphovorus*, a high-G+C gram-positive bacterium accumulates aerobically polyphosphate and consumes it under anaerobic conditions, but fails to take up acetate or accumulate PHA under anaerobic conditions (130,131). FISH, with a probe specific for *M. phosphovorus*, demonstrated the presence of this organism in an EBPR plant (2.7% of the total bacteria) (132), but no direct indications for the importance of this bacterium for EBPR are available. Furthermore, *Lampropedia* spp. were shown to possess the basic metabolic features of a PAO (133), but their acetate-uptake phosphate-release ratio was much lower than what EBPR models predict, and no additional data regarding the abundance or activity of these morphologically conspicuous bacteria in EBPR systems have been published.

Compared with these cultivation-based attempts, the hunt for PAOs was more successful using molecular tools for analyses of EBPR systems. β-subclass *Proteobacteria* and high-G+C gram-positive bacteria (actinobacteria) increased in number after addition of acetate to the raw sewage of a EBPR full-scale wwtp suggesting that these groups benefit from the enhanced availability of short-chain fatty acids in the anaerobic basin and thus represent candidates for PAOs (8). Additional support for the importance of both groups for EBPR stems from FISH experiments in an efficient EBPR laboratory-scale

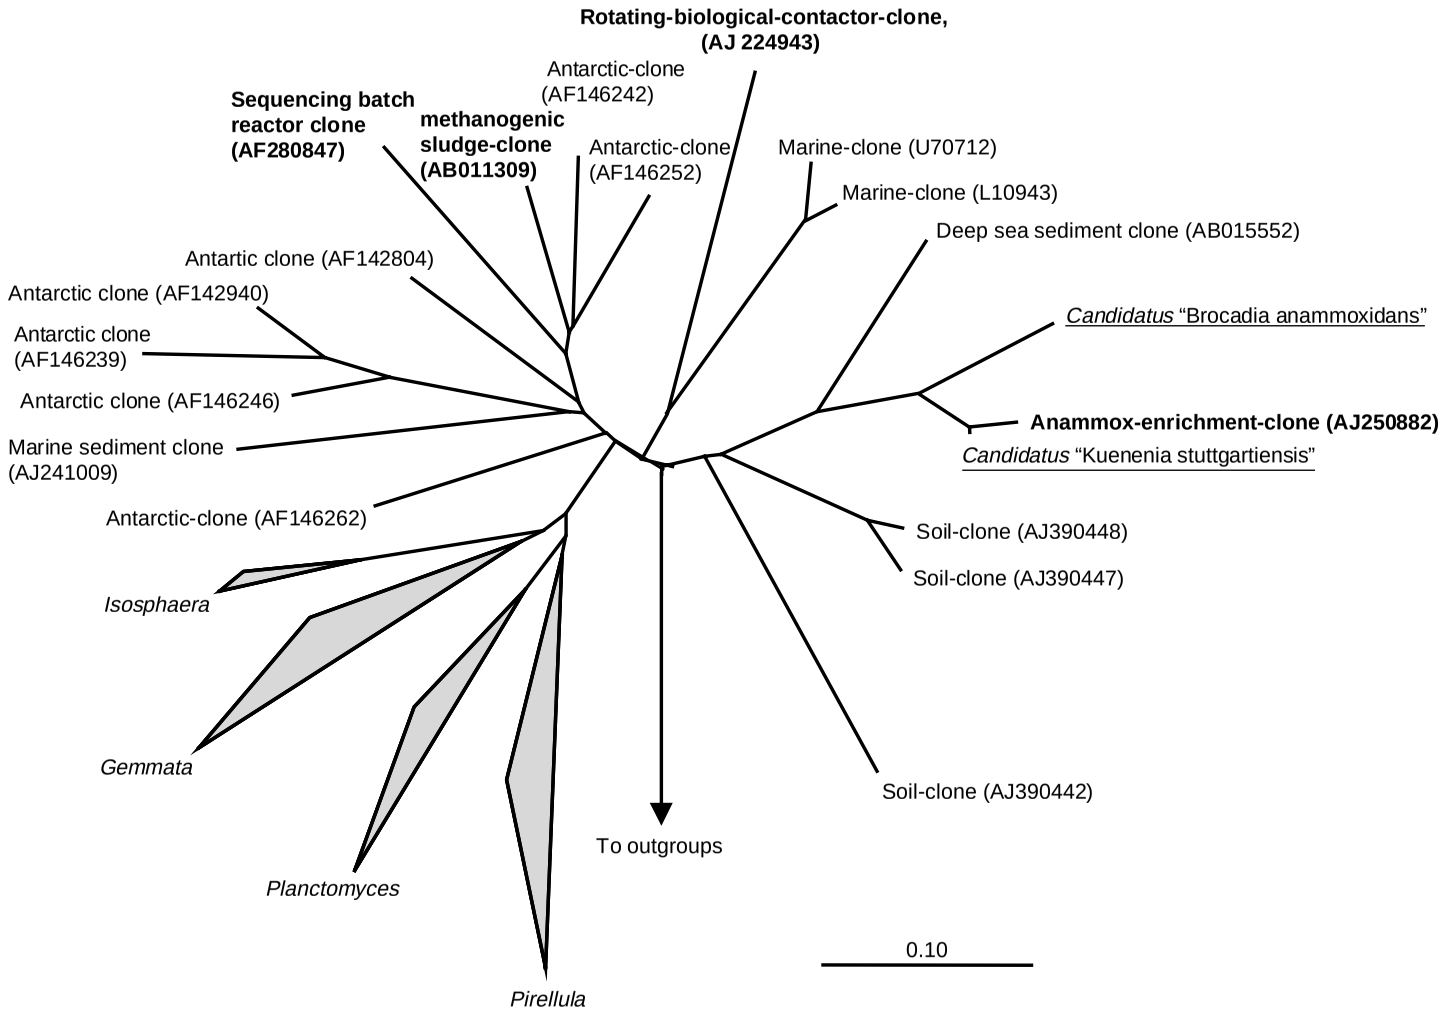

Figure 5. Phylogenetic 16S rDNA tree showing the deep-branching of the anaerobic ammonium oxidizers within the *Planctomycetales*. In addition to the described anaerobic ammonium oxidizers *Candidatus* "Brocadia anammoxidans" and *Candidatus* "Kuenenia stuttgartiensis," several environmental clone sequences, including sequences from wwtps depicted in bold, are unaffiliated with cultured members of the division. The physiology of the organisms represented by these sequences still needs to be clarified. Figure modified from M. Schmid et al. (71).

sequencing batch reactor (72) and respiratory quinone profiling in a lab-scale EBPR system (6). Recently, high-G+C gram-positive bacteria related to *Terrabacter tumescens*, *Tetrasphaera japonica*, and *Tetrasphaera australiensis* were reported to be abundant in EBPR systems and thus might be important for EBPR (25,76,93). Although the function of actinobacteria as PAOs still has to be proven, evidence is available that β2-subclass *Proteobacteria* related to *Rhodocyclus* and *Propionibacter* are important PAOs in many EBPR systems. These bacteria, for which the name *Candidatus* "Accumulibacter phosphatis" was suggested (89), were detected in high numbers in EBPR systems (26,75,89,93,134). Furthermore, phosphorus accumulation by these bacteria in the aerobic phase was demonstrated by sequential FISH and polyphosphate staining (25,93). In addition, acetate uptake in the anaerobic phase and phosphorus uptake under aerobic conditions could be demonstrated for *Candidatus* "Accumulibacter phosphatis" using FISH and microautoradiography (134).

A potential reason for the failure of EBBR plants is the presence of bacteria that use previously stored compounds such as glycogen (also referred to as *glycogen accumulating organisms* (GAOs)) to compete with the PAOs for substrate uptake under anaerobic conditions (41,135,136). Cech and Hartmann (135) described gram-negative cocci in clumps and packages of tetrades in activated sludge and called these morphotypes *G-bacteria*, because their numbers increased after glucose addition. Mino and coworkers (123) suggested that bacteria with a similar morphology are GAOs. However, recent molecular and physiological analyses of various G-bacteria isolated from wwtps revealed a high phylogenetic diversity of this morphotype and provided no support for their role as GAOs (Fig. 6; 137). Molecular community analyses of deteriorated EBPR reactors revealed the predominance of a novel bacterial group within the γ-subclass of *Proteobacteria* (40). The phylogenetic affiliation of this deeply branching group cannot unambiguously be resolved (Fig. 6). These bacteria are good GAO candidates because they occur in deteriorated EBPR systems, probably accumulate PHA, and store little or no polyphosphates (25,40).

CONCLUSION

During the last decade, the application of molecular tools in wastewater microbiology has revolutionized our view on the microbial ecology of these systems. Different groups of still not culturable bacteria were identified and shown to be responsible for nitrite oxidation, denitrification, and enhanced biological phosphorus removal. Surprisingly, the model organisms described in text books for these processes and for ammonia oxidation were shown to be generally not of importance for wastewater treatment. Furthermore, a new process, anaerobic ammonium oxidation, was detected in wwtps and the responsible (still not cultured) microorganisms were identified. It is important to note that significant diversity exists in each of these functional groups of bacteria. In the next research phase in wastewater microbiology, more detailed knowledge on the biology of the aforementioned noncultured bacteria needs to be gained. Therefore, an increased effort on the development of suitable cultivation strategies for these bacteria is needed. In parallel, the use of techniques referred to as *environmental genomics* should allow to investigate the genome composition of these bacteria without the need of cultivation (138).

Although researchers interested in microbial ecology will probably find the results summarized in this article interesting and important, engineers might ask what practical value can be extracted from the accumulated knowledge. Regarding application, the most obvious benefit of the progress described is that it provides a basis for a more knowledge-driven treatment of wwtp failures. One strategy to improve a particular aspect of process performance in a wwtp, for example, during start-up or after its breakdown, is the addition of specialized microorganisms or activated sludge from another wwtp (139). This operational tool that is called *bioaugmentation* does however frequently fail ((63) and references therein). Such failure is typically caused by addition of the "wrong" microorganisms, for example, the model organisms for nitrification, which cannot compete successfully with the autochthonous bacteria in the plant and are thus eliminated or washed-out. Therefore, it is important to identify those microorganisms responsible for nitrogen or phosphorus removal in a functioning wwtp. If problems arise, these results can be used as guidance to select the appropriate bacterial additive (for culturable microorganisms) or a well-suited activated sludge from a neighboring wwtp containing a comparable microbial flora. Once the appropriate bacteria have been selected, they need to be protected, for example, by polymer embedding from grazing by protozoa (63).

Compared with curing failure of a certain process in a wwtp by bioaugmentation, protecting the plant from process deterioration is a more sustainable strategy. For this purpose we need to understand the links between the diversity of a functionally important bacterial group and the stability of the catalyzed process. Preliminary observations indicate that plants with low functional redundancy caused by the presence of a low diversity of bacteria of a certain functional group are more sensitive to failure of the respective process than plants harboring a high diversity of the same bacterial group. If increase in diversity can indeed be proven to cause process stabilization, then it will be important to learn how plant design and process parameter control can be optimized to increase the diversity of functionally important bacterial groups. To answer these ecologically and economically important questions it will be necessary to determine the microbial community composition of a large number of different samples obtained from tightly controlled reactor studies and full-scale wwtps. Because of the tediousness of many of the established molecular methods, this kind of research will greatly benefit from the implementation of modern high-throughput techniques such as DNA microarrays for measuring microbial community composition in complex samples (140).

ACTIVATED SLUDGE — SEQUENCING BATCH REACTORS

R. L. Irvine
University of Notre Dame
Notre Dame, Indiana

P. A. Wilderer
Technical University of Munich
Garching, Germany

The sequencing batch reactor (SBR) belongs to a broad class of treatment systems that use a flocculated suspension of microorganisms referred to as activated sludge. This microorganism suspension is mainly composed of many different species of bacteria (i.e., a mixed rather than a pure culture that is spatially organized in the form of clusters and microcolonies) that destroy, transform, or simply remove unwanted contaminants present in liquid streams. Within this frame of reference, the objective of the SBR and virtually all other biological reactors is to select and enrich a mixed culture of microorganisms that convert biodegradable contaminants into new cellular material, carbon dioxide, water, and other stable innocuous organic and/or inorganic products. Although they are sustained by the consumption of readily biodegradable

energy-rich compounds called *contaminants*, the resulting microbial community also removes nonbiodegradable and some slowly biodegradable contaminants by physical, chemical, or physiochemical means. In such instances, insoluble contaminants and soluble contaminants that precipitate or sorb become part of a flocculated mass of microorganisms (i.e., the "flocs") and are thus removed from the waste stream that is being treated. The SBR differs from conventional continuous-flow activated sludge systems because it is a periodically operated, time-oriented system, with flow, energy input, and tank volume varying according to a predetermined operating strategy. As a result, the SBR is a time-oriented, periodic process that readily and easily develops controlled unsteady state conditions that are required to meet discharge limits dictated by the regulators. These distinguishing features and others are described in this article.

BACKGROUND

Contaminants

Unwanted contaminants are present in liquids (e.g., municipal sewage, industrial wastewater, landfill leachate, and contaminated groundwater), solids (e.g., soils after a gasoline spill), and gases (e.g., odors from a composting plant). They are organic or inorganic, more or less dense than water, and either soluble or insoluble in water. Some are emulsions in water while others are not; some are volatile and some nonvolatile. Those contaminants that are sparingly soluble in water are termed *hydrophobic* or *nonaqueous phase liquids* (NAPLs) and those that are not are termed as *hydrophilic*. Contaminants that are biodegradable serve as electron donors for microorganisms that catalyze a plethora of conversions that range from the minor modification of a contaminant's structure (e.g., through the addition or removal of a hydroxy group) to the complete mineralization or oxidation of the contaminant to carbon dioxide, water, and other inorganic compounds.

The primary conversions that take place in biological reactors involve soluble organic compounds that provide carbon and energy for the growth of a mixed culture of heterotrophic microorganisms present in the biomass. As a result, the success of a biological treatment system is often judged first by its ability to remove soluble biodegradable organic compounds. When combined with powdered activated carbon (PAC), the "partitioning power" of the floc (i.e., the flocculated mass of microorganisms, PAC, and other associated materials) is appreciably enhanced because soluble nonbiodegradable organic compounds are removed more aggressively. Biological systems are also often operated to minimize the discharge of the nutrients, namely, nitrogen and phosphorus. The success of such treatment systems is then judged by their ability to remove soluble biodegradable organic compounds and the nutrients of interest.

Biological treatment systems are categorized in a number of ways:

1. *The microbial community's ability to use exogenous electron acceptors*. Some use oxygen (i.e., in aerobic zones of the treatment system); others use nitrite-nitrogen or nitrate-nitrogen (i.e., in anoxic zones); and some use none at all (i.e., in anaerobic zones). It is noted that strict aerobes only grow in the presence of oxygen; strict anaerobes only grow in the absence of oxygen; and facultative anaerobes grow in the presence or absence of oxygen.
2. *The ability of bacteria to grow attached to a surface as a biofilm or unattached and in suspension as dispersed organisms or in clusters or flocs.* The most common treatment systems distinguish organisms that grow attached as fixed films (e.g., in trickling filters or rotating biological contactors) from those that grow in suspension as "activated sludge." In both these systems, the mixed cultures of microorganisms convert the contaminants to end products that depend on the nature of the contaminants and the organism distribution that is present.
3. *The mixing pattern established in the reactor*. Two mixing patterns are most commonly employed: completely mixed or plug flow. Intermediate mixing intensities are often employed but are difficult to model effectively.
4. *The type of reactor used*. These include the completely mixed batch reactor (CMBR), the completely mixed flow reactor (CMFR), the plug flow reactor (PFR), the plug flow reactor with dispersion (PFDR), and the sequencing batch reactor (SBR). Microorganisms in these systems are either in suspension or attached to a bed of support medium (e.g., packing material such as rocks, sand, ceramic, styrofoam, etc.) that is fixed, fluidized, or expanded.
5. *The control strategy used to operate the reactor (i.e., periodically operated or used under continuous flow conditions)*. Continuous-flow reactors normally recycle settled biomass but can also be operated with no-recycle.

A typical process schematic of a continuous-flow activated sludge system is shown in Figure 1. The schematic represents one of the typical "controlled unsteady state systems" that are in use today. As shown, the biological wastewater treatment system is depicted as a cascade of three CMFRs with biomass (or sludge) returned (i.e., recyled) from the third CMFR in the cascade to the first CMFR after settling in the clarifier, which is sketched in Figure 1 as a cone-shaped vessel. In this system, the microorganisms circulating in the system are periodically exposed to different substrate concentrations with the highest concentration in the first CMFR and the lowest in the last CMFR. As a result, biomass settled and recycled to the first tank is repeatedly subjected to high and low growth-rate environments as it moves from reactor to reactor and back again into the cascade.

In order for the sludge to concentrate well in the clarifier, the rate at which flocs settle must be sufficient. Unfortunately, the rate of sedimentation is slowed when the relative abundance of microorganisms that grow head to tail within long sheaths as filaments is

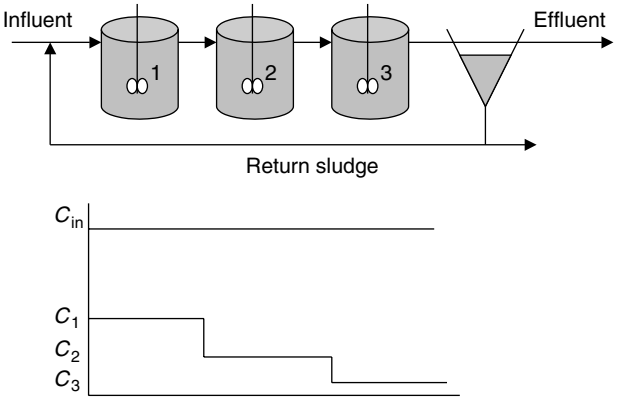

Figure 1. Process schematic of a continuous-flow activated sludge system with the aeration basin designed as a reactor cascade (top) and a profile of the substrate concentration from the influent port of the cascade to the discharge from the cascade (bottom). Microorganisms circulated in the system are repeatedly exposed to high and low substrate concentration.

greater than some minimum acceptable level. When this happens, poor sedimentation results and the microorganism (or activated sludge) shown in the shaded zone of the clarifier in Figure 1 extends upward toward the overflow weir causing the "clarified" effluent to contain unacceptable quantities of suspended solids (i.e., the flocs). Various researchers (2,3,10) demonstrated experimentally that the repeated exposure of activated sludge to feast (e.g., in the first CMFR in Fig. 1) and then famine (e.g., in the third CMFR) conditions is a very effective means of controlling the excess growth of filamentous organisms. The frequent shifting of activated sludge between aerobic, anoxic, and anaerobic zones establishes the conditions needed to enrich for microbial communities that carry out nitrification, denitrification, and enhanced biological phosphate removal. Frequent shifts of certain process conditions and the resulting controlled unsteady state conditions have significant and very important long-term effects on microorganism selection and enrichment and on the physiological state of the microorganisms enriched. Accordingly, these short-term unsteady state conditions, if properly selected and controlled, are an effective tool to maintaining long-term quasi–steady state conditions that control the structure and function of the microbial communities on which the performance of activated sludge systems is so greatly dependent.

In practice, the factors known to be effective in controlling the structure and function of microbial aggregates (e.g., activated sludge or fixed films) are difficult to maintain in continuous-flow systems. The frequency and amplitude of the changes needed to control variations in rate and time (e.g., from feast to famine) are not easily applicable to continuous-flow systems as they are to periodically operated systems such as the SBR. Because of inflow rate variations, biological treatment systems are often subjected to suboptimal control conditions even when they are designed to operate as controlled unsteady state systems.

THE CONCEPT

The SBR technology is used to gain control over the structure and functions of the microbial community in a multipurpose bioreactor that is exposed to varying influent conditions. An SBR system differs from a continuous-flow activated sludge systems in the following manner

1. The influent and effluent streams are uncoupled.
2. Biomass separation occurs in the biological reactor and not in a separate clarifier, as was shown in Figure 1.
3. The unit operations and unit processes that take place in a reactor follow each other in a time sequence that is progressively repeated in a "periodic" or "cyclic" manner and not from tank to tank as is done in space-oriented systems.
4. A portion of the treated water is periodically discharged from each tank to make room for a new batch of wastewater (see Fig. 2).

Because of these features, SBRs are referred to as periodic processes, single-tank systems, fill and draw reactors, or as variable volume reactors.

As represented in Figure 2, the SBR process is characterized by a series of process phases (e.g., fill, react, settle, draw, and idle), each lasting for a defined period. During the fill phase, the SBR behaves as a semicontinuous CMFR (if the reactor is well mixed and/or aerated during fill) that receives flow but has no discharge. As is described later, the fill phase may be unmixed, mixed, or mixed and aerated. During the react phase, the SBR behaves as a CMBR. Sludge wasting as a means to keep the biomass concentration in the reactor at a certain level normally takes place after the settle phase but may take place near the end of react phase or during the settle phase and may take place weekly, daily, or during each cycle.

As originally defined, the idle phase was included as a "buffer" phase in the SBR (4,5) (Fig. 2). No wastewater enters the reactor during the idle phase and, unless sludge is wasted during this phase, there is no discharge. It is usually neither mixed nor mixed and aerated. As such, the name "idle" is suitable. However, the time in the idle phase has an important function in the SBR as originally defined. Idle phase provides the excess capacity in the system so

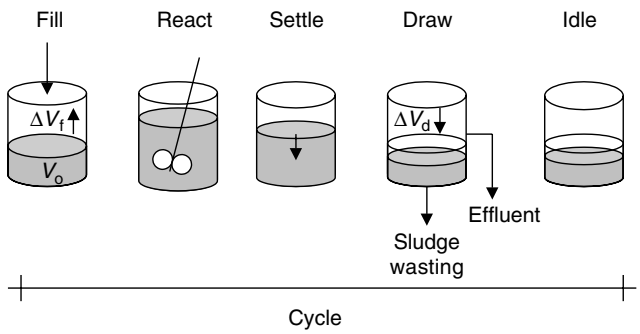

Figure 2. Schematic of a typical SBR cycle. The Idle phase is optional if an alternative means for handling excess inflow is provided. A cycle may include aerobic, anoxic, or anaerobic phases.

that permit limits are met during periods of high flow. The time for idle phase seamlessly reduces toward zero when high volumetric flow rates are observed and it increases when there are low volumetric flow rates. The idle phase can only be eliminated when an equalization tank or holding tank is available or when there is some other means for handling the excess inflow (e.g., continuous influent as in the intermittent cyclic extended aeration system depicted in Table 1).

In some of the variable-volume activated sludge systems, there is no distinct react phase, and the settle and draw phases occur while the influent enters the system. These differences are briefly described in Table 1 for selected variable-volume activated sludge systems.

In addition to the descriptions given earlier, the fill-and-react phases can have several subphases based on the energy input to the system that results in various aeration and mixing operating strategies. These subphases have been labeled in various ways as follows

- static fill — no energy input to the system allows the accumulation of unreacted substrate.
- mixed fill — mixing without forced aeration typically allows either anoxic or anaerobic reactions.
- aerated fill — mixing with forced aeration typically allows aerobic reactions.
- mixed react — mixing without forced aeration allows anoxic and possibly anaerobic reactions.
- aerated react — mixing with forced aeration allows aerobic reactions.

Contaminants in the wastewater enter the reactor during the fill phase. Unless a temporary influent storage volume is provided, more than one SBR is required to handle a continuous inflow of wastewater. When a holding tank for the influent is used, the time for the fill phase is often only a small fraction of the total cycle time and the wastewater constituents accumulate, thus providing the conditions required for "feast" and for the control of filaments. Without a holding tank, feast conditions are established during static fill for the following reasons

1. The reaction rates are reduced in systems with little or no mixing. The only energy supplied to the system during this static fill comes from the introduction of the wastewater. The highest rates of reactions occur in well-mixed systems.
2. Because of the lack of mixing, contact between the microorganisms and contaminant is minimal.
3. The extent of oxidation is limited by the availability of exogenous electron acceptors. Accordingly, although some electron donors (i.e., contaminants) and electron acceptors are utilized, and despite some fermentation reactions occurring in the absence of exogenous electron acceptors, anoxic and/or anaerobic reactions take place at a much greater rate during the mixed fill than during the static fill.

Similarly, initial aerobic reactions take place during aerated fill. In general, the extent of the aerobic reactions depends on the mass flow rate of the readily biodegradable substrates and the specific fill strategy employed. For example, anoxic reactions also occur during the aerated fill if oxidized forms of nitrogen are present, the concentration of dissolved oxygen is sufficiently low, and an adequate supply of electron donors (i.e., oxidized forms of nitrogen) is available.

The reactions initiated during the fill phase are completed during the react phase by initiating the proper mixing and/or aeration strategy. The settle (separation of the biomass from the treated waters), draw (withdrawal of the treated water, i.e., the supernatant that forms during the sedimentation), and idle (time between draw and fill that reflects the excess hydraulic capacity of the system) phases complete the cycle.

The generic cycle arbitrarily commences with the fill phase and terminates at the end of the idle phase. The volume of wastewater introduced into the reactor is ΔV_f (Fig. 2). It is added to the volume of water and sludge that remains in the reactor at the end of the past cycle (V_o). At the end of the fill phase, the reactor contains $V_R = V_o + \Delta V_f$. Once the react phase has been

Table 1. Distinguishing Features of Selected Variable-Volume Activated Sludge Systems (6)

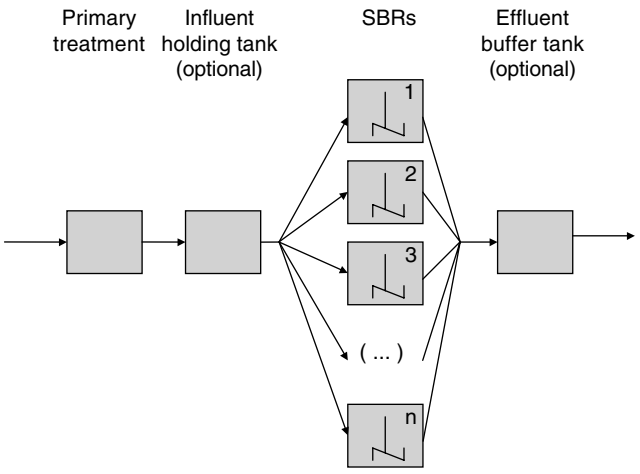

Figure 3. Schematic of an SBR plant.

completed and the mixing energy has been dissipated, the activated sludge starts coagulating and settling. After wasting excess sludge (ΔV_w) and discharging the treated supernatant (ΔV_d), the reactor is available to receive a new supply of wastewater.

Thus, a SBR process is characterized by the following set of parameters:

t_i	Time for the ith phase
t_c	Total time of one cycle ($t_c = \Sigma t_i$)
FTR	fill time ratio, t_f/t_c, where t_f is the time for fill
VER	Volumetric exchange ratio, $\Delta V_f/V_R$
HRT or τ	Hydraulic residence time, $n \bullet V_R Q^{-1}$, where n is the number of tanks and Q is the volumetric flow rate of the influent to the treatment plant

In addition, process parameters that are typical for activated sludge or biofilm systems apply. For instance, the design and operation of an activated sludge SBR usually includes considerations of key factors such as HRT, sludge age, and sludge loading.

DESIGN AND OPERATION OF SBR PLANTS

SBR plants typically consist of a number (n) of reactors. Pre- and posttreatment facilities may be added. A general layout of an SBR plant is shown in Figure 3. Four generic groups of SBRs can be distinguished (6). The specific fill strategy used and/or the inclusion of a react or idle phase characterize each of them. The generic groups are as follows:

(A) Systems with a periodic influent, a react phase, and an idle phase
(B) Systems with a periodic influent, a react phase, and no idle phase
(C) Systems with interrupted influent, a selector, and no react and idle phases
(D) Systems with a continuous influent.

Each of these generic groups is described in detail in the following section (Fig. 4).

Group A. The SBR as originally defined (4–6) is shown in Figure 4a. Two or more tanks are normally used. The influent is diverted from the tank being filled when its water level reaches a predetermined maximum value. The fill time ratio (FTR) for each tank is less than one. The time for the fill phase is defined by

$$t_f = \frac{t_c}{n}$$

where t_f is the fill time, t_c is the total cycle time, and n is the number of SBR tanks available.

Group B. SBR systems with a holding tank in front (Fig. 4b) are often used in Germany (3). The influent enters a holding tank before being distributed into the SBR tanks. Two or more tanks are normally used. The configuration of tanks allows the system to be operated with a variable fill strategy including instantaneous fill to control filaments or extended fill strategies to avoid the accumulation of inhibitors (e.g., as could be present in industrial wastewater). Therefore, an idle phase is not required to control the system during variable flow conditions. The holding tank in Group B provides the same function as the idle phase in group A.

Group C. Figure 4c describes SBR systems with an internal or external constant volume selector basin. In these systems, fill is interrupted either during the draw phase (e.g., as in the Cyclic Activated Sludge System) or during the settle and draw phases (e.g., as in the Cyclic Activated Sludge Technology). All of these systems have a recirculation line that returns mixed liquor from the main reactor to the selector. The Cyclic Activated Sludge System has a chamber that follows the selector to buffer the flow during settle.

Group D. Figure 4d describes SBR systems that have a continuous inflow of wastewater that is not interrupted during the settle and draw phases. These SBRs can be operated as single tanks or as sets of tanks operated in parallel. Once the water level in a tank reaches a predetermined maximum value, the aerators and mixers are switched off, the activated sludge is allowed to settle, and the supernatant is withdrawn from the reactor. To minimize cross-contamination of the treated effluent with the influent wastewater during the draw phase, the reactor is divided into two zones separated by a baffle. The first of the two zones limits cross-contamination and serves as a selector. Normally, SBRs such as the Intermittent Cyclic Aeration System operate with a completely aerated fill. In contrast to the operation of Groups A and B, static fill occurs at the end of the cycle and is termed *settle* when there is no discharge, and *draw* when the treated effluent is discharged.

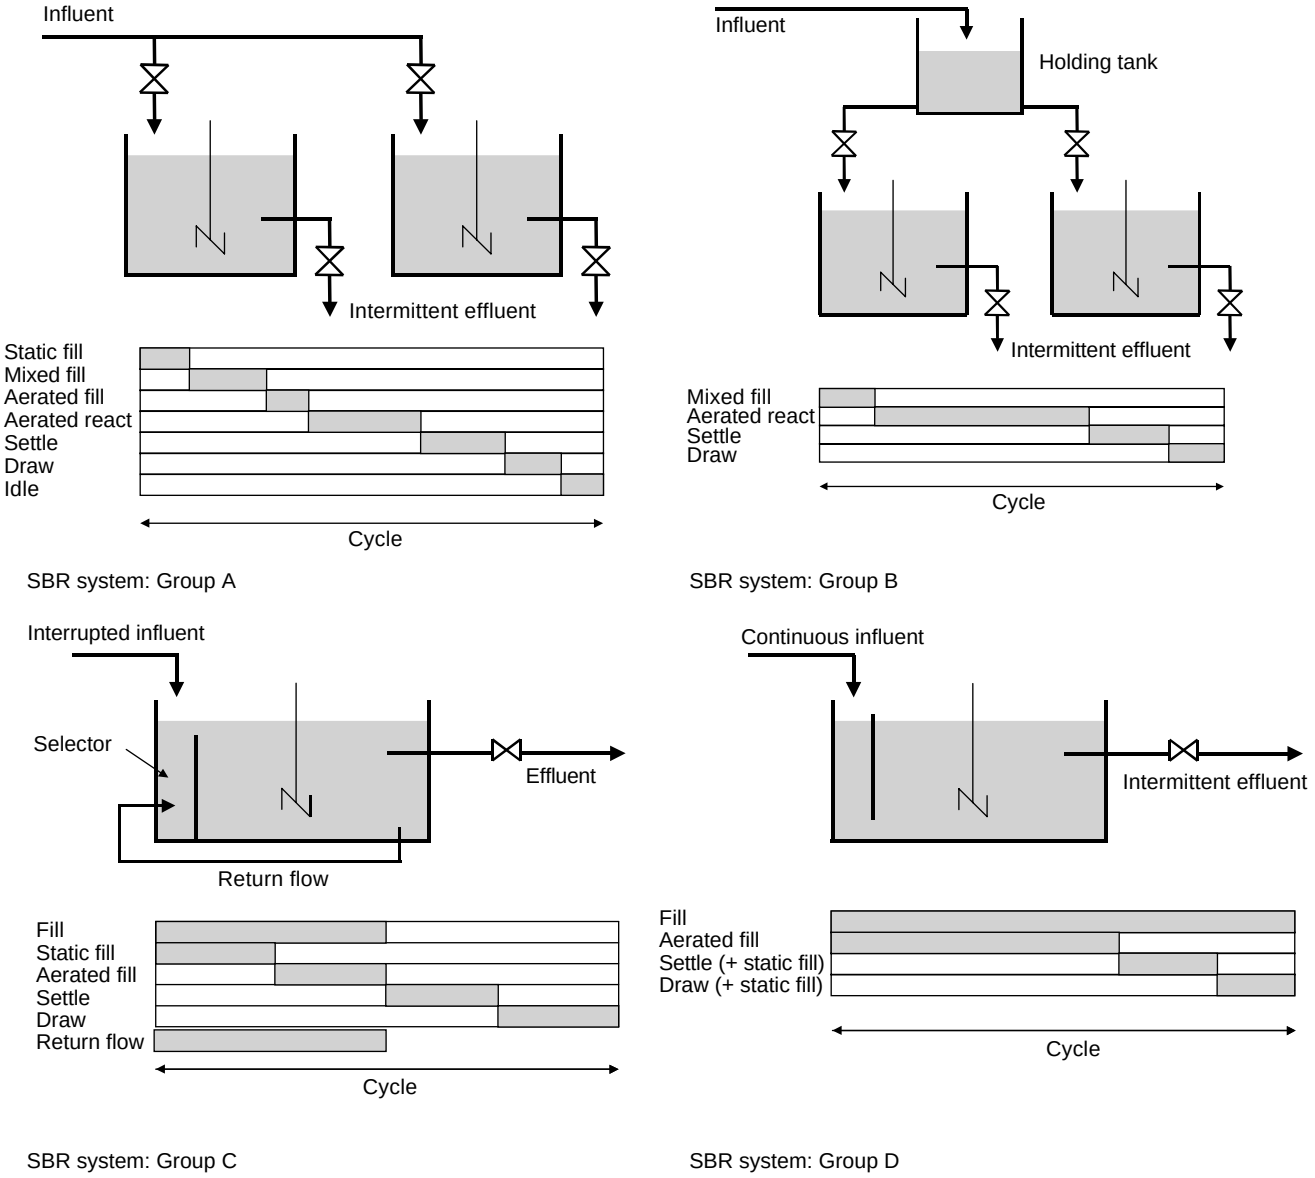

Figure 4. Four different groups of SBR systems currently applied in practice (6).

Each of these modifications provides specific advantages and disadvantages. Selection of a specific SBR type must be made on a case-to-case basis after taking into account the conditions under which the SBR will be operated and the treatment goals that must be achieved (6). Care should be taken, however, to select a system that maximizes the difference between the "intensity" of the feast and the "depth" of the famine. Doing so will provide protection against bulking sludge while maximizing the potential for biological nutrient removal.

SIZING OF SBRS

Whenever possible, design calculations for an SBR plant for tank size and cycle program (i.e., the operating strategy that defines the sequence and duration of phases) should be based on results obtained from treatability studies conducted at either bench or pilot scale. Treatability studies are especially recommended when the wastewater to be treated is unique with respect to composition, concentration, and variability as is the case for virtually all industrial wastewaters and landfill leachates. In these cases, design is based on a mathematical description of the facility that integrates projections of future flow and loading conditions with the data collected during the treatability studies (e.g., stoichiometric, kinetic, settling, oxygen transfer, nutrient requirements, etc.).

The design of SBRs for municipal wastewater treatment facilities is often done without the aid of treatability studies because it is assumed, sometimes incorrectly, that municipal wastewater varies little from location to location. When the characteristics of municipal wastewater

is "typical," the design and operating conditions that are selected are based on experience using methods that simply set the hydraulic residence time (HRT) and organic loading to size the system. In other cases, especially for the design of large facilities and/or when nutrient removal is required, engineers often combine experience with one of the many commercially available versions of computer models based on International Water Association (IWA, formerly IAWQ) (10) to test and refine possible design. These simulation programs use default values for stoichiometric and kinetic coefficients. An intermediate approach to these two extremes is used in Germany where the Waste and Wastewater Association (ATV) issued guidelines (11) for the design of SBR plants treating municipal wastewater. This guideline is based on established design procedures for continuous-flow systems. Table 2 describes the various assumptions and calculations that must be made when using these guidelines.

It is assumed that the mass and the activity of the activated sludge in the SBR will be the same as in a continuous-flow activated sludge system with plug flow characteristics (i.e., a cascade of three CMFRs). It is further assumed that the order and the duration of the SBR process phases are proportional to the design setting and to the mean volumetric retention time in the various zones of the continuous-flow systems (e.g., anoxic zone and aerobic zone).

One of the several possible design procedures directly based on mass balances is presented in Table 3. The example chosen is based on COD as a measure for the organic fraction of the wastewater constituents.

In determining an appropriate θ_X needed for nitrogen removal, nitrification capacity (N_{OX}) and denitrification potential (N_{DP}) are two important factors that were first defined for recirculation-type continuous-flow processes (12,13).

After selection of the relevant sludge age (θ_X), the total biomass present in the SBR reactors is calculated on the basis of the mass of influent COD removed. The water volume needed in the reactor after the draw phase, V_0, is calculated by determining the volume occupied by the biomass after settling for 30 minutes. The value is multiplied with a safety factor (SF_V) to cover any uncertainties with respect to the ability of the sludge to settle and growth of the respective groups of microorganisms.

The exchanged volume (ΔV_f) depends on the selected cycle time. The total volume of the SBRs (V_R) is obtained by adding V_0 and ΔV_f. Further information on using mass balances for the design of activated sludge systems can be found in Orhon and Artan (14) and Artan and coworkers (15).

EXPERIENCES

Unlike conventional technology, SBRs tend to be designed and marketed by equipment suppliers. To date there is little well-documented information on how existing SBRs are performing, including their cost-effectiveness, reliability, optimum design and operation, cost, and performance associated with different SBR configurations and equipment suppliers. The growth and acceptance of SBRs appear to be based on their ability to meet permit limits and at their competitive capital and operating costs.

During the past three years, several surveys were conducted in various countries to study the performance of SBR facilities (6). Survey results revealed that designer and operators were often not aware of the full range of control that is provided by SBR technology. Despite these problems, effluent values were well below permit limits.

In rural areas, the combination of a high-technology system (i.e., an SBR) and a natural system (e.g., effluent polishing ponds) was very effective with respect to chemical oxygen demand (COD) and five-day biological oxygen demand (BOD_5) removal. Only small variations

Table 2. Design of an Activated Sludge SBR Plant Based on the German ATV Guidelines (11)

1. Input: Design information from continuous flow system, operating strategy for the SBR	
2. Calculation of the time (t_a) during which biological reactions may take place	$t_a = t_c - t_s - t_d - t_{idle} - t_{staticfill}$
3. Effective mass of sludge in the SBR equals the mass of sludge in the continuous-flow system	$M_{X,SBR} = M_{X,Conti.} \cdot \frac{t_c}{t_c - t_s - t_d}$
4. Select MLSS in SBR after fill and, thus, $n \cdot V_R$	$n \cdot V_R = \frac{M_{X,SBR}}{C_X}$
5. Select V_0 depending on the volume of the settled sludge	$\min(n \cdot V_0) = M_{X,SBR} \cdot SVI \cdot SF_V$ or $VER = 1 - C_X \cdot SVI \times SF_V$
6. Select exchange ratio or cycle time	
7. Select number of SBRs (n) and calculate missing value (volumetric exchange ratio (VER) or cycle time)	$\frac{t_c \cdot Q}{n \cdot V_R} < VER$
8. For a system with nitrogen removal, select mixed and aerated process phases according to mixed and aerated volumes of the continuous-flow system	$\frac{t_D}{t_D + t_N} = \frac{V_D}{V_D + V_N}$
9. Check t_s and t_d based on settling velocity and maximal draw flow rate, respectively	

Note: Table prepared by E. Morgenroth, University of Illinois at Urbana-Champaigne, U.S.A.

Table 3. Design Procedure Based on Mass Balances

1. Input: operating strategy for SBR	
2. Select solids retention time (θ_X)	
3. Estimate effective fraction of t_c from t_s and t_d	$\text{effective fraction} = \frac{t_c - t_s - t_d}{t_c}$
4. Calculate mass of sludge in all reactors	$M_{X,SBR} = Y_{H,net} \cdot Q \cdot \Delta C_S \cdot \theta_X \cdot \frac{t_c}{t_c - t_s - t_d}$
5. Calculate volume of settled sludge in all reactors	$n \cdot V_0 = M_{X,SBR} \cdot \text{SVI} \times \text{SF}_V$
6. Select exchange ratio or cycle time	
7. If exchange ratio was selected, then calculate cycle time from	$t_c = \frac{n \cdot V_0 \cdot \text{VER}}{Q \cdot (1 - \text{VER})}$
8. Calculate exchange volume of all reactors	$n \cdot \Delta V = Q \cdot t_c$
9. Calculate total volume of the SBRs	$n \cdot V_R = n \cdot V_0 + n \cdot V_f$
10. Select number of SBRs (n)	
11. Calculate minimum aerated fraction of reaction time on the basis of minimal aerobic solids retention time, for example, nitrification	$\text{min .aerated fraction} = \frac{\min \theta_{X,a}}{\theta_X} \cdot \text{SF}_X$
12. Choose number of fill phases and distribution of the influent on the fill phases depending on the wastewater composition (e.g., TKN/COD ratio)	
13. For a system with nitrogen removal, check nitrification capacity and denitrification potential depending on cycle design	$N_{nit} = TKN_0\text{-}NH_{4,e}\text{-}N_{org,e}\text{-}N_{SL}$ $N_{DP} = (1 - Y_{H,net}) \cdot C_{S,in} \cdot \frac{1}{2.86} \cdot f_{DN} \cdot \eta$
14. Check react time for nitrogen removal using denitrification rates	$t_D = \frac{N_{DP} \cdot n \cdot V_f}{r_{DN,X} \cdot M_{X,SBR}}$
15. Check t_s and t_d based on settling velocity and maximum draw flow rate, respectively	

Note: Table prepared by E. Morgenroth, University of Illinois at Urbana–Champaign.

are found in the effluent despite the wide range of influent concentrations. Even very low effluent standards such as 40 mg L^{-1} COD were safely met.

A study funded by Ontario Ministry of the Environment, Environment Canada, and the Water Environment Association of Ontario evaluated 75 SBR-like installations in Ontario and the United States Great Lakes Region (16). A telephone and mail survey was conducted and 10 SBR facilities were visited in 1998 to define possible design and operational problems. The average daily design flow for the 67 of the 75 SBR plants providing such data was approximately 3,600 $m^3\,d^{-1}$ and ranged from a low of 7 $m^3\,d^{-1}$ to a high of 22,710 $m^3\,d^{-1}$. Results obtained from the 75 SBR plants were prioritized according to operating costs, plant capacity, effluent quality, and frequency of occurrence. No effort was made to subcharacterize the findings in terms of the four generic groups of SBRs described earlier.

The average daily flow for the 49 of the 75 SBR plants reporting actual flow data was nearly 2,600 $m^3\,d^{-1}$. Forty-six of the plants reported effluent readings for BOD_5; 58 for SS; 52 for ammonia-nitrogen; and 33 for total phosphorus (as P). The average results for those reporting were less than 6.5 $g\,m^{-3}$, 9 $g\,m^{-3}$, 1.5 $g\,m^{-3}$, and 1.4 $g\,m^{-3}$ for BOD_5, SS, NH_3, and phosphorous, respectively. These results are quite impressive for facilities located in either warm or cold regions. In addition, a preliminary cost comparison between SBRs and continuous-flow activated sludge plants indicated that for similar effluent requirements, SBRs-like facilities were more economical than continuous-flow activated sludge plants.

The responses received during the survey were used to generate a list of concerns, which, if addressed, would likely improve the performance of these SBR-like installations. The top ten of these are summarized in the following text:

1. Operators have no formal training on SBR operation or process control.
2. Mechanical equipment located outdoors may freeze or malfunction (e.g., air valves, solenoid valves, decanter arms, and level monitoring floats).
3. Decanters were unable to meet some specific treatment requirements (e.g., the discharge of floatables).
4. Discontinuous SBR effluent flow have an impact on downstream treatment processes (e.g., ultraviolet (UV) disinfection and the backwashing of filters).
5. Lack of online DO monitoring and control instrumentation eliminated the possibility of increased energy savings.
6. No specific control strategy was provided for the solids residence time.
7. The pretreatment systems (e.g., bar screens and comminutors) were inadequately designed.
8. Lack of automation for the selection of the time needed for sludge wasting.
9. Potential secondary phosphorus release in aerobic digesters.
10. Partial failure of the SBR control program during peak flows.

Most of the concerns listed earlier could easily be corrected if the operators were given a formal training program. Unfortunately, there is not a simple solution because the term *SBR* is used to include many different types of periodically operated reactor configurations, even more than the four generic types described earlier, and the specific training for each type would be different. The SBR is also a new technology that is being implemented by some who have little basic understanding of how to make it work best.

A few of the concerns listed previously are specific to the equipment used for SBR facilities. These are difficulties that can be overcome by using the equipment specified by qualified engineers and manufactured and installed by reputable vendors. The remaining concerns were independent of the type of treatment facility installed and are just as likely to cause difficulties at a conventional continuous-flow activated sludge plant as they are at an SBR system. It is worth noting that the effluent data compiled showed that the effluent criteria were consistently met, and in most cases, exceeded.

The evaluations indicate that SBRs are a cost-effective wastewater treatment technology (17,18). Unfortunately, limited historical data have been compiled comparing the cost of SBRs with other types of activated sludge treatment systems. Clearly, the lack of need for an external secondary clarifier and its associated hardware and the return sludge pumping system offers potential savings in construction costs. In addition, primary clarification is not normally employed (none of the 75 plants evaluated had primary clarifiers).

NOVEL APPLICATIONS FOR BIOFILM AND SLURRY SYSTEMS

The concept of implementing short-term unsteady state conditions to control the long-term performance of biological reactors is applicable to either aerobic or anaerobic systems, or to suspended growth or biofilm, or fluidized bed systems that treat wastewater, contaminated soil, or gases. Over the past years, a wide variety of innovative batch treatment technologies have been described in literature. The common basis of these novel approaches is application of well-defined sequences (i.e., operating strategies) that alter process conditions in a controlled manner. The common goal is control of the composition and activity of microbial communities by targeting the microorganisms that should be selected, enriching these organisms to the levels needed, and then adjusting their physiological state so that permit limits are achieved. Two of those systems, the Sequencing Batch Biofilm Reactor (SBBR) and the Soil Slurry-Sequencing Batch Reactor (SS-SBR), are described briefly here.

Gonzales and Wilderer (19) and Wilderer (20) proposed the sequencing batch operation of a biofilm reactor. The schematic of a SBBR plant is presented in Figure 5. The sequence of process phases is sketched in Figure 6.

Kaballo and coworkers (21) compared the response of continuous-flow and SBBR reactors to peak loading.

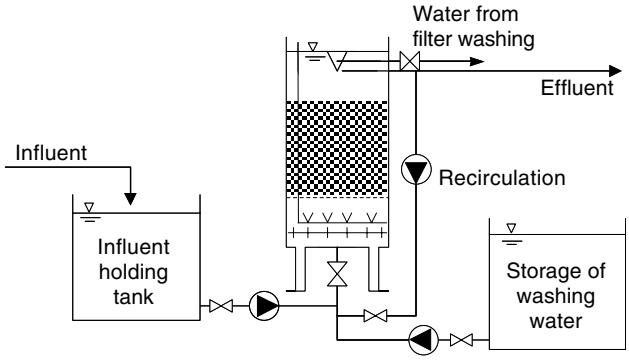

Figure 5. Schematic of a SBBR plant (6).

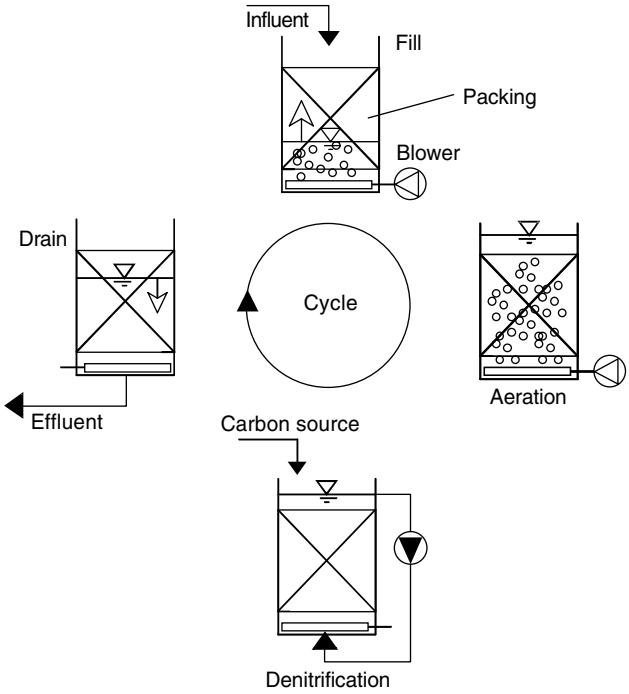

Figure 6. Schematic representation of the SBBR process.

Breakthrough events can be successfully avoided by temporary prolongation of the duration of the react phase.

Jaar and coworkers (22), Kolb (23), Chozick and Irvine (24), and Irvine and coworkers (25) packed the reactor with granular activated carbon. By means of adsorption processes during the fill phase, the concentration of critical pollutants (e.g., volatile organic compounds or inhibitory organic substances) were reduced in the bulk liquid. During the react phase, biodegradation and desorption became the dominant processes. The wastewater was effectively treated and the activated carbon was regenerated biologically.

Irvine and Montemagno (26) proposed the sequencing batch operation of a soil slurry reactor in 1989 for the remediation of trinitrotoluene-contaminated soils. In 1993, Irvine and coworkers (27,28) reported on how the SS-SBR can be used to treat soil contaminated with the plasticizer bis-(2-ethylhexyl) phthalate and petroleum products.

The schematic of an SS-SBR facility is presented in Figure 7.

The SS-SBR is operated on a fill and draw basis in a manner similar to that described for the SBR. Each tank is filled during a discrete period (fill phase), and then operated as a batch reactor during the react phase. Just as for the SBBR, the cycle for the SS-SBR does not include the settle phase (Fig.7). After the desired contaminant levels have been reached, a fraction of the slurry is removed from the SS-SBR (draw phase). A certain fraction of the treated slurry remains in the reactor to provide acclimated microorganisms for the next batch of untreated slurry. The optimum recycle fraction in the SS-SBR must be determined for each contaminated soil (27–29).

As can be seen in the bioslurry system illustrated in Figure 7, the soil is first screened to remove rocks, branches, and other debris. Water is added to the screened soil to make a slurry in a small mixing tank. The concentration of solids in a bioslurry reactor can range from 5 to 50% (weight/volume) depending on the contaminant concentration and the capacity of the mixing and aeration equipment. Nutrients and other possible amendments (e.g., microbes and surfactants) are also added to the mixing tank if needed. The slurry is then transferred to the bioslurry reactor via a slurry pump. Compressed air diffusers or surface agitators can be used to provide oxygen. Bioslurry reactors are easily covered and equipped with an emissions recovery system. Fugitive emissions may require a separate treatment before discharge or they can be recycled back into the slurry reactor for biodegradation. After the soil is treated, solids are separated from the slurry water using standard dewatering techniques.

The SBR has also been shown to be a cost-effective and energy-efficient means of removing hazardous organic compounds found in industrial wastes (30) and leachates from landfills (31–33). Periodically operated biofilters have recently been proposed for the treatment of air contaminants (33,34–36).

CONCLUSION

SBR technology defines a controlled unsteady process that imposes selective pressures and manipulates both the community structure and expression of a heterogeneous microbial consortium in a multipurpose bioreactor so that the impact of varying influent conditions is minimized. The SBR concept can be applied to the treatment of wastewater in both activated sludge and biofilm systems and to the treatment of contaminated soils and gases.

In contrast to the continuous-flow activated sludge systems, biomass separation occurs in the biological reactor and not in a separate clarifier. The unit operations and unit processes that take place in each reactor follow each other in a time sequence that is progressively repeated in a "periodic" or "cyclic" manner and not from tank to tank as they do in space-oriented systems. A portion of the treated water is periodically discharged from each tank to make room for a new batch of wastewater. Because of these features, SBRs are referred to either as periodic processes, single-tank systems, fill-and-draw reactors, or as variable volume reactors.

The SBR process is characterized by a series of process phases (e.g., fill, react, settle, draw, and idle) each lasting for a defined period. Four generic groups of SBRs were distinguished, each characterized by the specific fill strategy utilized, or the inclusion of a react or idle phase. Each generic group provides specific advantages and disadvantages. Selection of a specific SBR type must be made on a case-to-case basis after taking into account the conditions under which the SBR will be operated and the treatment goals that must be achieved. Care should be taken, however, to select a system that maximizes the difference between the "intensity" of the feast and the "depth" of the famine; this will protect against bulking sludge while maximizing the potential for biological nutrient removal. The technical report on SBR technology issued by the International Water Association (IWA Publishing) was written to provide a comprehensive description of the information needed by designers and operators (6).

NOMENCLATURE

BOD_5	Five-day biological oxygen demand	$g\,m^{-3}$
COD	Chemical oxygen demand	$g\,m^{-3}$
C_S	Substrate concentration	$g\,m^{-3}$
C_x	Biomass concentration	$g\,m^{-3}$
FTR	Fill time ratio, t_f/t_c, where t_f is the time for fill	–

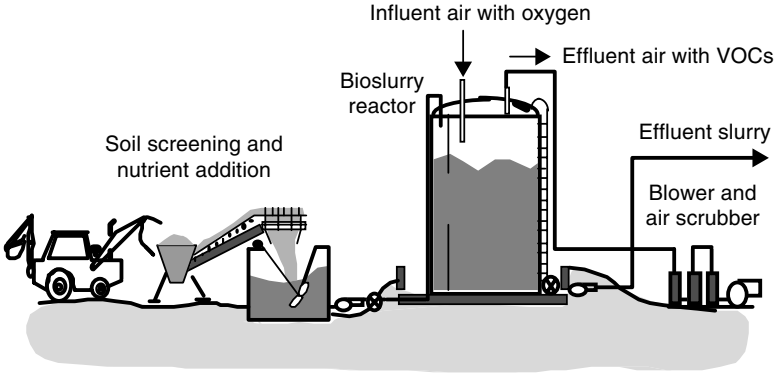

Figure 7. Schematic representation of a SS-SBR.

f_{DN}	Fraction of electron acceptors potentially associated with anoxic reactions	–
HRT	Hydraulic residence time, $n \cdot V_R Q^{-1}$	h
M or M_x	Mass of sludge	g
MLSS	Mixed liquor suspended solids	$g\,m^{-3}$
N	Concentration of nitrogen compounds	$g\,m^{-3}$
N_{DP}	Denitrification potential	$g\,m^{-3}$
N_{nit}	Nitrification potential	$g\,m^{-3}$
N_{SL}	Nitrogen concentration of the waste sludge	$g\,m^{-3}$
N	Number of tanks or reactors	–
PAC	Powdered activated carbon	–
Q	Flow rate (plant influent)	m^3h^{-1}
$r_{DN,X}$	Denitrification rate	$g\,g^{-1}h^{-1}$
SVI	Sludge volume index	$ml\,g^{-1}$
t_c	Total cycle time ($t_c = \Sigma t_i$)	h
t_d	Time of the decant phase	h
t_D	Time of the denitrification phase	h
t_i	Time of the ith phase	h
t_{idle}	Time of the idle phase	h
t_f	Time of the fill phase	h
t_N	Time of the nitrification phase	h
t_s	Time of the sedimentation phase	h
$t_{staticfill}$	Time of the no-mix/no-aeration fill phase	h
SF_v	Safety factor	–
TKN	Total Kjeldahl nitrogen	$mg\,L^{-1}$
VER	Volumetric exchange ratio, $\Delta V_f / V_R$	–
V_0	Liquid volume at low water lever	m^3
ΔV_f	Fill volume	m^3
V_R	Total liquid volume at high water level	m^3
V_D	Volume of the denitrification zone (continuous-flow plant)	m^3
V_N	Volume of the nitrification zone (continuous-flow plant)	m^3
ΔV_w	Volume of the wasted sludge	m^3
ΔV_d	Volume of the decanted effluent	m^3
Y	Cell yield	$g\,g^{-1}$
θ_X	Sludge age (HRT)	d
$\theta_{X,a}$	Aerobic sludge age	d
η	Correction factor for oxic respiration	–
τ	Hydraulic retention time (HRT)	h

ACTIVATED SLUDGE — THE FLOC

PER HALKJÆR NIELSEN
Department of Environmental Engineering
Aalborg University
Aalborg, Denmark

Use of activated sludge is the most common process worldwide for treatment of numerous types of wastewaters. The main process is the biological conversion of organic matter, nitrogen, phosphorus, and other compounds into biomass (sludge) and gaseous compounds (1,2). Another key process is the separation of the biological sludge flocs from the treated water, the solid-liquid separation. This process relies entirely on the formation of good, activated sludge flocs to ensure a proper effluent quality and a good dewaterability of the sludge (1,3,4).

The solid-liquid separation involves several steps (Fig. 1): floc formation in the process tanks and flocculation, clarification, and settling in the final clarifier to retain the majority of the sludge. A large percentage of the retained sludge (typically 80–97%) is recycled in order to keep a sufficiently high sludge concentration in the process tanks. In a typical activated sludge treatment plant, the amount of suspended solids in the process tanks, the mixed liquid suspended solids (MLSS), is typically 3 to 5 g suspended solids/L (gSS/L). To meet effluent standards of less than 20 to 30 mgSS/L, it is obvious that the entire floc formation and the separation process must work well. Typical problems are often encountered because of poor flocculation or poor settling of the sludge flocs (1,3,4).

The dewatering and further treatment of the surplus sludge is also an important step in the solid-liquid separation (5). This step is usually costly, and special care must be taken to handle sludge with a high content of pathogenic bacteria, heavy metals, micropollutants, and other unwanted substances. The dewatering process is strongly affected by the floc properties, and problems with the dewatering process caused by poor floc properties are often encountered (5).

Activated sludge flocs, like other biological aggregates such as biofilms, are complex heterogeneous structures in which bacteria and other chapter provides an overview of the physical, chemical, and microbial composition of the flocs. Furthermore, the principles of flocculation and possible correlations between floc composition, floc properties, and functional sludge properties are described.

PHYSICAL AND CHEMICAL STRUCTURE OF FLOCS

An activated sludge floc consists of many different components as shown in Figure 2. The components are bacterial cells, various types of extracellular polymeric substances (EPS), adsorbed organic matter, organic fibers, and inorganic compounds. The bacteria can be single, growing in microcolonies (sometimes termed clusters or microflocs) or growing as filaments. This basic composition is common to all flocs, but the relative proportion of the components and the exact types of chemical compounds or types of microorganisms vary from plant to plant. In plants treating domestic wastewater, the cell biomass typically constitutes 10 to 20% of the organic matter, whereas the size of other fractions is not certain. Typical values from various sources are shown in Figure 3 (6–8).

The size of activated sludge flocs ranges from very small aggregates of only a few cells (few μm) to large flocs of more than 1 mm. In most activated sludges, the flocs are typically 40 to 100 μm in diameter, relatively strong, and not easy to break apart (3,4,9). Usually, this fraction also constitutes the largest part of the sludge as measured by volume, whereas very small flocs that are numerous and single cells are less important in terms of mass or volume. An example of size, surface area, mass, and volume distribution of activated sludge flocs for five conventional treatment plants is shown in Table 1 (10). Under certain circumstances, very dense flocs or granules

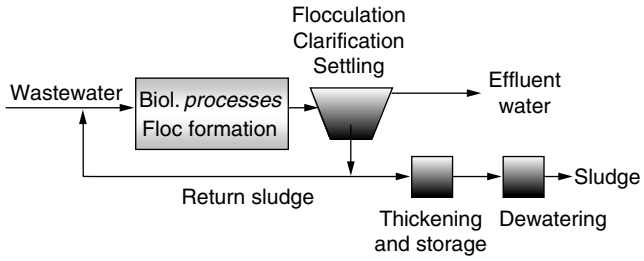

Figure 1. Floc formation and solid-liquid separation in an activated sludge treatment plant.

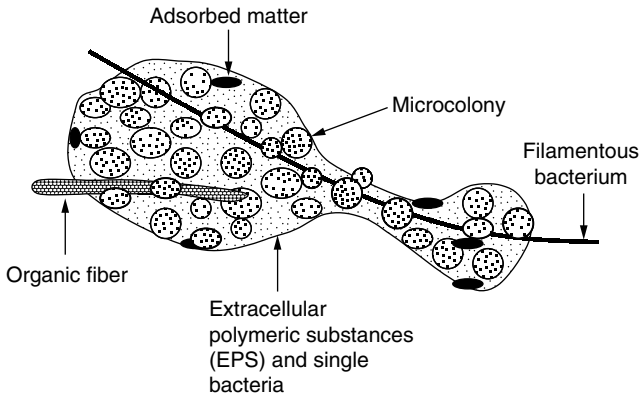

Figure 2. Schematic illustration of the constituents of activated sludge flocs.

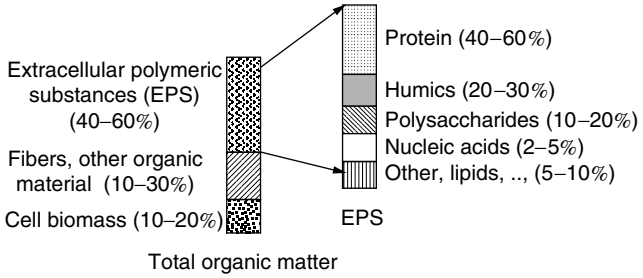

Figure 3. Composition of the organic part of sludge (EPS: Extracellular polymeric substances).

with a diameter of 300 to 500 μm can be formed in aerobic activated sludge systems. So far, however, aerobic granule formation has only been reported from laboratory-scale reactors (11).

The individual flocs can undergo three main types of transformation when they are subjected to some stirring (shear): erosion, fragmentation, and flocculation (Fig. 4). Fragmentation, during which flocs are split into a few large new flocs, is not considered important for activated sludge flocs (4). Erosion takes place when small particles, typically bacteria or EPS fragments are sheared off the main floc because of several processes that are described later.

Flocculation of the individual flocs into loosely connected, voluminous floc-aggregates takes place in the process tanks and in the final clarifier because of the high content of mixed liquor suspended solids. In the clarifier, the floc-aggregates have sizes up to several mm in diameter. Although these may have a lower density than smaller flocs, they settle faster on account of their greater size and lower friction (Fig. 4). The very loose structure of large floc-aggregates appears to allow a flow of water through the porous structure during the movements in the process tank and during settling (12).

Morphology of individual flocs is highly variable, ranging from dense, strong flocs to very irregular, loose structures (Fig. 5). The organization of the various structures, microcolonies, bacteria and the like is very heterogeneous (8,13). It is possible to quantify the floc shape by its fractal dimension. Typical values of 1.9 to 2.5 (14) have been reported, showing the loose structure and high porosity of flocs. The floc size, shape, and other properties can be described qualitatively (3,15) according to simple microscopic investigations and related to common operational problems in activated sludge plants (3):

1. Dispersed growth, where hardly any true flocs are formed and cells are freely suspended in liquid;
2. Pinpoint floc, where the flocs are small and fragile without a proper macrostructure or backbone from filamentous bacteria;
3. The ideal floc, where the filaments are largely restricted to the floc interior with limited extension into bulk water;
4. Filamentous bulking sludge, with extensive growth of filamentous bacteria inside and between the flocs.

Table 1. Examples of Distribution in Activated Sludge Flocs in Size, Surface Area, Volume, and Mass (10)

	Distributions			
Size (μm)	By Number	By Area	By Volume	By Mass
<2	30–80%	<2%	Negligible	2–8%
2–16	17–70%	1–8%	Negligible	5–28%
16–128	1–4%	20–70%	10–80%	50–80%

The Chemical Composition of Flocs

On the basis of weight, the organic matter (the volatile suspended solids, VSS) is usually the largest fraction, typically 60 to 80% of the dry matter weight (16). The inorganic fraction consists of various ions, some within the bacteria and some (mainly Mg^{2+}, Ca^{2+}, Fe^{3+}) adsorbed in the EPS matrix, and attached minerals, such as clay. Most of the organic matter in activated sludge is protein

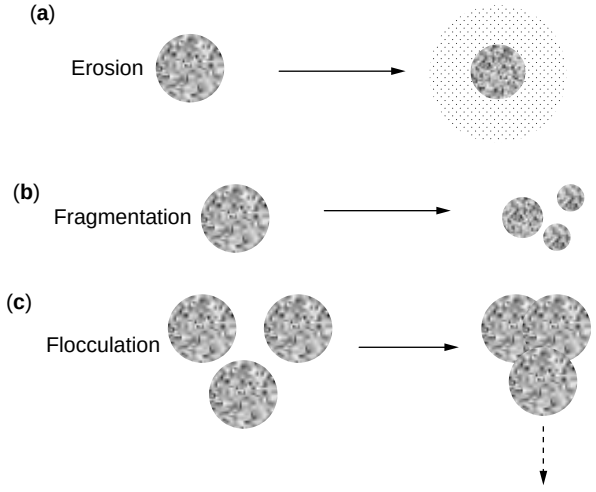

Figure 4. Flocculation behavior of activated sludge flocs.

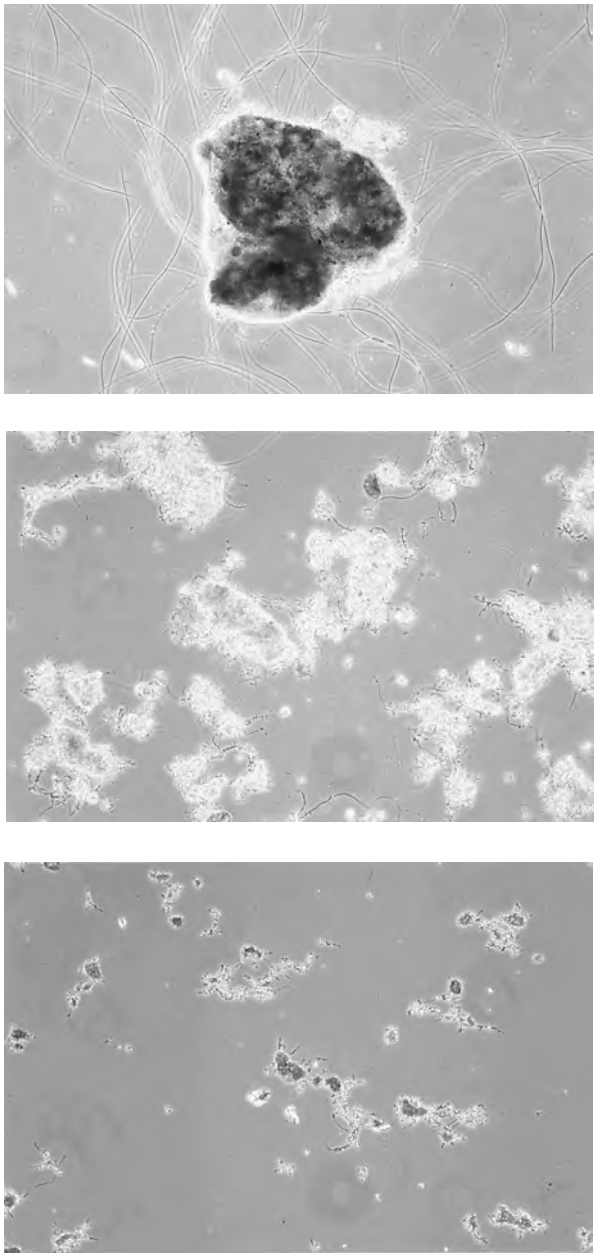

Figure 5. Examples of activated sludge flocs. (**a**) Large strong flocs form a nutrient removal plant, (**b**) Typical activated sludge from nutrient removal plant, (**c**) Small, dispersed flocs.

(40–60%), and polysaccharide material, humic substances and other compounds (e.g., lipids, nucleic acids) each constitute 10 to 20% (6). Only a minor part of these compounds represents the living cell biomass. Therefore, these compounds arise mainly from the EPS fraction, the adsorbed organic debris, and the fibers.

The EPS matrix consists of various macromolecules, such as proteins, polysaccharides, nucleic acids, humic substances, various heteropolymers, lipids, and so on. (Fig. 3). The macromolecules are partly exopolymers produced by bacterial activity and lysis and hydrolysis products, but they are also adsorbed from the wastewater. Because the EPS matrix is widely acknowledged to be very important for the floc properties (see the following section), several attempts have been made to quantify and characterize this fraction in greater detail. However, today there is no single universal extraction method that effectively extracts all EPS components without cell lysis (17). The most efficient extraction method at present is based on a combination of shear and ion exchange (17) and shows that protein is the predominant compound (Fig. 3). The total amount of EPS has been estimated to constitute 40 to 60% of the organic matter in activated sludge flocs (17). The exopolymers may be very different from one microcolony-forming species to another, and because part of the EPS components seems to be loosely attached to the flocs as a "cloud" (18), it is difficult to extract EPS that is representative of the entire floc.

It is important to note that polysaccharides, which are assumed to be an important part of bacterial exopolymers, are not present in large amounts in typical sludge flocs (6,17). Instead, protein seems to act as the most important "glue" component. The exact function of the large protein pool is not well understood, but exoenzymatic activity is present (19,20) and lectin-like proteins may have a structural function (21). Humic substances can be a large fraction in systems in which these substances are present in the wastewater and in which the sludge age is long.

As described in the next section, the EPS fraction is important for the formation of a three-dimensional gel-like network that keeps all the cells and other constituents together. The surface charge of the EPS-covered entities is generally assumed to be important for the gel properties and can be characterized by the zeta potential (or electrophoretic mobility), pH titration, and colloid titration. Typical values for the surface charge of activated sludge floc components are -0.5 to -1 meq/g SS (22,18).

Floc Microbiology

Most bacteria are known to grow in aggregates (flocs or biofilms) in natural and engineered systems, which provide a number of advantages for the bacteria when compared to suspended growth. In particular, the presence of EPS components ensures a well-buffered local chemical environment that provides substrate and important ions and protection against predators and toxic compounds. Furthermore, close proximity to other cells improves interspecies substrate and gene transfer. Considerable effort has been made in recent years to gain knowledge about the most important mechanisms controlling floc and biofilm formation. This has been supported by the recent development of tools, such as light microscopy, epifluorescence microscopy, and confocal laser scanning microscopy (CLSM) (23), for in situ studies. Use of microsensors has provided valuable knowledge about chemical gradients (24); fluorescence in situ hybridization (FISH) with gene probes and other molecular methods have revealed information about the identity and phylogeny of important microorganisms (25,26, FILAMENTOUS BACTERIA IN ACTIVATED SLUDGE: CURRENT TAXONOMIC STATUS AND ECOLOGY), and microautoradiography (MAR) provides information about their ecophysiology (27,28).

The bacteria within the flocs are present as single cells, as microcolonies, or as filamentous bacteria (Fig. 2). The filamentous bacteria are, in general, well known and well described in municipal treatment plants (3,15, ACTIVATED SLUDGE — MOLECULAR TECHNIQUES FOR DETERMINING COMMUNITY COMPOSITION), but much less is known about filamentous bacteria in industrial plants. Little is known about single cells in the flocs. Some are probably attached and incorporated into the floc matrix from the incoming wastewater and may not be active. However, several species, for example, *Spirochaetes* and *Spirillum*, can be observed by microscopy to be moving around in some sludge types (15), showing that not all active bacteria grow in microcolonies.

Microcolony formation is described among several bacterial groups in activated sludge, including *Zoogloea* spp., often forming very typical finger-like colonies easily recognizable by microscopy (15,29). *Zoogloea* spp. were originally believed to be the most important species forming flocs in activated sludge, but it appears that they are mainly present in large amounts in high-loaded conventional systems and hardly present in advanced treatment plants with N- and P-removal (30,31). They are also often present in treatment plants with plug flow or selectors to control filamentous bulking (1). Bacteria belonging to the genus *Thauera* can form zoogloeal clusters in industrial wastewater treatment plants (31). Little is known about other important microcolony-forming heterotrophic bacteria with regard to both their phylogeny and physiology. Several species have been isolated from flocs (2), but their importance remains unknown. In activated sludge from treatment plants performing biological phosphorus removal, microcolonies of phosphorus accumulating organisms (PAOs) are present and seem to form strong colonies of importance to the floc properties. However, these bacteria have not yet been properly identified (ACTIVATED SLUDGE — MOLECULAR TECHNIQUES FOR DETERMINING COMMUNITY COMPOSITION). In many plants the so-called "G-bacteria" are also present, and they form small, distinct microcolonies (ACTIVATED SLUDGE — THE "G-BACTERIA").

Autotrophic nitrifying bacteria can form large microcolonies within the flocs in nitrifying treatment plants. Several studies using FISH have clearly shown that ammonium oxidizers (mainly *Nitrosomonas*, *Nitrosococcus*, and *Nitrosospira*) as well as nitrifiers (mainly *Nitrospira*) grow in colonies, often in close proximity to each other (32: ACTIVATED SLUDGE — MICROBIOLOGY OF NITROGEN REMOVAL). These colonies appear to be strong and difficult to break apart.

The total number of bacteria in activated sludge, as determined by DAPI-staining using epifluorescence microscopy, is reported to be approximately 10^{12} per g VSS (6). Living or active cells can be identified using fluorescence in situ hybridization (FISH) with gene probes, by reduction of the redox dye CTC, or by microautoradiography (26,33,34). This fraction typically constitutes 80 to 90% of all cells in activated sludge although CTC active cells are often fewer (33). Most of the bacteria seem to be heterotrophic (34). In nutrient removal plants, the nitrifiers typically constitute 1 to 10% of the total bacterial population. Less is known about the other groups such as Fe(III)-reducers and sulfate- reducers, but they are always present (35).

Mechanisms of Floc Formation

Formation of activated sludge flocs (bioflocculation) is controlled by several processes as illustrated in Figure 6. Formation is partly determined by adsorption or flocculation of various components (e.g., of bacteria from the wastewater) and partly by growth and other biological processes taking place within the floc. Among the dominant physicochemical processes are adsorption-desorption of bacteria, EPS-components, and other organic and inorganic compounds. The desorption process, that is, when the components are detaching, is usually termed deflocculation, disintegration, or erosion of the flocs (4).

It is also important to note, as illustrated in Figure 6, that bacteria that do not properly adhere to the flocs will not be retained in the treatment plant and will leave with the treated effluent from the treatment plant. Thus, an accumulation and selection of bacteria (and other compounds) only takes place if they adhere well to the flocs or if they grow within the flocs.

Physicochemical Factors. The different constituents of the floc are embedded in an EPS matrix (or gel) kept together by various intermolecular forces. The forces are the DLVO interactions (van der Waals and electrostatic forces) and non-DLVO interactions (hydrogen bonds, hydrophobic forces, steric forces, and bridging of EPS by means of multivalent cations) (36,37). Furthermore, physical entanglement of the long EPS macromolecules may be important in the formation of the network structure of the floc. In particular, electrostatic forces and bridging are believed to be important. Most floc constituents are negatively charged overall because of the presence of proteins, polysaccharides, and humic substances with net negative charges at neutral pH (e.g., carboxylic groups). These are largely cross-linked by divalent (Mg^{2+}, Ca^{2+}) and trivalent cations (Fe^{3+}, Al^{3+}). The hydrophobic forces are probably also important, but less understood. It is known, however, that when relatively hydrophobic bacteria are added to activated sludge, they adhere better to sludge flocs than more hydrophilic bacteria (38).

Figure 6 deals with adsorption-desorption phenomena and consequently with various equilibria. These are determined by the turbulence in the system (e.g., aeration, stirring, and pumping) and by the interactive forces of the entities, which are largely determined by the ionic strength, ionic composition, and pH mentioned earlier. As described in the following section, changes in these parameters will affect the floc composition and the floc strength.

Biological Mechanisms. A main process in floc formation in the activated sludge is growth and activity of the bacteria within the floc. In addition, bacteria and particles from the incoming wastewater are adsorbed by existing flocs. Most bacteria entering the treatment plant are already aggregated in the sewer system or

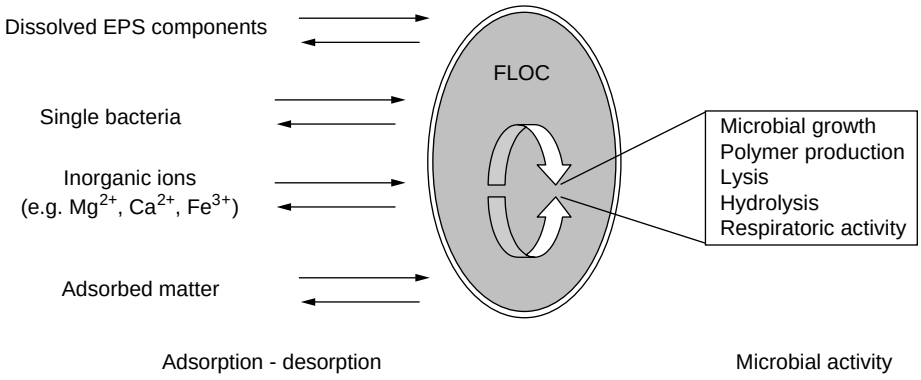

Figure 6. Formation of activated sludge floc.

present as detached sewer biofilm components. Therefore, the aggregation mechanisms known from pure culture, including specific adhesion and aggregation of a number of single cells (39), rarely occur in activated sludge systems.

Biological activity within the floc encompasses cell growth, exopolymer production, hydrolysis, death, and lysis (Fig. 6), as is also described for biofilm systems (40). Cell growth depends on the availability of soluble substrates, which is controlled by their diffusion into the floc, and by hydrolysis of the particles adsorbed from the wastewater. Often most of the organic substrate in wastewater is present as particles and colloids, and hydrolysis is required before it is available for consumption. This is reflected by the high activity of extracellular enzymes in the floc matrix (19,41). Very little is known about the controlling factors for general exopolymer production within the flocs. From pure culture studies it is known that a number of factors, such as bacterial species, their growth stage, type, concentration of substrate, and limitation of N, P, or micronutrients, and so on (40), affect the production of exopolymers (mainly proteins and polysaccharides). In activated sludge, bacteria are generally starved and exposed to dynamic conditions (1). These conditions seem to promote floc formation, perhaps as a result of an increased exopolymer production compared to cell production.

Flocs and other aggregates are characterized by high cell densities, which induce inter- and intraspecific interactions between the cells. An example is the production of low molecular weight, diffusible signaling molecules (autoinducers). These compounds can be involved in the induction of various genes that are responsible for aggregation behavior, EPS-production, disaggregation, and so on. Thus, cell-to-cell communication may be of fundamental importance to the dynamics of aggregation in flocs and biofilms and needs more attention in the future (42,43).

Stability of Activated Sludge Flocs. If activated sludge in a specific treatment plant is exposed to changes in certain environmental parameters, changes in the stability of the flocs also take place. A change typically causes a weakening of the floc and thus an undesired deflocculation, in particular if it is exposed to shear forces. This is illustrated in Figure 7, where the floc strength is characterized by the development in suspension turbidity with time when sludge is stirred under

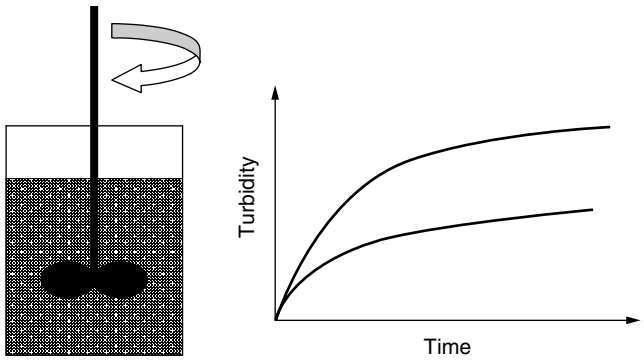

Figure 7. Measurement of the floc strength of activated sludge flocs. The sludge is stirred under defined conditions for two to three hours, and the increase in small particles in suspension (measured as turbidity after centrifugation) reflects the strength, that is, a high turbidity reflects a weak floc (44).

defined conditions (44,45). The floc weakness or the shear sensitivity can be quantified using the initial slope (45) or the ratio between the developed turbidity and total mass in the system after equilibrium (44). A more fundamental approach and more comprehensive modeling can be applied where the interaction energies and enthalphies for flocculation-deflocculation of activated sludge particles can be determined (44). The model by Parker describes the production of small particles by floc-breakup (4).

Strong flocs are believed to be formed from strong microcolonies, a large amount of exopolymers with a high charge density, many cations that effectively cross-link the matrix, and the presence of a macrostructure (filamentous bacteria or fibers). Changes in floc strength may be due to changes in the electrostatic interactions among exopolymers and particles in the floc, which can be induced by changes in environmental parameters such as ionic composition or pH, or to microbial activity, either directly or indirectly (Table 2).

Changes typically observed are a decreased floc strength when pH increases and when ionic strength is lowered, both a result of increased electrostatic repulsion. Changes can also be induced indirectly by microbial activity, for example, by denitrifying activity (which increases the local pH) or by the activity of Fe(III)-reducing bacteria, in which Fe(III) is reduced to a poorer flocculant, Fe(II) (46,47). The presence of sulfide, either produced by

Table 2. Examples of Changes in Floc Strength Due to Short-Term Changes in Environmental Factors or Microbial Activity

	Increased Deflocculation (decreased floc strength)
Environmental Condition	
pH	Increased pH (>8–9)
Ionic concentration	Change from high to low concentration
Ionic composition	Reduced ratio: (trivalent + divalent)/ monovalent ions
Detergents	Increased concentrations (>10–20 mg/l)
Microbial Activity	
Lack of oxygen	Lack of EPS production?
Denitrification	Increased pH (>8–9)
Fe(III)-reduction	Removal of the floc-forming Fe(III)
Sulfide production	Precipitation of Fe(III) to black FeS

sulfate-reducing bacteria or present in the wastewater, can seriously damage the flocs because of precipitation of the Fe(III) as ferrous sulfide (48). Furthermore, the active aerobic metabolism of the bacteria is essential to maintain strong aggregates on a short-term basis so that any lack of oxygen may induce some deflocculation of activated sludge flocs (49). The floc strength has been shown to have a seasonal variation in a certain treatment plant, with the strongest floc present during the summer period (50). The reason for this is yet to be ascertained.

Influence of Floc Structure on Functional Sludge Properties

The important functional sludge properties in the activated sludge process are flocculation and clarification, settling, and dewatering. Possible parameters that are believed to lead to floc formation with certain sludge properties are shown in Figure 8. Different environmental factors determine the microbial population as well as other components present in the floc. All these components, with their inherent properties, build up the flocs, determining size distribution, shapes, density, and strength. Ultimately, these floc properties determine the functional sludge properties that largely determine the operation of the plant.

Today, only little is known about the cause-effect relationship between the external factors that determine the various floc properties, whereas slightly more is known about which floc properties determine certain sludge properties. This mainly is due to (*1*) lack of knowledge about the composition of the microbial community, (*2*) lack of reproducible and comprehensive measurements of floc and sludge properties, and (*3*) difficulties in comparing the large diversity of wastewater types, process designs, and plant operations. Some of the generally accepted correlations are presented below.

Flocculation and Clarification. If the floc formation is working well in the process tanks and in the inlet to the clarifier, relatively large flocs are formed with an irregular shape that can collect smaller flocs during the initial flocculation and formation of floc-aggregates. The flocs must be strong to prevent breakup and production of many small particles. A number of factors are known to be important for flocculation (4). Among the physical factors are the level of turbulence (shear rate) and the design of the tanks. Important biological parameters include the F/M ratio (food to microorganisms, kgCOD/kgSS day) or sludge age (defined as total sludge mass divided by daily sludge production). At high F/M ratio or low sludge age (5–10 days), production of large but weak flocs has been reported, whereas smaller and stronger flocs are produced at lower organic loading and longer sludge ages (20–30 days). However, conflicting observations are reported in the literature, undoubtedly because other factors are important as well. For instance, large amounts of humic substances in the incoming wastewater or large variations in salinity can be expected to affect the floc composition and the floc properties.

Settling. A high settling velocity is observed if the flocs are spherical and large with a relatively high density and without too many filamentous bacteria extruding from the flocs (1,3). A high density is obtained if the inorganic fraction is high and if the porosity of the flocs is low. It is also reported that often flocs from plants with biological removal of phosphorus settle well, despite the presence of a high number of filamentous bacteria, probably because of high-density microcolonies of phosphorus-accumulating bacteria or precipitates. Low floc density often appears due to formation of conglomerates of flocs and filaments or due to extensive amounts of water-binding EPS, either adsorbed from wastewater or produced by certain bacteria (e.g., *Zoogloea* spp., (51)). Lack of inorganic cations has been reported to cause deflocculation and production of flocs with low density (52).

Dewatering. Good sludge dewatering properties are defined by low consumption of conditioning agents (organic

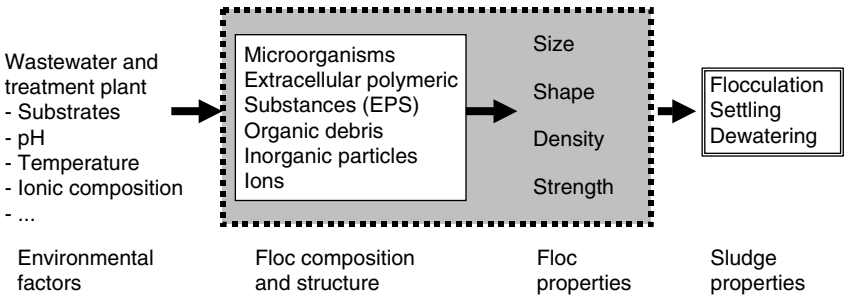

Figure 8. Overview of factors leading to floc formation with certain functional sludge properties.

polymers or iron/lime), a high dewatering rate, and a high dry matter content in the dewatered sludge cake (5). Conditioning agents are used to flocculate small particles, often by neutralizing the negative surface charges of the particles. Therefore, it is important to minimize the number of small particles (and thus the surface area) and, if possible, only have large flocs with a narrow floc size distribution. It is also important that the flocs are strong and do not break apart during dewatering, when a high shear is applied. This comment also applies to the rate of the dewatering, which is affected by many small particles because of filter clogging. Examples of poor dewatering are often observed when the floc size distribution is broad with many small particles resulting from low floc strength (53). A high dry matter content requires sludge with a low water-binding capacity, that is, a relatively low content of highly charged EPS (54). The presence of an extensive amount of water-binding EPS in zoogloeal bacteria can deteriorate the dewatering (31).

The Ideal Floc. It is not simple to define the "ideal" floc, one that is optimum for clarification, settling, and dewatering. For instance, strong flocs are good for flocculation and clarification but not necessarily for settling and dewatering. Regarding dewatering, the high water-binding capacity of most strong flocs (caused by many charged EPS components and cations) reduces the obtainable sludge dry matter content during dewatering (54). Furthermore, this high water-binding capacity may reduce the density of the flocs and thus, potentially, the settling velocity. The best compromise for floc properties that ensure good sludge properties for the entire solid-liquid separation process is probably for it to be relatively large, irregularly shaped with some filaments present, not too strong, and high density. However, it is obvious that an ideal floc with respect to solid-liquid separation is different from the ideal structure for biological transformations because for the latter, small flocs with low diffusional resistance would be desirable.

CONCLUSION

The activated sludge floc is a heterogeneous, complex structure consisting of a multitude of bacteria, extracellular polymeric substances, and other organic and inorganic components. Floc formation is determined partly by biological activity (growth-related processes, lysis, and hydrolysis) and partly by physicochemical, adsorption-desorption processes. Little is presently known about the identity of the dominating bacteria involved in these processes and about what controls their activity, whereas more is known about the dominating physicochemical factors. The most significant sludge properties for a well-working treatment plant (flocculation, settling, and dewaterability) are determined by the floc properties (mainly floc size, shape, density, water-binding capacity, and strength). Future investigations of both microbiological and physicochemical aspects of the flocs, for example, by using novel in situ methods, will improve our knowledge about cause-effect relationships between (*1*) wastewater characteristics, plant operation, and floc composition or structure, (*2*) floc structure and floc properties, and (*3*) floc properties and sludge properties. Such knowledge can be used for troubleshooting and optimization of the solid-liquid separation in existing treatment plants and to facilitate the development of new concepts, including active control of important floc properties.

ACTIVATED SLUDGE — THE "G-BACTERIA"

ROBERT J. SEVIOUR
La Trobe University
Bendigo, Australia

Many enhanced biological phosphorus removal (EBPR)–activated sludge systems (ACTIVATED SLUDGE — MOLECULAR TECHNIQUES FOR DETERMINING COMMUNITY COMPOSITION; ACTIVATED SLUDGE — THE PROCESS), where the biomass is recycled alternatively through anaerobic and aerobic regimes, contain large numbers of bacterial cells with a distinctive morphology. In the absence of any detailed physiological or biochemical information about them, they are defined here as a morphotype, appearing as cocci in tetrads or clusters, often of different sizes and usually closely associated with the flocs (ACTIVATED SLUDGE — THE FLOC), as shown in Figure 1. They are also seen in large numbers in sequencing batch reactors (ACTIVATED SLUDGE — SEQUENCING BATCH REACTORS) operating under aerobic–anaerobic conditions. An early report (1) suggested that they occurred more commonly in systems-fed glucose and not acetate, and so they were referred to as *G-Bacteria* (glucose-bacteria). Bacteria with the same appearance were reported earlier by Takii (2), and have now been recorded in plants all over the world (3).

Unfortunately, most of these have probably not been obtained in pure culture as they are very difficult to grow (3), although now enough have been cultured to demonstrate that the term *G-Bacteria* describes a group of phylogenetically quite different organisms, all sharing the same microscopic morphological appearance. Because their taxonomy is so different, it is likely that their physiologies and ecologies also vary. Hence their significance in activated sludge systems will probably differ and interpretations of their impact on plant performance need to be made with caution. This article briefly discusses the systematics of these "G-Bacteria," what is known and would like to be known about their biology, and how such information might help in understanding activated sludge systems better.

TAXONOMY OF THE "G-BACTERIA"

Taxonomy of the Gram-Negative "G-Bacteria"

It is now clear that the term *G-Bacteria* embraces both gram-negative and gram-positive bacteria, all capable of growing in this distinctive manner. The gram-negative "G-Bacteria" named by (1) were initially wrongly "identified" on their morphology only as members of the genus *Methanosarcina*, an Archaea. It is now known from 16S rRNA gene sequence data obtained from pure cultures, most of which possess the same distinctive morphology as seen in plant biomass, that these belong to a novel genus, *Amaricoccus* in the *α-Proteobacteria* (4). Some (e.g., *Amaricoccus kaplicensis*) often appear pleomorphic and produce large amounts of extracellular capsular material (Fig. 2a), which on drying appears to join the cells together in a microfibrillar network (Fig. 2b). Other *Amaricoccus*

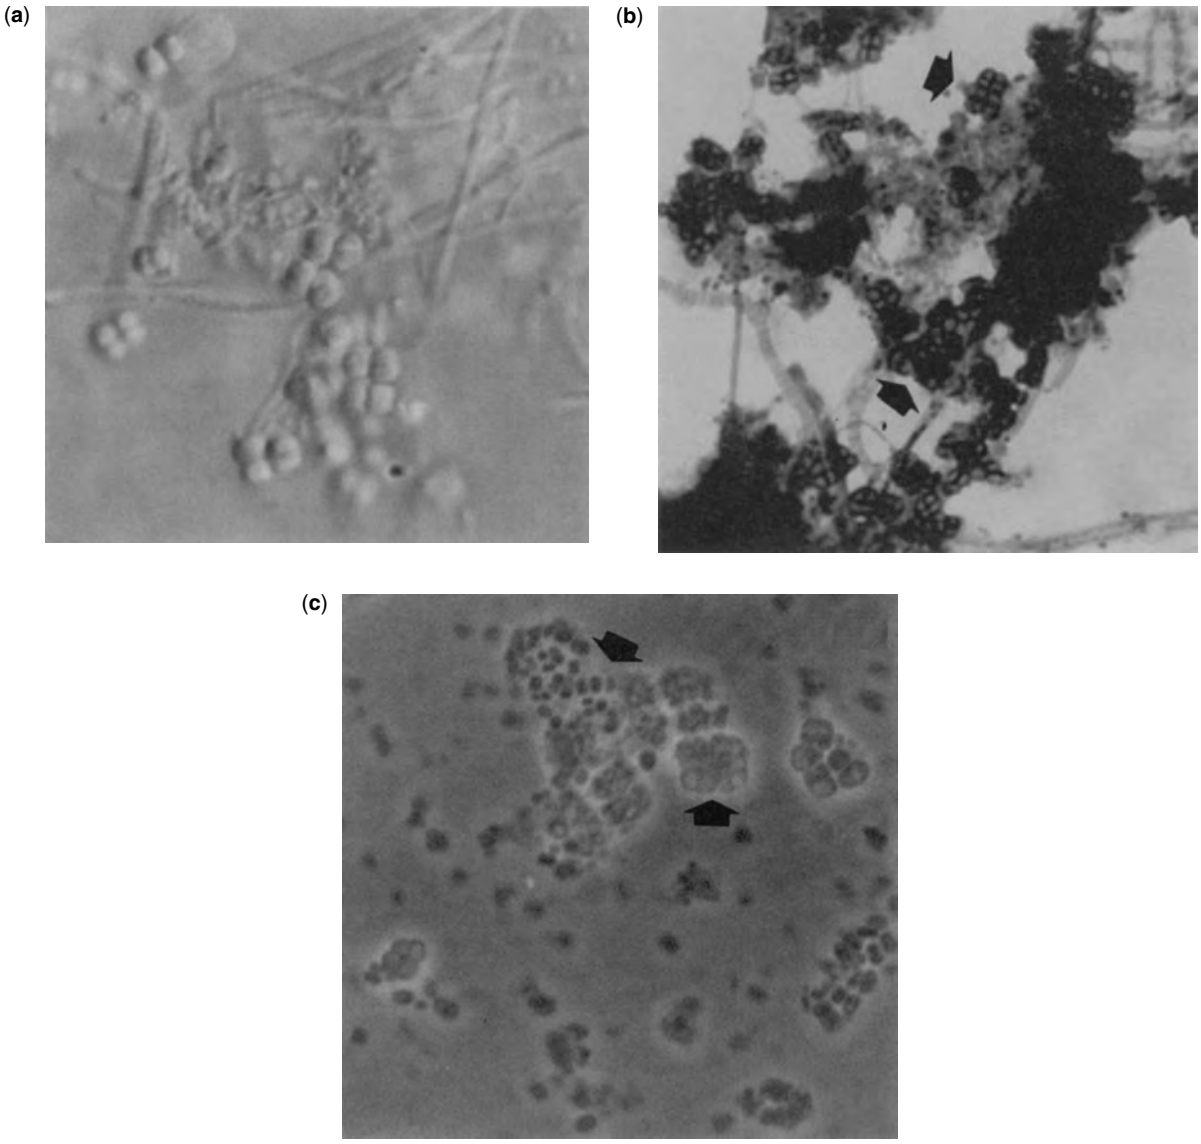

Figure 1. (**a**) Light microscope view of biomass showing "G-Bacteria" as distinctive cocci in tetrads and clusters associated with the floc. (**b**) "G-Bacteria" showing distinctive staining reaction with Neisser stain for polyphosphate, where cell contents do not stain but cell walls do. (**c**) Size variation in "G-Bacteria" from same biomass sample, where small and large cocci are visible (arrowed).

isolates are more regular in appearance in axenic culture (Fig. 2c). It also seems that isolates from different parts of the world represent several different species of *Amaricoccus*, and these have been named after their places of isolation, that is, *A. kaplicensis*, *A. veronensis*, *A. tamworthensis*, and *A. macauensis*. Some of the same isolates characterized by (4), that is, *A. kaplicensis* were also sequenced in a parallel study by (5) who named them *Tetracoccus cechii*. Under the rules of the Code of Bacterial Nomenclature, the genus name *Amaricoccus* has precedence, although the name *Tetracoccus* still appears in the literature. *Amaricoccus kaplicensis* and *A. tamworthensis* have been isolated from plants in countries other than where they were initially grown (Maszenan, 2000).

Once the 16S rRNA sequence data are available, it is then possible to design oligonucleotide probes that are specific for organisms at different taxonomic levels, that is, genus, species, and so on for fluorescent in situ hybridization or FISH (ACTIVATED SLUDGE — MOLECULAR TECHNIQUES FOR DETERMINING COMMUNITY COMPOSITION). A genus-specific probe for *Amaricoccus* has been designed (AMAR 839) and used to survey the occurrence of this organism in several plants (Fig. 3). There was no clear evidence from this survey that it was seen more commonly in EBPR plants with poor P-removal performance, although high numbers were detected, but not exclusively, in aerobic–anaerobic SBR systems and plants treating carbohydrate-rich wastes (6). These bacteria were also seen in many conventional systems, and in some plant biomass samples, the probe

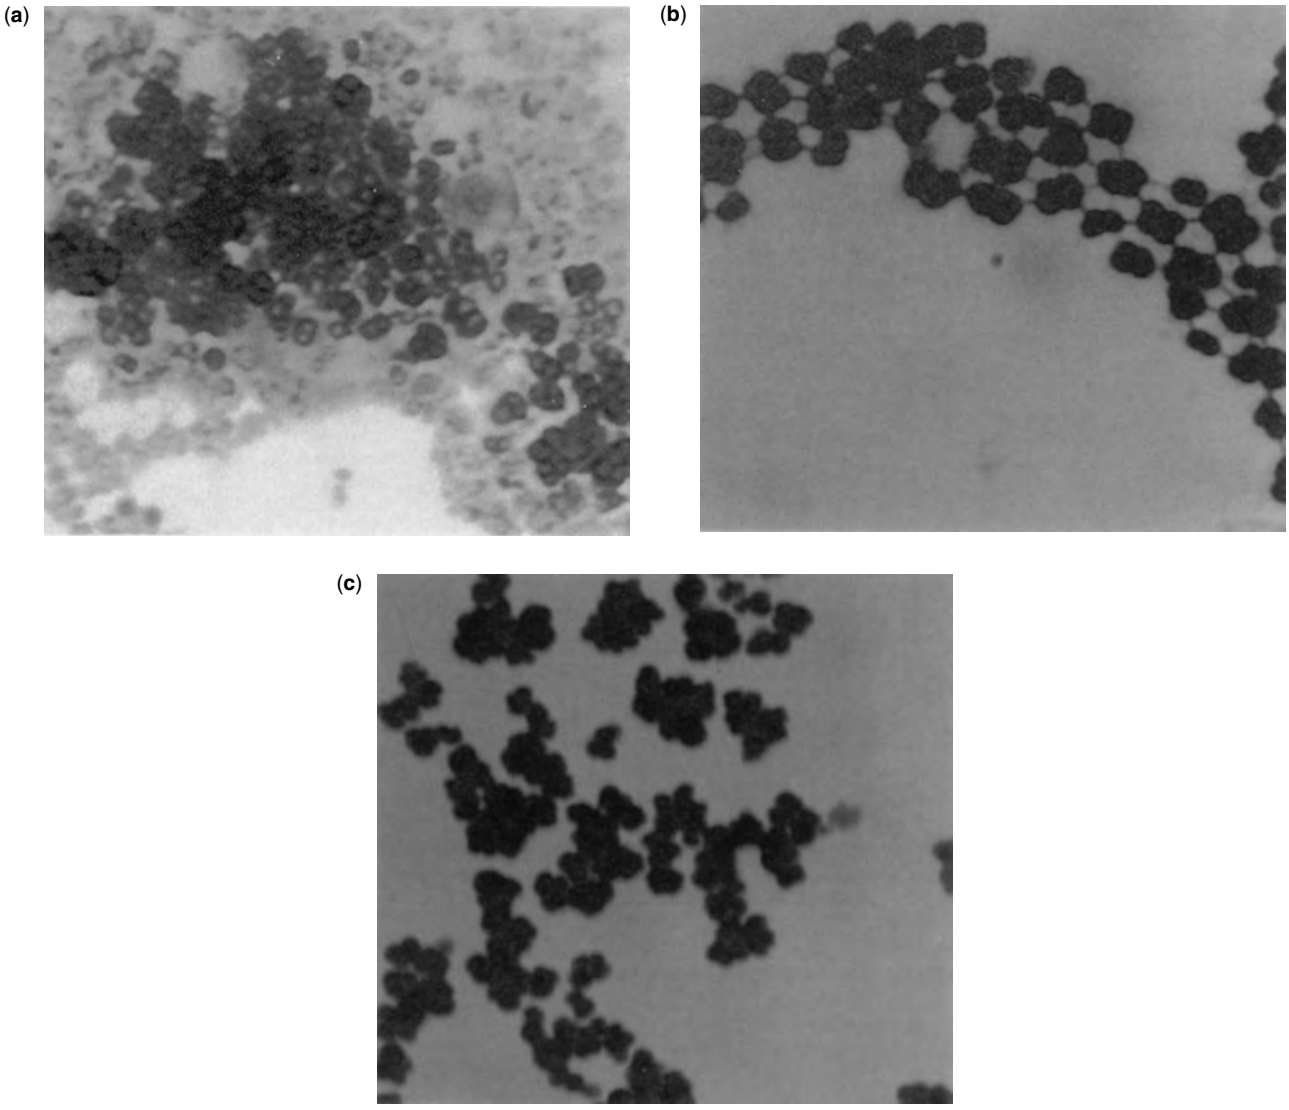

Figure 2. Light microscope of pure cultures of *Amaricoccus*, the gram-negative "G-Bacteria" (**a**) isolated originally by (1), showing the cells associated with large amounts of extracellular capsular material. (**b**) Dried capsular material in gram stained pure cultures of the isolate from Tamworth, NSW appearing as an interconnecting microfibrillar matrix between cells. (**c**) The strain from Macau showing no capsular material associated with the tetrads.

AMAR 839 was able to confirm that the "G-Bacteria" visible under the microscope but never successfully recovered into pure culture, were in fact *Amaricoccus* spp. (see following section).

It is now clear that *Amaricoccus* is not the only gram-negative coccus associated with activated sludge systems. Thus, molecular techniques using 16S rDNA fragments separated by DGGE (ACTIVATED SLUDGE — MOLECULAR TECHNIQUES FOR DETERMINING COMMUNITY COMPOSITION) detected bacterial sequences in a laboratory reactor showing poor P-removal, which emerged on sequencing as phylogenetically novel *α-Proteobacteria* and *β-Proteobacteria* (7). After FISH probing based on only their partial sequences, they appeared in biomass samples as large cocci (i.e., "G-Bacteria"). Neither of these has been cultured and so whether they do accumulate PolyP or another storage polymer is not known. Two other gram-negative "G-Bacteria" have been grown in an laboratory, which after 16S rRNA gene sequence analysis appear as novel genera. One, an unusual *α-Proteobacteria* has been placed in the genus *Defluvicoccus* (8), whereas the other, strain Ben 117, a *β-Proteobacteria*, has been allocated to the new genus *Cardococcus* (9). These data clearly demonstrate that these gram-negative coccal "G-Bacteria" are phylogenetically diverse (Fig. 4), and it is highly probable that many more await description.

Taxonomy of the Gram-Positive "G-Bacteria"

It is now clear that the gram-positive coccal "G-Bacteria" are also taxonomically diverse, but until more have been

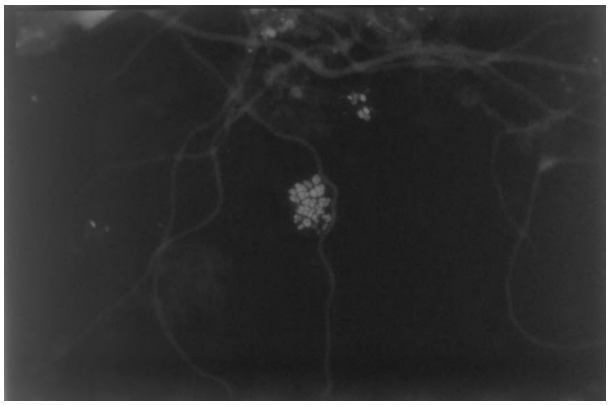

Figure 3. In situ identification of *Amaricoccus* by FISH using the fluorescein labeled AMAR 839 probe, showing the distinctive cell arrangement of tetrads and clusters in a sample of biomass. See color insert.

grown in pure culture and fully characterized, the true level of their biodiversity remains unknown. Those that have been grown axenically in the laboratory, and for which 16S rRNA sequence data (Fig. 5) have been obtained include

- possibly novel *Micrococcus* strains (10),
- two new species of *Friedmanniella*, *F. spumicola*, and *F. capsulata* (11), which grow in clusters of tetrads in a mucilaginous mass (Fig. 6),
- two novel genera, *Tessaracoccus* (as *T. bendigoensis*) (12) and
- *Tetrasphaera* (as *T. australiensis* and *T. japonica*) (13).

The taxonomies of *Friedmanniella* and *Tetrasphaera* are particularly interesting. The only other *Friedmanniella* species currently known, the slow growing *F. antarctica* was isolated, not from activated sludge, but from antarctic sandstone, a nutritionally stressed habitat (14). *Tessaracoccus japonica* is the coccus isolated from activated sludge after prolonged starvation by (15) and incorrectly "identified" then as a *Micrococcus*. Totally unexpectedly, it also emerges as a member of the same genus as the bulking activated sludge filamentous bacterium *"Nostocoida limicola"* II (FILAMENTOUS BACTERIA IN ACTIVATED SLUDGE: CURRENT TAXONOMIC STATUS AND ECOLOGY), which is known to grow as cocci in clusters (16), even though *Tetrasphaera* has never been seen to grow as filaments in pure culture. Such an outcome serves to emphasize the dangers inherent in relying solely on morphology to "identify" bacteria (17), especially those in activated sludge.

These strains are in addition to those gram-positive cocci so far isolated only from Japanese activated sludge plants and not described originally as "G-Bacteria." These are also in the high mol% G + C gram-positive bacteria and include the novel genera

- *Microlunatus* (as *M. phosphovorus*) (18) with a distinctive cell morphology
- *Microsphaera* (as *M. multipartita*) obtained from a plant treating a sugar-rich synthetic waste (19).
- *Micropruina glycogenica* (20) closely related to *Friedmaniella* and *M. phosphovorus* and obtained from an EBPR system.

The phylogenetic relationships based on 16S rRNA sequence analysis between these and the other gram-positive "G-Bacteria" are shown in Figure 5. The questions of how widely occurring these gram-positive "G-Bacteria" are and what operating conditions might favor their presence in activated sludge systems await the development of 16S rRNA-targeted probes for FISH of each of these. Probes have been described for *Microlunatus* (21) and *Tessaracoccus* (Maszenan, unpublished) so their population dynamics should now become clearer. Clone library data have shown that organisms very similar to *Tetrasphaera* occur elsewhere (22), but surprisingly no reports of the presence of any of the other "G-Bacteria" in activated sludge biomass have appeared when molecular techniques of community analyses have been used.

PHYSIOLOGY OF "G-BACTERIA"

Evidence (largely anecdotal) suggests that these "G-Bacteria" are favored in activated sludge and SBR systems operating with alternative anaerobic–aerobic regimes. Thus they possibly share the same ecological niches as some of the so-called polyphosphate accumulating bacteria (PAB) (ACTIVATED SLUDGE — MOLECULAR TECHNIQUES FOR DETERMINING COMMUNITY COMPOSITION), but there is insufficient information on their physiology so far to really explain why. The physiology and ecology of the few pure cultures available have not been examined in detail, and so the information comes largely from using mixed liquor communities enriched with these organisms. The taxonomic status of the bacteria present in these is usually not known, and given the earlier discussions on the phylogeny of these "G-Bacteria," they may in fact represent additional novel organisms. The reader is directed to (ACTIVATED SLUDGE — MOLECULAR TECHNIQUES FOR DETERMINING COMMUNITY COMPOSITION) for a critical discussion on current understanding of how these EBPR plants are thought to work. The roles of polyphosphate (PolyP), poly β-hydroxybutyrate (PHB) and glycogen in aerobic–anaerobic systems in providing the PAB with a selective advantage in EBPR, and the crucial importance of anaerobic substrate uptake by them are also discussed.

It has been suggested that the "G-Bacteria' are undesirable in EBPR systems because of their ability to synthesize intracellular storage carbohydrates such as glycogen aerobically and to use these to provide the energy to assimilate readily utilizable substrates anaerobically (1). Thus, the PAB were considered in danger of being outcompeted in the anaerobic stage, and instead of PolyP accumulation occurring aerobically, cells store polysaccharide material instead.

This attractive idea has never received any direct support from pure culture work (23), and although none of the *Amaricoccus* isolates or *Defluvicoccus* that were examined store PolyP in pure culture (4), *Cardococcus* does. Whether these non-PolyP accumulators can

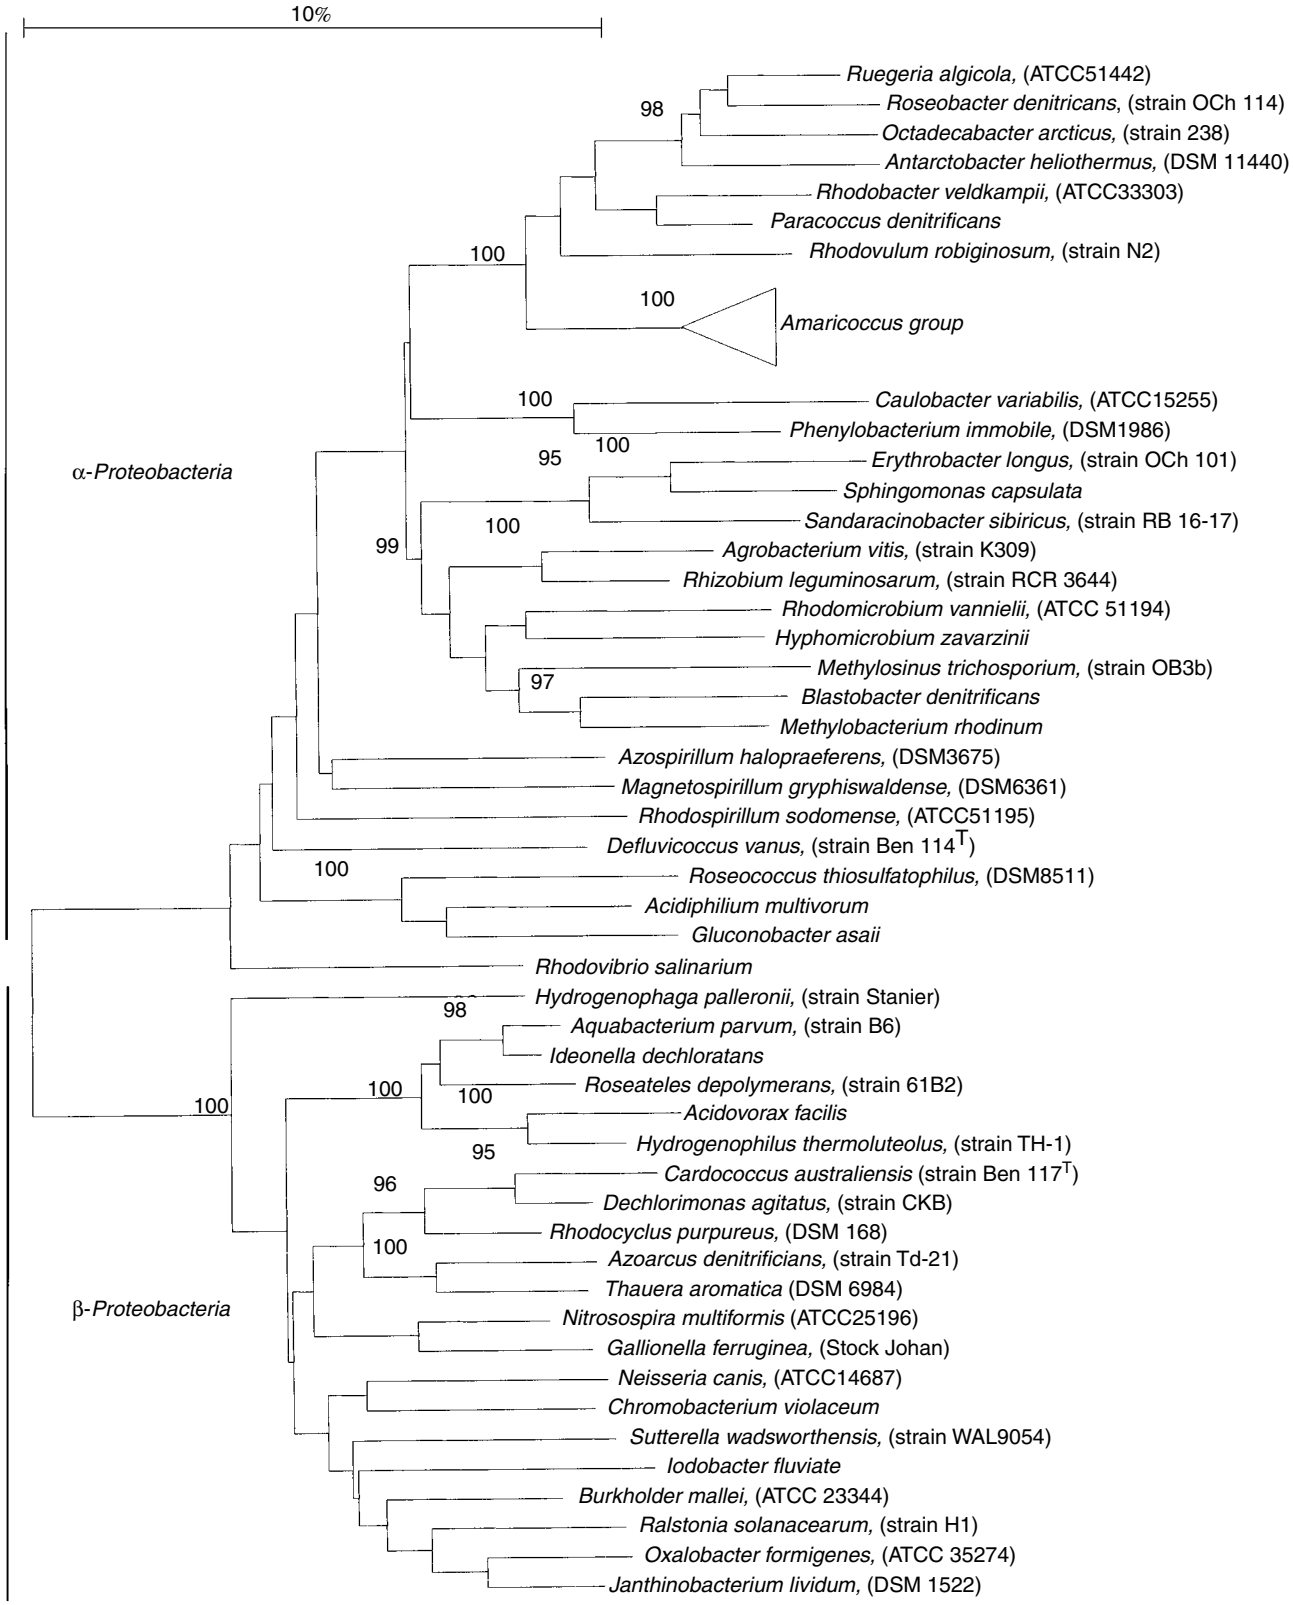

Figure 4. Phylogenetic tree (6) based on 16S rDNA sequence analysis of the cultured gram-negative "G-Bacteria" (in bold) among the *α-Proteobacteria* and *β-Proteobacteria*. Bootstrap values are given for the major clades and the bar marker indicates 10 nucleotide substitutions per 1,000 nucleotides.

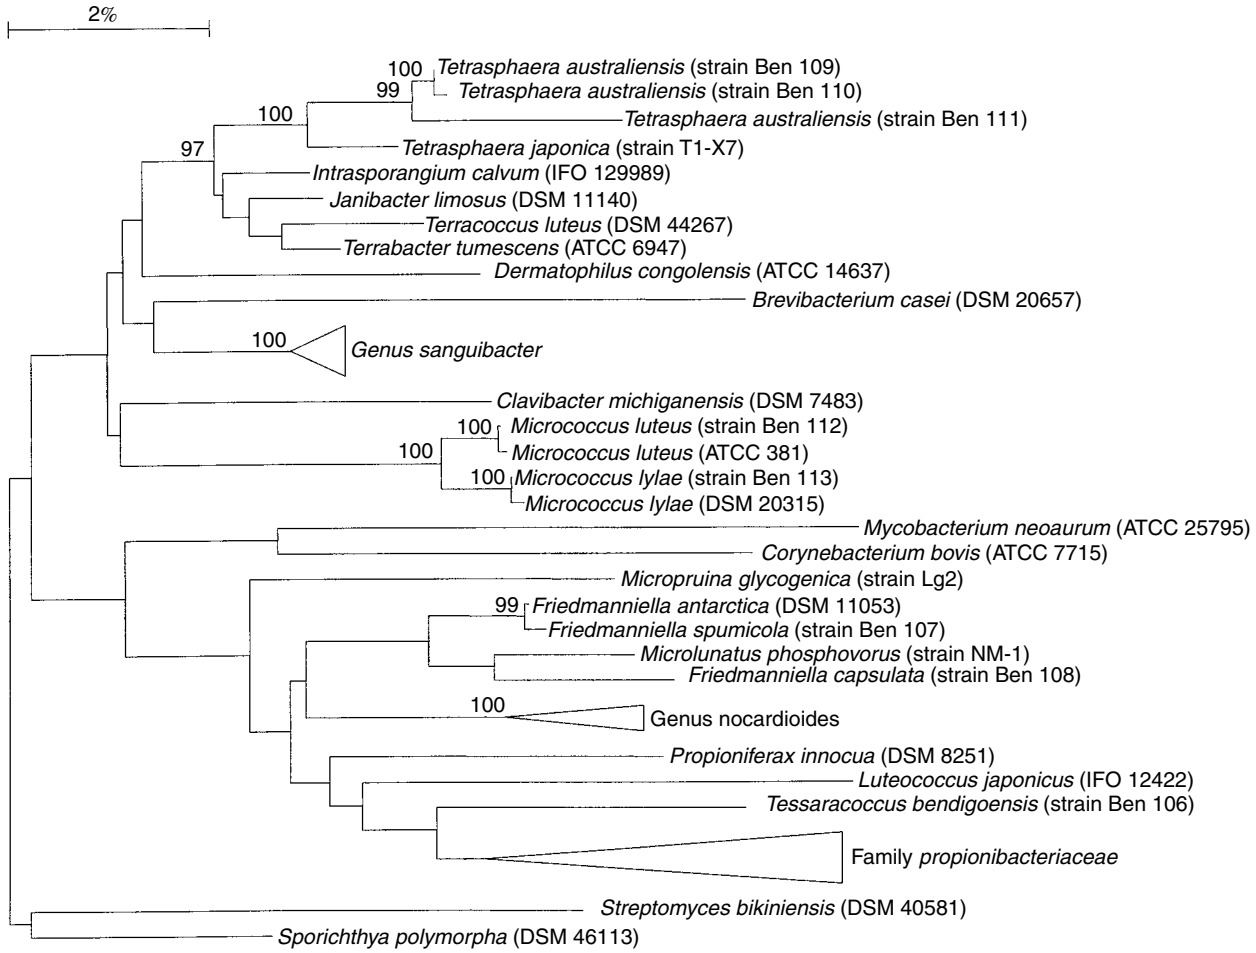

Figure 5. Phylogenetic tree (6) based on 16S rDNA sequence analysis of the cultured gram-positive "G-Bacteria" (in bold) among the high G + C gram-positive bacteria. Bootstrap values are given for the major clades and the bar mark represents 10 nucleotide substitutions per 1,000 nucleotides.

synthesize glycogen (either aerobically or anaerobically) instead is known only for *Amaricoccus*, where glycogen in high amounts (about 20% of cell dry weight) is stored under aerobic conditions from glucose (Kong, unpublished). PHB is also synthesized from acetate and several other carbon sources (23). Most of the gram-positive "G-Bacteria" that have been observed can accumulate PolyP in pure culture, although with the exception of *M. phosphovorus* (18,24), nothing is known about which conditions might influence its synthesis. This bacterium was described as behaving in pure culture in a manner close to that expected for the PAB, except that it could not assimilate acetate anaerobically. In fact, NMR studies (25) have shown that this organism fits little of the expected behavior of a PAB. Unable to grow anaerobically, it could still ferment glucose to accumulate anaerobically intracellular reserves of free acetate without synthesis of any PHB. Under aerobic conditions, glucose was respired without intracellular storage polymer (e.g., glycogen) production. However, it could assimilate and release phosphate at high rates in pure culture, similar to those measured in EBPR activated sludge samples. Similar experimental protocols applied to the other "G-Bacteria" are likely to be rewarding in the efforts to understand how these organisms function.

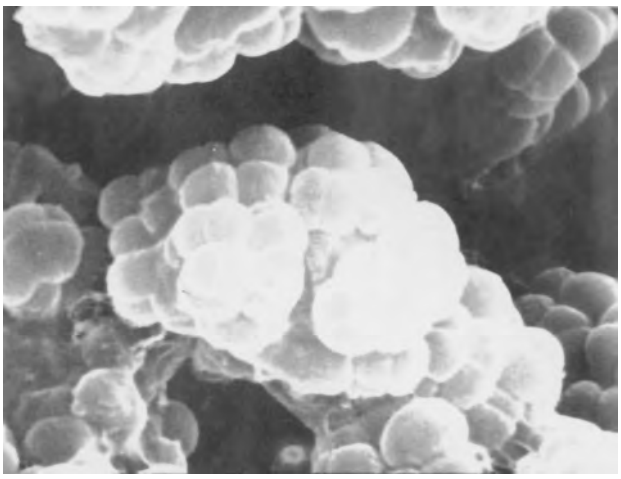

Figure 6. Scanning electron micrograph of *Friedmanniella spumicola* showing the coccal tetrads embedded in mucilage (bar marker = 2 μm).

MIXED CULTURE STUDIES WITH THE "G-BACTERIA"

Much of what is thought to be known about how these "G-Bacteria" behave in activated sludge comes from studies using mixed culture communities of unknown taxonomic status. Often the biomass in these experiments where conditions for very poor phosphorus removal have been established, has been dominated by morphotypes of the "G-Bacteria," although they were not always described as such, instead being referred to as the glycogen-accumulating bacteria, or GAO (25). As these bacteria have not yet been cultured, it is difficult to interpret the chemical transformations reported in terms of the organisms actually carrying them out. However, these experiments did attempt to explain why the PAB seemingly were replaced by GAO in EBPR systems-fed glucose and carbohydrate-rich substrates, and not acetate (1). The main proposition is that the GAO under these conditions could assimilate glucose anaerobically at a faster rate than the PAB could (who were thus disadvantaged), to synthesize PHB using glycogen as the source of reducing power and energy. Aerobically, glycogen was then replenished in the biomass from the PHB, and the PAB in the absence of PHB were no longer advantaged and able to accumulate PolyP. An acetate feed favored the PAB according to the models for EBPR (Activated Sludge — The Process). It was suggested (26) that the energy demand for acetate transport into the cells is high and cells need an energy source such as PolyP to support it, whereas glucose transport has a comparatively low energy demand that can be met from glycogen catabolism. However, no other convincing evidence has been produced to support such claims. Unfortunately, as we do not know yet which organisms are the GAO in these studies, and FISH-based identifications would help us here, it can only be explained in simplistic terms what might be going on. However, anaerobic glucose assimilation and aerobic glycogen synthesis may be a physiological adaptation of many of these "G-Bacteria," although some biomass samples dominated by *Amaricoccus* in fact remove phosphate very well (27).

ECOLOGY OF "G-BACTERIA"

Can the little that is known about these slow growing bacteria help understand why and how they survive in such highly competitive habitats as activated sludge systems, especially those removing phosphorus? They seem to possess the physiology to tolerate the wildly fluctuating availability of nutrients and the inevitable periods of nutrient stress and starvation encountered in such systems. An ability to synthesize energy storage polymers such as PolyP, PHB and/or glycogen appears to be a common attribute of these, and there is some evidence that they are able to withstand prolonged periods of starvation better than other activated sludge bacteria (15). It has also been shown (23) (albeit not for all these "G-Bacteria") that they can access any substrates when they do become available, immobilizing them almost exclusively into these storage compounds and not using them to increase what appears from pure culture evidence to be very slow growth rates. It could be argued from the organisms' perspective that this makes sound ecological sense because an "r-strategy" based on a high growth rate in activated sludge is certain to fail. Most of the 'G-Bacteria" that were observed appear to produce often large amounts in pure cultures of polysaccharide capsular material. Probably as a consequence of this material imparting hydrophobicity to their cell surfaces, the tetrads are usually seen closely associated with the activated sludge flocs. This may serve to

- protect them from possible predation from the protozoa feeding on suspended bacteria (Protozoa in Activated Sludge)
- provide protection against potentially harmful abiotic influences in the biomass
- ensure that they stay in the system in the return activated sludge and not leave the plants suspended in the bulk liquid

Their frequency of occurrence and predominance in biomass samples containing them together make them worthy of study.

CONCLUSION

- The cocci referred to as the "G-Bacteria" and often seen in activated sludge systems in large numbers are phylogenetically diverse and contain mainly novel gram-positive and gram-negative bacteria
- This finding reinforces the dangers in relying on morphology to "identify" bacteria and the risks in using this "identification" to interpret their possible role in communities such as activated sludge
- Generally, the literature seems to agree that these "G-Bacteria" appear to favor activated sludge systems where the levels and durations of periods of nutrient stress are particularly high, that is, SBR and EBPR processes
- These "G-Bacteria" appear to be found in niches shared by the PAB, although it is known how widely distributed each "G-Bacterium" is or the influences that promote or discourage their growth
- Although these organisms are difficult to obtain in pure culture, the molecular methods now available (e.g., FISH) provide the tools for studying their ecology and population dynamics
- The general understanding of their physiology is poor and so their role in EBPR plants is still not certain. All seem to possess an ability to synthesize intracellular storage polymers but the conditions affecting their production await clarification
- However, all seem to possess many of the required traits for a slow growing organism to survive in an activated sludge system that is able to cope with feast or famine conditions and remain in the system indefinitely. Therefore, with some confidence they might be described as true "K-strategists"

- It is likely that there are many more "G-Bacteria" in activated sludge systems and probably other stressful habitats (i.e., *Friedmanniella antarctica*) waiting to be described, and so views on what these bacteria might be doing will probably need to be revised.

Acknowledgments
I wish to thank all the people who provided data for this article, especially A.M.(Mas) Maszenan whose Ph.D. work this contribution largely uses.

ACTIVATED SLUDGE — THE MICROBIAL COMMUNITY

ROBERT J. SEVIOUR
A. M. MASZENAN
Biotechnology Research Centre
La Trobe University
Bendigo, Australia

The activated sludge process (see ACTIVATED SLUDGE — THE PROCESS), the most popular process for treating both domestic and industrial wastes has been used around the world for almost a century, yet it is still very much a "black box." Some of the major chemical changes that are taking place can be readily measured (Fig. 1), but still, little is known about the microbes that are responsible for these and how their activities are affected by variables such as influent composition, process configuration, and process operation. The reasons for such ignorance are probably many, but until quite recently the methods available to gather such information from systems designed and run largely by engineers were not available. This has now begun to change. The application of molecular methods to the activated sludge ecosystem (see ACTIVATED SLUDGE — MOLECULAR TECHNIQUES FOR DETERMINING COMMUNITY COMPOSITION) has not only revealed a previously unsuspected level of microbial diversity, but has also questioned many earlier ideas as to which bacteria were responsible for important processes such as phosphorus (see ACTIVATED SLUDGE — MOLECULAR TECHNIQUES FOR DETERMINING COMMUNITY COMPOSITION) and nitrogen (see ACTIVATED SLUDGE — MICROBIOLOGY OF NITROGEN REMOVAL) removal. However, it could be argued that such important advances in the understanding of these systems are yet to help operators run them better or engineers to achieve improved designs. This will take some time to happen, but it is clear that it will not occur until the microbiology of activated sludge is far better understood than it is now.

WHY THIS IGNORANCE?

Applying traditional or classical microbiological techniques to activated sludge is beset with difficulties (1,2). These are often a consequence of the biomass being organized into discrete complex aggregates called flocs (see ACTIVATED SLUDGE — THE FLOC). Their chemical and physical structures and how they are formed are still not well understood, but unless these flocs settle rapidly in the clarifiers, the treatment process will ultimately fail. Activated sludge is also a highly complex ecosystem, so microbiologists with a preference for working with pure cultures have not been attracted readily to its study. The impact of applying molecular methods to overcoming some, if not all, of the problems associated with culture-dependent methods has been considerable. These include

- *Sampling*. Floc structure and organization mean that representative samples are difficult to obtain,

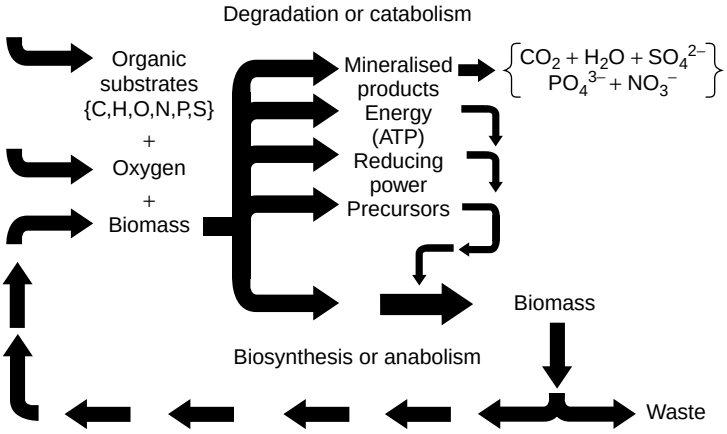

Figure 1. Summary of main chemical transformations thought to occur in the activated sludge process (2).

since the floc-associated microbes have to be suspended first. Various physical and chemical methods have been developed for this (2,3), but none are without problems, and all give serious underestimations of the bacterial numbers in quantitative studies (1) as well as the true level of bacterial biodiversity present in this system. Furthermore, it is not surprising that considerable heterogeneity can exist within individual flocs, where anoxic zones with different active bacterial populations have been detected in flocs in fully aerobic systems (4). Individual cells with a distinctive morphology (e.g., filamentous bacteria) can be recovered by micromanipulation (2), a technique with considerable advantages over other culture dependent methods, since the organism(s) of interest can first be "identified" under the microscope and can be selectively and physically separated from the rest. Flow cytometry allows for bacteria recovery but not for the growth of specific populations (5,6) that have been distinguished with fluorescently tagged (FISH) probes. (see ACTIVATED SLUDGE — MOLECULAR TECHNIQUES FOR DETERMINING COMMUNITY COMPOSITION).

- *Culturing and quantifying isolates*. Even the most nonselective microbiological media are unlikely to support the growth of more than a small subsample (<1%) of the bacteria present in activated sludge. Various molecular methods, which themselves are not without criticism (1,2,7,8), have all strikingly exposed the biased nature of culture-dependent techniques and the confusion that the data obtained from them have created (see ACTIVATED SLUDGE — MOLECULAR TECHNIQUES FOR DETERMINING COMMUNITY COMPOSITION). It is the view of the authors that there is still an important role for pure cultures in any study of activated sludge microbiology, especially if physiological and kinetic data are sought from individual populations (9). Unfortunately, without prior knowledge of the nutritional requirements or taxonomy of the bacteria sought (e.g., the bulking and foaming filamentous bacteria), it is not easy to design media rationally for their culture (2).
- *Measuring what they do*. One particularly difficult question to answer is what role these microbes are performing in the treatment process from the data using 16S rRNA targeted probes and FISH, it seems likely that most of the bacteria present are metabolically active and not dead or moribund (10) as once thought and thus probably contribute to the measurable chemical changes occurring. Only recently have attempts been made to find the specific microbial populations that are responsible for them in the hope that clearer structure–function relationships emerge. FISH probing directed at locating specific functional genes within particular populations is one approach. For example, the nitrate reductase gene in denitrifying bacteria (11,12), the sulfate reductase gene for dissimilatory sulfate reducing bacteria (4), and the ammonia monooxygenase gene for the nitrifiers (13) have all been used for this purpose. Respirometry via oxygen uptake rates (OUR) and substrate utilization and product formation rates for nitrifying and denitrifying bacteria (see ACTIVATED SLUDGE — MICROBIOLOGY OF NITROGEN REMOVAL) are popular general methods (2), especially for modelling purposes (see ACTIVATED SLUDGE — THE PROCESS). Dye reduction enzyme assays with CTC (14) and INT (15) for detecting respiratory active (i.e., viable) cells microscopically have been applied to activated sludge systems. However, when results obtained with all these different macrotechniques are compared, the data do not always correlate well (2). Determining carbon utilization patterns with the Biolog system to fingerprint heterotrophic metabolic activity, especially for systems treating industrial wastes, has also provided promising data, but these are not always easily interpreted (16).

  The fate of specific populations with metabolic activities of interest has been followed using green fluorescent protein tagging (17), which seems to be a technique of promise for the elucidation and assessment of their contributions to particular chemical events (18). Recent application (19,20) of microautoradiography (MAR) in combination with FISH probing to activated sludge

(see ACTIVATED SLUDGE — MOLECULAR TECHNIQUES FOR DETERMINING COMMUNITY COMPOSITION) has already provided invaluable information on the in situ physiology of bacterial populations of interest. A good example of how valuable this technique can be is seen in *Microthrix parvicella* (20). This bulking and foaming filament (FILAMENTOUS BULKING IN ACTIVATED SLUDGE, CONTROL OF; ACTIVATED SLUDGE — FOAMING) was shown to be selectively favored in aerobic : anaerobic systems such as enhanced biological nutrient removal (EBNR) plants (see ACTIVATED SLUDGE — THE PROCESS) because of its ability to assimilate hydrophobic substrates, such as oleate, anaerobically and anoxically as well as under aerobic conditions. Uptake of trioleate by *M. parvicella* was in fact best under anaerobic regimes and could be maintained under the starvation conditions inevitably encountered in such systems (see STORAGE POLYMERS: ROLE IN THE ECOLOGY OF ACTIVATED SLUDGE). As more bacterial populations are studied in this way, our current understanding of activated sludge microbiology will change dramatically, and such information should allow plant function to be related meaningfully to community structure.

- *Identifying the microbes present*. The classical approach with activated sludge has been to use phenotypic characters to identify those isolates that are obtainable in pure culture. For those not culturable (e.g., many of the filamentous bacteria and protozoa), "identification," by necessity, is based on their diagnostic microscopic appearance in biomass samples. Neither approach is appropriate if the aim is to understand which microbes are really present in activated sludge. Even if they can be cultured, most microbes, as is the case of many filamentous bacteria (see FILAMENTOUS BACTERIA IN ACTIVATED SLUDGE: CURRENT TAXONOMIC STATUS AND ECOLOGY), are novel organisms (21,22). Therefore, conventional identification methods are difficult, and morphology is a notoriously unreliable phylogenetic indicator with bacteria. Again, molecular RNA-based methods have provided the means for the in situ identification of many bacterial groups in the absence of any need to culture them, independently of their morphology, using FISH (see ACTIVATED SLUDGE — MOLECULAR TECHNIQUES FOR DETERMINING COMMUNITY COMPOSITION). The number of FISH probes available for detecting an increasingly diverse range of bacteria in activated sludge continues to grow rapidly and their advantages over both fluorescent and monoclonal antibody techniques, which have also been employed for the same purpose, are well recognized (10). Again, FISH techniques are not above criticism (7,23), but they have already supplied vital information about the role of the bacterial populations in processes such as nitrogen and phosphate removal (see ACTIVATED SLUDGE — MICROBIOLOGY OF NITROGEN REMOVAL). In combination with MAR, they appear to be even more powerful experimental tools, and it is not hard to predict that their application to activated sludge systems will continue to expand.

SO WHAT IS KNOWN SO FAR ABOUT THE MICROBIAL COMMUNITIES IN ACTIVATED SLUDGE PLANTS?

It is quite clear from recent studies applying these rRNA-based methods that perceptions of what were previously considered as more important (physiologically and numerically) populations in activated sludge systems are largely wrong. Organisms that are revealed using culture-dependent methods are a reflection more of these methods than the populations actually present. Several independent studies have shown that while the γ-Proteobacteria dominate cultured gram-negative bacterial populations, those revealed by using culture-independent methods are mainly the β-Proteobacteria (24–27). The relative importance of the high mol% G+C Bacteria differs between studies, which may reflect different operational conditions of the systems studied or variations in efficiencies of the individual methods of DNA extraction used, which are usually not checked for possible biases (28). Such observations also emphasize the well-known risks associated with trying to assess data quantitatively from these rRNA-based molecular approaches (7). The information available on which organisms are present in activated sludge is inevitably skewed. More effort has been directed at understanding those considered responsible for particular changes such as those involved in nitrogen and phosphate removal (see ACTIVATED SLUDGE — MICROBIOLOGY OF NITROGEN REMOVAL) or the bulking and foaming filamentous bacteria (see FILAMENTOUS BULKING IN ACTIVATED SLUDGE, CONTROL OF; ACTIVATED SLUDGE — FOAMING). Even so, these populations are still not always well understood, and often the picture is much more complex now than once thought likely. A brief overview of some recent additions to the view of the microbial composition of the activated sludge community follows. This community is likely to change in response to many factors in ways that are not yet understood, and so any generalization made here is risky.

- *Viruses*. As might be expected, activated sludge systems contain many viruses of animal and human origin, but because of problems in their isolation and characterization, their diversity is poorly understood, and many more different types may be present about which little is known. Molecular methods (e.g., probes) may eventually provide this information. These viruses are known to include the HIV virus, which is unlikely to survive the process, and more robust viruses including the rotaviruses, many of which will survive (29). Bacteriophages are readily isolated. Although their possible roles in bacterial population density control have not been fully assessed, it seems that some may have broad host ranges making such a function likely.
- *Bacteria*. Unquestionably, applying a battery of molecular rRNA-based techniques has changed views on the true extent of biodiversity among activated sludge bacterial populations, and many populations

previously unknown or ignored, or considered to represent unimportant members of this community, now emerge as numerically significant. Often, the populations detected in large numbers have no known function, and most of these are yet to be cultured in the laboratory and it is usually not known why they predominate. Activated sludge systems will certainly contain pathogenic bacteria of human fecal origin such as *Salmonella* spp., and some will survive the process. These will need to be removed by disinfection later because it is important to recognize that these processes are designed primarily to remove nutrients and not bacteria.

a. Chemoheterotrophs. The process relies on aerobically respiring bacteria to degrade and mineralize organic compounds present in raw sewage that are often complex and chemically diverse. Yet, little is known about the main bacteria that are responsible or how the communities of these might change with different operating conditions. Fingerprinting techniques such as denaturing gradient gel electrophoresis (DGGE) (30) and terminal restriction length polymorphism (T-RFLP) (31) (see ACTIVATED SLUDGE — MOLECULAR TECHNIQUES FOR DETERMINING COMMUNITY COMPOSITION), which allow changes in community composition to be followed with time, may help provide answers. Substantial progress has been made in properly identifying some of the distinctive bacterial morphotypes readily seen under the microscope. These include the bulking and foaming bacteria (see FILAMENTOUS BACTERIA IN ACTIVATED SLUDGE: CURRENT TAXONOMIC STATUS AND ECOLOGY) and the "G-Bacteria" (see ACTIVATED SLUDGE — THE "G-BACTERIA"). Both contain bacteria that were not described previously, and emphasize how collections of bacteria indistinguishable morphologically can be phylogenetically quite unrelated to each other. Spiral bacteria, often recognized in biomass samples because of their characteristic corkscrew pattern of movement, are not spirochaetes as they have often been referred (2). Instead, on the basis of molecular characteristics, they were previously undescribed members of the *Cytophaga-Flavobacterium* division (6), a group long known to exist in activated sludge systems (2). Novel isolates readily detected among populations of *Aeromonas*, *Acinetobacter*, *Acidovorax, Sphingomonas*, and *Hyphomicrobium* (32–36) confirm activated sludge as a relatively unexploited natural source of bacteria. In addition, some bacteria that were never considered previously as important members of this community now appear to be present in significant numbers. These include the Planctomycetes (25,37,38) and oligotrophs such as *Hyphomicrobium* (36). What the reason or reasons for their presence might be are not understood, but such data imply that appreciation of the total spectrum of the metabolic changes occurring in activated sludge must also be simplistic.

   Molecular approaches have also forced us to reappraise anaerobic respiration in activated sludge systems. For example, the ANAMMOX process illustrates how much is still to be learned about the diversity of denitrifying bacteria (39), and their ability to reduce nitrate under aerobic conditions now seems to be a common one (12,40) (see ACTIVATED SLUDGE — MICROBIOLOGY OF NITROGEN REMOVAL). Which bacteria are the more active denitrifiers is not clear although unexpected candidates such as *Hyphomicrobium* may dominate in some systems (41). Bacteria that are capable of reducing Fe^{3+} during anaerobic respiration are readily detected in activated sludge systems in which their activity may lead to floc destabilization (42) and one isolated strain is closely related to *Geobacter sulfurreducens* (43). Sulfate reduction may also occur in anoxic microniches in flocs, even in fully aerated systems (4).

   The microbes responsible for phosphate removal, often appearing in large clusters, have proven elusive despite a great deal of directed effort, with the early favorite candidate *Acinetobacter* increasingly dismissed from molecular evidence (44) (see ACTIVATED SLUDGE — MOLECULAR TECHNIQUES FOR DETERMINING COMMUNITY COMPOSITION). The puzzle is still not satisfactorily resolved in the absence of pure cultures that behave as the models require but the β-Proteobacteria seem to be more likely participants (45) than yeast spores (46). Many different populations, each possibly achieving importance under different operational conditions, may be involved in phosphate removal, which will only complicate the story.

b. Chemoautotrophs. Although it was thought that the microbiology of nitrification in activated sludge is quite well understood, molecular data have shown this not to be the case, and doubts are now raised about a role in activated sludge for the genera that was once considered to be the major bacteria involved in NH_3 oxidation (13,47). What FISH has elegantly shown is that the Nitrosobacteria and the Nitrobacteria are closely and physically arranged in distinctive clusters in the biomass, allowing syntrophism to occur readily between the NO_2-producing and NO_2-consuming organisms (48) (see ACTIVATED SLUDGE — MICROBIOLOGY OF NITROGEN REMOVAL). Nitrifying bacteria are not the only autotrophic bacteria present in activated sludge. Thus, Fe^{2+} oxidizers have been detected (42) and some bulking filamentous bacteria such as *Thiothrix* may obtain energy from H_2S oxidation. However, whether these are strict autotrophs or mixotrophs that are unable to use carbon dioxide as a carbon source is uncertain (2).

- *Fungi*. The importance of fungi in activated sludge is not well understood, although their role as predators in consuming nematodes (49) deserves further study. Most of the fungi that have been cultured appear to be the Deuteromycotina that is commonly seen as part of the air microflora or in soil

samples (50), but experiences with activated sludge bacteria might suggest that many more that are currently nonculturable may be present.

- *Protozoa*. Because of their occurrence in such large numbers, the protozoa have attracted much interest, and it is quite clear that they play a vital role as predators in reducing the levels of suspended particles (e.g., bacterial cells) in the bulk liquid, thus reducing its turbidity (see PROTOZOA IN ACTIVATED SLUDGE). Most studies have looked at the ciliates, especially their ecology and value as indicators of plant performance. Less is known about the roles of the flagellates and ameboid protozoa, and it may turn out that their importance has been underestimated so far. Current interest in pathogenic protozoa such as *Giardia lamblia* and *Cryptosporidium parvum* is high, and many sensitive molecular and other methods are now available for their detection and enumeration at low levels in water and wastewater samples. Activated sludge seems to be more effective at removing cysts of *Giardia*, which could be detected in influents at high levels, than *Cryptosporidium* oocysts (51). How selective the predatory bacteriovorous protozoa are in their feeding habits is uncertain, but an increasing body of evidence suggests that feeding is not random. Thus, cell size (52), hydrophobicity (53), and floc-forming abilities of the bacteria have all been suggested to directly determine their fate in activated sludge. Yet, some ciliated protozoa appear to prefer filamentous bacteria to unicells (54).
- *Metazoa*. Under the microscope, activated sludge biomass samples from plants operating well contain nematodes, rotifers, and oligochaete worms (55). All probably act as predators contributing to the removal of suspended bacterial cells, although how rapidly they feed and the selectivity or otherwise of their feeding are less well understood than with those of the protozoa.

THE ACTIVATED SLUDGE FOOD CHAIN?

Despite a poor understanding of how individual populations might interact, models based on simple food chains have been proposed, and these often fit experimental data quite well. Most of these are simplified and based on predator–prey relationships. They recognize several trophic levels, with the activated sludge bacteria (both freely suspended and associated with the flocs) representing the base level. These bacteria are the main degraders of the soluble and colloidal organic substrates present and are then fed on by the flagellate and free-swimming, crawling and sessile, ciliated protozoa, which then serve as prey to the carnivorous ciliates (Fig. 2). The population dynamics of such a complex process is not easy to detail until the understanding of the basic microbiology of activated sludge is improved.

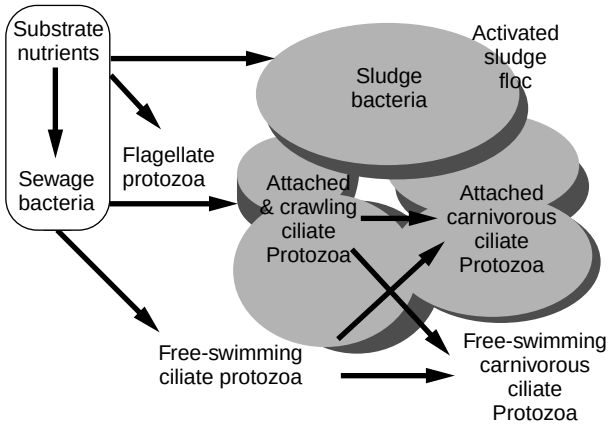

Figure 2. Proposed food chain for the activated sludge community (2).

WHICH FACTORS DECIDE THE FATE OF THESE MICROBES IN ACTIVATED SLUDGE?

An activated sludge process in simple terms is a continuous culture system with biomass recycling (56). Therefore, the microbial community there is subjected to considerable selective pressures. These will (at least partly) decide whether they remain in the system, die, or leave in the treated effluent. Some of the more influential selective factors are assumed to be the following:

- Growth rate of a population will decide how successfully an organism can compete for limiting resources, and the chemostat theory states that an organism with a higher μ_{max} and a lower k_s will outcompete one in which the μ_{max} is lower and the k_s is higher for a growth-limiting nutrient (57). Whether this happens in an activated sludge is doubtful. Little is known about how fast different populations can grow in activated sludge, and with such a diverse range of available substrates that are possibly utilized preferentially by different populations, any kinetic analysis of activated sludge becomes a daunting task. Furthermore, the opportunity for populations to interact both negatively and positively is considerable. Such interactions will certainly influence their fate, but what these are and what effect they might have on population dynamics is still completely unknown.
- Ability to tolerate the prevailing abiotic factors will affect an organism's μ, and, possibly, its ability to survive. These factors include pH, pO_2, redox potential, and temperature, as well as toxic chemicals including heavy metals (2). There is little information on how any of these might influence community composition and activity, and because of the physical heterogeneity of flocs, many microbes will experience conditions quite different from those that can be measured in the plant biomass as a whole (2). However, temperature may affect the communities of foaming bacteria (see ACTIVATED SLUDGE — FOAMING), and a low pH may favor fungi in bulking episodes (see FILAMENTOUS BULKING IN ACTIVATED SLUDGE, CONTROL OF).

The composition of the protozoan community may also be affected by heavy metals (58).

- Becoming part of the floc means that a population will be recycled in the return activated sludge (RAS) and thus survive longer. This ability probably is more important than a high μ, since fast-growing freely suspended cells will still leave in the bulk liquid. How cells might achieve this is simple to detect microscopically. Many apparently slow-growing bacteria (see ACTIVATED SLUDGE — THE "G-BACTERIA") often produce extensive capsular material enabling them to become integrated into the floc, and probably at the same time resisting predation by the floc-grazing protozoa (2). The sessile protozoa, also probably slow growers, attach to flocs with holdfasts, and many of the filamentous bacteria that certainly grow slowly in the laboratory are part of the floc matrix.
- Accumulate storage compounds such as glycogen, polyphosphate, and poly β-hydroxyalkanoates to provide them with the biochemical equipment to survive the inevitable periods of famine, which will be encountered in an activated sludge system. These are especially acute in anaerobic : aerobic systems such as EBNR plants in which only cells that are able to assimilate substrates into these polymers in the anaerobic stage can then grow in the subsequent aerobic stage in which available nutrients are no longer present. Many slow-growing bacterial isolates possess this ability, and the evidence suggests that cells provided with readily metabolizable substrates use them very rapidly not to maintain an increased μ but to synthesize one or more of these storage polymers.

CAN OUR COMMUNITIES BE MANIPULATED TO IMPROVE PLANT PERFORMANCE?

The idea of adding populations of microbes with specific, desirable, metabolic, or other properties to activated sludge is not a new one (59). Yet, when this has been attempted, the results have generally been unimpressive (60). It is not too surprising from an ecological perspective that most of the niches in activated sludge would already be occupied, and any introduced strains would struggle to overcome the prevailing selective factors. However, some success has been achieved in laboratory studies with genetically engineered bacterial strains carrying plasmids, which by conjugation may spread through the activated sludge community (61). It may be that we are trying to add the wrong organisms to the system, and once we understand better what populations do, the more success will be achieved with this aproach.

CONCLUSION

Understanding the composition of the microbial communities of activated sludge systems has been revolutionized by the increase in the interest shown in them by molecular microbial ecologists and by the techniques they have used in their studies. However, much is still to be learned. Obtaining this information will be slow and fragmentary and will tax the experimental skills of the microbiologist. The real challenge then is to translate this basic microbiological information into improved engineering outcomes in both plant design and operation.

ACTIVATED SLUDGE — THE PROCESS

K. C. Lindrea
Robert J. Seviour
Biotechnology Research Centre
La Trobe University
Bendigo, Australia

Although recorded history and surviving archaeological sites show that the Babylonians and Assyrians, and later Romans, used quite sophisticated technology to collect and dispose off their wastes, this environmental awareness was not adopted by later societies, until the Industrial Revolution in Britain in the 19th century forced political intervention (1–3). Poor quality, densely packed housing with no provision for proper sewage disposal led to overbearing odor problems, polluted river systems, and inevitably epidemics of fatal diseases caused by pathogenic bacteria of faecal origin such as *Vibrio cholerae* and *Salmonella* spp. dispersed by them. Eventually, authorities were forced to take action and after several royal commissions, the Rivers Pollution Prevention Act was brought into effect in 1876. In fact, this act was fairly ineffectual, and achieved little except that it led to another Royal Commission on Sewage Disposal in 1898, with the function of coordinating evaluation of new treatment systems. Those that had been developed following the disease epidemics in Britain such as biological trickling filters, land effluent percolation, and septic tanks (see Septic Tank Systems) suffered from two major disadvantages. They were slow and inefficient and/or operated on a relatively small scale.

One important outcome of the Commission was the stipulation of standards for treated wastes, and in 1908, it recommended that treated effluent should meet the 30:20 standard (for BOD_5 and Suspended Solids, respectively), which was adopted in Britain in 1912. This requirement provided further impetus for developing more satisfactory treatment systems that could meet this standard, and undoubtedly played an influential role in the development of the activated sludge process in 1914.

In fact, this process grew from a trip Dr. Gilbert Fowler of the University of Manchester made in 1912 on behalf of the Manchester Corporation to the Lawrence Experimental Station in Massachusetts to look at different systems of treating sewage, including aerated processes under study there. On his return to Manchester, he passed on his experiences to Edward Arden and William Lockett at the Manchester-Davy Hulme wastewater treatment plant. They both understood the importance of the American work, and were inspired to carry out laboratory scale research during 1913 and 1914, which led to the activated sludge process. Their brilliantly original idea was to retain the sedimenting biomass (sludge) produced from the waste and reuse it to treat further waste material, instead of discarding it as had been the standard practice until then. By adopting this strategy, they showed that the aeration times needed to degrade the organic compounds in the sewage and achieve complete nitrification were spectacularly shortened over those in existing wastewater treatment systems.

The solids were perceptively called "activated sludge" by Arden and Lockett, the results of their work were published (4,5) and their process, very similar in configuration to current conventional activated sludge systems, was tested on a pilot plant scale in 1914. Both continuous flow and fill-and-draw (the Sequencing Batch Reactors Technology, which is discussed elsewhere) configurations were so successfully tested that a full-scale continuous plant was installed in Worcester, England, in 1915, the first one of its kind in the world. It used a mechanical aeration system (which is still preserved and functioning at a plant in Stockport, England) since the submerged diffusers used in the pilot plant system became rapidly clogged, a problem still encountered in many plants today and one which led to development around the world of a variety of aeration systems. The attractions of the activated sludge system soon spread outside of Britain, and by the beginning of World War II, plants had been built in many European and Commonwealth countries (2,3).

Since then the activated sludge process, which was developed originally mainly to remove carbonaceous materials and produce an effluent meeting the 30:50 standard, has undergone many modifications to its design and operation to increase its efficiency and flexibility so that many plants built now will also effectively remove both nitrogen and phosphorus (6,7).

FEATURES OF THE PROCESS

In terms of the volume of material handled, the activated sludge process probably ranks as the largest biotechnology process in the world (8). Its features (Fig. 1) include (9–11) the following:

- It uses a complex community of mixed populations of bacteria and protozoa (ACTIVATED SLUDGE — THE MICROBIAL COMMUNITY).
- This community has to cope with an uncontrollable diverse range of organic and inorganic compounds, some of which will be toxic to these microbes.
- The microbes are organized into discrete aggregates called flocs (ACTIVATED SLUDGE — THE FLOC), which are maintained in suspension in the aeration tank by mechanical agitation/aeration or by the mixing action of air bubbles from submerged aeration systems.
- The flocs must have good settling properties so that separation of solids (biomass) and liquid phases, upon which the success of the process ultimately depends, can occur efficiently and rapidly in the clarifier.
- In many plants this separation is not achieved because of the operational problems of bulking (FILAMENTOUS BULKING IN ACTIVATED SLUDGE, CONTROL OF) and foaming (ACTIVATED SLUDGE — FOAMING).
- Most of the settled biomass, the activated sludge, is recycled as "return activated sludge" or RAS to inoculate the incoming raw sewage, with the understanding that it will contain a selected community of microbes well adapted to treating that particular raw sewage.
- Some of this sludge is discarded or wasted, and although rich in nutrients, valuable minerals, and a possible food source, the sludge is viewed as a liability that is disposed of, often at great expense.

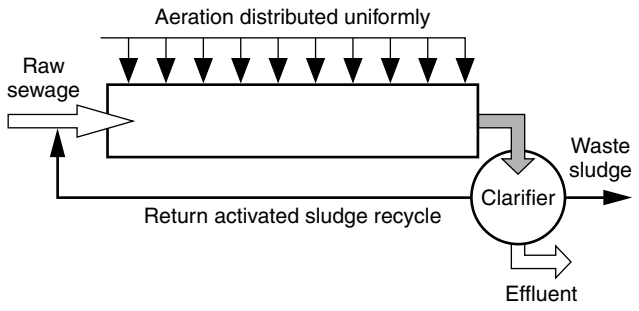

Figure 1. The activated sludge process.

Because of all these uncontrollable operational variables, it seems remarkable that activated sludge systems work as well as they do. However, because they are so versatile and adaptable, it is very likely that they will continue to represent the most widely used methods for aerobic waste treatment into the foreseeable future and evolve as they have in the past to meet additional requirements and process stringencies (7,11).

CONFIGURATIONS FOR ACTIVATED SLUDGE SYSTEMS

Many activated sludge configurations are in use around the world, differing in their design features and their performance criteria. It is convenient here to categorize them on their abilities to remove different organic and inorganic chemical components in the influent, a feature that reflects their design and operation into:

- conventional (those plants designed to remove primarily organic carbonaceous compounds) and
- nutrient removal (where the plants remove nitrogen and/or phosphorus either chemically or microbiologically) (7,12).

CONVENTIONAL ACTIVATED SLUDGE SYSTEMS

These were the early activated sludge systems introduced. Some of the first ran as semicontinuous "fill-and-draw" systems, the basis for the increasingly popular sequencing batch reactor configurations (7), while most conventional systems now run continuously and operate either as "plug flow" or "completely mixed systems", although the distinction between them when operating is not always clear (2,3,13).

Plug Flow Systems

These are systems in which the incoming sewage is thought to move as a discrete plug through the reactor(s), although some mixing will inevitably accompany aeration, either from submerged diffusers or surface agitators. The general view is that these plug flow systems are less prone to filamentous bacterial bulking (FILAMENTOUS BULKING

IN ACTIVATED SLUDGE, CONTROL OF), although they also operate relatively inefficiently because of their hydraulic characteristics that generate an uneven load distribution along the reactors in terms of their oxygen demand (7,11). Engineering approaches to this problem include adjusting the aeration systems to redistribute the oxygen to meet these different requirements, through modifications such as tapered aeration (Fig. 2), step aeration (Fig. 3), or altering the feed regime as in the step feed (Fig. 4; 6,7,11).

Completely Mixed Systems

Such systems evolved to overcome the problems with "plug flow" systems, in which all the components, including the RAS, are rapidly mixed (Fig. 5). There is a price in terms of loss of nitrification efficiency if underaeration or plant overloading occurs, short circuiting may be a problem, and the sludge usually settles less well than with "plug flow" systems (2,3). Completely mixed systems were found to be less susceptible to toxic materials in the feed due to the rapid dilution of the incoming waste.

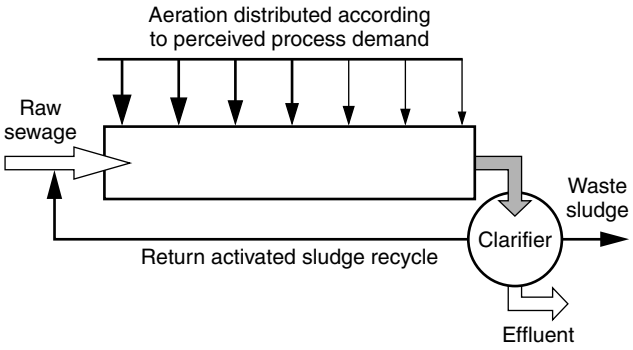

Figure 2. The activated sludge process with tapered aeration.

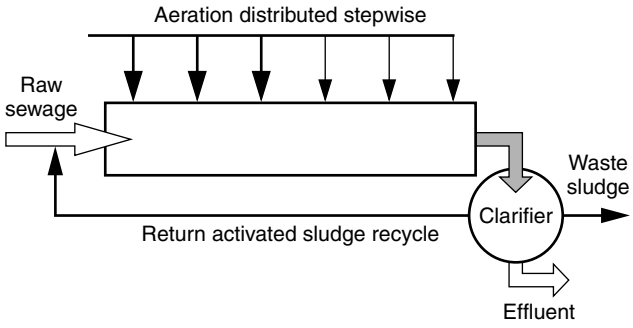

Figure 3. The activated sludge process with step aeration.

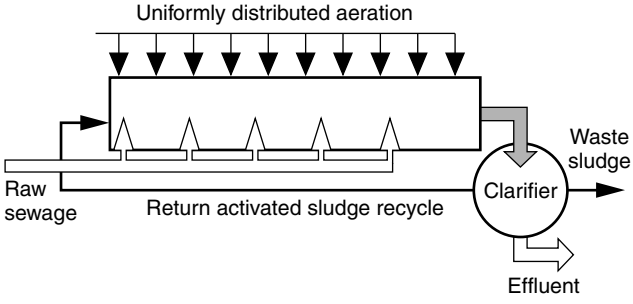

Figure 4. The activated sludge process with step feed.

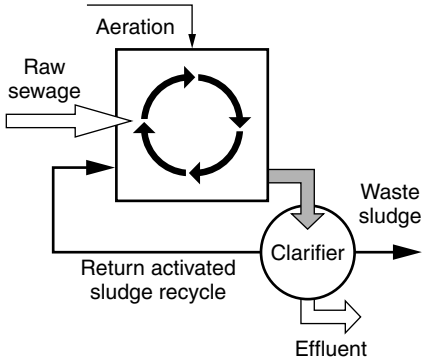

Figure 5. The complete mix activated sludge process.

Extended Aeration Systems

As the name suggests these processes operate best with low loadings, and long sludge ages (2,3). These systems were designed as inexpensive processes for small rural communities and were called Pasveer ditches after the Dutch Engineer who introduced them. These small plants were operated intermittently ("fill-and-draw") but the later-introduced Carrousel plants, which borrowed and developed the original concept, operated continuously and used separate clarifiers (Fig. 6). Surface agitation provides aeration and circular mixing, in which high dissolved oxygen levels close to the agitators encourage nitrification and denitrification then follows in the anoxic regions, which develop as the liquid moves further away from them (ACTIVATED SLUDGE — MICROBIOLOGY OF NITROGEN REMOVAL). Less sludge is produced because of their long sludge ages and they need little maintenance as long as the mixing is sufficient to keep the solids/sludge in suspension.

Stimuli for Improving Performances of Conventional Plants

Most attempts at improving performances of these plants have been directed at increasing their operational rates, especially with potentially toxic industrial wastes and reducing the volumes of sludge produced. Modifications include "contact stabilization," high rate systems including processes such as the Deep Shaft process in which pure O_2

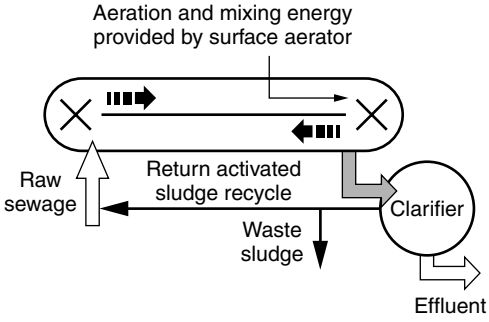

Figure 6. The Carrousel activated sludge process.

is used instead of air. Gray (2) discusses these processes in detail. Also, conventional systems fail to remove sufficient levels of inorganic nutrients such as nitrogen and phosphorus, both of which are serious environmental hazards, to prevent eutrophication and formation of "algal" or blue-green bacterial (Cyanobacterial) blooms in receiving rivers and lakes. So, many of the changes to conventional activated sludge processes have been in developing systems to remove these nutrients. Only microbiology-based activated sludge systems are discussed here, and the reader is directed to the reviews of References 6 and 14 for discussions on chemical nutrient removal systems, which pose their own environmental problems (15). Some plants using microbes often have facilities for chemical polishing when they fail to perform adequately to satisfy discharge license requirements (6).

ACTIVATED SLUDGE SYSTEMS DESIGNED TO REMOVE NITROGEN

Some nitrogen (N) removal will always occur in conventional plants since cells in the microbial community require nitrogen to grow, and some of these will be removed in sludge wasting. Furthermore, nitrification and denitrification leading to N removal will occur as long as conditions for these processes are met (ACTIVATED SLUDGE — MICROBIOLOGY OF NITROGEN REMOVAL). Because the amount of N removed by conventional processes is often small, some plants are deliberately designed and configured to achieve much higher rates and levels for its removal. Several conditions need to be met and all plants deliberately designed to remove N incorporate these features. These (ACTIVATED SLUDGE — MICROBIOLOGY OF NITROGEN REMOVAL) and their operational requirements are (10,16,17):

- an aerobic zone in which nitrification by the chemoautotrophic nitrifying bacteria can occur. This step is essential to generate nitrate from the oxidation of ammonia as the levels of nitrate in domestic sewage from prior nitrification are generally too low to encourage microbial activity and permit the chemical transformations needed for N removal;
- an anoxic zone in the reactor, with high levels of nitrate from the nitrifying bacteria, which acts in the absence of dissolved oxygen as the terminal electron acceptor for the anaerobically respiring chemoheterotrophic denitrifying bacteria. Many taxonomically diverse bacteria can denitrify, although it is still unclear as to which ones are important in activated sludge systems. It is known that many of these can also denitrify under aerobic conditions, although the impact of these aerobic denitrifiers on nitrogen removal in activated sludge systems is again unclear (16);
- most plants designed to remove N use the same biomass for both the nitrification and denitrification steps. In the aerobic zones of many such plants, simultaneous nitrification/denitrification (SND) is thought to occur (16), raising the tantalizing possibility of manipulating SND to make future N removal plants simpler in configuration and enabling a reduction in the size of the anoxic zone;
- an organic carbon and energy source to allow the denitrifying microbial community in the anoxic zone to reduce the nitrate to nitrogen gas. Deliberate addition of chemicals such as methanol for this purpose was once common, but as their costs increased, plants were designed to use substrates already present for this anaerobic respiration. Many plants, for reasons not yet understood, probably only partially reduce the nitrate to nitric oxide and nitrous oxide, both serious long-term air pollutants, in the anoxic zone (16);
- in plants in which the aerobic zone precedes the anoxic zone, as seen in the early Wuhrmann (18) design (Fig. 7), these organic substrates originate from lysis of the biomass as most readily biodegradable organic substrates would already have been utilized in the aerobic zone. Consequently, denitrification rates are low;
- later designs (19) placed the anoxic zone in front of and in partial contact with the aerobic zone (Fig. 8). Variable plant performance with this configuration and a better comprehension of the process requirements led to the suggestion by Barnard to modify it by physically separating the anoxic and aerobic zones and providing a recycle between the two into a two-stage process (Fig. 9). However, this also has an inherent weakness since nitrate removal will always be incomplete because the liquor recycled to the anoxic zone and the clarifier feed are derived from the same source (the aeration basin);
- Barnard (20) recognized these faults and came up with the four-stage Bardenpho process (Fig. 10) by incorporating a secondary anoxic reactor after the aerobic zone, with the dual advantage of maintaining a higher denitrification capacity and a nearly nitrate-free effluent. It also included a secondary aerobic reactor (reaeration reactor) to allow nitrification of any ammonia produced in the secondary anoxic zone;
- this configuration should be regarded as the direct ancestor of most of the nutrient removal systems that have followed, and required only minor modification to successfully remove P (6,7,11,20,21).

ACTIVATED SLUDGE SYSTEMS DESIGNED TO REMOVE PHOSPHORUS

Conventional activated sludge systems remove very little of the phosphorus that enters in the raw sewage, except that required by the biomass to grow. Thus, their effluents are usually rich in P and they are recognized as one of the major point sources for environmental P pollution (22). P-removing activated sludge systems work because the microbes assimilate more P than is needed for their growth, and so are also called enhanced biological phosphorus (EBPR) systems (7,20,21). Their detailed microbiology is discussed elsewhere (ACTIVATED SLUDGE — MOLECULAR TECHNIQUES FOR DETERMINING COMMUNITY COMPOSITION). Most agree that current EBPR systems, if properly designed, should yield a final effluent P level of less than 1 $mg\,l^{-1}$ (21).

Much of the development of these processes occurred in South Africa and most of the plants currently in

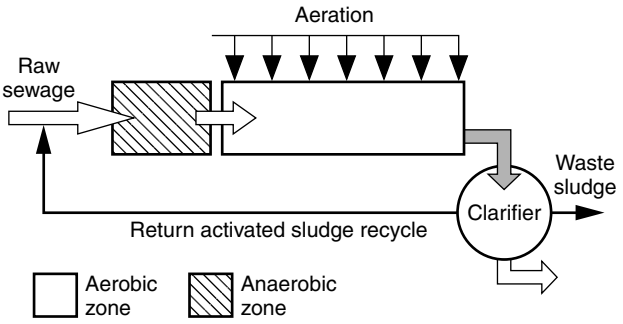

Figure 11. The two-stage or high rate Phoredox process.

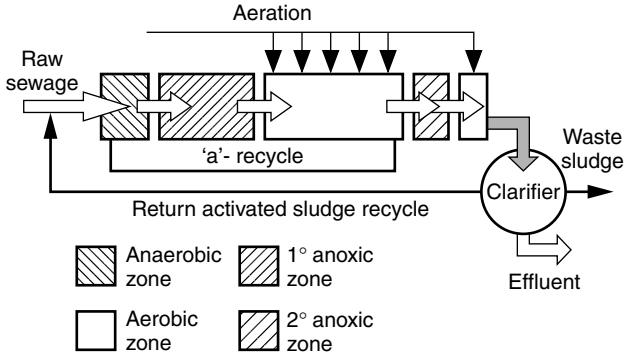

Figure 12. The five-stage Bardenpho or Phoredox process.

use have evolved from there. Barnard's pioneering work in the 1970s helped to strictly define the operational requirements for EBPR, although this phenomenon of EBPR was reported much earlier (23). He showed empirically that adding an anaerobic zone to the head of a conventional plant gave a process (the high rate Phoredox system, Fig. 11) that would remove P when the system was operated at a low enough sludge age to avoid nitrification. This process, in combination with the four-stage Bardenpho (Fig. 10) configuration, gave rise to what is known as the five-stage Bardenpho or Phoredox system (Fig. 12), a plant configuration capable of removing both N and P.

His and other studies elucidated the main design features needed for successful P removal. These include

- an initial anaerobic zone or reactor, which is an essential component of all EBPR systems. This zone appears to selectively favor bacteria [including the P accumulating bacteria (PAB) responsible for EBPR] that are capable of anaerobically assimilating the organic substrates present there (mainly short-chain volatile fatty acids, SCVFA, such as acetate). Cells store these substrates as intracellular reserves of poly β-hydroxyalkanoates (PHA) to be used as sources of energy and carbon for their growth in the aerobic zone (see later), where now other metabolizable substrates are no longer available.
- the stored polyP that is used as the energy source for PHA synthesis and the phosphate produced is released into the bulk liquid. Strictly anaerobic

conditions are essential here to eliminate any aerobic respiration of these organic substrates, reducing their availability to the PAB.

- a prefermenter using an anaerobic digestion of settled sludge that is installed in many EBPR plants before the anaerobic reactor to guarantee a supply of high levels of SCVFA to cells in the anaerobic zone (24). In some designs, acetate itself is added to the anaerobic reactor. Claims are that these modifications both improve and stabilize EBPR in systems in which they have been introduced, although odor can become problematic. However, the size of the anaerobic reactor can now be reduced.
- an anoxic zone where denitrification is encouraged (in plants that nitrify) so that the levels of nitrate entering the anaerobic zone are insufficient to permit any anaerobic respiration of these organic substrates, reducing their availability to the PAB. Consequently, most of the later designed plants removing P also remove N, although the presence if not the importance, of denitrifying PAB in activated sludge systems has been well documented (25) and these may make a contribution to denitrification in the anoxic zone.
- an aerobic zone, where the nitrifying bacteria function and those with stores of PHA produced in the anaerobic zone can grow and use the energy made available from them to assimilate phosphorus from the bulk liquid and store it as polyP granules. As more P is assimilated aerobically than released anaerobically, net P removal occurs, and this assimilated P immobilized in the biomass is wasted with it.
- alternating the biomass between the anaerobic and aerobic zones in the plants, although this was not a deliberate design feature of some of the earlier plants.

Stimuli for Improving Performances of EBPR Systems

Many of these improvements have been based on a better understanding of the microbiology of these systems, which is a trend that is likely to continue. These were introduced in attempts to (26):

- simplify plant configuration, reduce the size of the reactors (see the preceding text) making them inexpensive to build and run
- cope with high sudden flow rates, which would dilute SCVFA levels below those capable of supporting good EBPR
- overcome the perceived operational problems in many of the earlier design changes caused by returning nitrate back to the anaerobic zone, a stimulus that led to many new plant designs, some of which are operating successfully around the world. Thus, the three-stage Phoredox process evolved from the five-stage system by increasing the size of the primary anoxic zone to increase denitrification levels and reduce recycled nitrate, so that the protecting secondary anoxic zone and reaeration reactor were no longer needed (Fig. 13).

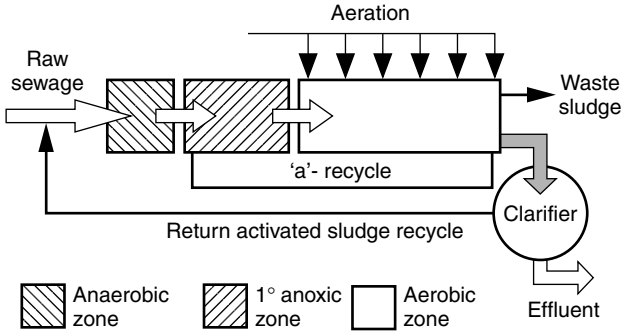

Figure 13. The three-stage Phoredox process.

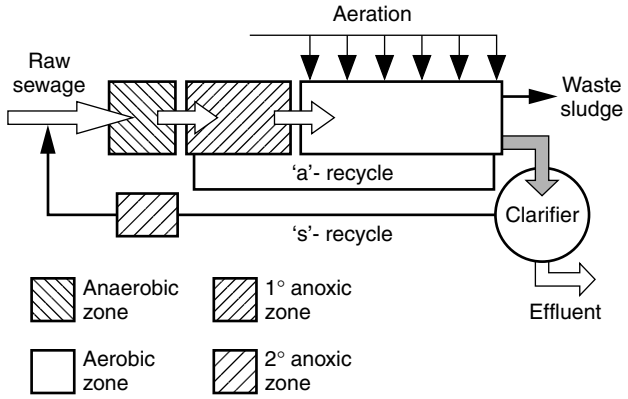

Figure 14. The Johannesberg process.

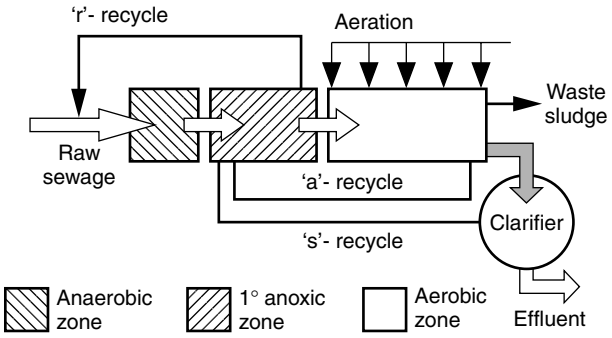

Figure 15. The University of Cape Town (UCT) process.

This design has in turn produced several progeny with characteristics to cope with difficulties encountered over time with their use. A few examples are given here. The Johannesburg process (Fig. 14) incorporated a secondary anoxic zone in the RAS line to the anaerobic reactor to ensure complete nitrate removal, but not without operational consequences, which were addressed by the University of Cape Town (UCT) process that recycles the RAS back into the anoxic rather than the anaerobic zone first before another recycle then transfers it from the anoxic to the anaerobic reactor (Fig. 15). Additional improvement was achieved when the anoxic zone was split into two separate reactors to provide further control, as seen with the Modified UCT (MUCT) process (Fig. 16). The

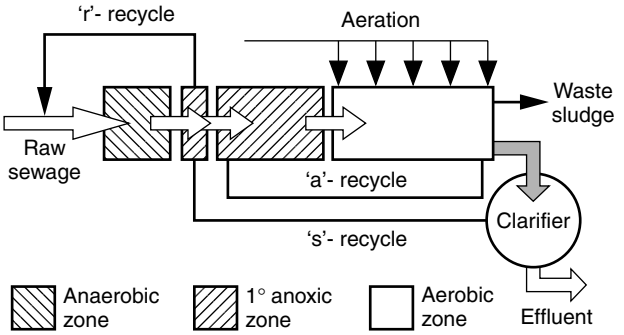

Figure 16. The modified UCT process.

MUCT process sacrifices some of its overall denitrification capacity to insure that nitrate is completely removed from the recycle to the anaerobic basin, thus protecting this zone and optimizing the P removal process.

- prevent P release (secondary release) from the settled sludge in the clarifier and the RAS by avoiding establishment of anaerobic conditions anywhere in the sludge handling processes (e.g., by avoiding prolonged sludge storage).

THE FUTURE FOR ACTIVATED SLUDGE PROCESSES?

What activated sludge plants might look like and how they might operate in 50 or 100 years from now is difficult to predict, but a few speculations are allowed.

- Methods and instrumentation for automatic monitoring and control of these systems will rapidly continue to increase.
- Single "add-on" units containing communities of bacterial populations with specific metabolic traits to treat particular wastes (e.g., toxic and industrial) will become common.
- Advances in membrane technology will revolutionize solids separation so that clarifiers will become archaeological oddities and problems such as bulking will become simple to handle.
- Membranes will be used increasingly in plant design so that most will use them to polish treated effluent water for reuse as potable water.
- Our knowledge of the bacteria responsible for N and P removal and the factors that affect these processes in these organisms will undoubtedly increase significantly, and this information will lead to the design of novel configurations with input from both engineers and microbiologists, ensuring that these populations and their pertinent metabolic properties are particularly encouraged.
- Sludge reuse will also become more sophisticated and less costly.

It is possible that few or none of these changes will occur, and future developments in the treatment of wastewater will use totally different technology. In either case, the costs of building the systems and running them will increase and additional demands will be placed on the operational staff who will need to be highly skilled.

ACTIVITY AND CARBON TRANSFORMATIONS IN BIOFILMS

ANDREW LEIS
HANS-CURT FLEMMING
Gerhard Mercator Universität
Duisburg, Germany

Biofilms are an important sink of the carbon-associated biomass in aquatic and terrestrial ecosystems. Much of this biomass comprises eubacteria, although archaebacteria, cyanobacteria, fungi, and various forms of algae can be quantitatively important or perhaps, dominant in biofilms under favorable circumstances. The superior growth rates of prokaryotes enables a rapid turnover of usable substrates generated by primary producers, thus establishing the critical role of these organisms in the cycling of organic matter. It is an apparent paradox that biofilms form in natural waters, which are considered to be nutrient-depleted or "oligotrophic." While a reduction in the supply of nutrients in technical systems below a certain threshold level can minimize the formation of biofilms (1), this principle cannot be extended to the fundamental complexities of natural environments. A complete description must take into account the diversity of substrates available for use, the fluxes of substrates to and from biofilms, the taxonomic diversity of biofilm organisms, and the numerous metabolic pathways, which have evolved to enable the transformation of structurally dissimilar and dilute carbon sources into potentially utilizable forms. The majority of abiotic carbon compounds in soils, sediments, and natural waters are decay products known as humic substances, which bear only a superficial resemblance to their molecular precursors. The quantitative dominance of humic substances in the dissolved phase is a consequence of the relative recalcitrance of these compounds and the fact that most assimilable carbon compounds are immobilized as cellular biomass in biofilms. The use of humic substances as a source of carbon and energy is not necessarily restricted by an absence of suitable degradation pathways; at least, part of the explanation for the dominance of these compounds in natural systems is related to the inefficiency of microbial degradation pathways. Microorganisms have evolved diverse and efficient pathways for the utilization of those carbon substrates that warrant a metabolic investment.

DIVERSITY OF STRATEGIES FOR CARBON METABOLISM BY BIOFILM ORGANISMS

Environmental biofilms contain both eukaryotic and prokaryotic organisms, which act as primary and secondary producers. Primary production is the process by which photosynthetic organisms synthesize organic carbon compounds from carbon dioxide. Secondary producers convert the products of primary production into biomass (2).

By convention, metabolism of carbon substrates is divided into two closely linked processes.

- Dissimilatory metabolism involves catabolic (degradative) activities performed to provide energy for cellular respiration.
- Assimilatory metabolism describes anabolic reactions, in which energy is expended for the assimilation of low-molecular-weight substrates into macromolecules, which have structural or physiological functions.

Most of the energy obtained from catabolic reactions is used for growth, although biofilm cells spend a disproportionate part of their energy budget on maintenance and the production of the biofilm hydrogel matrix (extracellular polymeric substances, EPS). Planktonic bacteria seem to have adopted a strategy for maximum substrate utilization, rather than efficiency (3). The major transformation carried out by microorganisms in biofilms can be summarized as the metabolism of inorganic and organic electron donors and acceptors to produce soluble by-products, EPS, carbon dioxide, and/or methane, and water (4). The mechanisms used to achieve these goals are considerably more diverse, and all major metabolic classes of microorganism are represented in biofilms. In fact, it is often the biofilm that creates the potential for a metabolic group of organisms to become established. Recent studies employing either microelectrodes or fluorescent in situ hybridization (FISH) in combination with confocal laser scanning microscopy (CLSM) have provided direct evidence for the existence of different metabolic groups within discrete areas of the biofilm matrix (5). In general, classifications of biofilms according to metabolic pathways include the designations aerobic, anaerobic (sulfate-reducing bacteria, methanogens), anoxic (denitrifying), and fermentative, depending on the type and concentration of the electron donor and acceptor (6). Microorganisms can also be described in terms of carbon utilization:

- Autotrophs assimilate single-carbon (C-1) compounds, including CO_2, CH_4, and methanol.
- Photoautrophs harness electromagnetic energy to generate ATP and the reducing power required for the assimilation of carbon dioxide.
- Chemoautotrophs (lithotrophs, *lithos* Gr. for rock) obtain cellular carbon by assimilative carbon dioxide reduction or from reduced C-1 compounds and energy from oxidation of inorganic compounds such as NH_4^+.
- Heterotrophs (chemoorganotrophs) obtain energy from the oxidation of complex organic carbon sources.

The terms autotrophy and heterotrophy can apply to both dissimilatory and assimilatory metabolism. Autotrophs may require additional carbon in the form of growth factors or vitamins (6), but they assimilate all necessary elements as inorganic forms. The energy expenditure required for synthesizing macromolecules

partly accounts for the lower growth rates of strict autotrophs compared to most biofilm bacteria, which are (chemo)heterotrophic — they depend on organic compounds to generate energy and the precursors used to synthesize cellular biomass. A low-molecular-weight substrate may serve as a source of carbon for building macromolecules and as a source of cellular energy, producing carbon dioxide as a by-product (6). Phototrophic microorganisms use different catabolic and anabolic substrates. The complete metabolism of carbon substrates to CO_2 or CH_4 is called "mineralization." Confusingly, some of the inorganic carbon in biofilms is converted to mineral forms such as calcium carbonate, partly by abiotic processes and partly as a result of microbially-induced increases in pH (7). The biotic mechanisms are known as "biomineralization." Together with various geologic processes, these reactions form sedimentary deposits known as microbialites, which constitute fossilized biofilms. More specifically, stromatolites and thrombolites are formed by a consortia of bacteria and filamentous cyanobacteria, and bacteria and unicellular cyanobacteria, respectively (7).

Energy-yielding processes (catabolism) are further categorized as fermentation, respiration, phototrophy, and methanogenesis.

Fermentation

Fermentation is often used in a general sense to describe the utilization of a substrate by a microbial culture (heterotrophic fermentation). In a metabolic sense, fermentations are anaerobic processes in which the substrates are sequentially transformed by reduction-oxidation (redox) processes in the absence of an external electron acceptor. The redox levels of the substrate and metabolite(s) remain the same, and the energy yields are low. Fermenting bacteria may be:

- strict (obligate, O_2-sensitive) anaerobes, for example, *Clostridium* spp.;
- facultative anaerobes, which are capable of oxidative phosphorylation (production of adenosine triphosphate, ATP) in the presence of O_2, for example, *Pseudomonas* spp.; or
- aerotolerant anaerobes, for example, *Lactobacillus* spp., some *Streptococcus* spp.

Facultative anaerobes are especially suited to the gradients, which develop suddenly within biofilms as a consequence of the rapid depletion of oxygen in the vicinity of immobilized cells. Anaerobic fermentation of simple sugars yields little energy compared with aerobic metabolism. This type of fermentation is exploited in industry, but it is rare in environmental biofilms because the heterotrophic microorganisms usually ensure that high concentrations of sugar substrates do not accumulate. Amino acids can be fermented via the Stickland reaction, whereby one kind of amino acid is used to oxidize another to acetate and ammonia (8). This process is important when high concentrations of proteins are available for anaerobic degradation. Planktonic microorganisms can encounter relatively high-protein concentrations on suspended particles (9), where anaerobic zones form within flocs (see Microbial Flocs Suspended Biofilms, this Encyclopedia).

Respiration

The primary goal of respiration is the production of ATP (phosphorylation) by any combination of organic or inorganic electron donor and electron acceptor. Aerobic respiration of an organic substrate is described most simply as:

$$(CH_2O) + O_2 \rightarrow CO_2 + H_2O \qquad (1)$$

This process yields the most energy of all catabolic processes, so it is preferred by facultative microorganisms when oxygen is available. Many microorganisms are able to perform oxidative phosphorylation of organic substrates. Most respiratory organisms use the citric acid (or tricarboxylic, TCA) cycle for the oxidation of acetate to carbon dioxide, whereas phototrophic green sulfur bacteria and some archaea use the reverse of this cycle to assimilate carbon dioxide. Purple nonsulfur bacteria use the same electron transport system for both respiration and photophosphorylation. Anaerobic respiration is characterized by the use of exogenously derived terminal electron acceptors other than oxygen. Energy yields are always lower than those obtained by oxidative phosphorylation. Ecologically important anaerobic respiration processes include the reduction of sulfate, nitrate, iron, and manganese, although some low-molecular-weight organic compounds may also serve as terminal electron acceptors. Nitrate or nitrite reduction is performed by many facultative anaerobes, including members of the ubiquitous genera *Bacillus* and *Pseudomonas*. In these organisms, O_2 inhibits synthesis of the key enzyme, nitrate reductase (6).

Sulfate-reducing organisms are common in biofilms due to the depletion of oxygen by respiring organisms and subsequent diffusion limitation within the EPS matrix. Sulfate reduction is an important contribution to anaerobic metabolism in both freshwater and marine sediments. The principal carbon substrates for this process are low-molecular-weight organic acids (acetate, butyrate, propionate, lactate), alcohols, and H_2. Sulfate reducers can be subdivided into two further groups on the basis of carbon utilization. Organisms such as *Desulfovibrio* spp. do not use a citric acid cycle. They can use H_2 or lactate as substrates. The use of lactate is inefficient in that the carbon product is acetate (rather than methane), but this substrate is readily assimilated by heterotrophs within the biofilm matrix. Other organisms such as *Desulfobacter* spp. make use of a citric acid cycle to oxidize acetate completely. Members of the genus *Desulfuromonas* use elemental sulfur rather than sulfate for the complete oxidation of acetate, but also produce CO_2 and HS^-. The methanotrophs in soil and aquatic environments are gram-negative bacteria, which oxidize methane or other C-1 compounds, such as methanol or methylamine. They act as biofilters for methane produced in anaerobic environments. Methanotrophs are classified into three groups, partly according to their ability to assimilate the key intermediate, formaldehyde (10). Anaerobic oxidation of CH_4 takes place in sediments and soils; when oxygen

is present, soil methanotrophs can oxidize atmospheric methane. Some methanotrophs can synthesize a soluble methane monooxygenase capable of oxidizing priority pollutants such as trichloroethylene (10).

Methanogenesis and Acetogenesis

Methanogens belong to the archaea domain and reduce carbon substrates to methane, using H_2 as electron donor. The carbon substrate is usually carbon dioxide, which also constitutes autotrophy. Carbon dioxide, carbon monoxide, and formate comprise one group of potential substrates for methanogens. A second group of substrates comprises compounds with methyl groups, which can act as both electron donor and acceptor. The cleavage of acetate (acetotrophy) is a third mechanism, producing methane and carbon dioxide. Methanogenesis is important in anaerobic wastewater treatment, during which soluble organics are degraded to fatty acids and subsequently converted to methane and carbonate. The fermentation of acetate is responsible for the bulk of the methane formation (11). This process is performed by acetogens and homoacetogens.

Phototrophy and Photoautotrophy

Phototrophy and photoautotrophy are terms to describe carbon dioxide fixation, which is mediated by photosynthesis:

$$nCO_2 + 2nH_2O \rightarrow n(CH_2O) + O_2 + nH_2O \qquad (2)$$

Light energy is converted to chemical energy (ATP and the reduced form of nicotinamide adenine dinucleotide phosphate, NADPH) in the "light" reactions, and subsequently used to reduce carbon dioxide to organic compounds in the "dark" reactions. Phototrophs and some other microorganisms contain various forms of chlorophyll and accessory pigments, including carotenoids and phycobilins. Carotenoid pigments can transfer energy, but not directly through photophosphorylation. Phycobiloproteins are the principal light-harvesting pigments of cyanobacteria and red algae. They are arranged as high-molecular-weight aggregates called phycobilisomes. The energy transfer from the biliprotein complex to chlorophyll *a* is very efficient, enabling growth under low-light conditions. The phycobilisome content correlates with light intensity.

The two modes of phototrophy are oxygenic photosynthesis and anoxygenic photosynthesis. Oxygenic photosynthesis can be performed by organisms that contain chlorophyll *a*, including various microalgae. Light energy is used to synthesize ATP and NADPH by noncyclic photophosphorylation, whereby O_2 is produced from water. Cyanobacteria are the only prokaryotes capable of oxygenic photosynthesis (12). Filamentous cyanobacteria dominate shallow sediments and microbial mats, which are essentially thick, photosynthetic biofilms. The unicellular cyanobacteria (e.g., *Synechococcus*) are poorly represented in microbial mats, but they are important as planktonic primary producers (13). Oxygenic phototrophs have two, spectrally distinct forms of chlorophyll *a*, enabling the operation of two separate reaction systems, Photosystem I and Photosystem II. The so-called purple and green bacteria carry out photosynthesis, but do not produce oxygen. This form of photosynthesis involves the production of ATP by cyclic phosphorylation. Anoxygenic photosynthesis occurs in illuminated sediments, microbial mats, and anoxic zones in (other) biofilms, in which H_2S acts as proton and electron donor, and elemental sulfur is produced. The exposure of oxygenic, sediment-dwelling cyanobacteria to sulfide inhibits Photosystem II; however, the active Photosystem I allows anoxygenic photosynthesis with HS^- as the electron donor. In dark and anaerobic conditions, some cyanobacteria seem to be capable of fermentation or sulfate reduction (6). Four, unrelated groups of eubacteria can perform anoxygenic photosynthesis, and different groups have different combinations of carotenoid pigments. The purple bacteria contain bacteriochlorophyll *a* or bacteriochlorophyll *b*. The purple sulfur bacteria (e.g., *Thiocapsa*, *Chromatium*) use reduced sulfur as an electron donor, and also store elemental sulfur. The "purple nonsulfur bacteria" (e.g., *Rhodospirillum*) do not store elemental sulfur, and they are more sensitive to high sulfide concentrations. The designation is a misnomer because these organisms are also capable of using HS^- as electron donor. Purple nonsulfur bacteria are versatile in that they can use some carbon compounds (and Fe^{2+}) as electron donors, and they can assimilate low-molecular-weight compounds such as acetate. The green sulfur bacteria (e.g., *Chlorobium*) have bacteriochlorophylls *c* or *d*. They are autotrophic, strictly anaerobic organisms, which use sulfide as an electron donor, but they only oxidize it to S^0, which is excreted. The green nonsulfur bacteria (e.g., *Chloroflexus*) are also erroneously named, being able to use HS^-. These are filamentous gliding forms found in microbial mats, and they can live as photoautotrophs using HS^- and CO_2 or as aerobic heterotrophs. The heliobacteria are strict phototrophic anaerobes, which have been isolated from anoxic soils. Halobacteria are a group of archaebacteria, which usually act as aerobic heterotrophs, but under conditions of anoxia and light, they revert to phototrophy. A "purple" membrane consisting of a photosensitive pigment, rhodopsin, facilitates proton export from the cell. The proton motive force is then harnessed by ATPase in the cell membrane for ATP synthesis.

SYNTROPHY AND ANTAGONISM IN BIOFILMS

Ultimately, the establishment of different organisms within a biofilm is dependent on competition, and many interactions may be antagonistic (14). There is no convincing, direct evidence for antagonistic interactions within a biofilm, as can be observed frequently in the case of inhibition zones surrounding colonies of microbial soil isolates on laboratory media. It can be inferred, however, that sulfate reducers and methanogens will compete for carbon dioxide. Also, methanogens and homoacetogens use the same precursors, CO_2 and H_2, to produce methane and acetate, respectively. Unless carbon dioxide is subject to considerable diffusion limitation within a biofilm, its availability is far better than the relatively

insoluble O_2, which is depleted rapidly by respiring organisms. Competition is especially relevant for the limited supply of low-molecular-weight carbon substrates such as monosaccharides and amino acids, which constitute a "superlabile" carbon pool. The proximity of metabolically diverse neighbors and selection pressures, however, implies that neutral or even favorable interactions will allow particular metabolic groups to establish within the biofilm matrix. This is especially important for photosynthetic biofilms, in which the carbon and oxygen cycles are intimately related. Algal exudates in epilithic biofilms provide heterotrophic bacteria with significant quantities of organic and inorganic substrates (15,16). Syntrophy occurs when two or more organisms catabolize substrates in a mutually-dependent manner. In freshwater systems, purple nonsulfur bacteria commonly form syntrophic associations with heterotrophic sulfur reducers. Methanogens depend on other organisms for a supply of the few compounds, which can act as precursors for methane production, including some products of respiration. Respiring organisms can hydrolyze polysaccharides, proteins, and other macromolecular organic substrates. Low-molecular-weight organic acids produced by fermenting bacteria can be used by sulfate reducers, accounting for the presence of these organisms in consortia (6). Fermentation of organic substrates proceeds only as far as acetate + H_2, but the acetate can be respired by other organisms. Thus, complete mineralization depends on the supply of substrates by actively fermenting bacteria. In the case of phototrophs, energy derived from the oxidation of a noncarbon substrate, such as sulfide, requires the assimilation of some other carbon source, such as carbon dioxide produced by fermenting organisms. The expected carbon transformations in a mixed phototrophic/heterotrophic biofilm are depicted in Figure 1. The fermentation of glucose to acetate and H_2 by obligate acetate-producing bacteria requires the recycling of hydrogen by reoxidation of NADH. In thermodynamic terms, this process is only possible when the hydrogen tension is low (less than 10^{-4} atm). The close proximity of H_2-consuming biofilm bacteria such as sulfate reducers or methanogens facilitates "interspecies hydrogen transfer" (6), and the equilibrium hydrogen tension largely determines the dominant organisms.

The diversity of microbial metabolism is exemplified by the fact that some classes of microorganisms use more than one metabolic strategy. The most obvious and important example is the switch between autotrophy and heterotrophy under different conditions. Purple nonsulfur bacteria are strictly autotrophic during the day, when they use H_2 or HS^- as reductants for photosynthesis and for assimilating carbon dioxide. At night, they can also respire oxygen by using low-molecular-weight organic substrates, such as acetate. Some chemoautotrophs can assimilate organic substrates, and under anaerobic conditions, some sulfur bacteria can either reduce sulfur or perform heterotrophic fermentations. Autotrophy is an ambiguous term for biofilm organisms because the energy cycle is intimately related to other cycles occurring in close proximity. For example, purple sulfur bacteria carry out photosynthesis using HS^- as an electron donor, thereby assimilating carbon as carbon dioxide, but the reducing agent is often supplied by organisms performing oxygenic photosynthesis and subsequently degraded under anaerobic conditions. When referring to the use of HS^- as a substrate, the designation of autotrophy is only justified if the HS^- is provided abiotically, for example, geothermal vents or acid mine drainage. In the water column of a deep lake, temperature gradients induce "thermal stratification," in which the lower strata are colder and oxygen-depleted (reducing conditions). This prevents admixing among the lower, hypolimnion, and other layers. Photosynthesis is limited to the upper (euphotic) zone, which is defined by the penetration depth of solar radiation, and commonly measured by the Secchi disk method. Particulate matter absorbs much of the radiation, such that when POC levels in natural waters are high, the euphotic zone is extremely small. Within biofilms, absorption or other attenuation of incoming radiation confines some types of photosynthetic activity to the upper strata (17). Significant physicochemical gradients also exist in sediments and soil microcosms. Thus, substrate and physicochemical gradients become established within other gradients. Biofilm organisms are ultimately affected by the trophic status of the bulk fluid compartment.

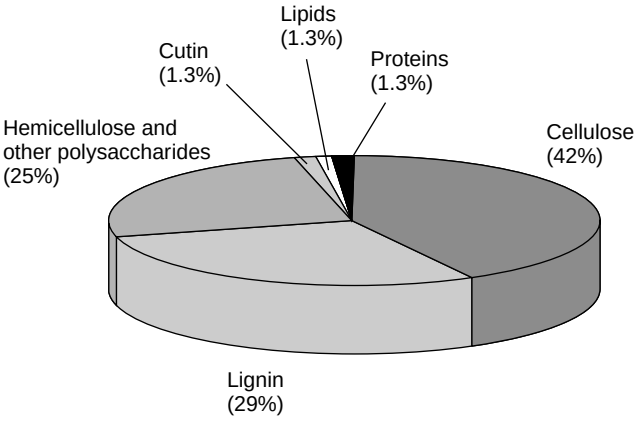

Figure 1. Schematic diagram showing the syntrophic metabolic interactions in a mixed phototrophic/heterotrophic biofilm. Note the concentration gradients within the biofilm, and the dependence of O_2 and CO_2 gradients on diurnal and nocturnal cycles. Carbon dioxide is buffered to hydrogen carbonate and is approximately 5 times more soluble in water than oxygen.

SOURCES OF NATURAL ORGANIC CARBON SUBSTRATES

Carbon substrates belong to the dissolved or particulate organic carbon pools (DOC and POC, respectively). Colloid scientists use the thermodynamic concept of speciation, where the term "dissolved" refers to chemical potential (18). In this sense, DOC is the fraction of greatest significance to surface phenomena because it adsorbs onto surfaces to form conditioning films (see CONDITIONING FILMS, this Encyclopedia). This molecular diffusion is considerably more rapid than the adsorption of colloids, including bacteria, as described by Fick's First Law of molecular diffusion. Thus, a continuous flow of (albeit limited) substrate replenishes nutrients within a porous biofilm matrix. These nutrients can be in the form of

trapped particles or macromolecules, which are degraded if the appropriate exoenzymes are available. Sorption of kaolin particles to a *Pseudomonas fluorescens* biofilm caused an increase in microbial activity compared to biofilms grown in the absence of clay particles, as explained by the greater biomass in the former (19). Nutrient sources are described as allochthonous or autochthonous, depending on their origins. Allochthonous carbon sources are produced in locations remote from the environment of interest and reach the location by some physical process. The leaves of vascular plants, for example, provide an exogenous source of lignin to lakes and rivers. This may be a direct event, such as in the case of the leaf falling into a stream, or a consequence of a more indirect route, such as the leaching of soluble components into the water from an adjacent soil matrix, in which case the microbial decomposition processes are initiated prior to reaching the water. Anthropogenic carbon sources (i.e., derived from human activity) are mostly allochthonous. Autochthonous carbon sources, as the name suggests, are produced in situ. Examples include cell lysis products and exudates from planktonic algae. The availability of autochthonous substrates is determined by the rates of incorporation into biomass, but also by the remobilization of carbon from particles. This is especially important when sediments are mixed by advection. Most of the DOC in oceans is autochthonous, especially in coastal regions and estuaries, due to the photosynthetic activity of phytoplankton (20). The broad range of potential substrate compositions (Table 1) is dependent on the extreme variability of spatial and temporal parameters.

The low DOC of groundwater may be due to any combination of limited leaching from aquifer solids (kerogen), complete mineralization of carbon substrates by heterotrophic microorganisms, and adsorption-immobilization (22). Like humic substances, kerogen is thought to be derived from the decay of plants and microorganisms (23). Ultimately, the major source of terrestrial organic matter is vascular land plants. Some of these carbon compounds, such as lignin, appear to degrade more readily in the ocean than would be expected from laboratory-based studies. Some of the most important findings were derived from the use of specific biomarker compounds, which can be traced with some level of certainty; however, only a small fraction of the organic matter dissolved in seawater and preserved in marine sediments appears to be terrestrial in origin, despite the fact that annual exports from rivers are more than sufficient to account for deposition in sediments (24). This anomaly is the most elusive aspect of the global carbon cycle. Similar difficulties apply to soil ecosytems, in which percolation of water-soluble organic carbon through the soil matrix is relatively small in comparison to inputs from leaf material, roots, and root exudates. It is possible, however, to estimate the above-ground organic matter prior to its incorporation into the soil matrix (Fig. 2). Microorganisms in some groundwater systems live in conditions that are completely remote from aquatic or soil inputs. The substrates in these environments are the products of microbial metabolism and lysis and kerogen. These two different scenarios emphasize the ability of microorganisms to live under conditions of "feast and famine," in which the latter predominates.

Table 1. Concentrations of Dissolved Organic Carbon in the Major Types of Natural Waters

Type of Water	[Dissolved Organic Carbon] (mg/L)
groundwater	0.2–15 (0.7[†])
marine	0.5–3.0
lake	2–10
—oligotrophic	1–3
—eutrophic	2–5
—dystrophic[‡]	20–50
rivers	5–60[§]

Sources and Classes of Proteins, Carbohydrates, and Lipid Substrates in Natural Environments

Hydrolysis of proteins and protein conjugates from seawater produces both dissolved free amino acids (DFAA) and dissolved combined amino acids (DCAA). DCAA derived from marine organisms constitute the largest, well-defined form of all DOC; however, studies of the amino acid composition of DCAA have yielded little information because proteins from living organisms have similar amino acid compositions (25). Carbohydrates are quantitatively dominant over proteins in soils, freshwater, and marine environments, accounting for up to 20% of seawater DOC. Most of this is associated with photosynthetic activity in irradiated surface waters. All major classes of carbohydrates occur in marine DOC, including amino sugars, uronic acids, and aldoses (26). Like amino acids, carbohydrates in natural waters exist both as free monomers and as polymers. Polysaccharides can account for 80% or more of the total dissolved carbohydrates in seawater. Fibrillar polysaccharides may account for up to 25% of the entire pool of natural organic matter (NOM) in fresh waters (27) and therefore constitute the second largest pool of aquatic DOC after humic substances. The major polysaccharides in soils are cellulose and hemicellulose. The most abundant protein in photosynthetic organisms is Rubisco (ribulose-1,5-bisphosphate carboxylase). The turnover time of this enzyme is thought to be rapid (28), although incubation with the nocturnal Rubisco inhibitor 2'-carboxy-D-arabitinol-1-phosphate was shown to confer protection against proteolytic enzymes (29).

Lipids constitute a small fraction of the total dissolved organic carbon. The major classes of lipids in DOC are hydrocarbons, chlorins, and their esters (i.e., pigments), alcohols, sterols, triacylglycerols, free fatty acids, and phospholipids (30), which can usually be regarded as

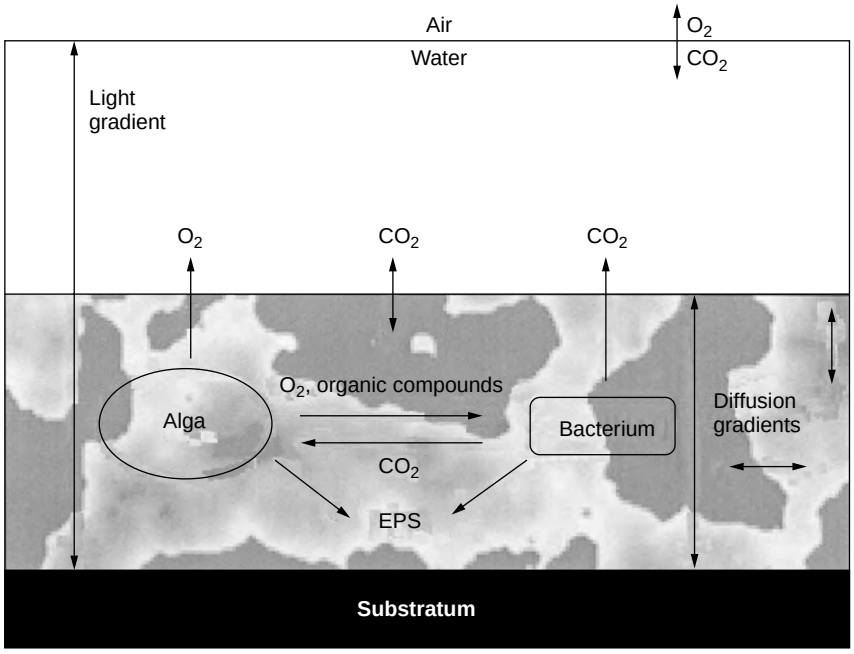

Figure 2. Carbon inventory of aboveground, terrestrial plant matter (data from A. M. Romani and S. Sabater, *Freshwater Biol*. 41(4), 729–736 (1999)).

autochthonous. The aqueous solubilities of many lipids are in the range of milligrams per liter (31); however, because they are relatively hydrophobic, most lipids tend to partition to air-water and solid-water interfaces, including particles. Alternatively, the lipids may be released as particles or micelles. Lipids represent 10 to 25% of POC in marine surface waters. Interestingly, a large proportion (approx. 70–90%) can be found in the dissolved fraction (less than 10 kDa) (31). Free fatty acids are thought to be liberated by microbial degradation of particulate substrates, whereas the phospholipids are considered to be derived almost exclusively from cell membranes (32). Some lipids are more refractory than others, and migrate through the water column relatively intact, where they are converted into alkanes at the sediment-water interface (30). A predominance of odd-carbon-number *n*-alkanes greater than $C_{23}H_{48}$ has been used as a marker for inputs of terrestrial plant waxes to sediments. The uncommon predominance of even-carbon alkanes is considered to be an indication of specific microbial inputs, degradation of algal detritus, and the reduction of alkanoic acids or other lipids (33). The degradation of lipids and triacylglycerols from algae and terrestrial plants produces long-chain (nonvolatile) fatty acids, such as palmitic acid and stearic acid. These compounds are poorly soluble in water and thus poorly bioavailable. Long-chain fatty acids predominate over short-chain forms in surface waters (oxidizing conditions), especially in the hydrophobic air-water slick. Conversely, microbial oxidation of POC and DOC produces volatile fatty acids, which accumulate only under reducing conditions. These conditions establish significant gradients within the biofilm matrix, but also more generally, such as in hypolimnetic waters and sediment cores.

Humic Substances

The bulk of DOC compounds are described as humic substances, which are complex and variable polyhydroxycarboxylates. These compounds account for 50 to 75% of aquatic dissolved organic carbon (34) and differ from other polymers in that they are the products of random chemical synthesis rather than intentional biological processes. The long-standing assumptions of soil humic chemistry were changed to reflect the fact that aliphatic, rather than aromatic, compounds form the major carbon reservoir (35). Aquatic humic substances have always been considered predominantly aliphatic and comparatively low in molecular weight, as inferred from solubility characteristics. Much recent information on the aliphatic and aromatic nature of humic substances has come from Nuclear Magnetic Resonance spectroscopy (NMR). NMR spectroscopy of humic substances usually involves sequential extractions with sodium pyrophosphate. Pyrolysis in conjunction with mass spectrometry yields molecular fragments, which must then be reconstructed into a coherent network. It is difficult to make specific statements about the microbial degradation of humic compounds if their chemical identities cannot be determined with any degree of certainty, or if they cannot be separated from biochemical compounds without altering their original properties. Far from being inert and irrelevant to microbial metabolism, humic substances can hinder the hydrolysis of bound compounds and may act as electron donors for some metabolic reactions (36).

Anthropogenic Carbon Sources

Increasing amounts of environmental carbon compounds are misappropriated by human activity. These include vast quantities of untreated or partially treated sewage effluent, point inputs of pesticides and fertilizers, and (other) xenobiotic carbon compounds. Not all of these compounds are unique — for example, phthalate esters and halogenated organic compounds are often described as undesirable anthropogenic compounds (37), yet natural sources of these compounds can be significant. Phthalate

derivatives are abundant in natural humic substances, as are organohalogens in emissions from volcanoes and hydrothermal vents (38). Methane is produced in vast quantities from the fermentation of cellulose by the intestinal flora of termites and ruminant animals. Only very preliminary estimates are available to predict the total impact of anthropogenic carbon on total microbial activity in terms of the global carbon cycle. It should be noted, however, that the oceans act as a major buffer system for carbon as soluble carbon dioxide, and that biofilms act as efficient buffer matrices for (nonxenobiotic) point disturbances. This property is exploited in wastewater treatment and bioremediation.

ASSIMILABLE ORGANIC CARBON AND BIOAVAILABILITY CONCEPTS

Descriptions of metabolic pathways give the impression that all heterotrophic activities are dependent on a limitless supply of low-molecular-weight precursors, such as glucose. In aquatic environments, low-molecular-weight substrates have very low turnover times in the range of minutes to hours, and are therefore exceedingly rare (Table 2; 34). The major part of the dissolved organic carbon pool comprises high-molecular-weight compounds from primary production and decay processes. The utilization of high-molecular-weight organic compounds depends on the ability of an organism to degrade the polymer into its constituent oligomers or monomers. This, in turn, depends on the proximity of degradable substrate, the production of appropriate exoenzymes, and the optimum size for passive transport through the cell wall. Proteins and polynucleotides are easily hydrolyzed, and the constituent monomers are mineralized fully to CO_2 or CH_4. Simple sugars are also easily hydrolyzed. Hydrolytic activity is mostly confined to the biofilm matrix (39). Structural polysaccharides constitute a considerably larger pool of potential substrates, which is directly related to the resistance of these compounds to hydrolysis. The β-1,4 polysaccharide linkage is especially resistant to degradation. Interestingly, this linkage may be the key to the cohesiveness in some biofilms (40), and is an intrinsic part of the holdfast structure of at least one, stalked bacterium (41). Suggestions that microorganisms produce humic substances independently of lignin-type mechanisms are not convincing, since infrared spectra of aged extracts from laboratory cultures (42) resemble the spectra of bacterial isolates (43).

The use of a compound as a metabolic substrate is linked intrinsically to the concept of bioavailability. In general terms, "bioavailability" describes the accessibility or otherwise of a substrate to living microorganisms, and can therefore be independent of the physiological capability of the organism to degrade the substrate. Physical accessibility is governed by parameters such as pH, ionic strength, temperature, and water activity. These parameters have a pronounced effect on factors such as solubility and partitioning. For example, an increase in temperature enhances the solubility and hydrolysis of macromolecular substrates, thereby increasing their availability (44). Even for common macromolecular substrates such as proteins, the presence of appropriate enzyme systems is not a trivial issue. Some bacteria are apparently unable to utilize high-molecular-weight substrates under any conditions, suggesting the name "dissipotrophs" (45). Especially in aquatic environments, dissolved organic matter can become more bioavailable by the action of solar radiation. Photochemical degradation of NOM produces carbonyl compounds, including carboxylic acids and aldehydes, and probably generates assimilable amino acids and carbohydrates (46,47). Ozonation has a similar effect on high-molecular-weight organic compounds during the treatment of drinking water. The activity levels of humic bound enzymes are also partially restored by UV photolysis (48). If particulate organic carbon in the euphotic zone of natural water contains chromophores, which strongly absorb solar radiation, then photolysis will have a major influence on bioavailability. A dual effect is observed when extensive absorption by humic compounds is sufficient to significantly raise the temperature in shallow, brown-colored lakes and surface soils. Chemical accessibility for a particular compound must also be considered. Different isomers or functionalized forms of molecules can be comparatively labile or nonlabile. For example, chitin is generally less bioavailable than the deacetylated form, chitosan.

Particles are less easily degraded than individual macromolecules; physical disintegration of particles increases the sites available for enzyme action. Adsorbed macromolecules must be hydrolyzed before assimilation by attached organisms. Surface immobilization may promote access of bacterial enzymes to the substrata, thereby facilitating utilization. In some circumstances, immobilization can have the opposite effect. High-molecular-weight substrates with extended conformations can have multiple binding sites that hinder hydrolysis, and the activities of bacterial enzymes can be reduced or even inhibited if they are immobilized by adsorption (49). Nucleic acids and enzymes can be preserved through interactions with humic substances, organic sediment, or clay minerals (50).

Table 2. Concentrations and Turnover Times for Dissolved Free Amino Acids (DFAA), Dissolved Free Carbohydrates (DFCHO) and Recalcitrant, "Humic" Substances in Natural Waters (34)

	Marine		Freshwater	
Substrate	Concentration (nM)	Turnover Time	Concentration (nM)	Turnover Time
DFAA	3–1,400	1.4 hrs–948 days	2.6–4,124	2 hrs–51 days
DFCHO	0.4–5,000		14–1,111	
recalcitrant	70–90% of compounds, with turnover time of 2,000–6,000 years			

Some inorganic particles, such as three-layered clay minerals can reduce the availability of citrate and glucose (51). Similarly, bacterial degradation of herbicides such as (2,4-dichlorophenoxy)acetic acid (2,4-D) or insecticides such as diquat can be inhibited by adsorption onto particles. In other words, some substrates must desorb before they can be assimilated, a phenomenon described as "desorption limitation" (52). Ogram and coworkers (53) showed that in one system, the degradation of 2,4-D could only take place if the substrate was in solution. Of special relevance to biofilm organisms is the fact that solid substrata may also act as a metabolic substrate. Some common examples are the bacterial degradation of agar, cellulose, wood, and poly (vinyl) chloride (PVC) in drinking water distribution systems. Alternatively, the substrate may leach from the solid phase and percolate through, for example, a soil column. The water-soluble organic matter from leaf litter is a major source of biodegradable carbon. Removal of leaf litter at a test site yielded soil respiration rates one-third lower than at control sites (54). Cycling of interstitial carbon by biofilm organisms undoubtedly contributes much of the remainder, but the relationship between POC and DOC in the soil matrix is not clear.

The major concept for bioavailability is the recalcitrance of the bulk pool of NOM. Humic substances, according to classical definitions, are refractory to both chemical and biological degradation. This definition is problematic in that some humic compounds may be artifacts of the harsh extraction procedures. Structurally related, but immature compounds, such as lignin and cutin have been shown to degrade extensively during incubation experiments (55), and a measurable percentage of the operationally defined humic substances are readily biodegradable. Studies that show "surprisingly" high levels of humic substance degradation by biofilms seem to contradict the classical definitions. At least in freshwater environments, this discrepancy can be explained by the strong affinities of carbohydrates and amino acids for the truly recalcitrant, humic compounds (56), resulting in humic fractions, which contain large amounts of relatively assimilable substrates. Unfortunately, it is difficult to abandon classical definitions without comprehensive information on chemical structure, which is clearly unfeasible given the demands on analytical techniques, and the extensive variability of humic substances in different environments. More useful terms such as "refractory organic carbon" are becoming more common, although it would be desirable if these terms discriminated between biotic and abiotic processes. Measurements of assimilable organic carbon (AOC) and biodegradable organic carbon (BDOC) are based on bioassays (57), which therefore give operationally useful data concerning the substrate. Conversely, these parameters are of limited benefit to the understanding of natural environments if the microbial inoculum is not representative of the system (AOC), or if the physical and chemical parameters represent "ideal" conditions for degradation, such as an absence of adsorptive mineral phases.

It has, only recently, been established that many of the recalcitrant compounds in freshwater sediments and possibly marine sediments are a distinct class of aliphatic products produced by the degradation of phytoplankton. These nonhydrolyzable and insoluble "algaenans" are components of the cell walls of many algae. Algaenan-like compounds reportedly present in cyanobacteria, and some bacteria are probably artifacts resulting from the hydrolysis procedure used in their isolation (58). Thus, algaenans have so far only been reported from a relatively few species of photosynthetic microorganisms. The comparative abundance of algaenan-containing organisms has not been investigated, so the cumulative effect of this class of compounds on biogeochemical cycles is mostly unknown. It seems likely, however, that aliphatic products from planktonic algae contribute much of the humiclike substances in marine environments. Table 3 shows a summary of these waxy compounds and their origins. It is postulated that algaenans comprise polymethylenic (*n*-alkyl) chains cross-linked via ether bridges (23). The persistence of these compounds in aquatic sediments has led to the suggestion of a humification route known as the "selective preservation" pathway (59). Although, it might appear from these discoveries that the humic substances in marine environments are exclusively aliphatic, and therefore somewhat unrelated to freshwater or soil systems, many recalcitrant aromatic compounds are present in these environments, and the origins of these compounds have not been established fully. Lignin phenols are easily detected in estuaries, but quickly become diluted in the marine environment (60). Other peculiar but common forms of carbon are the condensed residues from incomplete combustion processes, known as "carbon black" or "black carbon." Highly aromatic compounds can be produced from oxidized black carbon (61), suggesting that humic substances in some environments can be produced from charred biomass. Black carbon is extremely resistant to biodegradation (62), which partly explains its accumulation in many soil environments, and freshwater and marine sediments.

Table 3. Classes of Poorly Hydrolyzable, Aliphatic Compounds and Their Origins

Compound(s)	Origin
Algaenans	Freshwater and marine algae
Cutans	Cuticles of higher plants
Suberins	Periderm tissue of Higher plants
Tegmens	Inner seed-coats of Freshwater plants
Sporopollenins	Spores and pollen grains
Polycadinenes	Resins

MICROBIAL TRANSFORMATIONS OF DIVERSE AND DILUTE SUBSTRATES

The biofilm mode of existence demonstrates a dependence on transfer processes, or flux, to and from the biofilm. The ecology of biofilm organisms is unique in terms of the proximity of the attachment substratum, the comparatively high cell density, and the long residence time of the cells (63). There are several means by which biofilm cells can obtain nutrients: from the attachment

substratum, which can be degradable, but always contains an adsorbed conditioning film (but see Schneider and Leis, CONDITIONING FILMS, this Encyclopedia); from sorption of compounds (DOC or POC) onto biofilm cells and EPS; or from degradation of adjacent biofilm components. Geesey (64) suggested that an organism will not degrade its own EPS. Biofilms treated with dissolved organic carbon derived from decomposing macrophytes contained 10 to 57% less EPS than control biofilms (65), suggesting that the amount of EPS, which is produced by biofilm organisms is closely related to the type and amount of DOC. Classical microbiology has centered on the concept of a "limiting" nutrient, and the ability of microorganisms to use only one carbon source at any one instant, as exemplified by the diauxic growth of *Entamoeba coli* on glucose and lactose. In natural systems, assimilable, low-molecular-weight substrates are rarely present in high concentrations. Under these conditions, the formation of a biofilm would not take place if all cells were specialized for the utilization of a single substrate. Furthermore, biofilm organisms cannot translocate to nutrient sources as readily as planktonic organisms. Carbon starvation or slow growth induces the expression of many catabolic systems, despite the absence of the appropriate carbon source. This "catabolite repression" gives microorganisms an almost instantaneous ability to utilize a substrate should it become available, and in general, serves to optimize an organism's growth rate. In most bacteria, the enzymes involved in sugar transport and phosphorylation are important for signal transduction, although the regulation mechanisms vary widely between organisms (66). In one study, it was found that a strain of *Pseudomonas aeruginosa* was able to form a biofilm in tap water with a mixture of 45 carbon compounds, each present at just 1 $\mu g\ C\ L^{-1}$, whereas any one of these compounds in isolation could not produce growth at this concentration (67). The sorption of particulate organic matter by biofilms represents a major input of nutrients. These abiotic particles and flocs contain a relatively small proportion of easily biodegradable matter, but newly attached cells, and their metabolites and lysis products contribute to the cycling of organic matter. The turnover time for total organic carbon (TOC) in marine "snow" is approximately eight to nine days, suggesting that flocs are "hotspots" for microbial respiration (68). The biofilm environment is therefore, a dynamic exchange interface, even when the activity levels of the biofilm organisms are observed to be low.

MEASUREMENT OF TRANSFORMATIONS AND ACTIVITY IN BIOFILMS

The ability of microorganisms to rapidly alter levels of metabolic processes explains their ability to resume activity after extended stages of dormancy. Microbial activity can be measured in terms of individual metabolic reactions, or as a cumulative effect, as in the case of biomass measurements. Approaches to determine microbial activity include measurements of substrates, metabolic intermediates, or products of primary and secondary production. Primary production is measured as reactants such as CO_2 or H^+ (pH), while the products are usually measured as O_2 and ΔpH. Direct measurements of carbon dioxide production are useful for estimates of metabolism in whole systems, but do not provide any insight into transformations or partitioning of key components. The use of radiotracers such as $^{14}CO_2$ is more specific. Radiolabeled, low-molecular-weight compounds are certainly not representative of the bulk of NOM, and the use of labeled, high-molecular-weight compounds depends on their commercial availability and their ability to disperse within a system (69). Clearly, the use of any standards for high-molecular-weight NOM is subjective. Microautoradiography can be used for the analysis of labeled carbon dioxide assimilated by photosynthesis (9), but the visualization of biofilm cells in photographic emulsions requires considerable technical effort to avoid artifacts.

The fundamental prerequisite for studies of biofilm activity is the ability to distinguish between the metabolic processes of biofilm and planktonic environments, which in turn depends on the development of appropriate techniques for in situ measurements. The inadequacies of culture-based methods for measuring growth processes have been appreciated for some time, especially for biofilms. The purposeful detachment of microorganisms from particles is a selective process, and the extrapolation from total cell number to biomass is problematic because it is necessary to assume a universal conversion factor to account for the variations in cell volume among species, and among nutrient-limited phenotypes of the same species (32). Estimates of primary producers by measurement of chlorophyll *a* requires the same assumptions for average biovolume. Measurements of specific biochemical components is one strategy to avoid culture-based techniques and microscopy, but there are a number of assumptions inherent to these methods. Universal indicators of metabolism, such as ATP, can persist after cell death (70), and the turnover times of excreted compounds, which become localized in the biofilm matrix can be totally dissimilar to the turnover time of these compounds in the bulk phase. Measurements of extracellular enzymes are complicated by the fact that the enzymes often bind to the EPS matrix, and therefore do not necessarily represent the presence of active cells (71). Humic compounds complex with microbial phosphatases, thereby reducing enzyme activity (48). The same applies for the coenzyme, F420, which is found in nonviable cells of archaea and some eubacteria, as well as extracellularly (72). Conversely, polar lipids such as the cell wall phospholipids are degraded rapidly after cell death, with the added advantage of diversity profiles obtained from fatty acid analysis (32). High levels of activity do not necessarily imply an actively growing population. Cells in immature biofilm populations can be outnumbered by planktonic organisms, yet the biofilm carbon demand and hydrolytic enzyme activity can account for close to 100% of the system's total (73). Protease activity can be measured with the protein substrate azocoll, which yields a blue product on hydrolysis. The incorporation of radiolabeled nucleotides into DNA allows an

estimate of DNA synthesis, and therefore an estimate of the rate of cell division. This is commonly measured by the incorporation of ^{3}H-thymidine (74), although measurement of protein synthesis from the incorporation of radiolabeled amino acids such as ^{3}H-leucine is useful as an independent validation, and is probably more sensitive because of the large amounts assimilated by growing cells (2,75). Both methods are specific for heterotrophic bacteria, and contain a number of implicit assumptions. Measurements of the rates of nucleic acid synthesis from the incorporation of adenine, and perhaps also $^{35}SO_4$ into bacteria and algae provide a measure of the entire microbial community. An alternative to radioactive isotopes is an immunoassay in which the uptake of 5-bromo-2'deoxyuridine is measured by chemiluminescence (76).

Measurements of transformations and microbial activity within biofilms constitute a unique challenge because of the microscale heterogeneity within the biofilm matrix. Total cell counts of biofilm populations are hindered by the presence of aggregates, although confocal microscopy is an indispensable tool in this respect. With the aid of suitable fluorescent dyes, it is possible to observe relatively undisturbed biofilm populations as three-dimensional reconstructions, and to probe for features such as membrane integrity and redox activity. Membrane integrity is conveniently tested with the Live/Dead™ kit (Molecular Probes, Oregon). A potential complication of this technique is that dye uptake could vary depending on the size and charge of the dye molecules, and the uptake systems of particular organisms. Further indications of actively metabolizing cells are provided by the cleavage of fluorogenic substrates such as fluorescein diacetate to fluorescein, providing an indication of total esterase activity (77), and the reduction of tetrazolium salts by cellular redox mechanisms, generating an insoluble, colored, and perhaps fluorescent product. Changes in intracellular components such as organic phosphorus and carbohydrate, or NADH, can be measured by NMR spectroscopy and fluorescence spectrophotometry, respectively (14,78). Measurements of small amounts of heat from metabolic activity are possible using microcalorimetry (79). Measurements of changes in the isotope compositions of carbon, nitrogen, and sulfur are possible using an isotope ratio mass spectrometer (IRMS), since microorganisms discriminate against heavy isotopes during metabolic processes (80). This approach is especially useful for determining the sources and fates of groundwater carbon, and its partitioning between biotic and abiotic phases. Isotope enrichment is especially important for methanogenesis, acetogenesis, and methanotrophy. Microbially produced methane represents the most ^{13}C-depleted carbon compound in nature (80).

Microelectrodes allow the measurement of metabolites, diffusion coefficients (81) and flow velocity (82) in situ. Specific microelectrodes have been developed for measurements of several important compounds, including nitrate, nitrite, ammonium, carbon dioxide, hydrogen sulfide, and methane, and fiber-optical sensors are available for measurements of O_2, pH and temperature (83). In *P. aeruginosa* biofilms, microelectrodes have shown that a lack of oxygen restricted limited active protein synthesis to the top 30 μm of a biofilm (84). Other studies have demonstrated stratifications in nitrifying and sulfate-reducing biofilms (85). Planar optodes are superior to conventional O_2 microelectrodes because the latter create hydrodynamic disturbances, which can affect an area of several millimeters surrounding the measurement site (86). Reporter gene techniques allow the identification of genetic changes, which are invoked on recognition of an attachment substratum (87,88). These changes include the production of exopolysaccharides (89), and presumably other components of the EPS. Observations relating to cellular morphology are less discriminate because they depend on an ability to recognize a particular species within a complex biofilm community. This is only feasible with biofilms containing one or a few organisms, preferably with simple, distinguishing characteristics. The best examples are given by the initial attachment and subsequent morphological changes of the prosthecate (stalked) bacteria belonging to the genera *Hyphomicrobium*, *Flexibacter*, *Caulobacter*, *Prosthecobacter*, and *Hyphomonas* (41). In studies of an *Acinetobacter* sp. attaching to solid substrata, it was found that a nutrient-rich medium induced a transition from coccoid morphology to a bacillary form, and the converse occurred when cells were supplied with a nutrient-depleted (starvation) medium (90). Figure 3 shows the variability in morphology of a single species of marine bacterium, which

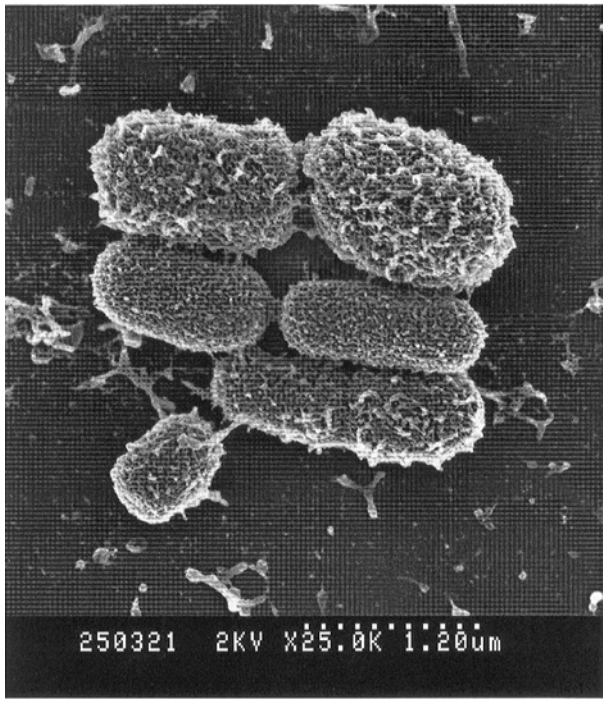

Figure 3. Differences in the morphologies of dividing bacteria (*Psychrobacter* sp. SW8) from a colony grown on minimal medium with acetate as the sole source of carbon. In continuous culture with carbon as the limiting nutrient, all cells of this isolate have a similar shape and indistinguishable surface morphology.

was isolated for its ability to attach to hydrophobic substrata, thus implicating it as a primary colonizer of immersed surfaces.

CONCLUSION

Sustainable, high levels of microbial productivity in low-nutrient environments are testimony to the diversity and adaptability of environmental microorganisms. Most of this growth is associated with biofilms. Microorganisms have evolved many mechanisms to utilize available substrates, only some of which are efficient. Biofilms can sometimes account for nearly all of the enzyme activity in a natural environment. The bioavailable natural organic matter is rapidly utilized, leaving a recalcitrant macromolecular skeleton. While much is known about the mechanisms of substrate utilization, and to a lesser extent, the genetic mechanisms regulating microbial activity, the largest knowledge gaps are the extent to which the poorly characterized pool of natural organic matter is available for microbial growth, and the mechanisms controlling this bioavailability. Further knowledge of the bioavailable organic carbon must consider the flux of particulate substrate to biofilms, the identification of biodegradable substrates using nondestructive techniques, and the measurement of metabolic activity in situ. Such fundamental knowledge requires the use of complex biofilms and substrates, monospecies biofilms and fractionated organic matter, and model systems capable of simulating key aspects of natural environments.

ADENOVIRUSES

CARLOS ENRIQUEZ
Clorox Services Company
Pleasanton, California

As early as 1926, several outbreaks of swimming pool conjunctivitis had been documented in the United States (1). It is likely that some outbreaks were caused by adenoviruses, as no bacterial pathogens could be identified, and the description of clinical manifestations matched that of pharyngoconjunctival fever caused by adenoviruses (2–6). Strong epidemiological evidence of the waterborne transmission of these agents was obtained in 1955, when adenoviruses were isolated from patients suffering form conjunctivitis during an outbreak that originated in a swimming pool (3). Numerous waterborne

outbreaks of pharyngoconjunctival fever, caused by adenoviruses, have been documented since then (5,7–12). The first detection of adenoviruses during a waterborne outbreak of gastroenteritis was recorded in Finland in April 1994 (13), when approximately 25 to 50% of the population (1,500 to 3,000) of a municipality developed acute gastroenteritis. This outbreak was associated with contaminated well water. In addition to adenoviruses, a Norwalk-like agent, small round viruses (SRV), and group A and C rotaviruses were identified as the etiological agents, Norwalk virus being the most prevalent of the implicated viruses. In addition to gastroenteritis (adenovirus types 31,40, and 41) and pharyngoconjunctival fever (adenovirus types 3,7,8,11,14,19, and 37), adenovirus infections may cause other clinical conditions such as acute respiratory disease (adenovirus types 1–7, 14, and 21), acute hemorrhagic cystitis (adenovirus types 11 and 21), and acute respiratory disease (ARD) of military recruits (types 3, 4, 7, 14, and 21) (14).

CLASSIFICATION

Adenoviruses were first identified in 1953 as agents causing spontaneous degeneration of primary cultures of human adenoid tissue (15). In 1956, the name adenovirus was given to these agents denoting the tissue in which these viruses were discovered. Adenoviruses belong to the *Adenoviridae* family, which is represented by the *Mastadenovirus* and the *Aviadenovirus* genera (16). The *Mastadenovirus* genus contains human (49 serotypes) (14), simian (27 serotypes), bovine (10 serotypes), equine (1 serotype), porcine (4 serotypes), ovine (1 serotype), and canine (3 serotypes) viruses. The *Aviadenovirus* genus (11 serotypes) includes only bird viruses (4). The 49 human serotypes have been further classified into six subgroups (A through F) based on their ability to agglutinate red blood cells, capacity to cause tumors in rodents, relatedness of tumor antigens, electrophoretic mobility of viral proteins, genome homology, cross hybridization, and DNA digestion with restriction endonucleases (16).

STRUCTURE

Adenoviruses are nonenveloped icosahedric viruses of approximately 70 to 100 nm in diameter, composed of DNA (13% of mass), protein (87% of mass), and trace amounts of carbohydrates present in the virion fibers (16). Members of the *Adenoviridae* family possess a linear double-stranded (ds) DNA molecule with about 30,000 base pairs (17) and molecular weight of $1.5–1.8 \times 10^8$ (14). Virions consist of a protein shell (capsid) surrounding a DNA-containing core. This structure is composed by 252 subunits (capsomeres), 240 hexons, and 12 pentons. Each penton contains a projecting fiber that varies in length in different adenovirus serotypes. All human adenoviruses seem to possess a single fiber protein, with the exception of the enteric adenoviruses 40 (Eda 40) and 41 (Ead 41) that possess two fiber proteins (16).

GENETICS

Evolution and diversity of adenoviruses result mostly from recombination among members of the same subgroup; however, recombination among adenoviruses of different subgroups can also occur. In fact, adenovirus type 4 (the only member of group E) originated, apparently, from recombination between viruses from groups B and C (16).

BIOLOGY

Adsorption and internalization in adenoviruses is a two-step process. Attachment of adenovirus to susceptible host cells is mediated by the fiber protein; however, for internalization to occur, the penton base protein needs to attach also to a cell receptor of the family of "integrins." The penton–integrin interaction precipitates a receptor-mediated endocytosis. Once the virion enters the cell, it is disassembled by a systematic elimination of structural proteins, leading to the transport of the viral DNA into the cell nucleus (16). The adenovirus genome replicates by an unusual mechanism in which single-stranded (ss) DNA intermediates are formed, and a protein, but not short RNA molecules serves as a primer to initiate replication (17). Adenovirus DNA replication can start at one or both ends of the molecule. A similar general organization has been found in the genomes of different adenoviruses. The adenovirus ds-DNA molecule possesses two identical origins for replication, which is found in each of the virus short terminal repeats. Adenovirus mRNA synthesis takes place in the cell nucleus (16) adenovirus genes are expressed in two stages, early transcription (before viral DNA synthesis), and late transcription (after viral DNA synthesis); however, the functional distinction of the two stages is frequently obscure. A cellular RNA polymerase II transcribes each adenovirus gene into multiple mRNAs that are differentiated by alternative splicing (18). The accumulation of large quantities of viral proteins and DNA induces virus assembly. The formation of empty capsids seems to be followed by the internalization of the DNA. Virus release is mediated by disruption of cytoskeleton intermediate filaments, which renders the cell more susceptible to lysis (16).

EPIDEMIOLOGY AND CLINICAL DISEASE

Clinical Symptoms

Most adenovirus human diseases are associated only with one-third of adenovirus types. Although many adenovirus infections are subclinical, these viruses may cause acute respiratory disease (types 1–7,14, and 21), conjunctivitis (types 3,7,8,11,14,19, and 37), acute hemorrhagic cystitis (11 and 21), acute respiratory disease (ARD) of military recruits (types 3,4,7,14, and 21), and gastroenteritis (types 31,40, and 41) (Table 1; 14). Enteric adenoviruses 40 and 41 have been recognized as important etiological agents of gastroenteritis in children (2,19–25), second in importance only to rotavirus.

Table 1. Disease Caused by Human Adenoviruses

Subgenus	Serotype	Human Illness
A	12	Meningoencephalitis
	18,31	Gastroenteritis
B	3	Acute febrile pharyngitis; adenopharyngo-conjunctival fever; pneumonia; follicular conjunctivitis; fatal infection of neonates
	7	Acute febrile pharyngitis; adenopharyngo-conjunctival fever; acute respiratory disease with pneumonia; fatal infection of neonates; meningoencephalitis
	11	Follicular conjunctivitis; hemorrhagic cystitis in children
	21	Hemorrhagic cystitis in children; fatal infection in neonates
	14,16	Acute respiratory disease with pneumonia
	34,35	Acute and chronic infection in patients with immunosuppression and AIDS
C	1,2,6	Acute febrile pharyngitis; pneumonia in children
	5	Acute febrile pharyngitis; pertussis-like syndrome; acute and chronic infection in patients with immunosuppression and AIDS
D	8,19,37,9,10,13, 15,17,42,19, 20,22–29	Epidemic keratoconjunctivitis
	30	Fatal infection in neonates
	32,33,36,38	Asymptomatic infections
	39,42–47	Acute and chronic infection in patients with immunosuppression and AIDS
E	4	Respiratory infection
F	40,41	Diarrhea

Adapted from Maier, Pepper, and Gerba (107)

Children infected with enteric adenoviruses can shed up to 10^{11} particles/g in feces (26).

An electron microscopy survey of stool samples in London, from patients suffering from viral gastroenteritis, showed that enteric adenoviruses were found in 14% of the examined specimens (27). Enteric adenoviruses are ubiquitous, and antibodies to these viruses have been found throughout the world (28). An investigation in Guatemala (25) showed that Ead 40 and Ead 41 were associated with diarrheal episodes in ambulatory children three times more often than rotaviruses.

Adenovirus in AIDS patients

Adenovirus may cause opportunistic infections in immunocompromised patients, including individuals suffering from AIDS (29). Although uncommon, these infections may result in a high mortality (30). Several clinical conditions associated with adenovirus infections in immunocompromised patients have been described. These conditions include encephalitis (31,32), gastroenteritis (33,34), liver necrosis (35), nephritis (36), parotitis (29), hemorrhagic cystitis (37,38), and fatal pneumonia (39–41).

Modes of Transmission

Adenoviruses can replicate in the respiratory tract, the eye mucosa, the intestinal tract, the urinary bladder, and the liver. Adenoviruses can gain access into susceptible individuals through the mouth, the nasopharynx, or the conjunctiva. Although initial infection may occur through the respiratory route, the fecal-oral transmission accounts for most adenovirus infections in young children due to prolonged shedding of large numbers of viruses in feces (14). This may explain the high rate (close to 50%) of adenovirus secondary transmission in households (42). In addition to the type of infection, the duration of adenovirus shedding depends on the age, and immune status of the infected individual. Adenovirus can be isolated for one to three days from the throat of adults suffering from the common cold, and for three to five days from nose, throat, stool, and eye of adults with pharyngoconjunctival fever. At a younger age, adenovirus excretion in throat or stool is more prolonged than in adults. In children suffering from respiratory or generalized infection, adenoviruses can be recovered from throat or stool for three to six weeks, and in immunocompromised patients for up to 12 months or longer from urine, stool, throat, or organ biopsies. In some individuals, intermittent shedding of adenoviruses may occur for months or even years (14).

Most, if not all, waterborne outbreaks of viral conjunctivitis are caused by adenoviruses. Documented waterborne outbreaks of conjunctivitis, by adenovirus type 3 (3,8,43) and type 4 (5) have been reported; however, adenovirus types 1,7, and 14 have also been associated with family outbreaks of pharyngoconjunctival fever (44). According to the Centers for Disease Control (45), the only viral waterborne outbreak between 1991 and 1992 in the United States, associated with recreational waters, was caused by adenovirus type 3. In this outbreak, conjunctivitis, pharyngitis, and fever were the most common clinical manifestations among 595 affected individuals (8).

The leading routes of transmission of adenoviruses are direct contact via host-to-host, and indirect contact via fecally contaminated water, food, and fomites (46). Intact conjunctival mucosa seem to be resistant to infection by adenoviruses.

The enteric adenoviruses 40 and 41 have been recognized as the second most important etiological agents of gastroenteritis in children (21). These viruses, in contrast to other adenoviruses, are not shed in respiratory secretions (47,48), thus their transmission is likely to be limited to the oral-fecal route. It has been suggested that among

the adenoviruses, Ead 40 and 41 are the most likely to be transmitted by water (49), probably through recreational or drinking water (50). This idea was supported by findings by researchers from the United Kingdom (51), who reported a gastroenteritis outbreak in which a common unknown source of enteric adenoviruses affected several children from a long-stay ward at the same time.

Not only are the enteric adenoviruses a significant cause of gastroenteritis among the enteroviruses, adenovirus type 31 has been increasingly detected during the last few years as an important cause of infant gastroenteritis (52).

Contaminated inanimate surfaces may also play a significant role in adenovirus transmission because of their resistance to drying. At room temperature, adenovirus 2 survives for 8 and 12 weeks under low (7%) and high (96%) relative humidity, respectively. This virus was more stable under these conditions than poliovirus 2, vaccinia virus, coxsackievirus B3, and herpesvirus (53).

Reservoirs

Although adenoviruses are common in many types of animals, including simian species (14), adenoviruses infecting humans seem naturally limited to humans (46).

OCCURRENCE AND PERSISTENCE IN THE ENVIRONMENT

A greater number of adenoviruses than enteroviruses has been consistently found in raw sewage around the world (50,54–58). Results of a comparative study of cytopathogenicity, immunofluorescence and in situ DNA hybridization as methods for the detection of adenoviruses from water have suggested that 80% of infectious adenoviruses in raw sewage may be enteric adenoviruses (50). Adenoviruses are also commonly found in primary sewage sludge, where they have been found in concentrations ten times greater than that of the enteroviruses (59). In contrast to these reports, a five-year study of river water in Japan (60) indicated that adenoviruses were present throughout the duration of the study, but in lower number than enteroviruses or reoviruses. The peak concentration of reoviruses and enteroviruses was observed in winter and summer, respectively, whereas the number of adenoviruses remained constant throughout the year.

Adenoviruses seem to be relatively stable in the aquatic environment. Adenovirus type 5 survives longer in tap water, at either 4 or 18 °C, than either poliovirus 1, or echovirus 7 (61). In contrast to the survival patterns observed with enteroviruses, the enteric adenoviruses do not survive significantly longer in wastewater. The increased survivability of the enteric adenoviruses in tap and seawater and their faster inactivation in sewage may indicate that these viruses are inactivated by mechanisms that are different from those affecting the enteroviruses. The enteric adenoviruses are more thermally stable than poliovirus type 1 (polio 1), which is inactivated faster at temperatures above 50 °C (62).

Differences in survival among members of the same adenovirus type have been reported. The survival of two clinical isolates of adenovirus type 5 in tap water at room temperature was longer than that observed for a laboratory strain (61).When the same study compared the survival of adenovirus type 5 with that of poliovirus 1 in tap water at 4 and 22 °C, it was found that poliovirus 1 was inactivated faster at both temperatures.

Adenoviruses seem to be more stable than enteroviruses under different relative humidity conditions. A comparative study on the survival of several viruses at different temperatures and relative humidity values, reported that adenovirus type 2 survived longer than poliovirus 2, vaccinia virus, coxsackievirus B3, and herpesvirus, at relative humidity values ranging from 3 to 96%, at either 25 or 37 °C (53). In a study that compared the stability of enterovirus 70 and human adenovirus type 19 at room temperature (63), it was observed that the drying of these agents on ophthalmic instruments resulted in a 5-$\log_{10}$ reduction of the titer of enterovirus 70, whereas the titer of adenovirus 19 decreased by less than 1 $\log_{10}$ after 11 days. A study on the survival of hepatitis A virus (HAV), human rotavirus (HRV), polio 1, and Ead 40 on porous and nonporous materials showed that when dried on these materials, HAV and HRV were more stable than either polio 1 or Ead 40; however, Ead 40 survived longer in porous surfaces such as paper or cotton cloth than in nonporous surfaces such as latex, aluminum, china, and glazed tiles (64). The presence of fecal matter affected the survival of Ead 40, depending on the type of material. On nonporous surfaces, this agent persisted longer in the presence of fecal matter, whereas in porous materials the presence of feces resulted in a diminished infectivity of this agent (64).

When the survival of the enteric adenoviruses 40 and 41 was compared with the survival of poliovirus type 1 (polio 1) and HAV (in tap water at 4 °C, and at room temperature, and with the survival of polio 1 in primary and secondary wastewater at 4 and 15 °C, and with seawater at 15 °C), it was observed that the survival of Ead 40 and Ead 41 in primary and secondary wastewater was slightly greater than that of polio 1. However, in tap and seawater, the enteric adenoviruses were substantially more stable than either polio 1 or HAV (65).These results are in agreement with previous research in which it was reported that adenovirus type 5 survived longer than both poliovirus 1 and echovirus 7 in tap water, at either 4 or 18 °C (61), and that HAV in groundwater was more stable than polio 1 at different temperatures (66).

Additional evidence of the stability of the enteric adenoviruses at higher temperatures was obtained in an experiment in which both Ead 40 and polio 1 were held at 50,65, and 80 °C in phosphate buffered saline. After incubation at 50 °C for six minutes, polio 1 lost 0.88 $\log_{10}$, whereas Ead 40 lost less than 0.2 $\log_{10}$. Similarly, at 65 °C, polio 1 lost more than 2.5 $\log_{10}$ in 30 seconds, whereas Ead 40 lost only 1 $\log_{10}$ after the same incubation time. When the thermal inactivation was conducted at 80 °C polio 1 lost more than 4 $\log_{10}$ in 30 seconds, in contrast, adenovirus 40 lost only 1.8 $\log_{10}$ during the same period (62).

In addition to thermal stability, Ead 40 shows some resistance to extreme pH levels. No reduction of its infectivity in 0.1 M glycine buffer was observed after

Table 2. UV Doses for 90% and 99.99% Inactivation of Test Viruses

Virus Type	Inactivation Dose (mW sec/cm^2) 90%	99.99%	Relative Sensitivity
Ead 40	30	124	1.0
Ead 41	23.6	111.8	1.16
MS-2	14	65.2	1.8
PRD-1	8.7	31.6	4.08
Polio 1	4.1	21.7	5.6

Adapted from Meng and Gerba (69)

45 minutes at either pH 3.5, 9.5, or 10. However, after 45 minutes at pH 10.5, Ead 40 underwent a titer reduction of 2.7 $\log_{10}$. These results are in contrast to those reported earlier (67) in which the infectivity of adenovirus type 5 decreased steadily at pH higher than 9.0, with rapid inactivation at pH 10.

ULTRAVIOLET DISINFECTION

Differences in the stability to inactivating factors among adenovirus types were first reported in 1962 (68). Research on the inactivation of several adenoviruses by ultraviolet irradiation showed that the adenoviruses represent a very diverse group. Adenovirus 4 and 20, for instance, were more resistant to inactivation by ultraviolet (UV) light than adenovirus 1. Adenovirus 4 and 20 had a titer reduction of approximately 2.5 $\log_{10}$. In contrast, adenovirus type 1 lost almost 3 $\log_{10}$ during the same period. In another study, when the enterovirus 70 and human adenovirus type 19 were exposed to UV irradiation, it took less than 10 mW/cm^2/min to cause a 4.5 $\log_{10}$ reduction of the enterovirus 70 titer, whereas a UV dose of 60 mW/cm^2/min was necessary to reach similar levels of inactivation of adenovirus 19 (63). These results agree with a previous investigation that compared the resistance of enteric adenoviruses to UV disinfection with poliovirus type 1 and coliphages MS-2 and PRD-1 (Table 2; 69). Purified stocks of the viruses in deionized-sterile water were exposed to collimated UV irradiation in a stirred reactor for a total dose of up to 140 mW sec/cm^2. The doses of UV to achieve a 90% inactivation of adenovirus 40, adenovirus 41, coliphages MS-2 and PRD-1, and poliovirus type 1 were 30,23.6,14,8.7, and 4.1 mW sec/cm^2, respectively. Although MS-2 is considered to be much more resistant to UV disinfection than enteroviruses and enteric bacteria, and has been suggested as a good model for enteric viruses disinfection (70), adenovirus 40 was significantly more resistant to UV irradiation than this coliphage. Therefore, adenoviruses appear to be among the most resistant waterborne enteric viruses to UV light disinfection (69).

CHEMICAL DISINFECTANTS

Differences in the susceptibility to chlorine among members of the adenovirus group have been reported (71). A 99% reduction of human adenoviruses 3 and 7 was achieved with a concentration of free chlorine of 0.69 and 0.89 mg/L, respectively. In contrast, a similar disinfection level of the simian adenoviruses M2,M3, and M4 was only obtained with 0.93 mg/L of residual chlorine. Disinfection experiments with HAV, human rotavirus, poliovirus 1, and adenovirus 5 in tap water by copper and silver ions and reduced levels of free chlorine (1. 0.5 or 0.2 mg/L) showed that adenovirus type 5 was more resistant to all disinfection treatments than poliovirus 1 but less resistant than either HAV or human rotavirus (72). Similar results were reported in a study that estimated the time required to eliminate adenovirus 40 from artificially contaminated mussels in a continuous flow of ozonated marine water. This investigation showed that it took much longer to eliminate Ead 40 than poliovirus 1. However, it was depurated faster than either HAV or human rotaviruses (73).

ENVIRONMENTAL STABILITY OF ADENOVIRUSES

The increased resistance showed by enteric adenoviruses when compared with other enteric viruses may be associated with the double-stranded nature of their DNA, which if damaged, may be repaired by the host cell DNA-repair mechanisms, which in human cells, in addition to repairing pyrimidine dimers can also repair a wide range of DNA damages (74). In addition, both adenovirus DNA strands may serve as template for replication (75). Thus, if one strand is damaged by environmental factors, the other may still serve as template for replication of progeny DNA. This mechanism would not be effective on ssRNA-genome viruses such as polio 1 or HAV. It has been suggested that nucleic acids from DNA viruses would persist longer in the aquatic environment (76) because indigenous DNAases require cofactors to be active and are denatured by temperature more readily than RNAases. It could be speculated then, that the longer survival of the enteric adenoviruses in tap and seawater might have been associated with DNA damage that could have been repaired by the host cell, whereas the faster inactivation in sewage might have resulted from protein capsid damage, rendering the virions unable to attach and enter the host cell.

CONCENTRATION AND RECOVERY

Although Ead 40 and 41 are important human pathogens (19), methods for their concentration in water are very limited (77). However, some research has been conducted on the concentration of adenoviruses (67,78–82) and enteric adenoviruses (77).

The earliest attempts to concentrate adenoviruses from water were conducted in 1965 (78). Sanitary napkins were suspended for two to three days in sewage or sewage effluents. In the laboratory, the napkins were wrung, the liquid centrifuged, and the resuspended pellet inoculated into different combinations of primary cultures of African green monkey kidney cells (MK), human amnion cells (HA), and a continuous green monkey kidney

cell line (BCS-1). Using this procedure, 96 adenovirus isolates were obtained from 661 samples positive for viruses.

The concentration of adenovirus was improved by a protamine-sulfate precipitation procedure (79).Using this method, a 50- to 400-fold concentration of adenovirus was achieved. It was observed that adenoviruses were preferentially precipitated when mixed with enteroviruses, and it was pointed out that the protamine-sulfate precipitation method could be used to prevent overgrowth of adenoviruses by faster replicating enteroviruses. This methodology was used successfully to detect indigenous adenoviruses from raw sewage in Greece (55).

Electronegative epoxy-fiberglass filters and fiberglass textile filters have been used as primary adenovirus-adsorbing filters. Elution of adenovirus 5 from fiberglass filters was more efficient with 3% beef extract pH 9.0 than with 0.05 M glycine pH 11.5, which resulted in inactivation of this agent (67). An adenovirus high-pH sensitivity was observed in another study in which the simian adenovirus SV-11 infectivity was greatly reduced at pH 10 or above (83).

Elution of viruses from adsorbing materials is often achieved by the use of high pH solutions (28). However, when adenoviruses are exposed to an eluting solution of pH 11.5, more than 90% of the viruses are inactivated in less than one minute. Enteroviruses, on the other hand, can be reconcentrated with an overall efficiency of 15.4% (81). This suggests that the enteroviruses may not be good surrogates for adenovirus recovery from water, and that failure to recover adenoviruses from water samples may be due, in part, to virus inactivation during elution of filters with high pH solutions.

In a study to evaluate the ability of microporous filters to recover Ead 40 from different types of water, it was found that with electronegative filters the recovery of this virus from drinking water was of 36%, whereas with electropositive filters, the average recovery efficiency was 26.5% (77).These results suggest that adsorption Ead 40 to electropositive filter surfaces at neutral pH may be less affected by specific electrostatic characteristics of the virions than their attachment to electronegative surfaces at pH 3.5, and that the higher recovery of this virus with electronegative filters may have been associated with a more efficient elution of the virus from the electronegative filtering medium (77).

Reconcentration of Adenoviruses

Although the filter-adsorption-elution procedure allows for the processing of large samples of water (84), the volume of the eluate still needs to be reduced to be assayed in a practical way. Among the methods for second-step reconcentration, the organic flocculation procedure (85) continues to be the most efficient (86). The organic flocculation method (85) is widely used to reconcentrate viruses from environmental water samples. It has been used efficiently for the recovery of Simian adenovirus SV-11, with recoveries of 50 to 60% (80). A limitation of this technique, in addition to extreme pH changes, is that it is not equally effective with all viruses. The reconcentration efficiency by the organic flocculation method, may be different even among different serotypes of the same virus (86).

In a study that compared two aqueous-polymer-phase separation methods, as a second step of adenovirus reconcentration, it was demonstrated that a dextran-methyl cellulose-polyethylene glycol phase separation method was superior to a sodium dextran sulfate-polyethylene glycol sodium chloride procedure (67). Furthermore, the dextran-methyl cellulose-polyethylene glycol phase separation method selectively concentrated adenovirus 5 when mixed with poliovirus 2 (16 : 2 ratio).

As an alternative to the organic flocculation method, polyethylene glycol (PEG) precipitation has been used to concentrate Ead 40 from beet extract (BE). The reconcentration efficiency by this method (40%) was similar to that obtained by organic flocculation (38%). PEG precipitation may offer some advantages over the organic flocculation procedure to obtain high-quality RNA for RT (reverse transcriptase)-PCR analysis, especially when the number of viruses in the sample is low (87).

METHODS OF DETECTION

Several methods have been used to detect adenoviruses. Clinical specimens for detection may include feces (88), nasal washes, and pharyngeal, anal, and conjunctival swabs (42); whereas environmental samples consist mostly of water (58) and wastewater (58,59). Adenoviruses in these types of samples are relatively stable and will withstand freezing and storage at $-70\,^{\circ}C$ (14). Although adenovirus isolation by cell culture is the procedure used by most diagnostic and reference laboratories, it requires highly trained personnel and specialized facilities. Therefore, the enzyme immunoassay (EIA) is the method of choice for the detection of adenoviral soluble antigens in feces or respiratory secretions (42). Other methods used for the detection of adenoviruses include direct electron microscopy (89), immune electron microscopy (90), immunofluorescence (21), enzyme-linked immunosorbent assay (ELISA) (91), gel electrophoresis, and restriction analysis of viral DNA (92), nucleic acid hybridization (93,94), and polymerase chain reaction (PCR) (9,57,58,88). With the exception of PCR, detection by these techniques is only possible if a relatively large number of viral particles are present in the sample.

Enteric adenoviruses propagate poorly, or not at all, in conventional human cell lines in which other adenoviruses can be propagated effectively (95). The enteric adenoviruses 40 and 41 are even difficult to grow in fetal intestinal organ cultures (96). However, in 1992 the successful propagation of both Ead 40 and Ead 41 in PLC/PRF/5 human liver cell line was reported (97). Later, these agents were also propagated in a cell line derived from a human colon carcinoma (CaCo-2 cells) (98). The availability of these cell lines has provided a practical method for the propagation and detection of Ead 40 and Ead 41 to study these viruses in the aquatic environment (62,65).

Purification and Separation

Several continuous cell lines have been used in the propagation of many types of human adenoviruses. Some of these include Graham 293, HeLa, Hep-2, KB, and A549 cells (99). Propagation of the enteric adenoviruses 40 and 41 has been accomplished in PLC/PRF/5 human liver cell line (97) and CaCo-2 cells (98). Adenovirus cytopathic effect (CPE) is distinguished by large pycnotic cells that eventually aggregate into sheets that detached from the culture vessel (99).

Adenoviruses replicate in the nucleus of infected cells, and most virions remain cell-associated; therefore, the release of viral particles can be achieved by disruption of the nuclear membrane by freezing and thawing, sonication, or by extraction with an organic solvent such as Freon (100). Because of environmental concerns resulting from the use of Freon, other organic solvents have been proposed as an alternative for the extraction of nonenveloped viruses (101). After removing cell debris, virions can be purified by density gradient centrifugation (100). Depending on the adenovirus type, titration of can be accomplished by the plaque method or by an end point CPE method such as the tissue-culture-infectious dose fifty ($TCID_{50}$) (65). Although the plaque method is more accurate, it requires lengthy incubation periods and a very stable cell monolayer (100). Furthermore, not all adenovirus types respond to plaquing (97). In contrast, the end point CPE method is less sophisticated than the plaque method, but still sensitive and accurate enough for most applications (100).

Assay

Immune Assays. The enzyme immunoassay (EIA) is the method most commonly used for the detection of adenoviral soluble antigens in feces, or in respiratory secretions (42,91). Monoclonal antibodies (Mab) directed to a family-shared hexon epitope can be used in EIA to identify any member of the *Adenoviridae* family. If needed, a type-specific Mab can be utilized to further determine the precise adenovirus type (42). All known mastoadenoviruses share a family antigen that can be detected by the Complement-Fixation (CF) (102) and immunofluorescence (IF) tests (14). The hemagglutination inhibition (HAI) and serum neutralization (SN) tests can be used to further differentiate specific members of the *Adenoviridae* family (14,21).

Molecular Methods

PCR. The polymerase chain reaction (PCR) has been used to identify adenovirus DNA in tissue specimens and body fluids (14), diluted stool (52,88), air filters (103), swimming pool water (9), sewage, and polluted river water (58). Most primers for PCR have been selected from the hexon coding region because there is an extensive homology among adenovirus serotypes; whereas sequences from the early coding region E1B have been used for the detection of specific adenoviruses (88). Although PCR using hexon primers is more sensitive than culture methods, it may give false-positive results from stool samples of healthy patients. It has been suggested that PCR using these primers may be detecting latent adenoviruses of different types because EIB primers are usually negative in normal individuals (14).

Oligoprobe Hybridization and Restriction Endonuclease Digestion. Adenoviral DNA can be characterized by oligoprobe hybridization (59,94,104) and restriction endonuclease digestion (52,95). In contrast to the relatively small regions of the genome analyzed by either hemagglutination inhibition (HI) or serum neutralization (SN) tests, restriction endonucleases recognize and cleave DNA at specific sequences throughout the viral genome. The sensitivity of restriction endonuclease digestion can be increased by Southern blotting of the DNA restriction digests (105). Depending on the hybridizing probe, DNA from adenovirus isolates can be identified and classified by group or type (14). Hybridization of adenoviral DNA from fecal extracts by the direct-spot method has been successfully used to identify enteric adenoviruses from clinical specimens from patients suffering from gastroenteritis (106).

CONCLUSION

Adenoviruses are important human pathogens causing an array of clinical conditions ranging from asymptomatic infections to fatal illness. These viruses are ubiquitous in sewage-contaminated water and are relatively resistant to environmental stresses. Although their impact on human health, from the environmental point of view in particular as a waterborne organism, has not been fully assessed, evidence suggests that these agents may represent a significant hazard to public health. Further research on detection methods and disinfection procedures could provide the tools to assess the risk that adenoviruses pose for the population more objectively and also to implement actions to reduce their threat to public health.

ADHESION, IMMOBILIZATION, AND RETENTION OF MICROORGANISMS ON SOLID SUBSTRATA

CRISTINA GÓMEZ-SUÁREZ
HENNY C. VAN DER MEI
HENK J. BUSSCHER
University of Groningen
Groningen, The Netherlands

Microorganisms occur in nearly all natural fluid environments on earth and have a strong tendency to become associated with surfaces (1). The interaction mechanism between microorganisms and substratum surfaces involves the physicochemical properties of the interacting surfaces (2) and, in fact, microorganisms can be considered as living colloidal particles with a density slightly greater than that of water, and size of about 1 μm in length or diameter (3). Stable suspensions of microorganisms in dilute electrolytes result, in part, from a mutual electrostatic repulsion between like charges on microbial cell surfaces. Virtually all microorganisms known at present possess a net-negative surface charge at the pH range found in most natural habitats (4), as revealed by zeta potential measurements. The pH dependence of four selected microbial strains are shown in Figure 1. Charge reversal upon association of acidic (carboxyl or phosphate) groups at low pH values is indicative of the presence of charged basic (amino) groups on the cell surface. Microorganisms also exhibit variation in surface-free energies, with some strains being hydrophilic and others being relatively hydrophobic (5). In contrast to inert colloidal particles, however, microorganisms are living microorganisms capable of metabolism, growth, and, in some instances, independent motion. An expression of the metabolism of the microorganisms is the production of various amounts of extracellular polymers (6) that together with flagella, pili, fimbriae, and fibrils (4,7) (Fig. 2) are important in the interaction between microorganisms and solid substrata. Microorganisms can interact with inorganic, living, or dead materials such as plants, animals, artificial structures, rocks, clays, sand grains, and organic remains of living microorganisms in various stages of decomposition.

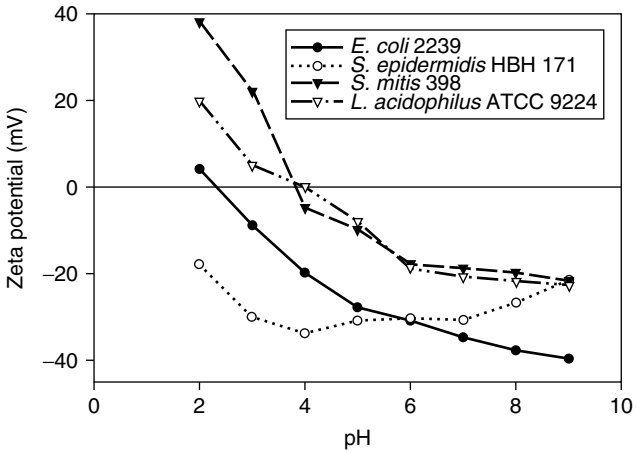

Figure 1. Zeta potentials as a function of pH for *E. coli* 2,239, *Staphylococcus epidermidis* HBH 276, *Streptococcus mitis* BA and *Lactobacillus acidophilus* ATCC 9,224 as measured in 10 mM potassium phosphate, with pH adjusted by addition of HCl or KOH. Data from H. C. van der Mei, R. Bos, H. J. Busscher, and P. S. Handley, in A. Baszkin and W. Norde, eds., Physical Chemistry of Biological Interfaces, Marcel Dekker, New York, 2000, pp. 431–458.

Once microorganisms are attached to a surface, a multistep process starts leading to the formation of a complex, adhering microbial community termed *biofilm*. A biofilm can be defined as a microecosystem in which different strains and species efficiently cooperate to protect themselves against environmental stresses and to facilitate more efficient nutrient uptake (8). Biofilms can be beneficial, for instance, in sewage treatment (9), bioreactors (10), and animal microflora (11). However, biofilms are most frequently unwanted as in food processing (12,13), on ship hulls (14), in drinking water (15) and dairy manufacturing plants (16), in pipelines (17), on biomaterial implants (18), or in the oral cavity (19). Although the function and appearance of biofilms in various environments may be different, all biofilms form from the same basic sequence of events (20), as depicted in Figure 3.

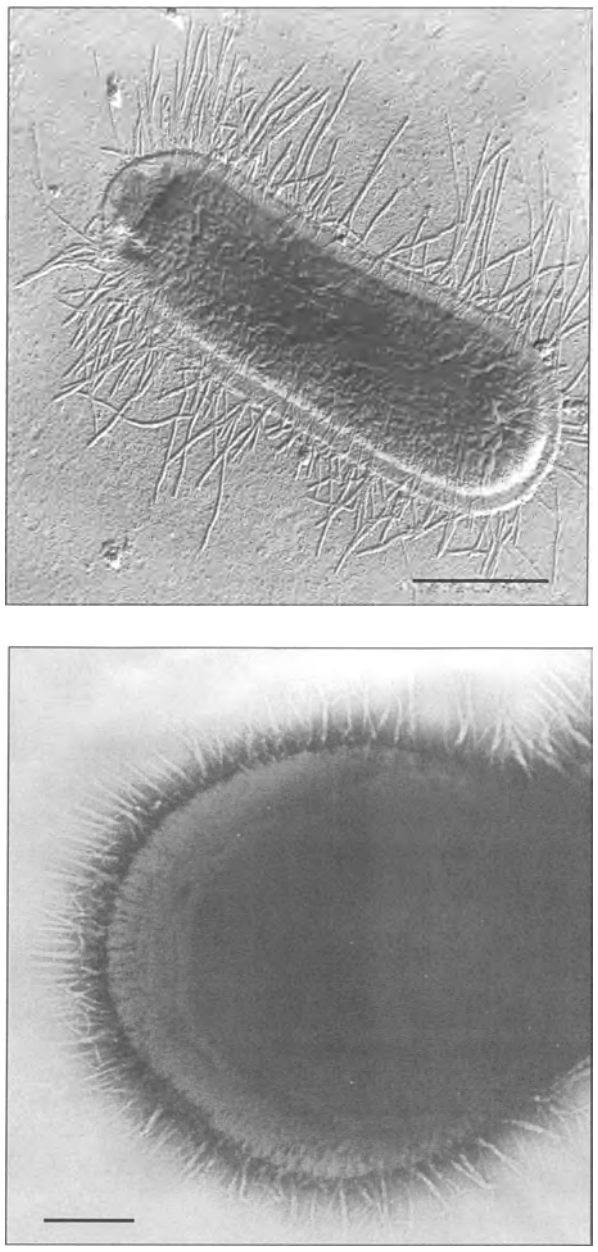

Figure 2. Electron micrographs of (**a**) *E. coli* with rigid, peritrichous fimbriae, approximately 7 nm in diameter and up to 1.0 μm length. Cells are shadowed with palladium. Bar marker represents 0.5 μm; (**b**) *Streptococcus salivarius* showing peritrichous clumped fibrils with a length of 191 nm. Cells are negatively stained with 1% methylamine tungstate. Norde, eds., *Physical Chemistry of Biological Interfaces*, Marcel Dekker, New York, 2000, pp. 431–458.

When organic matter is present in an aqueous environment (e.g., blood, saliva, tear fluid, seawater, milk, or urine), a so-called *conditioning film* of adsorbed components (i.e., proteins and other organic molecules) is formed on the substratum surface before adhesion of microorganisms, because molecules diffuse much faster than microorganisms (21). As a second step, microorganisms are transported toward the solid surface through diffusion, convection, sedimentation, or by intrinsic motility. Alternatively, planktonic (suspended) microorganisms may be transported toward each other to form microbial coaggregates (22) and subsequently adhere, or a few sessile (already adhering) microorganisms may stimulate coadhesion of planktonic microorganisms (23). In later stages, microbial anchoring occurs through extrapolymer (i.e., polysaccharides) production (6,24) and eventually, adhering microorganisms start to grow, which is the main contributing factor for the accumulation of microorganisms in a biofilm.

The thermodynamic theory (25,26) considers the surface-free energies of the solid substratum, the microbial cell surface, and the suspending medium yielding the interfacial free energies between the interacting surfaces, as schematically illustrated in Figure 4. Accordingly, this comparison is expressed in the so-called free energy of adhesion

$$\Delta G_{\mathrm{adh}} = \gamma_{\mathrm{sm}} - \gamma_{\mathrm{sl}} - \gamma_{\mathrm{ml}} \qquad (1)$$

where γ_{sm}, γ_{sl}, and γ_{ml}, are the interfacial free energies, where "s" denotes the substratum, "m" the microbial cell surface and "l" the liquid surface. Adhesion is thermodynamically favorable if ΔG_{adh} is negative, because systems tend to minimize their free energy, whereas adhesion is energetically unfavorable when ΔG_{adh} is greater than zero.

A three-point hypothesis of microbial interaction mechanisms (27) related to the distance between the microbial cell and substratum surfaces is schematically illustrated in Figure 5. At large separation distances (>50 nm), only Lifshitz-Van der Waals forces are operative. Upon closer approach, both Lifshitz-Van der Waals and electrostatic forces (i.e., nonspecific interactions) occur for separation distances between 10 to 20 nm. Finally, at near contact, Lifshitz-Van der Waals forces, electrostatic and acid-base interactions, and so-called specific interactions dictate adhesion. Specific interactions may be defined as the interactions between stereochemically complementary surface components and act over extremely short distances allowing specific ionic, hydrogen, and possibly chemical bonds to form.

In this paper, a distinction is made among adhesion, immobilization, and retention of microorganisms on substratum surfaces, and the importance to make such a distinction is exemplified. A microorganism adheres to a substratum surface when it maintains the same separation distance from the substratum surface as a function of time through a balance of attractive and repulsive interactions homogeneously acting over an entire substratum surface. Consequently, adhering microorganisms are still free to move parallel to the substratum as opposed to immobilization. Immobilized microorganisms adhere to substratum surface but are kept at the same position by immobilization forces acting parallel to the surface. Often, both in natural habitats and in laboratory experiments, adhering microorganisms are challenged by external forces yielding detachment of all or subpopulations of adhering organisms. Retention will be explained to as the capacity of adhering microorganisms to remain

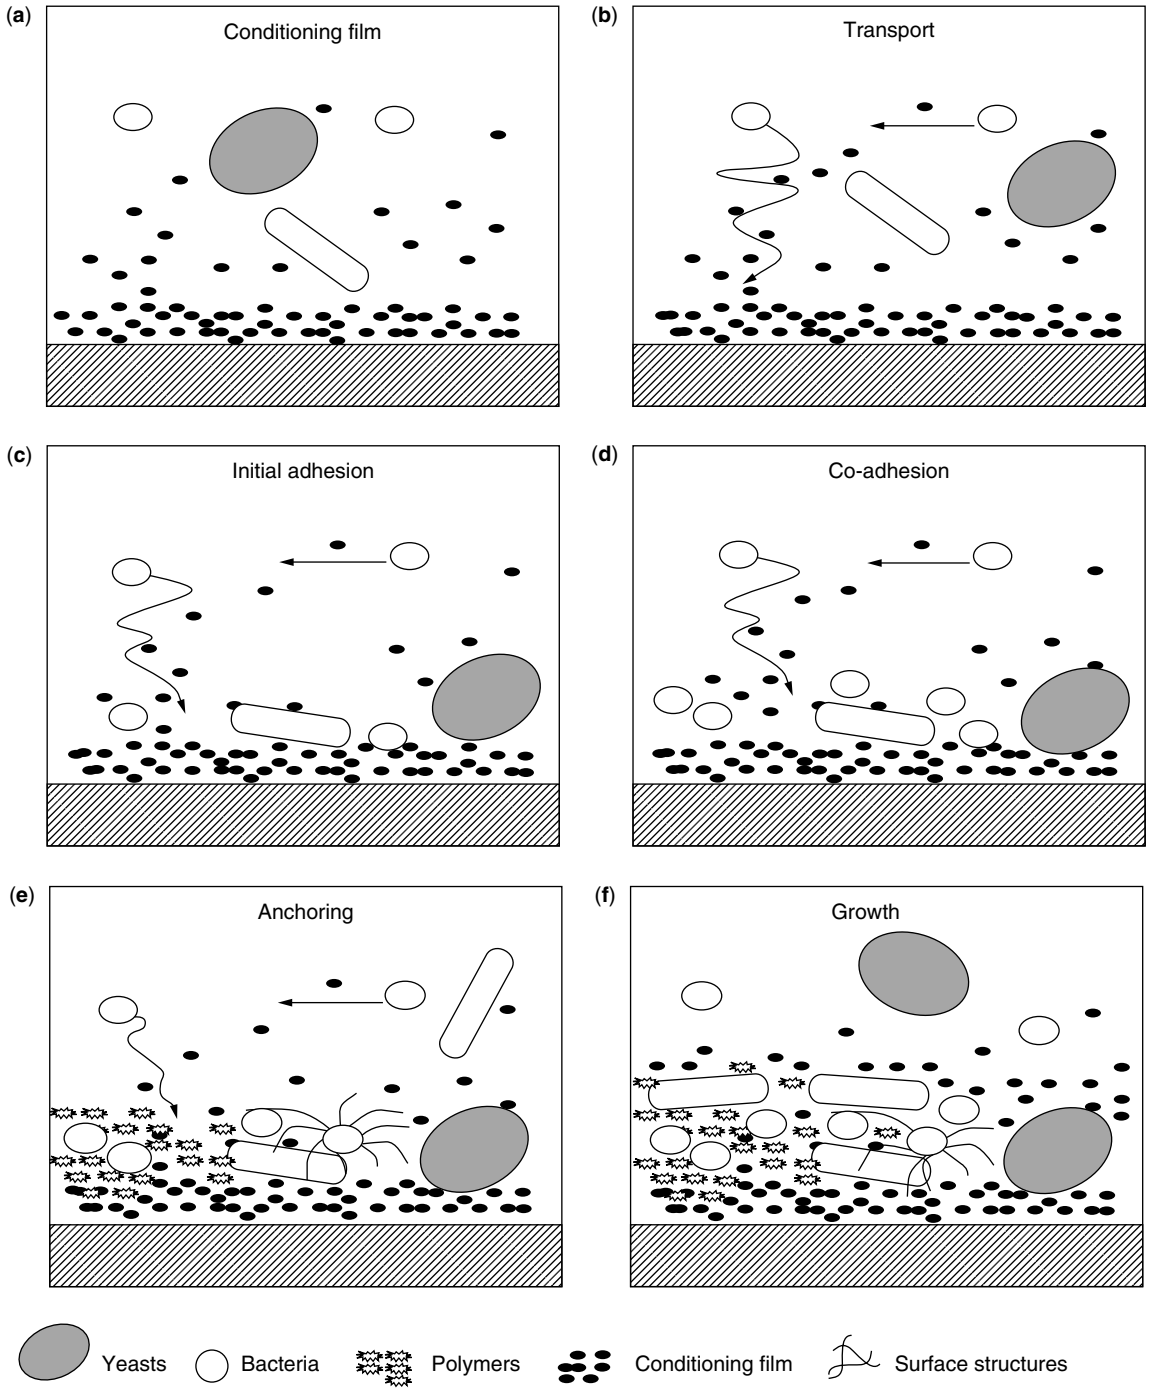

Figure 3. Sequential steps in the formation of a biofilm on a solid substratum. (**a**) Adsorption of conditioning film components. (**b**) Microbial transport and coaggregation. adhering after having been submitted to an external force other than their mutual interaction.

ADHESION AND THE DLVO THEORY

The perpendicular interaction between microorganisms and a substratum surface consists of Lifshitz-Van der Waals, electrostatic, and acid-base components. In the original theory by Derjaguin, Landau, Verwey, and Overbeek (the classical DLVO theory), microbial adhesion is described as a balance between attractive Lifshitz-Van der Waals and repulsive or attractive electrostatic forces. Accordingly, the interaction energies between

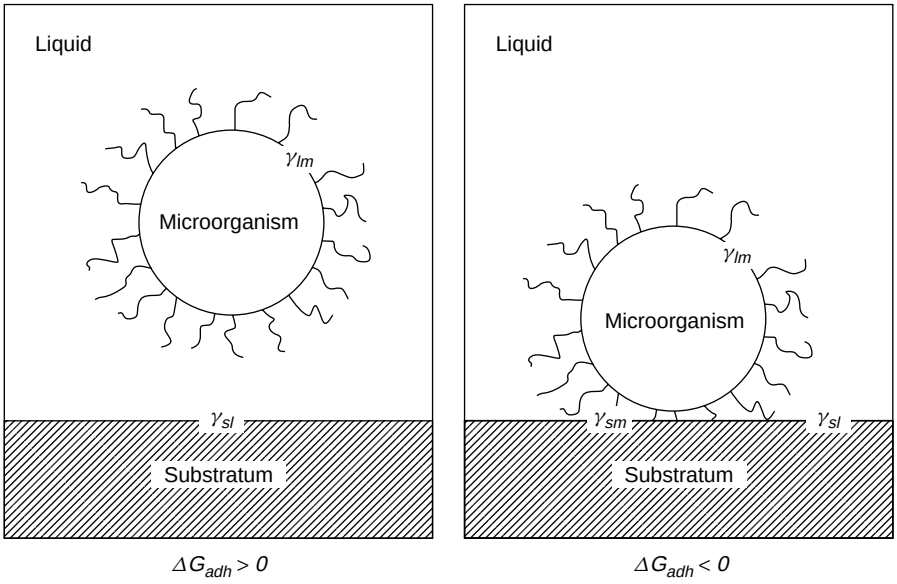

Figure 4. Schematic presentation of the interfacial free energies (γ_{ij}) involved in the adhesion of a microorganism to a solid substratum surface from a liquid suspension. The solid-microorganism (γ_{sm}), the solid-liquid (γ_{sl}), and the microorganisms-liquid (γ_{ml}) interfacial free energies are indicated.

microorganisms and substratum surfaces as a function of their separation distance (d) can be expressed as (28–30)

$$G^{TOT}(d) = G^{LW}(d) + G^{EL}(d) \tag{2}$$

where G^{TOT}, G^{LW}, and G^{EL} denote the total, the Lifshitz-Van der Waals, and the electrostatic interaction energies, respectively (31,32).

Lifshitz-Van der Waals Interactions

The Lifshitz-Van der Waals interaction between a microorganism and a solid surface at separation distances small enough to ignore retardation effects is given by

$$G^{LW}(d) = -\frac{A}{6}\left[\frac{a}{d} + \frac{a}{d+2a} + \ln\left(\frac{d}{d+2a}\right)\right] \tag{3}$$

where A denotes the Hamaker constant (i.e., an indication of the polarizability of the interacting surfaces) and a is the radius of the microorganism. The Hamaker constant depends on the nature of the interacting media. For the interaction of a microorganism (m) with a substratum (s) in a liquid medium (l), A is (29)

$$A_{msl} = (A_{ss}^{(1/2)} - A_{ll}^{(1/2)})(A_{mm}^{(1/2)} - A_{ll}^{(1/2)}) \tag{4}$$

In most cases, A is positive (attractive Lifshitz-Van der Waals forces), because in aqueous systems A_{ss} is greater than A_{ll} and A_{mm} is greater than A_{ll}, and consequently G^{LW} is less than zero.

Electrostatic Interactions

In aqueous media, electrostatic interactions are present in addition to Lifshitz-Van der Waals forces. These forces arise from the electrical surface charge of microorganisms and substratum surfaces, and can be influenced by introducing an electrolyte into the liquid phase, yielding changes in the electrostatic double layer at a surface (33,34). Electrostatic double-layer attraction or repulsion arises from the interpenetration of interacting double layers, and assuming constant potentials during interactions it is given by

$$G^{EL}(d) = \pi\varepsilon a(\zeta_m^2 + \zeta_s^2)\left\{\frac{2\zeta_m\zeta_s}{\zeta_m^2 + \zeta_s^2}\ln\frac{1+\exp(-\kappa d)}{1-\exp(-\kappa d)} + \ln[1-\exp(-2\kappa d)]\right\} \tag{5}$$

where ε denotes the permittivity of the medium, ζ_m and ζ_s the zeta potential of microorganism and substratum, respectively, and κ^{-1} is the double layer thickness, and constant potentials are considered. κ^{-1} depends on the total ion concentration in the solution and can be calculated from

$$\kappa = \left[\frac{e^2}{\varepsilon kT}\sum_i z_i n_i\right]^{(1/2)} \tag{6}$$

where e denotes the electron charge, k the Boltzmann constant, T the absolute temperature, z_i is the valence of the ions present and n_i is the number of ions per unit volume. For a symmetrical 1-1 electrolyte this equation reduces to

$$\kappa = 0.328 \times 10^{10}(z_i^2 M_i)^{(1/2)} \tag{7}$$

where M_i is the molarity (mol/L) of the ions.

Figure 6 illustrates the decay with the distance of the Lifshitz-Van der Waals and electrostatic energies between a charged microorganism and a substratum surface for repulsive electrostatic interactions (i.e., like charges) at different ionic strengths. It can be seen that at low ionic strengths (Fig. 6a), a high-energy barrier has to be overcome if the microorganisms are to come in close contact with the surface. At intermediate ionic strengths (Fig. 6b), the energy barrier, although still present,

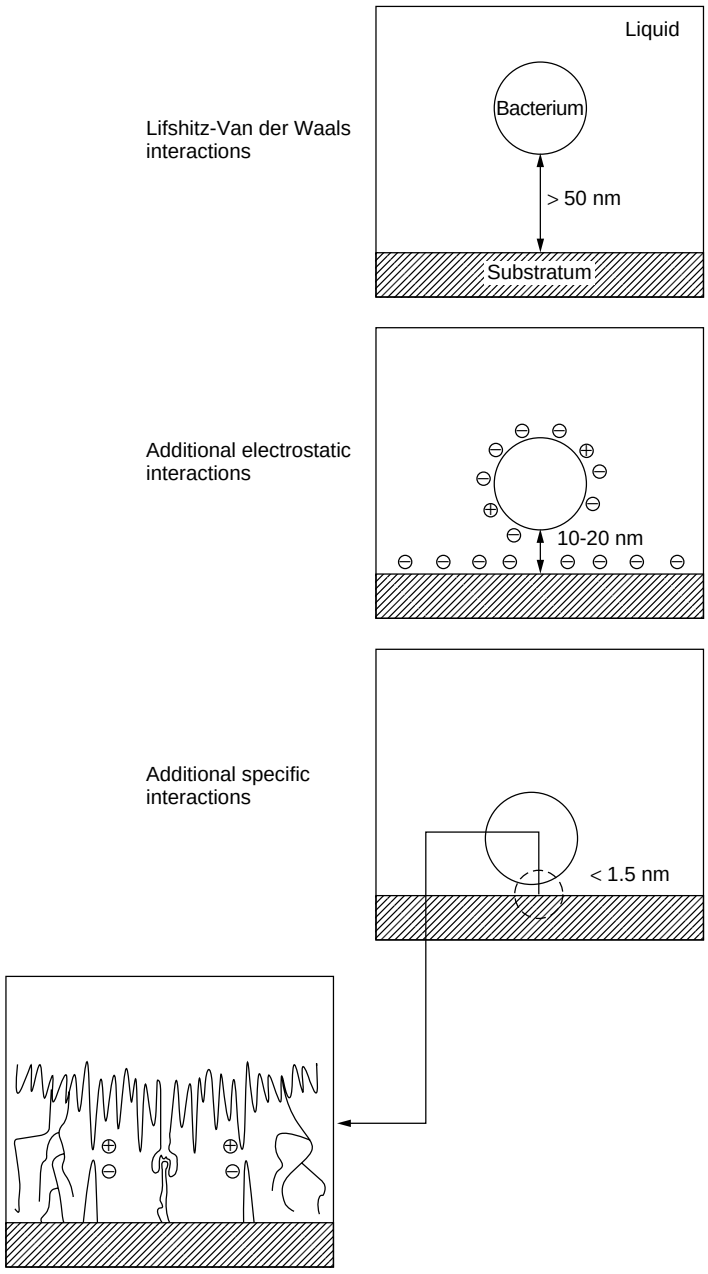

Figure 5. Three-point hypothesis of bacterial adhesion mechanisms related to the distance of the bacterium from the substratum surface. Adapted from H. J. Busscher and A. H. Weerkamp, *FEMS Microbiol. Rev.* **46**, 165–173 (1987).

is lower and microorganisms can become reversibly captured in a so-called *secondary minimum*. At high ionic strengths (Fig. 6c), the energy barrier disappears and a strong net attraction exists between microorganisms and the substratum surface at all separation distances. Microorganisms held in the deep primary interaction minimum are frequently considered to adhere irreversibly. Alternatively, Figure 7 depicts the interaction energies as a function of separation distance at different ionic strengths for unlike microbial and substratum surface charges. The net effect is a strong attraction regardless of separation distance, which decreases with the increasing ionic strength.

In summary, the Lifshitz-Van der Waals interaction between suspended microorganisms and a surface is not influenced by the ionic strength of the suspension, but both the range and the magnitude of the electrostatic interactions decrease with an increasing ionic strength.

The Extended DLVO Theory

The classical DLVO theory has been extended by Van Oss and coworkers (35) and recently related to the origin of hydrophobic interactions in microbial adhesion (36). The extended DLVO theory considers four fundamental, noncovalent interactions: Lifshitz-Van der Waals, electrostatic, Lewis acid-base, and Brownian motion forces.

Acid-Base Interactions

Acid-base interactions originate from electron-donating and electron-accepting interactions between polar moieties in aqueous solutions. The decay with separation

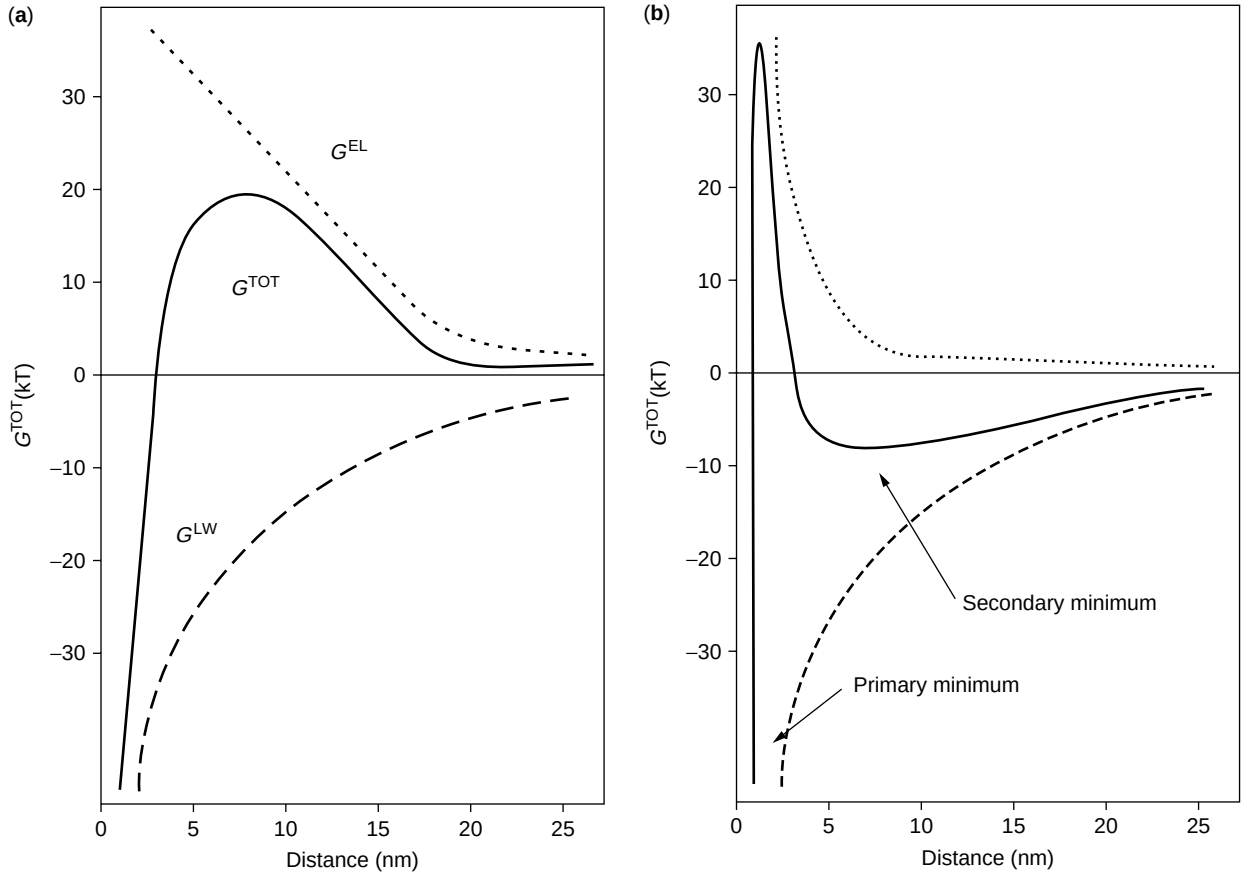

Figure 6. Interaction energy curves (classical DLVO theory) of a microorganism with a solid surface of like charge versus their separation distance for (**a**) low (i.e., one mM), (**b**) intermediate (i.e., 10 mM) or (**c**) high (i.e., 100 mM) ionic strength of the medium.

distance of the acid-base interaction energy (G^{AB}) between a microorganism and a substratum surface can be expressed as

$$G^{AB}(d) = 2\pi a\lambda\Delta G^{AB}_{adh}\exp\left[\frac{d_0 - d}{\lambda}\right] \qquad (8)$$

where ΔG^{AB}_{adh} is the acid-base interfacial free energy of adhesion, d_0 is the distance of closest approach between two surfaces 1.57 Å according to (37), and λ denotes the correlation length of molecules in a liquid medium and varies with the ionic strength and with the sign of ΔG^{AB}_{adh}. For ΔG^{AB}_{adh} less than zero ('hydrophobic attraction'), λ may be as large as 13 nm. For situations of *hydrophilic repulsion* ($\Delta G^{AB}_{adh} > 0$) λ equals 0.6 nm (38). The acid-base free energy of adhesion can be obtained from the following expressions

$$\Delta G^{AB}_{adh} = -2\left(\sqrt{\gamma^{AB}_{mv}} - \sqrt{\gamma^{AB}_{lv}}\right)\left(\sqrt{\gamma^{AB}_{sv}} - \sqrt{\gamma^{AB}_{lv}}\right) \qquad (9)$$

where γ^{AB}_{mv}, γ^{AB}_{lv}, and γ^{AB}_{sv} are, respectively, the microorganism-vapor, liquid-vapor, and substratum-vapor acid-base interfacial free energies, or from

$$\Delta G^{AB}_{adh} = +2\Big[\left(\sqrt{\gamma^{+}_{mv}} - \sqrt{\gamma^{+}_{sv}}\right)\left(\sqrt{\gamma^{-}_{mv}} - \sqrt{\gamma^{-}_{sv}}\right) - \left(\sqrt{\gamma^{+}_{mv}} - \sqrt{\gamma^{+}_{lv}}\right)\left(\sqrt{\gamma^{-}_{mv}} - \sqrt{\gamma^{-}_{lv}}\right) - \left(\sqrt{\gamma^{+}_{sv}} - \sqrt{\gamma^{+}_{lv}}\right)\left(\sqrt{\gamma^{-}_{sv}} - \sqrt{\gamma^{-}_{lv}}\right)\Big] \qquad (10)$$

where γ^- and γ^+ denote the electron-donating and electron-accepting parameters of the interfacial free energy, respectively.

Figure 8 illustrates the decay with the distance of the interaction energies in the extended DLVO theory between a microorganism and a substratum surface for apolar, monopolar, and bipolar surfaces under conditions of electrostatic repulsion. It can be seen that the influence of acid-base interactions is quite strong compared with electrostatic and Lifshitz-Van der Waals interactions. However, the acid-base interactions are only relatively short-ranged, and a close approach between interacting surfaces is required for these forces to become operative, which may well be impeded in microbial adhesion because of the different structural features on microbial cell surfaces (39).

IMMOBILIZATION: PERPENDICULAR AND LATERAL INTERACTIONS

In the case of adhesion, the main body of a microbial cell is held at a small, but finite, distance from the

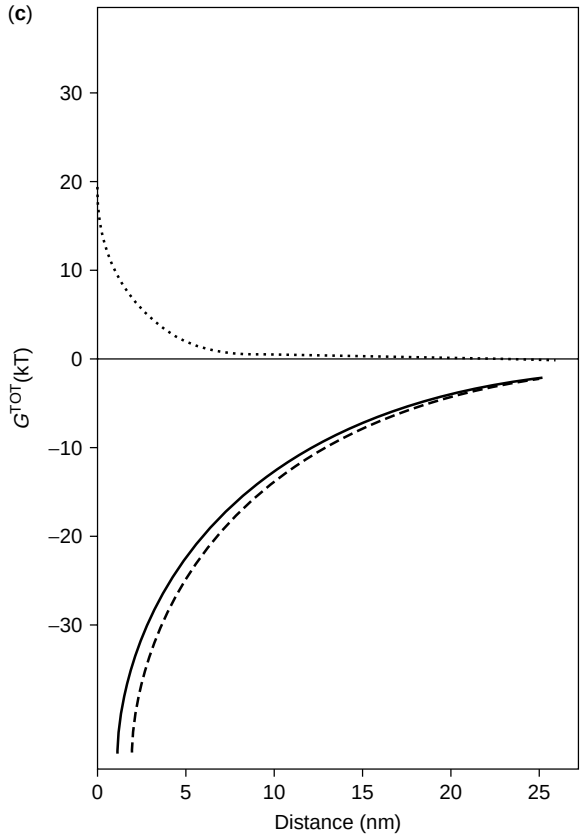

Figure 6. (*Continued*)

substratum surface by a balance between interaction forces acting perpendicular to the surfaces. Regardless of whether this position above the substratum surface is occupied in a reversible or irreversible fashion, the balance of forces acting perpendicular to the surface does not ensure immobilization of adhering organisms along the surface, which requires lateral interaction forces. As a consequence, mobile adhesion is not solely a property of the so-called mobile bacteria, but of all colloidal particles adhering on a surface in the absence of lateral interaction forces. The distinction between adhesion and immobilization is best illustrated by comparing the ease with which a magnet adhering on a smooth metal surface can be slid over the surface with the force required to pull the magnet off the surface (see Fig. 9).

Mobility of adhering microorganisms is due to forces on the adhering microorganisms acting laterally along the substratum surface and not due to perpendicular interactions between an adhering microorganism and a substratum surface (40). Accordingly, adhering microorganisms can be sheared, they can diffuse, or they can actively swim freely, laterally until they encounter a sticky patch on the surface (chemical heterogeneity) or become mechanically trapped in "rugosities."

Ideally Homogeneous and Smooth Substrata

On ideally homogeneous and smooth surfaces (see Fig. 10), the only lateral interactions operative result from a multibody DLVO interaction between all adhering bacteria, because the substratum surface cannot exert any lateral force. A lateral interaction minimum between microorganisms occurs at large separation distances (500 nm) and is extremely shallow (about 0.1 kT) as compared with the deep (i.e., 12 kT) perpendicular interaction minimum occurring at heights of around 6 nm above the substratum surface (see Fig. 10). Consequently, regardless of the strength of the perpendicular interactions, microbial adhesion is always mobile on ideally homogeneous and smooth surfaces.

Chemically Heterogeneous Substrata

Virtually all substratum surfaces contain chemical heterogeneities at a submicron level, which can be demonstrated by contact-angle hysteresis (41). Their importance in particle adhesion has recently been demonstrated by Wit and Busscher (42), showing that colloidal particles have a strong preference to deposit at the same locations on a substratum surface in repeated deposition experiments after detachment of the adhering particles. Different chemistries along a substratum surface yield different DLVO interaction energies with adhering microorganisms, as shown in Figure 11a, and secondary interaction minima with different depths are found for hydrophilic and hydrophobic regions on the surface, from which a lateral interaction force develops, driving adhering organisms to a location of minimum interaction energy, that is, the site with the deepest interaction minimum is occupied. The lateral interaction energy $dG = (G_2 - G_1)$ for a chemical heterogeneity in the example amounts to about -5 kT (see Fig. 11b), which is more than the lateral interaction energy on an ideally homogeneous and smooth surface (0.1 kT, compare with Fig. 10b).

Substratum Roughness

Because of rugosities on a substratum surface, macroscopically lateral interaction forces can arise from perpendicular interactions and stimulate immobilization. Microorganisms adhering near structural heterogeneities on a substratum surface have an energetically less favorable situation than when adhering on an overall smooth surface (43). Mobility on a rough surface is driven by a lateral interaction energy, which depends on the size of the rugosities and can be estimated to amount to several kTs in magnitude. In Figure 11b, it can be seen that lateral mobility of a microorganism adhering on a rough surface is inevitably associated with a change in the perpendicular position with respect to the overall substratum surface from which the majority of the interaction forces occur (44).

It is important to make a distinction between micrometer roughness and nanometer roughness, because new developed techniques (i.e., atomic force microscopy) permit the measurement of such values (45). A bacterial cell (size of about a micrometer) will interact laterally with a micrometer roughness and stipulate its mobility over the substratum. On the other hand, if the substratum surface has a roughness at a nanometer scale, the bacterial cell will not interact laterally with such rugosity and might even be repelled by it (46).

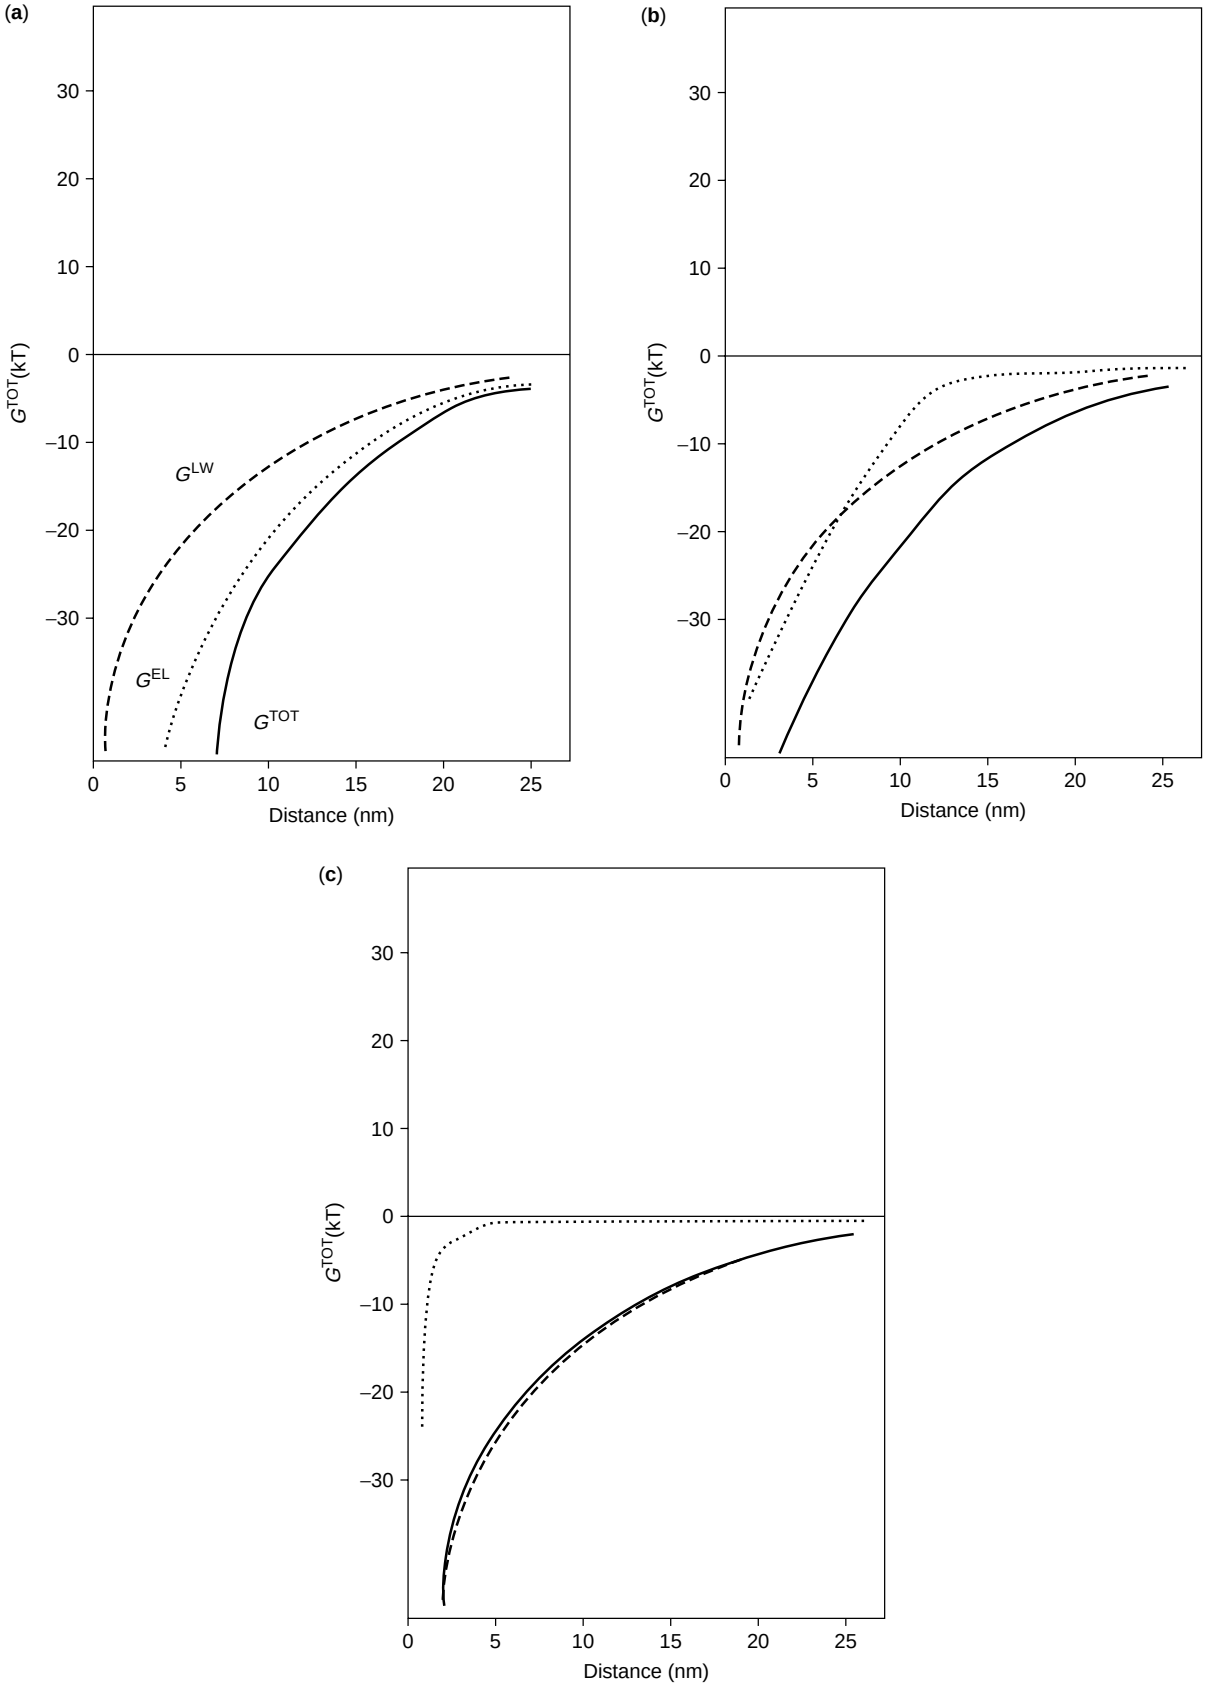

Figure 7. Interaction energy curves (classical DLVO theory) of a microorganism with a solid surface of unlike charge versus their separation distance for (**a**) low (i.e., 1 mM), (**b**) intermediate (i.e., 10 mM), or (**c**) high (i.e., 100 mM) ionic strength of the medium.

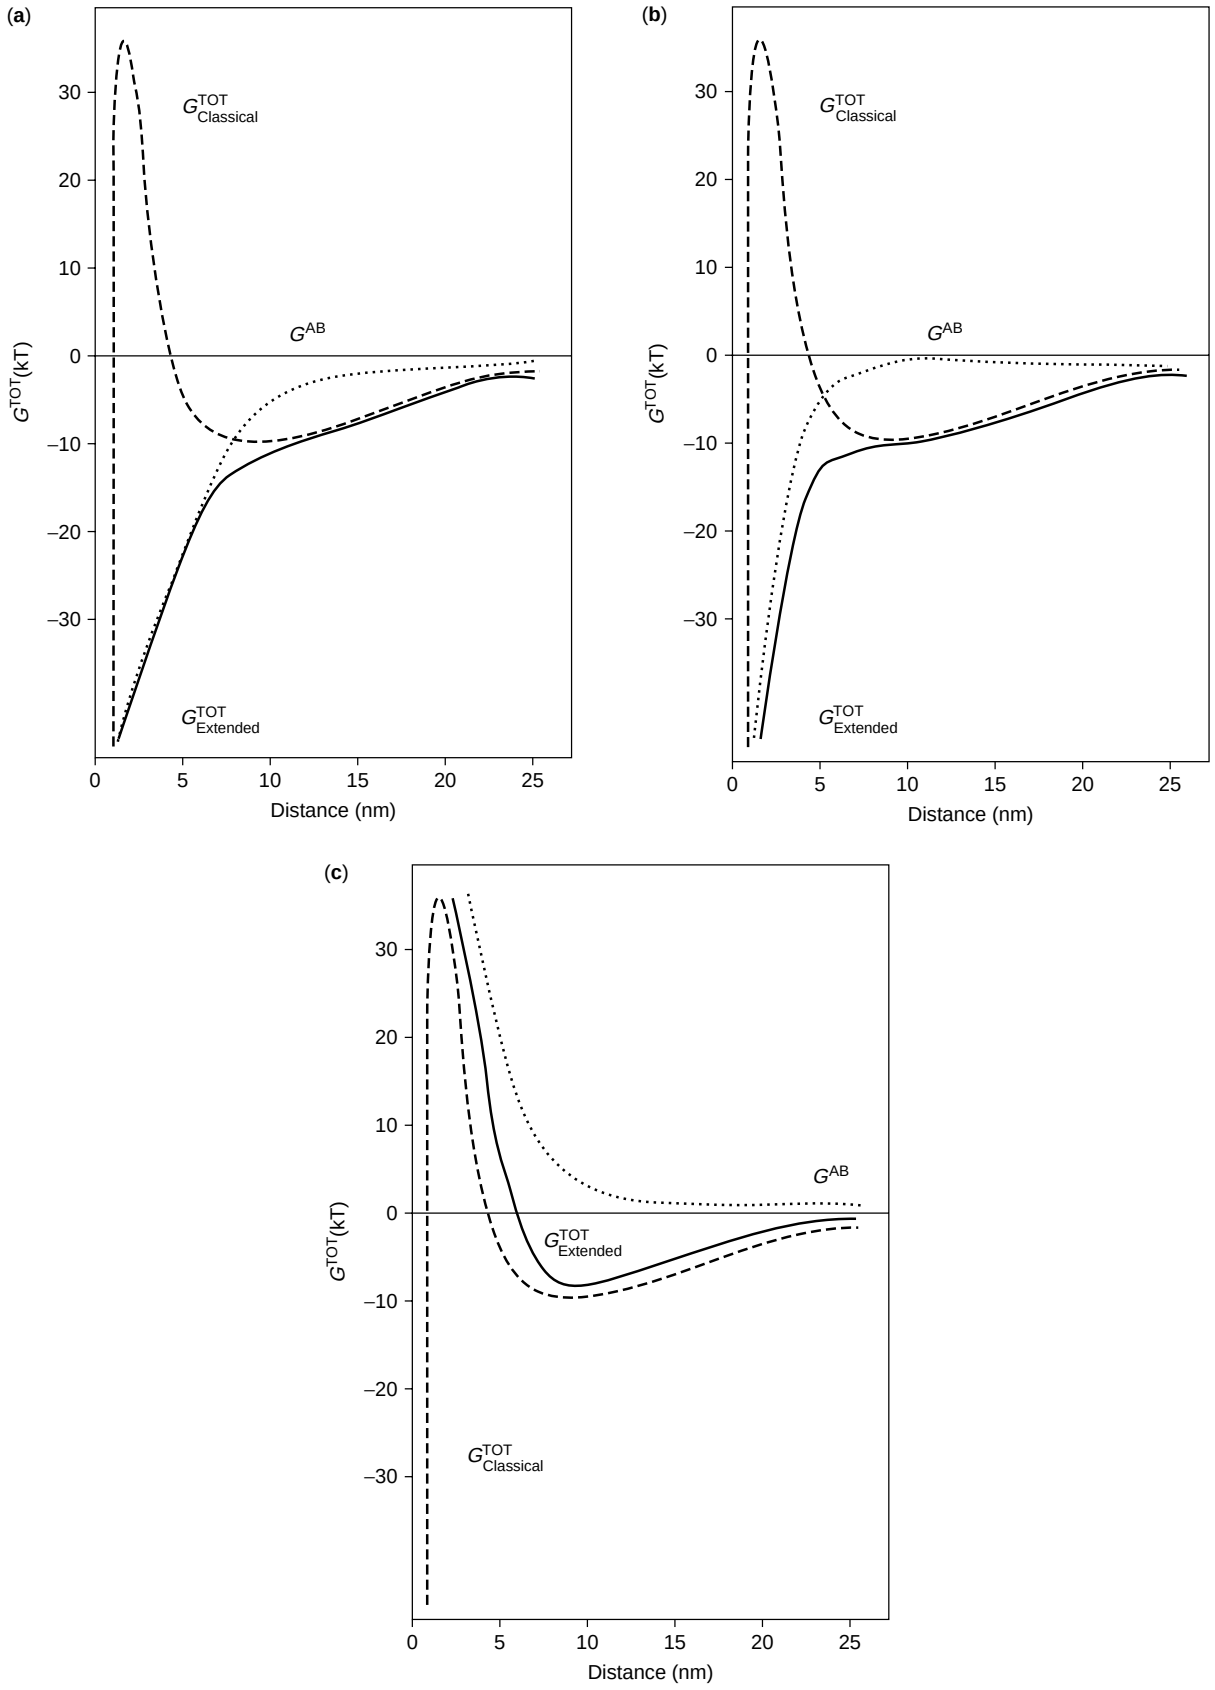

Figure 8. A comparison of the interaction energies according to the classical and extended DLVO theory between a microorganism and a solid substratum as a function of the separation distance for (**a**) apolar, (**b**) monopolar, and (**c**) bipolar surfaces.

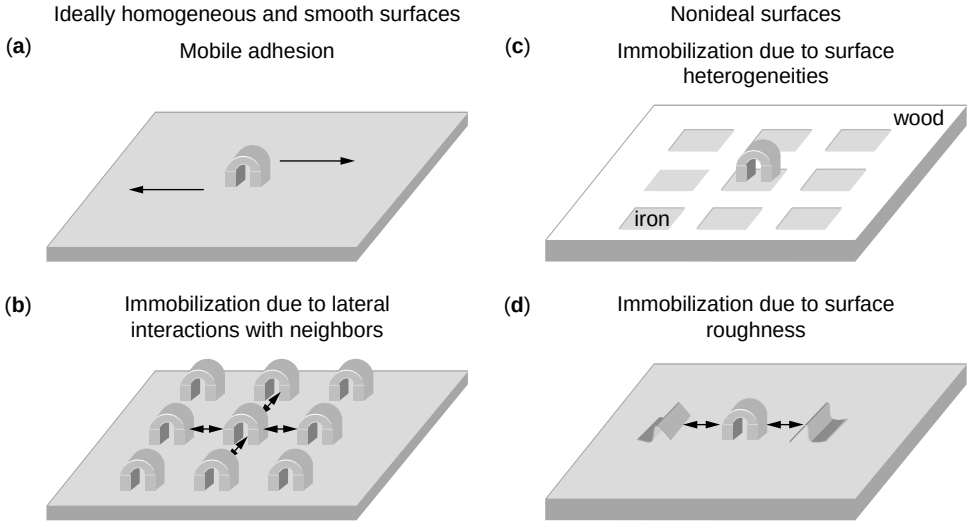

Figure 9. Motility of bacteria is, from a physicochemical point of view comparable with the interaction of a magnet with a metal plate. On an ideally homogeneous and smooth surface: (**a**) when a magnet can be easily slid over the surface of a metal plate, one speaks of adhesion without immobilization, (**b**) when a magnet is not free to move over the surface because of lateral interactions with neighbors, there is immobilization. On a nonideal surface: (**c**) Immobilization may result from lateral interaction forces as a result of heterogeneities on the metal surface, (**d**) surface roughness can provoke immobilization as a result of lateral interactions with the magnet.

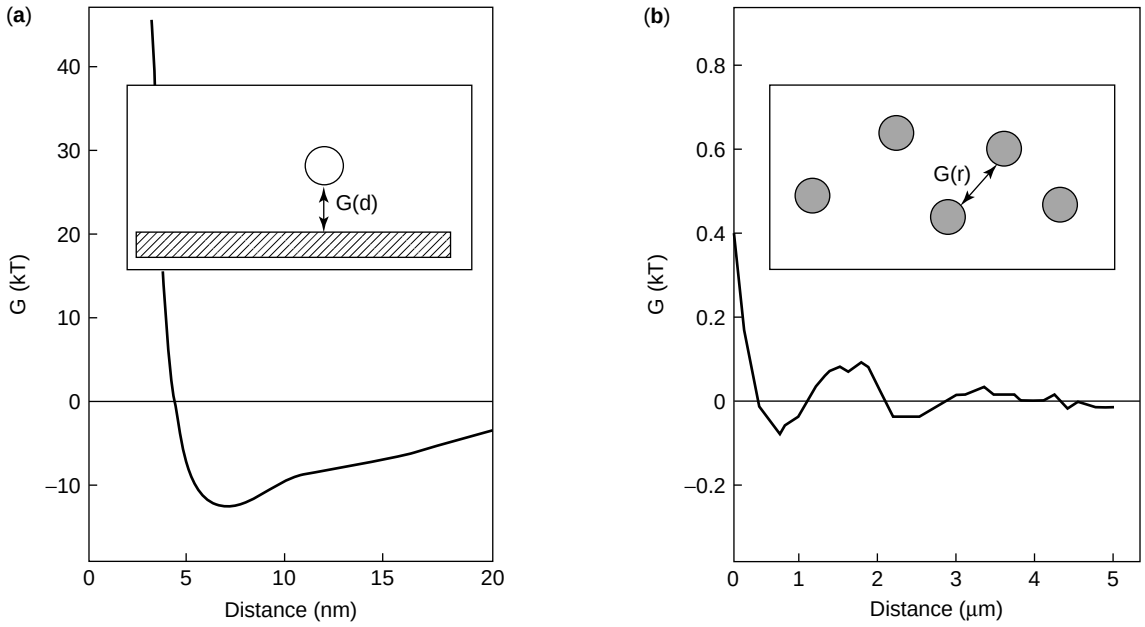

Figure 10. (**a**) The interaction energy $G(d)$ according to the extended DLVO theory as a function of separation distance between a microorganism and an ideally homogeneous and smooth, hydrophilic, and negatively charged model surface. (**b**) The lateral interaction energy $G(r)$ as a function of separation distance among microorganisms (r) is calculated from the radial pair distribution of the adhering microorganisms. With permission from H. J. Busscher, A. T. Poortinga, and R. Bos, *Curr. Microbiol.* **37**, 319–323 (1998).

Polymer and Other Short-Range Interactions

The surfaces of bacteria are covered with a variety of polymers, which differ from one species to another (47). The surfaces of gram-negative bacteria are mainly covered by lipopolysaccharides, surface proteins, or capsules of extracellular polysaccharides, whereas on gram-positive cells, lipoteichoic, teichoic, and teichuronic acids, mycolic acids, capsules of extracellular polysaccharides, and proteins can be present (48). Polymer interactions can be attractive or repulsive (49) and arise when bacterial

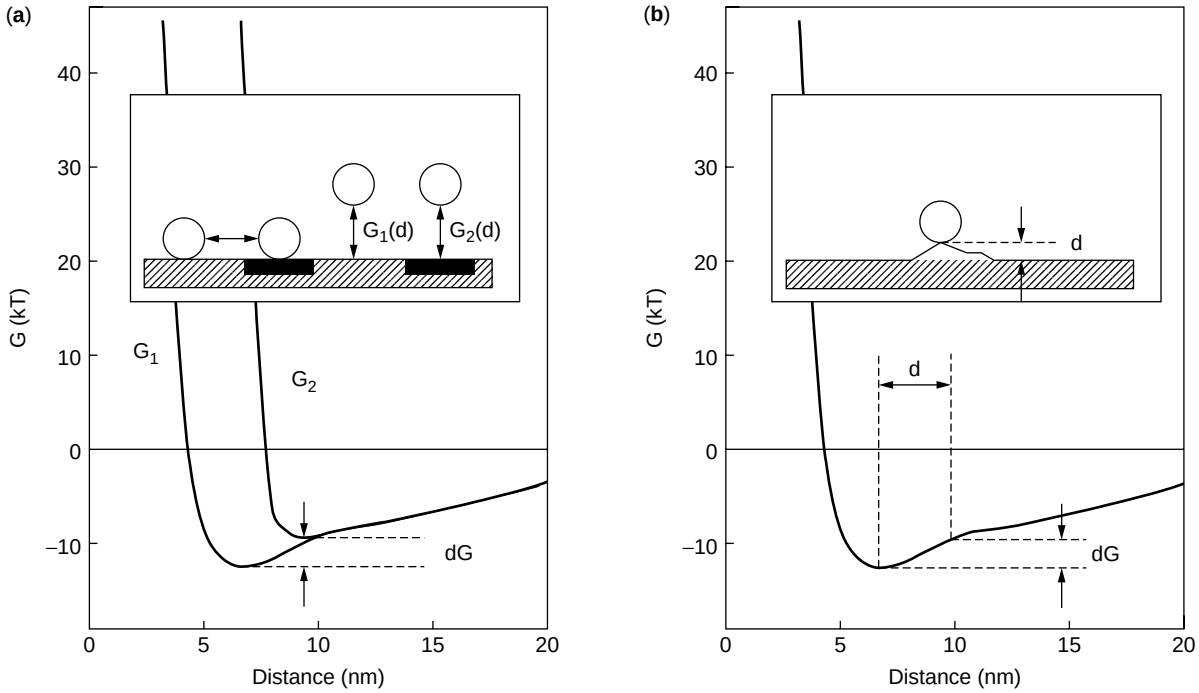

Figure 11. Interaction energies $G(d)$ of a microorganism, according to the extended DLVO theory, as a function of separation distance with different regions on a heterogeneous substratum surface. (**a**) Hydrophobic patches on a hydrophilic surface exert different interaction energies on an approaching microorganism, yielding a lateral interaction between the adhering microorganisms. (**b**) Microorganisms adhering on structural heterogeneities on a substratum experience lateral interaction forces on a macroscopic scale. *NB*. Organisms and heterogeneities are not drawn to scale. surface polymers have a high affinity for the solid surface and are long enough to reach and adsorb to the surface (see Fig. 12a). Such polymers may bridge the distance between a substratum surface and the microbial cell body, the latter of which is kept at a larger distance by electrostatic repulsion (30). If polymer interactions are site-specific on the substratum surface, they do not only assist in adhesion but also in immobilization. Excessive polymer production by bacteria may serve to effectively disperse bacteria in suspension and prevent them from adhering to a surface, as shown in Fig. 12b (50,51).

Short-range interactions arise upon direct contact between bacteria and solid substrata. Often these site-specific interactions involve covalent bonds, requiring 40 to 200 kT (52) to break, which is considerably more than, for instance, hydrogen bonds that can be disrupted at the expense of only 4 to 16 kT (53).

Motile Bacteria

Motility of adhering bacteria has been described so far from a physicochemical point of view, but motile bacteria constitute a special class of microorganisms in this respect. Depending on their orientation when approaching a substratum surface, bacteria (i.e., some strains of *Escherichia coli* and *Pseudomonas aeruginosa*) may exhibit a continuous gyratory motion around the pole of the cell or a propeller-like motion (54). Some motile bacteria near or adhering to a surface are able to overcome

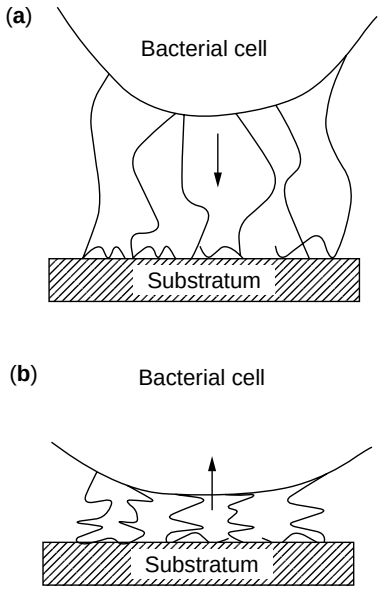

Figure 12. (**a**) Attractive polymer interaction occurs when bacterial polymers have affinity for the solid surface and are long enough to reach and adsorb to the surface. As a consequence, these polymers bridge the distance separating surface and bacterial cell. (**b**) On the other hand, when the bacterial cell produces an excessive amount of polymers, a repulsive polymer interaction occurs, which tends to keep the bacterial cell far from the substratum surface.

the attractive forces at the secondary minimum and swim away (55,56), often becoming reversibly attached at other sites. Gliding and near-surface swimming bacteria are a mobile form of microbial adhesion, as discussed earlier, with the major difference that the lateral interaction forces for mobile behavior now originate from the organism itself.

RETENTION

The balance between repulsive and attractive interactions in microbial adhesion is a delicate one and can be easily disturbed by dynamic factors in the natural microbial habitat or by experimental conditions in the laboratory. External forces other than the interaction forces between adhering microorganisms and a substratum surface frequently cause detachment of all or subpopulations of adhering organisms. Therefore, in natural habitats and experimental systems, microbial retention more readily occurs as a dominant factor in biofilm formation than microbial adhesion. Unfortunately, the distinction is not well made in microbial adhesion research (see section on Materials and methods, which mentions that "surfaces with adhering microorganisms were slightly rinsed to remove loosely adhering organisms.") Instead, a definition of "loosely adhering" should be given, along with a quantitative indication of the rinsing forces, although finally, such papers should be written in terms of microbial retention rather than adhesion. The reluctance of authors to do so greatly contributes to the inability of researchers in the field to compare microbial adhesion data, whereas, in fact, in many natural habitats, most notably the oral cavity, retention is more important than adhesion (57).

Methods to study microbial adhesive interactions (58,59) are summarized in Table 1, together with a critical evaluation of whether adhesion or retention is actually studied. In all the methods involving dipping, rinsing, and washing steps (60), adhering microorganisms are exposed to extremely large detachment forces provoked by the surface tension at the passing liquid-air interface (see Fig. 13). A significant detachment of adhering microorganisms can result from the passage of a liquid-air interface over adhering microorganisms depending on the velocity of the passing liquid-air interface, the surface tension at the liquid-air interface, the number of passing interfaces, hydrophobicity, the charge of the interacting surfaces, and the size of the microorganisms (60–62). As most of the methods summarized in Table 1 actually involve the passage of a liquid-air interface, retention of adhering microorganisms is measured in these assays rather than adhesion.

CONCLUSION

The interaction between microorganisms and substratum surfaces is mediated by different types of interaction forces. A distinction should be made with regard to the type of interaction according to:

1. adhesion, mobile or immobile, of microorganisms on substratum surfaces as a result of a balance between Lifshitz-Van der Waals, electrostatic, Lewis acid-base, and Brownian motion forces;
2. immobilization of adhering microorganisms on a substratum surface due to the lateral interaction forces, polymer bridging, or chemical bonds that keep an adhering microorganism at a certain location on a substratum surface;
3. retention of adhering microorganisms, denoting microorganisms that remain adhering on a substratum surface after application of an external force.

It is important to distinguish between adhesion, immobilization, and retention for a proper interpretation of experimental results. Real-life biofilm formation often

ADHESION (PRIMARY) OF MICROORGANISMS ONTO SURFACES

CHRISTOPHE J. P. BOONAERT
YVES F. DUFRÊNE
PAUL G. ROUXHET
Université catholique de Louvain
1348 Louvain-la-Neuve, Belgium

Microbial adhesion and biofilm formation are widespread phenomena that play a crucial role in natural environments as well as in industrial processes. Natural surfaces on which microbial adhesion occurs vary from inanimate materials to living tissues. In aquatic habitats, microorganisms accumulate on other living organisms, suspended particles, rocks, and sediments. Soil particles, often coated by clay minerals, metal oxides, and organic matter, constitute another complex microbial habitat. Biofilm formation has a deleterious effect in many situations (commonly called biofouling): decrease of heat transfer on heat exchangers, increase of pressure drop in pipelines, corrosion enhancement, and source of bacterial contamination (1). Development of biofilms on medical devices often requires their surgical replacement (2). Removal of biofilms using biocides (3) or antibiotics (2) is often a difficult task due to the protective role of extracellular substances. On the other hand, biofilm formation may be beneficial in water and wastewater treatment (4–6), in

bioremediation processes (7,8), in the production of fermented food (9,10), or in establishment of symbiosis on plant roots (11).

The formation of microbial biofilms at the interface between a bare solid surface and a cell suspension may be seen as a succession of various steps, as illustrated in Figure 1 (2,12,13). The solid substratum is first conditioned by adsorption of organic (macro)molecules (proteins, polysaccharides, lipids; humic substances, natural organic matter,...) which diffuse faster than cells and are likely to modify the substratum physicochemical properties. Transport of the microorganisms to the substratum surface will occur by Brownian motion (i.e., diffusion), sedimentation, convection, and possibly also intrinsic motility. During this step, aggregation occurring between planktonic microorganisms (14,15) may considerably affect the "simple vision" of one microorganism approaching a surface. Attachment may occur between single or aggregated microorganisms and the conditioned substratum, which is referred to as the "primary adhesion" step. It is worth noting that coadhesion between planktonic and adhering cells may also be encountered (15). Subsequently, the production of extracellular substances may allow the anchorage of attached bacteria while bacterial growth leads to biofilm development. Later, the detachment of biofilm portions from the substratum may occur as a result of flow shear or chemical treatment (see BIOFILM DETACHMENT). It may also be induced by the enzymatic activity of entrapped cells (16,17).

The aim of this chapter is to provide an overview of (*1*) the various methods available for studying the primary adhesion of microbial cells, and (*2*) the physicochemical approaches, which help to understand and control this process. The importance of considering microbial cells as complex colloidal particles is emphasized. However, the role of specific (key-lock) interactions between the microorganism and a biological substratum is not considered in detail; more comprehensive details on this subject may be found in (18–20).

TERMINOLOGY

It has been proposed to use the term "deposition" to designate the attachment of microbial cells to a surface, and the term "adhesion" to refer to the force necessary to separate the adherents, that is, to express the strength of the adhesive force (21). On the other hand, "adsorption" was proposed to designate immobilization of an organism on a collector surface, and "attachment" to designate the consolidation of the interface between an organism and a collector (22); however, these distinctions are not of universal use. In this article, in order to avoid the confusion between the denomination of a phenomenon (attachment, deposition, adhesion) and the name of a physical quantity characterizing the phenomenon or its result (rate, amount, strength); the terms deposition, attachment, and adhesion are considered as synonymous. Adsorption is sometimes used as a synonym of attachment or deposition; in this chapter, however, adsorption will be reserved for the retention of molecules at a surface.

METHODS TO STUDY MICROBIAL ADHESION

Overview

Generally speaking, two types of approaches are used in experimental microbial cell attachment studies (23). In the first type, adhesion is evaluated in environments of practical significance. To this end, test surfaces are placed in the environment of interest (water delivery system, cooling system, soil, etc.), left for a period of time, retrieved, and the number of attached bacteria is evaluated. Another approach, typical of laboratory studies (24), is more appropriate for investigating mechanisms or establishing guidelines. The aim is typically to determine (*1*) the ability of one or several microorganisms to adhere, (*2*) the influence of particular environmental conditions (ionic strength, pH, substratum nature) on adhesion, and (*3*) the adhesion force between the microorganisms and the substratum. Usually, model materials are used; they may be chosen according to their hydrophobicity (hydrophilic such as glass, metal oxides, minerals; hydrophobic such as nonoxidized polymers), surface electrical properties, roughness, or mode of conditioning. The results obtained may be strongly influenced by the hydrodynamic conditions (turbulent, laminar, resting liquid) and the rinsing step.

Two limiting cases may be distinguished when considering the kinetics of particle attachment. On the one hand, in the bulk transport controlled regime, the surface interactions create no resistance and the kinetics is determined by convection, diffusion, and/or an external force field (sedimentation). On the other hand, in the surface barrier limited regimen, the bulk transport is fast and the resistance is caused by physicochemical interactions between the two surfaces (25). The former case will be mainly considered in this section; the latter case will be mainly treated in the next section.

The experimental systems will be presented here according to the hydrodynamic conditions. Therefore, it is worth recalling the types of flow which may be distinguished on the basis of the Reynolds number, Re,

$$Re = \frac{\ell v_o}{\nu} \tag{1}$$

where v_o is the fluid velocity, ν is the kinematic viscosity (Table 1) and ℓ is a reference length scale (26,27). Regarding the flow around colloidal particles (size ≤ 1 μm), Re is usually much lower than 1. In the absence of particular force fields (gravity, concentration gradients, interfacial interactions), particles with sufficient symmetry follow the fluid streamlines. For higher Re, a laminar flow is obtained, that is, the fluid streamlines are parallel to each other. This is the case of the Poiseuille flow through a circular tube or a parallel-plate channel; the fluid velocity is 0 at the wall, while the velocity gradient, also referred to as the shear rate, is maximal at the wall and 0 at the center. For Re above a critical value, typically 2,100 in pipes, unsteady and chaotic motion occurs, giving a turbulent flow. However, near the wall, no random fluctuation occurs, thereby providing the laminar or viscous sublayer. The concept of boundary layer finds its origin

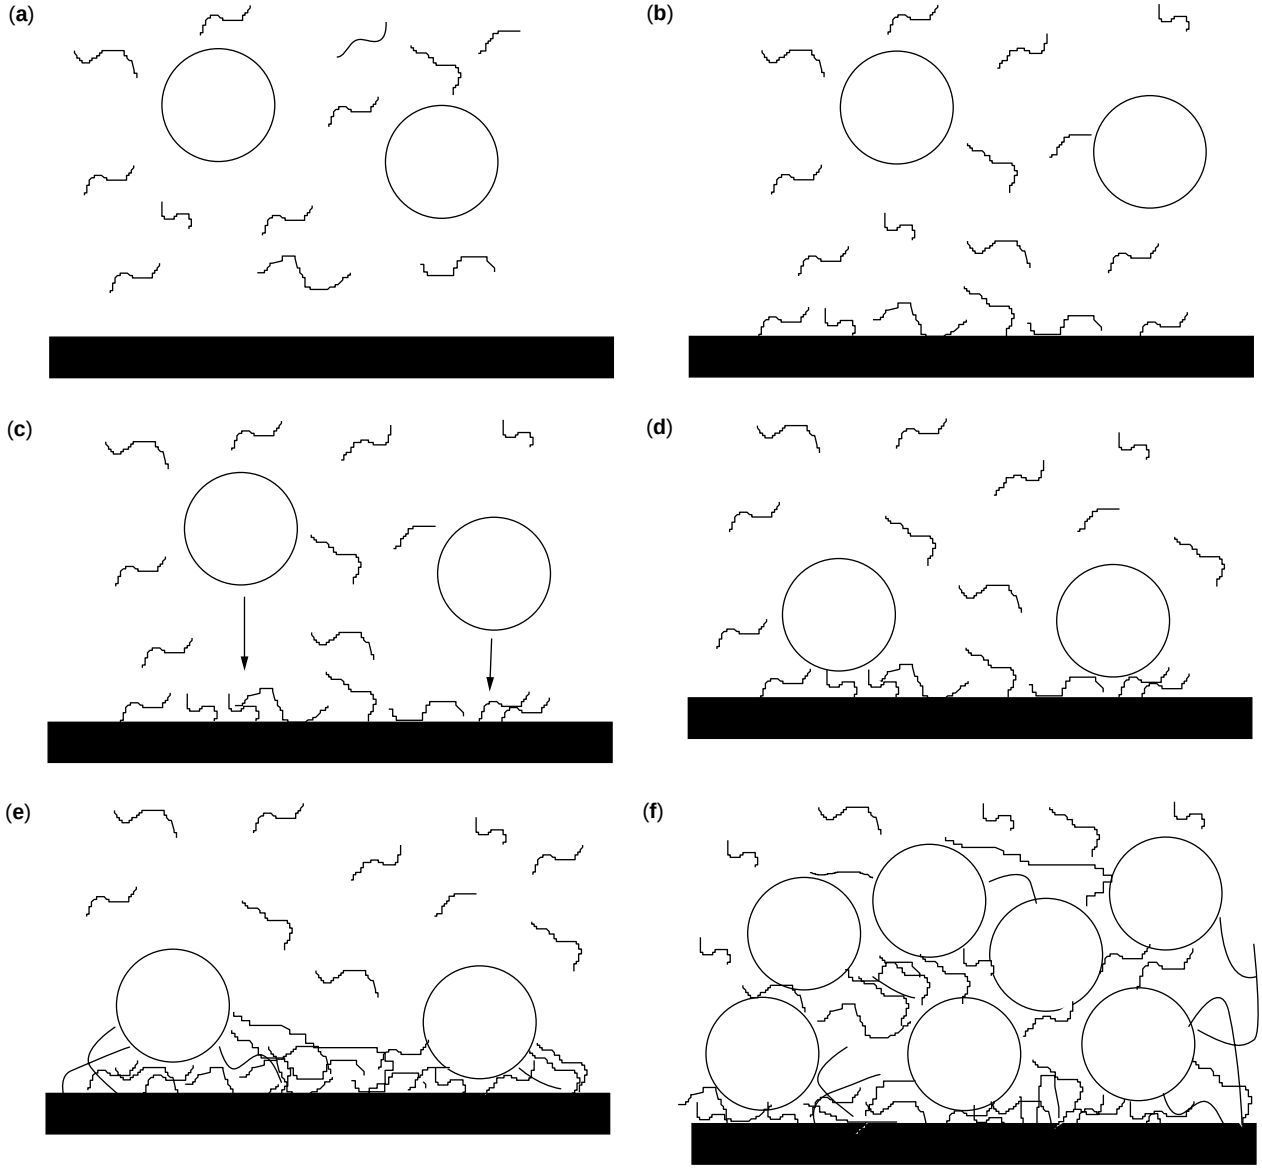

Figure 1. Schematic representation of the various steps involved in the formation of biofilms: (**a**), initial situation; (**b**), substratum conditioning; (**c**), cell transport; (**d**), primary adhesion; (**e**), anchorage; (**f**), growth.

in approximations, which involve a distinction between a fluid behavior near a wall and far from a wall.

Static Systems

In static tests, the microbial suspension remains stationary with respect to the substratum. Consider a quiescent liquid containing dispersed particles; the transport of which is governed by sedimentation and Brownian motion (diffusion). Table 1 presents the physical quantities, which influence the rate of transport according to the two mechanisms (26,27). It gives also indicative values for nonmotile bacteria. The characteristic distance L, that is, the distance along which the major concentration change takes place, may be evaluated as follows: a dense monolayer of bacteria represents about 5×10^7 cells/cm^2; with a suspension concentration of 5×10^8 cells/cm^3, the amount of cells present in a 1 mm layer of the suspension is needed to make a dense monolayer. The ratio of transport by sedimentation with respect to diffusional transport may be evaluated by the Peclet number, *Pe*, also defined in Table 1. For bacteria, *Pe* is about 300 (Table 1), indicating that transport caused by Brownian motion may be neglected compared to gravitational transport. The latter will control the transport to the upper face of a horizontal substratum immersed in a suspension of bacteria, but the cells will not contact the lower face.

A bacterial suspension may also contain macromolecules, which tend to be adsorbed onto the substratum. A deposition test performed using a closed cell with a rectangular section showed that *A. brasilense* cells were attached on the lower wall and not on the upper wall; however a surface analysis showed that the amount of

Table 1. Physical Quantities, with Indicative Values, Which Are Relevant to the Transport of Bacteria by Sedimentation and Diffusion (26,27)

Physical Quantity	Symbol and Definition	Indicative Values
Bacteria equivalent radius	a	0.8 μm
Acceleration of gravity	g	9.81 m/s^2
Viscosity coefficient	η	1.0×10^{-3} Pa s, for water
Kinematic viscosity	$\nu = \eta/\rho_{\text{liquid}}$	1.0×10^{-6} m^2/s, for water
Sedimentation velocity	$v_{\text{sed}} = 2\ g\, a^2 \Delta\rho/9\eta$	0.8 cm/day[a], 10^{-7} m/s
Difference of specific gravity	$\Delta\rho = \rho_{\text{cell}} - \rho_{\text{liquid}}$	0.07 g/cm^3[b]
Diffusion coefficient[c]	$D = kT/6\pi\eta a$	3×10^{-13} m^2/s[d]
Characteristic distance	L	1 mm
Rate of transport by diffusion	$v_{\text{diff}} = D/L$	3×10^{-10} m/s[d]
Particle flux[e]	$J = vC_0$	sediment.: 5×10^3 cells/cm^2 s diffusion: 15 cells/cm^2 s
Peclet number	$Pe = v_{\text{sed}}\ L/D$	300[d]

[a] close to the progression rate of the front of sedimentation measured in water for *Azospirillum brasilense* and *Pseudomonas* strains (non published).
[b] computed from v_{sed}
[c] k = Boltzmann constant, T = temperature (K)
[d] computed using the above data
[e] C_0 = initial bacterial concentration; indicative value of 5×10^8 cells/cm^3

adsorbed proteins was similar for the lower wall after cell detachment, and for the upper wall. This demonstrated that proteins were released by the cells into the solution and adsorbed by the substratum, and were not exclusively brought to the substratum by the cells (29,30).

A characteristic distance of 1 mm is still relevant for the migration of a macromolecule to a surface: consider a macromolecule with a molecular weight of 50 kDa, a specific gravity of 1 g/cm^3 and thus an equivalent radius of 2.7 nm; an adsorbed monomolecular layer represents about 6×10^{-8} mole/m^2 or 3 mg/m^2; this is equivalent to the amount present in a 1 mm thick layer of a solution at a concentration of 3 μg/cm^3. The diffusion coefficient of these macromolecules is about 8×10^{-11} m^2/s. It turns out that the ratio of the rate of sedimentation of bacteria (10^{-7} m/s) over the rate of diffusion of the macromolecules (8×10^{-8} m/s) is on the order of 1. This simple computation shows that, depending on the respective concentrations and properties of macromolecules and bacteria, different situations may occur: most of the bacteria may get in contact with the native substratum surface or with a surface fully modified by adsorption; the substratum surface may also be progressively modified by adsorption during the sedimentation process, which means that the substratum-cell interface will be different for bacteria contacting the substratum surface at different times.

By varying the cell concentration, the duration of the experiment and the height of the suspension, static tests allow the amount of cells brought in contact with the support to vary from a small fraction of a monolayer to a thick sediment. The thickness of the sedimented layer was found to influence the density of adhering yeast cells under conditions of low cell-support affinity; this was attributed to an increased pressure exerted on the bottom layer of cells or to a reorganization leading to the formation of a dense layer of cells in close contact with the substratum (31,32).

In practice, the cells are left to settle on the substratum and the nonattached cells are removed by rinsing. These tests are simple and quick, allowing rapid screening to be performed. However, the definition of adhering cells is strongly dependent on the conditions used for the washing procedure. Several rinsing procedures are used to remove microorganisms that are "unattached" or "loosely bound": successive dipping in the relevant fluid, mild shaking of the container with progressive replacement of the liquid, or washing under flow. All of these procedures may yield nonreproducible results due to the lack of control over the removal force (33). Progressive dilution and mild shaking avoid the passage of an air-water interface, and the possible influence of a water meniscus on the deposited cells. The hydrodynamic conditions may be controlled better by placing the test plates in a device, which ensures a laminar flow (31,34). The parallel-plate flow chambers described later can also be used to investigate bacterial adhesion under static conditions, while controlling the hydrodynamic conditions used for rinsing (29).

Evaluation of the Strength of Adhesion

An overview of earlier methods dealing with the determination of the strength of adhesion of small particles can be found in (35). Among the direct methods, a force is applied in a direction opposite to the adhesive force and the value required to cause cell detachment is measured. The centrifugal method is attractive due to its apparent simplicity; the applied force is given by

$$F_C = V_p(\rho_p - \rho_m)\omega^2 r \qquad (2)$$

where V_p is the particle volume, ρ_p and ρ_m are the densities of the particles and medium respectively, ω is the rotational speed and r is the radius of gyration. However, in the case of microbial cells, this method is strongly limited as a result of the small difference of density

between the cells and the usual types of surrounding liquid medium. Experiments performed with yeast cells adhering to glass in an aqueous medium showed that an acceleration up to 5,700 g did not cause cell detachment (unpublished). Centrifugation in air of a sample tilted with respect to the rotation axis allowed a cell detachment threshold to be determined. However, the interpretation of the data was not clear, because of possible interferences from capillary forces created by the water meniscus at the cell-substratum interface and of drying.

Indirect methods consist of measuring the force required to provoke cell detachment exerted by a liquid flow parallel to the surface (35,36); the force is thus of hydrodynamic origin. The drag force F_H exerted by a laminar liquid flow on a spherical particle of radius a adhering to a wall is given by

$$F_H = 32a^2\tau \tag{3}$$

where the wall shear stress τ is given by

$$\tau = \eta \frac{dv}{dz} \tag{4}$$

where v is the fluid velocity and z the direction perpendicular to the surface. Equations have been developed for the following systems: (i) flow between rotating concentric cylinders (21,35); (ii) flow created between two parallel discs with a narrow spacing, by injection of the fluid at the center of one disc (radial-flow chamber) (36,37); and (iii) flow in a rectangular pipe having a small thickness (38,39). In the latter case, provided a laminar flow is ensured in the pipe,

$$F_H = 96\nu v_{lo}\frac{a^2}{b} \tag{5}$$

where v_{lo} is the average linear flow rate and b is half the pipe thickness. However, the drag force required to detach an adhering cell has a clear meaning only when the cells are isolated and distributed with a low density on the substratum.

Dynamic Tests Under Controlled Hydrodynamic Conditions

Hydrodynamic conditions influence deposition tests in two ways: (i) the liquid flow governs the rate at which the suspended cells make contact with the substratum surface and, consequently, cell deposition; (ii) it also influences the shear stress near the substratum surface, thus the residence time of nonattached cells at a given spot of the surface and the drag force exerted on attached cells.

The transport of dissolved compounds or suspended particles in a moving liquid is governed by two mechanisms, convection and diffusion, the combination of which is called convective diffusion (26). The equations describing the convective diffusion have been solved when the collector is a smooth rotating disc immersed in an otherwise non agitated liquid (25–27). A fluid flow of well-controlled intensity is created by the rotation. At a distance from the disk larger than δ_o, the thickness of the hydrodynamic boundary layer, the liquid moves toward the disk and its velocity is v_z. Within the boundary layer, the radial and tangential velocity components are not 0. If the suspended particles are irreversibly captured when they arrive close enough to the collector surface ("perfect sink" model), the flux of particles to the disk surface J may be considered as being controlled by diffusion through a diffusion boundary layer. The thickness of the latter, δ, is constant over the entire disk surface, neglecting edge effects, and is much smaller than δ_o. Table 2 presents relevant physical quantities for two disk rotation frequencies. It gives also the apparent rate v_p at which the particles are transported to the surface. This is larger than the rate of diffusional transport in static conditions (Table 1), because δ is smaller than the characteristic distance used in the latter case. At a rotation frequency of 1 cycle/s, it becomes close to the sedimentation velocity that should no longer be neglected; note also that δ becomes close to the cell radius. The influence of particle size and density, and of Re is further discussed in (25). The rotating disk method has been used to study deposition of microorganisms associated with dental caries, namely, *Streptococcus mutans* (40), and with infections of biomaterials after blood contact, namely, *Staphylococcus epidermidis* (41).

The radial-flow chamber (36) mentioned earlier has been used under conditions of microbial growth, by pumping the culture fluid at a constant volumetric rate. The linear fluid velocity, and hence the surface shear stress decreases radially across the disc. With a suitable flow rate, a clear zone is found around the inlet, with attached cells beyond a certain distance from the inlet. This "critical radius" gives the critical shear stress below which attachment takes place. The radial-flow chamber was combined with automated videomicroscopy, which allowed the kinetics of bacterial attachment and detachment to be determined (24,42,43).

Deposition of colloidal particles has also been studied using the impinging jet method (25,44,45). The dispersion flows through a circular hole and the fluid impinges on the substratum. If the latter is transparent, the deposition process can be observed under the microscope. A stagnation point flow is created near the substratum surface facing the inlet hole. Mass transfer equations were solved for the stagnation point region, taking into account hydrodynamic, gravitational, and interfacial forces. The variation S of the density of deposited particles, as a function of time, can be approximated by

$$S = \frac{J_0}{\beta_m + \beta_e}[1 - \exp\{-(\beta_m + \beta_e)t\}] \tag{6}$$

where J_0 is the initial flux of particles towards the collector surface, β_m is a coefficient reflecting the surface blocked per particle, and β_e is an escape coefficient depending on the transport conditions near the collector surface and on the particle-support interactions. J_0 can be determined from the initial slope of S versus t; J_0, β_m, and β_e can be analyzed in relation to the characteristics of the system investigated, according to mass transport equations.

A theoretical analysis was made for the particle deposition kinetics onto walls of parallel-plate and

Table 2. Physical Quantities, with Indicative Values, Which are Relevant to the Transport of Bacteria to a Rotating Disc of Radius $r = 10$ cm at Steady State (26)[a]

Physical quantity	Symbol and definition	Indicative values		Units
Rotation frequency	—	10^{-2}	1	cycle/s
Angular velocity	ω	6.3×10^{-2}	6.3	radius/s
Rate of the liquid to the surface at a large distance from the disc	$v_z \approx 0.89\sqrt{\nu\omega}$	2.2×10^{-4}	2.2×10^{-3}	m/s
Thickness of the hydrodynamic boundary layer	$\delta_o \approx 3.6\sqrt{\nu/\omega}$	1.4×10^{-2}	1.4×10^{-3}	m
Thickness of the diffusion boundary layer	$\delta \approx 0.5(D/\nu)^{(1/3)}\delta_o$	4.7×10^{-5}	4.7×10^{-6}	m
Rate of transport of the particle to the surface	$v_p = J/C_o = D/\delta$	6.4×10^{-9}	6.4×10^{-8}	m/s

[a] ν taken for water, D and C_o taken for bacteria, as given in Table 1.

cylindrical channels through which a dilute suspension of spherical particles moves in laminar flow (46). Transport equations were formulated by taking into account surface forces as well as external forces. The parallel-plate flow chamber has been broadly used to investigate microbial adhesion (12,47). Therefore, the substratum of interest, which must be transparent, constitutes the main chamber walls and the cell deposition is observed directly under the optical microscope. The adhesion kinetics may be analyzed by using relations similar to Eq. (6) (48).

A flexible and frequently used device to study microbial adhesion is the modified Robbins device (49–51). Aseptically removable studs contain a dish of the substratum to be examined, which is exposed to the fluid passing through a pipe. This is a convenient method to compare different materials in the same conditions.

Table 3 shows a comparison of different systems regarding the possibility of examining a large substratum area, the possibility of direct observation, which facilitates the quantification of deposition kinetics, and the possibility of comparing different materials in the same run. Other systems consist of exposing several substratum samples in a flow chamber or on a rotating cylinder. They allow a comparison of different substratum samples to be made in the same conditions, but provide a less accurate control of the hydrodynamic conditions. The relation to biofilm reactors can be made using reference (52).

Batch Systems and Packed Beds

With batch systems, the amount of adhering cells is often determined by the difference between the initial and final concentration of microorganisms in the liquid phase. A direct quantification of adhering bacteria can be achieved by using cell labelling techniques, with fluorescent or radioactive probes (24,53,54).

In packed-bed systems, which are relevant to soil or to industrial bioreactors (55), the retention of bacterial cells, assumed to be caused only by attachment, is deduced from the concentration of cells remaining in the effluent and recording breakthrough curves (56–59). A disadvantage is that direct observation and localization of adhering microorganisms is not possible. In particular, microbial cells may be held in the bed by sedimentation in zones of low liquid velocity or by a mechanical retention of aggregates, which may erroneously be considered as attachment.

Rijnaarts and coworkers (60) compared bacterial attachment performed on glass and teflon surfaces, using packed-beds and batch systems, with a large collection of *Pseudomonas* and coryneform bacteria selected according to their environmental and biotechnological relevance. They showed that the transport of microbial cells from the bulk liquid to the substratum surface was faster in packed-bed columns (transport ensured by diffusion and convection) compared with batch tests (transport dominated by diffusion). The two methods were consistent for a

*provided the substratum is transparent.

certain number of strain-substratum combinations. Deviations observed for other combinations could be attributed to method-dependent effects resulting from specific cell characteristics such as ability to aggregate, presence of capsular polymers, large cell sizes or detachment by an air-liquid meniscus.

PHYSICOCHEMICAL ASPECTS OF PRIMARY ADHESION

In the course of the approach of a substratum by a microbial cell, physicochemical aspects become important when the separation distance is smaller than the cell size. Depending on the nature of the surfaces involved, they may be the factor controlling the rate of attachment and even determining the possibility of attachment. Former reviews can be found in (21,61–63).

DLVO (Derjaguin, Landau, Verwey, Overbeek) Theory

Theoretical Frame. According to DLVO theory (28,64), the free enthalpy of interaction, G_T, when two surfaces approach each other, may be accounted for by the sum of two contributions, corresponding respectively to electrostatic and van der Waals interactions

$$G_T = G_E + G_V \tag{7}$$

The electrostatic contribution, G_E, is caused by the overlap of electrical diffuse double layers. Remember that two regions can be identified near a charged surface of potential ψ_0, as illustrated by Figure 2 (65). In the first region, called the Stern layer, the ions, chemically adsorbed or retained by localized electrostatic attraction, are in close contact with the surface and the potential is considered to fall linearly as a function of the distance from the surface. In the second region, called the diffuse double layer, the potential falls exponentially as a function of the distance, caused by the balance between electrical interactions of ions with the surface and molecular motion. The electrical potential at the inner limit of the diffuse double layer is called ψ_d. The zeta potential, ζ, is the potential at the plane of shear between the surface and the solution.

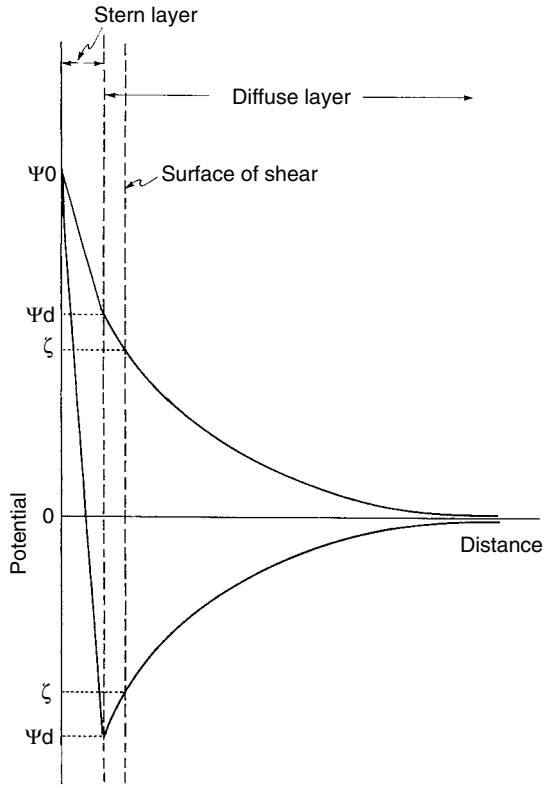

Figure 2. Potential decay curves for an electrical double layer associated with a surface of potential Ψ_0. The upper and lower curves arise, respectively, from weak and strong adsorption of counterions in the Stern layer.

Considering a sphere (cell) and a plate (substratum), G_E is expressed as follows for small values of the relevant electric potential ($\psi < 50$ mV) (62,66,67)

$$G_E = \pi\varepsilon a(\psi_M^2 + \psi_S^2)\left[\frac{2\psi_M\psi_S}{\psi_M^2 + \psi_S^2}\ln\left(\frac{1+\exp(-\kappa h)}{1-\exp(-\kappa h)}\right) + \ln(1 - exp(-2\kappa h))\right] \tag{8}$$

where ε is the permittivity of the suspending fluid; a is the cell radius; ψ_M and ψ_S are the values of ψ_d near the cell and the substratum surfaces, respectively; κ is the reciprocal of the Debye length; h is the separation distance between the interacting surfaces (28,68). For computing G_E, the value taken for ψ_d is usually the zeta potential (68). κ determines the rate of the variation of the electrical potential as a function of the distance within the diffuse double layer

$$\kappa = [(2{,}000Ie^2N)/(\varepsilon kT)]^{(1/2)} = 3.29 \times 10^9(I)^{(1/2)}(\text{at } 25\,^\circ\text{C}) \tag{9}$$

where I is the ionic strength of the bulk solution, e is the electron charge, N is the Avogadro number, k is the Boltzmann constant, and T is the temperature. At ionic strengths of 10^{-1}, 10^{-3}, and 10^{-5} M, κ^{-1} is close to 1, 10 and 100 nm, respectively. Note that the ionic strength is commonly in the range of 10^{-2} to 10^{-3} M for natural freshwater and near 10^{-1} M for most microbial culture media. Strictly speaking, h should represent the distance between the inner limits of the two diffuse layers facing each other. Considering that it is the distance between the two surfaces neglects the thickness of the Stern layer. For this reason and because of the uncertainties concerning the definition of ψ_d, computing G_E for distances shorter than 1 nm is meaningless.

The contribution of van der Waals interactions varies with the separation distance according to

$$G_V = -\frac{A}{6}\left[\frac{2a(h+a)}{h(h+2a)} - \ln\left(\frac{h+2a}{h}\right)\right] \tag{10}$$

which may be simplified for very small separation distance ($h \ll a$), giving

$$G_V = -\frac{Aa}{6h} \tag{11}$$

where A is the Hamaker constant (62,66,68). This is mainly determined by dispersion forces (surface-surface and surface-liquid interactions) and thus by the polarizability of the surface constituents. For bacterial cells suspended in water, A is estimated to be about 0.035, 1.54 and 3.58 kT for Teflon, glass, and iron oxide substrata, respectively ($kT = 4.1 \times 10^{-21}$ J/mol) (58,64,69).

Figure 3 presents the computed G_T vs h curves for microbial cells, considered as spherical particles of 1 μm radius, A = 1.54 kT, ψ_d of both cells and substrata = −20 mV, and $\kappa^{-1} = 10$ nm; the respective influence of variation of A, ψ_d, and κ^{-1} is also illustrated. The attractive contribution of van der Waals forces is shown in Figure 3 (center; $\Psi_d = 0$ mV). At physiological pH, most of biological and substratum surfaces have a negatively charged surface. As a consequence, an overall repulsion appears at a distance that may vary from 10 to hundreds of nanometers, depending on ionic strength (Fig. 3). The repulsion energy must be put in perspective, considering the kinetic energy associated with Brownian motion, equal to 1.5 kT. Figure 3 (left, center) shows that the chemical composition of the surfaces involved acts much more through the ionized functions, which determine the electrical potentials, than via the van der Waals forces. An increase of ionic strength from 10^{-5} to 10^{-1} M (reducing the Debye length from 100 to 1 nm) reduces considerably the magnitude of the potential energy barrier (Fig. 3, right). At sufficiently high ionic strength, the variations of G_E and G_V as a function of the distance bring about a secondary minimum, which may keep the cell near the substratum, although not in close contact. As illustrated in Figure 3 (center), a decrease of surface potential may favor microbial attachment by lowering the magnitude of the potential energy barrier. Such variation of surface potential can be encountered when comparing different bacterial strains, when comparing different substrata or when changing the pH of the surrounding solution.

Experimental data obtained during the last decades are in good agreement with trends predicted by DLVO theory. A more negative zeta potential of biotechnologically relevant microorganisms (70) and of soil bacteria (71), both hydrophilic, was shown to be unfavorable to attachment. Electrostatic repulsion may be reduced in different ways: (i) by increasing the ionic strength, (ii) by bringing the pH to a value closer to the cell isoelectric point, or (iii) by modifying the surfaces.

Surface Modification. The role of electrostatic interactions is illustrated by the influence of substratum modifications that confer a positive character to the surface. Figure 4 (left) presents a micrograph of a glass plate which had been partially immersed for one hour in a solution of 1.8 mM $Fe(NO_3)_3$ brought at pH 4, washed with distilled water and used as substratum for a static adhesion test of *Saccharomyces cerevisiae* suspended in water (unpublished). The cells did not attach to untreated glass but formed a denser layer on the modified substratum. Hydrolysis of ferric ions produces ferric hydroxide particles of about 10 nm size, which adsorb to negatively charged surfaces; this provokes a charge reversal that allows adhesion of a dense layer of yeast cells (72).

Figure 4 (right) presents data from static adhesion tests performed with *S. cerevisiae* and a glass substratum modified by particles of hydrous alumina with a 0.25 μm

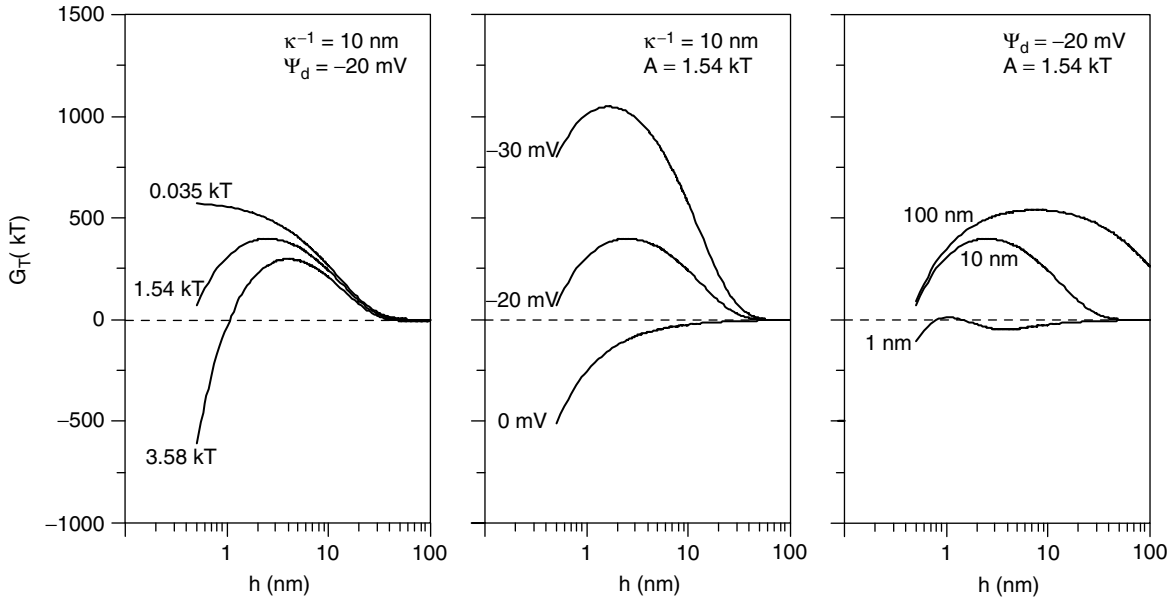

Figure 3. Variation of the free enthalpy of interaction as a function of the distance (h) between a sphere of 1 μm radius and a plane substratum, according to DLVO theory. Middle curve: Hamaker constant A = 1.54 kT; potential of the diffuse double layer $\Psi_d = -20$ mV; Debye length $\kappa^{-1} = 10$ nm. Left: $\Psi_d = -20$ mV, $\kappa^{-1} = 10$ nm, A varying from 0.035 to 3.58 kT; center: A = 1.54 kT, $\kappa^{-1} = 10$ nm, Ψ_d varying from 0 to −30 mV; right: A = 1.54 kT, $\Psi_d = -20$ mV, κ^{-1} varying from 1 to 100 nm.

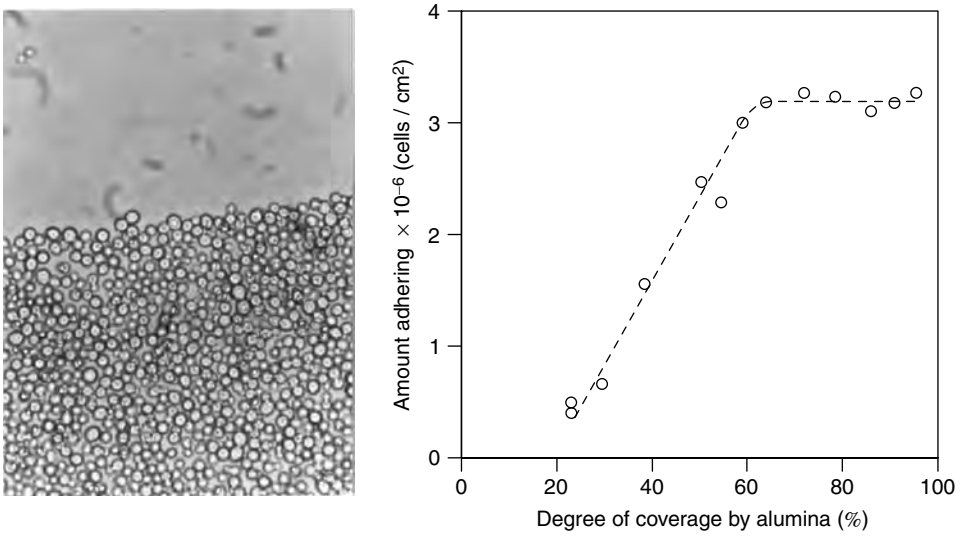

Figure 4. Left, micrograph of a glass slide partially immersed in a $Fe(NO_3)_3$ solution and subsequently submitted to a static adhesion test of *S. cerevisiae*. Right, variation of the amount of *S. cerevisiae* attached to a glass substratum as a function of the degree of coverage with hydrous alumina particles.

diameter and an isoelectric point at pH 9.3 (unpublished). Different surface coverages of the substratum surface with alumina particles were obtained by controlling the alumina concentration and were quantified by redissolution of the coating and chemical analysis. Below 20% coverage, the yeast cells were distributed in patches on the glass support. The amount of adhering cells increased with the degree of coverage by alumina up to 65% coverage, in which case it reached the amount typical of a densely packed cell layer.

Table 4 presents an overview of various systems in which treatments have been applied either to the cells or the substrata to promote primary microbial adhesion by decreasing electrostatic repulsion or achieving electrostatic attraction. These treatments include the use of positively charged colloidal particles (hematite, Fe_2O_3; hydrous alumina, $Al(OH)_3$), of cations (Fe^{3+}, Al^{3+}) and of polycations either adsorbed (chitosan, diethyl aminoethyl-dextran, polyethyleneimine) or grafted (aminosilane); further details may be found in (73). One may argue that these treatments may affect cell physiology. However, for various microorganisms, it was shown that the adhering cells retained their metabolic activity (34,74,75) or their germinating and growing capabilities (76).

It must be kept in mind that, when immersed in a solution, the positively charged substrata may tend to adsorb multivalent or organic anions, which will reduce or eliminate the effect of pretreatment. This can be examined by measuring the electrokinetic properties of the cells and of the substratum (34,65,72,85).

Influence of pH and Ionic Strength. The effect of ionic strength on adhesion may be easily understood from Figure 3 (right): the decrease of Debye length with increasing ionic strength causes a lowering of the potential barrier, which has to be passed by the cells in order to attach. In studies of the transport of soil bacteria through sand columns, an increase of ionic strength decreased the recovery of cells in the effluent, which may be attributed to an increase of cell attachment on sand particles (56,86). In similar experiments performed with negatively charged glass and Teflon beads, the retention of several negatively charged *Pseudomonas* and coryneform bacteria was enhanced by increasing ionic strength (57,59). Similar effects were reported for the attachment of these microorganisms to glass and Teflon plates (87), of several food-borne pathogens to stainless steel (88,89), of biomaterial pathogens to glass and to siliconized glass (50). The opposite was observed with a positively charged bacterium (57).

The effect of electrolytes may sometimes be more complex. Deposition of a *Pseudomonas* strain studied in sand columns was more efficient in solutions containing Mg^{2+} as the dominant cation compared with solutions of identical ionic strengths but containing Na^+. The authors showed, by electrophoretic measurements, that this could be explained by adsorption of Mg^{2+} within the Stern layer, reducing the zeta potential (90). Williams and Fletcher (91) showed that, although the attachment of *Pseudomonas fluorescens* to surface-treated polystyrene (water contact angle of 66°) was increased with a rise of ionic strength, the inverse effect was observed on native polystyrene (water contact angle of 90°). This apparent contradiction may be explained by the respective influence of electrostatic interactions (cfr. DLVO theory), which would dominate in the case of the more hydrophilic surface-treated polystyrene, and of other interactions (see below). The attachment of *Aureobasidium pullulans*, a fungus associated with the deterioration of polyvinyl chloride and painted wood surfaces was maximum at intermediate ionic strength (92). The explanation proposed by the authors was that the electrolyte inhibited attachment, either by screening short-range electrostatic attraction between oppositely charged groups, or by modifying the conformation of cell surface molecules.

In many instances, the isoelectric points of both cells and substratum are low (in the range of 1 to 4) and the zeta potential will generally become less negative when decreasing the pH, for a given ionic strength. Accordingly, the potential barrier preventing cell attachment will

Table 4. Immobilization of Microorganisms by Adhesion Through Modification of the Surface Charge of the Cells or of the Substratum

decrease or will be suppressed (Fig. 3, center). The density of attached cells has indeed been shown to increase when the pH of the suspending medium was brought near the isoelectric point. This was observed for *Moniliella pollinis* (a yeast — like fungus) (70), *A. pullulans* (92), and *A. aceti* (79).

Besides cell-substratum interactions, cell–cell interactions may be affected by the pH and the ionic strength of the cell suspension. In this context, an increase of ionic strength was shown to become unfavorable to attachment because of the formation of aggregates of *P. chrysosporium* conidiospores, the latter presenting higher susceptibility with respect to shear during rinsing (76). Also, flocculation of *M. pollinis* was found to compete with adhesion when decreasing the pH towards the cell isoelectric point (70).

Balance of Interfacial Free Energies

Conceptual Frame. This approach considers the adhesion process as the creation of a new microorganism-substratum (MS) interface, and the destruction of two preexisting interfaces, that is, the microorganism-liquid (ML) and substratum-liquid (SL) interfaces. Thus, this involves a molecular contact between the two adhering surfaces. The tendency of the surfaces to associate is expressed as a balance of the relevant interfacial free energies (γ)

$$\Delta G_{adh} = \gamma_{MS} - \gamma_{ML} - \gamma_{SL} \tag{12}$$

The interfacial free energy is the sum of several terms, each of which corresponds to different interactions: transient dipole-induced dipole interactions or dispersion forces (London), permanent dipole-permanent dipole interactions (Keesom), permanent dipole-induced dipole interactions (Debye), hydrogen bonding and ionic bonding (93). Like all systems in nature, the system made by these interacting surfaces will strive to reach a state of minimal free energy. Therefore, microbial attachment will be favored when ΔG_{adh} is negative.

Surface free energies are deduced by using the Young equation

$$\gamma_{LV} \cos\theta = \gamma_{XV} - \gamma_{XL} \tag{13}$$

where X stands for solid (either substratum, X = S, or microorganism, X = M) and V for the saturated vapor phase; θ is the contact angle measured on a lawn of microorganisms or on the substratum; γ_{LV} is the surface tension of liquid L. In this relation, two parameters can be experimentally assessed (θ and γ_{LV}). The other two parameters can be tentatively deduced using equations which relate γ_{XL} to γ_{XV} and γ_{LV}. Similar equations relate γ_{MS} to γ_{ML} and γ_{SL}, allowing ΔG_{adh} to be computed.

Several approaches have been used to establish these equations (32,94–96). One key point among the diverging hypotheses is whether γ_{XV} may be approximated by γ_X, the surface free energy of X under vacuum.

One approach assumes an Equation of State to relate the three interfacial free energies involved in the Young equation (97). It allows γ_X to be calculated from contact angles measured with one liquid. According to Spelt and coworkers (98), apolar and polar liquids of the same surface tension should give the same θ value for a given solid; however, conflicting results are reported regarding this aspect (99). According to this approach, if γ_{LV} is lower than γ_{MV}, ΔG_{adh} decreases with increasing γ_{SV}, predicting increasing bacterial adhesion with increasing surface tension of substrata. On the other hand, when γ_{LV} is higher than γ_{MV}, the opposite trend is observed (100).

In another set of approaches one assumes the additive contribution of dispersion and polar surface free energy components (γ^d and γ^p, respectively) in the total surface free energy ($\gamma = \gamma^d + \gamma^p$) (101). While γ^d is determined by London dispersion forces, γ^p comprises hydrogen bonding, Keesom, and Debye interactions. Moreover, it is considered that the dispersion and polar contributions of the interfacial energy γ_{XY} (where X and Y stand for M, S, or L) combine pairwise [$\gamma^d_{XY} = f\left(\gamma^d_X, \gamma^d_Y\right); \gamma^p_{XY} = f\left(\gamma^p_X, \gamma^p_Y\right)$]. In this frame, the methods differ according to whether the pairwise combination involves a harmonic- or a geometric-mean equation (102), and whether the vapor adsorption by the solids is neglected or not (103). The most frequently used approach, the Owens-Wendt method, is based on the geometric-mean equation and neglects the influence of vapor adsorption; it involves the use of two liquids, usually α-bromonaphthalene (apolar, $\gamma_L = \gamma^d_L$) and water (highly polar, $\gamma_L = \gamma^d_L + \gamma^p_L$). The γ^d_L value of water is determined from the water contact angle on a solid allowing only London dispersion forces (polyolefin). The dispersion component does not vary much with the nature of the substratum considered. As a consequence, if γ^p_M is lower than γ^p_L, adhesion will be favored if γ^p_S decreases (104). This fits the common understanding of hydrophobic bonding. A variant considers that γ_{XV} is different from γ_X, the difference being due to vapor adsorption by the solid (103).

Another type of approach proposed by van Oss (95) takes into account not only the polar character but also its electron-donor or electron-acceptor nature. It emphasizes that nonpolar interactions result from all three types of van der Waals interactions, lumped together in Lifshitz theory, giving γ^{LW} (LW for Lifshitz-van der Waals). Further, the polar interactions are designated as Lewis acid-base (γ^{AB}), resulting from the combination of electron-donor (γ^-) and electron-acceptor (γ^+) contributions. This method involves the use of at least three different liquids, such as water and formamide (two polar liquids), and α-bromonaphthalene or diiodomethane (assumed to be apolar).

Experimental Data. The validity of approaches on the basis of a balance of interfacial energies for predicting microbial adhesion has been tested. The adhesion of five bacteria (two strains of *E. coli*, *Staphylococcus aureus*, *S. epidermidis*, and *Listeria monocytogenes*), having a surface tension (γ_{MV}) lower than that of water (γ_{LV}), was studied on different solid substrata presenting a large range of surface tensions (γ_{SV}): as expected from the Equation of State approach, the adhesion density decreased with increasing γ_{SV}. Moreover, when dimethyl sulfoxide was added to water, the inverse correlation was observed when the added amount was sufficient to decrease the value of γ_{LV} below that of γ_{BV} (100). Similar results were reported by Fletcher and Pringle for *P. fluorescens* (105). More recently, Wang and coworkers (41) found that interfacial free energies, assessed by the Equation of State, are strong driving forces for adhesion of *S. epidermidis* to a large range of blood-contacting biomedical materials.

The Owens & Wendt approach was used to predict the adhesion of three bacteria encountered in implant infections (*E. coli*, *Pseudomonas aeruginosa* and *S. epidermidis*) to a large selection of orthopedic implant polymers (106). The comparison between computed ΔG_{adh} and experimental results revealed the following features: (*1*) as predicted by the negative values of ΔG_{adh}, significant adhesion was always detected whatever the microorganism and the substratum; (*2*) the least negative value of ΔG_{adh} obtained for *S. epidermidis* was related to a lower adhesion density; (*3*) when comparing the polymers, an inverse correlation between attached cell density and ΔG_{adh} was expected for the three bacteria, whereas it was observed only for *P. aeruginosa*.

Predictions based on the thermodynamic approach are not always in agreement with experimental data. According to the Owens-Wendt approach, a positive correlation between attached cell density and γ_S indicates that the polar component of the bacterial surface free energy M must be higher than γ^p_L (104). Nevertheless, the attachment of the teeth-colonizing *Streptococcus sanguis* bacteria ($\gamma^p_M = 52$ mJ/m^2) in phosphate buffered saline ($\gamma^p_L = 48$ mJ/m^2) was decreased with increasing γ_S (107). Adhesion of *L. monocytogenes* to relevant industrial surfaces (polypropylene, rubber, glass, and stainless steel) could not be correlated to the predictions when using the van Oss approach (108). Actually, the degree of success of the prediction of the adhesion of *Streptococcus thermophilus* and *Leuconostoc mesenteroides*, both at the origin of contamination in dairy processing, depended greatly on which thermodynamic approach was used to convert measured contact angles into surface free energies (94).

A more global but simpler approach is to consider the influence of surface hydrophobicity, as assessed from water contact angle measurements. The direct correlation between hydrophobicity, determined either on cell or substratum surface, and microbial adhesion was demonstrated in several studies. A study of eight strains of *Coryneform* and four strains of *Pseudomonas* showed denser attachment and stronger adhesion with increasing surface hydrophobicity of both bacteria and substrata, the latter being glass, polystyrene, and Teflon (58). The deteriogenic fungus *A. pullulans* adhered in higher amount on substrata of higher hydrophobicity (92). The incorporation of a biocide into polyvinylchloride provoked a reduced attachment of *P. fluorescens*, isolated from biofilm

developed on a swimming pool liner; this was partially attributed to a reduction of polymer hydrophobicity (109). The attachment of soil bacteria to sulfonated polystyrene, a hydrophobic substratum, was directly correlated with their water contact angle values, which were between 20 and 70° depending on the microorganism. It may be noted that, while electrostatic interactions were always repulsive, the effect of cell surface charge was visible only for more hydrophilic strains. Furthermore, the attachment of the same microorganisms to glass, a hydrophilic substratum, was shown to be controlled by electrostatic interactions, the cell surface hydrophobicity having only a small effect (71,110,111). Correspondingly, the attachment of hydrophilic microorganisms was found to be governed by electrostatic interactions (69). While these results demonstrate that water contact angles point to the role of hydrophobicity in the attachment mechanisms, they also illustrate that attachment results from a combination of hydrophobic and electrostatic interactions.

Limitations of Classical Physicochemical Approaches

Although the DLVO theory and the approach based on a balance of interfacial free energies have provided valuable insight into the mechanism of microbial adhesion, as illustrated earlier, they suffer from several limitations. In the DLVO theory, (i) the interacting surfaces are assumed to be chemically homogeneous, smooth, rigid, and nonpenetrable by ions; (ii) only long-range interactions, that is, electrostatic and van der Waals interactions, are considered, neglecting short-range interactions like hydrogen bonding. In the approach based on the balance of interfacial free energies, (i) the surfaces are considered as homogeneous and in molecular contact; (ii) the system is considered to be at equilibrium; (iii) the interfacial free energy computations rely on theoretical frames that lack accuracy; (iv) electrostatic interactions between approaching surfaces are not taken into account because the surface energies are determined from contact angles of liquids.

The extended DLVO theory includes an additional term G_{AB}, compared to classical DLVO theory, in order to account for short-range "acid-base" interactions (95). According to van Oss, these acid-base interactions form the basis of the hydrophobic or hydrophilic interactions. It is important to note that these acid-base interactions are short-range, that is, they become significant at small separation distance (5 to 10 nm) (12).

While examining the relevance of the extended DLVO theory, Bellon-Fontaine and coworkers (112) developed a partitioning method, called microbial adhesion to solvents (MATS), which is based on comparing microbial cell affinity to a polar solvent (electron acceptor or electron donor) and to a nonpolar solvent. The following pairs of solvents were used: (*1*) chloroform (electron acceptor) and hexadecane (nonpolar); (*2*) ethyl acetate (electron donor) and decane (nonpolar). Due to the similar Lifshitz-van der Waals components of the surface tension in each pair of solvents, differences between the results obtained with chloroform and hexadecane, on the one hand, and between ethyl acetate and decane, on the other hand, would indicate the electron-donor and electron-acceptor character of the bacterial surface, respectively. Recently, the adhesion behavior of *L. monocytogenes* to stainless steel was examined in the light of this method (89). The parameters γ^{LW}, γ^{+}, γ^{-} were assessed by the MATS method for bacteria and by the Van Oss approach for stainless steel: both surfaces had strong electron-donor and weak electron-acceptor characteristics. Nevertheless, a correlation between adhesion results to stainless steel and cell affinity for ethyl acetate was observed, indicating that Lewis acid-base interactions play an important role in the adhesion mechanism. It may be noted that this approach is equally open to criticism. Indeed, MATS is very sensitive to the surface area developed by the solvent droplets created during mixing of the two liquid phases, which can depend on the mixing conditions (temperature, type of mixing vessel ...). Moreover, an emulsion is frequently produced and the cells tend to accumulate at the interface between the two solvents. As a consequence there is no simple partition of the cells between two defined liquid phases and the measured decrease of the cell concentration in one liquid phase may be misleading. Moreover, the cells may have an amphiphilic character. Finally, the usage of organic solvents was reported to affect the bacterial integrity (113).

COMPLEXITY OF MICROORGANISM — SUBSTRATUM INTERFACES

This section is devoted to particular interfacial aspects, which may influence markedly the primary bacterial adhesion. Some features have already been pointed out as limitations for the classical physicochemical approaches.

Surface Roughness

Contrary to frequent assumptions made to model the cell-substratum interactions, cell and substratum surfaces are not atomically smooth. On the one hand, the presence of morphological heterogeneities on the substratum (roughness) may influence the biofilm formation. With regard to initial adhesion, a few reports have indicated that roughness has a minor effect. The adhesion of *S. thermophilus* and *L. monocytogenes* to stainless steel samples covering a range of finishes, representative of food industry equipment, did not vary significantly according to substratum roughness (88,114). In the same way, the density of *P. aeruginosa*, *E. coli*, and *S. epidermidis* attached on cast biomedical films was similar to extruded films, the latter being rougher than the former (106). However, surface roughness at the micrometer scale appears to be favorable by protecting the cells against shear stress or antimicrobial substances (115,116). Moreover, in conditions where the adsorption of a conditioning film plays an important role in the adhesion process, one may anticipate that substratum roughness at the nanometer scale will affect cell adhesion via changes in the organization of the adsorbed layer. It has indeed been shown that substratum roughness may affect the adsorption of macromolecules, such as proteins, and in particular, the supramolecular organization of the adsorbed layer (117).

On the other hand, microbial cells may bear surface appendages such as flagella, fimbriae, and fibrils (67). A relationship between the presence of flagella and cell behavior was pointed out for attachment of *P. aeruginosa* (colonizing contact lenses and catheters) to polyvinylchloride (118) and attachment of *P. fluorescens* in sand columns (119); this was made by comparing the behavior of a flagellated wild-strain and a nonflagellated mutant. However, interpretation of the data is delicate since the presence of flagella may affect both the transport step and the physicochemical interactions. To separate these effects, the attachment of the food-borne pathogen *L. monocytogenes* to stainless steel was studied by comparing the behavior of the wild-type strain possessing an inactive flagellum and a nonflagellated mutant: a higher adhesion was observed when the flagellum was present (120). The presence of a particular protein on fimbriae was shown to be necessary for the adhesion of the pathogen *S. epidermidis*, of concern in intravascular devices, to polystyrene spheres (53). Finally, the presence of fibrillar structures on the surfaces of *Streptococcus* strains has been linked to their ability to adhere to saliva-coated hydroxyapatite (121), to host surfaces (122), and to fibronectin-conditioned microwells (123).

The modes of action of cell surface appendages to allow bacterial attachment are still unclear. Firstly, cell surface appendages may influence bacterial adhesion through hydrophobic interactions. Water contact angles were significantly higher on fibrillated parent strains of *Streptococcus salivarius* and *S. sanguis* compared to their mutants devoid of fibrils (67). Similar observations were made for *Serratia marcescens*, a pathogen that is found in water, soil, sewage, and foodstuffs. Secondly, the interactions occurring between the cell and the substratum upon approach could be controlled by the physicochemical properties of surface appendages different from those of the overall cell surface. Handley and coworkers (124) used cationized ferritin to probe negatively charged sites, and colloidal gold to probe positive and hydrophobic sites on *S. sanguis* strains bearing fibrils. Their results suggested that these structures may have electrical and hydrophobic properties, which are different from the neighboring bald part of the cell surface (67,124). Thirdly, the radius of curvature ruling the DLVO interactions may be much smaller than the overall cell radius. In particular, it is conceivable that cells become bound via appendages through an electrostatic potential barrier, which results from average surface properties, as illustrated by Figure 5. The distinct role of the flagellum in bacterial adhesion is illustrated by the fierce rotation movements observed with attached *Pseudomonas putida* cells at low ionic strength, that is, when the overall electrical potential barrier is high (87). Finally, it must also be noted that appendages may be responsible for specific interactions with a biological substratum or with an inert material coated by substances of biological nature.

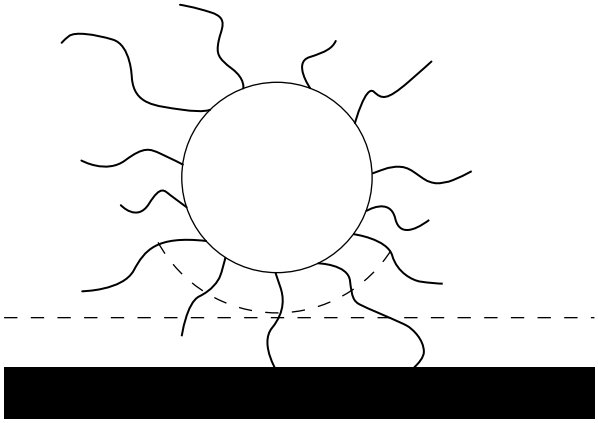

Figure 5. Schematic illustration of the penetration of surface appendages, allowing attachment of a microbial cell to a plane substratum, through a potential energy barrier (location represented by dashed line).

Surface Deformability

Although some microbial cells may be considered as rigid spheres, as assumed in DLVO theory, most of them should be viewed as soft and deformable. In recent years, atomic force microscopy (AFM) has made it possible to probe cell surface softness in a direct way (125–127). This is illustrated in Figure 6, which shows AFM force-distance curves recorded under water upon approach between a silicon nitride probe and the surface of fungal spores (Fig. 6a) and bacteria (Fig. 6b). For *P. chrysosporium* spores, no significant deviation from linearity was seen in the contact region, indicating that the sample was not deformed by the probe (128,129). Conversely, the curvature observed for both strains of *S. salivarius* may be attributed to surface softness (126). The difference in softness observed between the two strains was related to the presence or the absence of fibrils for *S. salivarius* HB and HBC12, respectively. Direct observation of bacterial surface deformability was provided after three-dimensional reconstruction of height AFM images of *Lactococcus lactis*, which revealed grooves induced by the scanning AFM probe (Fig. 7). While these grooves represent an alteration of the cell surface by the probe, they were informative about its nanomechanical properties (127).

Macromolecules at Interfaces

The presence of solvated macromolecules, either constitutive of surfaces or adsorbed, may generate interactions that may be either attractive or repulsive, depending on the properties of the macromolecules, the nature of the solvent and the degree of coverage (64). When two surfaces carrying nonionic (or uncharged) polymers approach each other, the segments of these macromolecules overlap, which leads to a repulsive force (Fig. 8a). The latter is caused by the decrease of entropy associated with a closer confinement of the polymer chains between the two surfaces and is known as steric repulsion. The extent of this repulsive force will be influenced by the nature of the solvent: in a good solvent, that is, in a solvent in which the polymer segments have a higher affinity for the solvent than for one another, the repulsion will occur at a large separation distance (Fig. 9). On the other hand, attractive forces may also be mediated by adsorbed macromolecules (Fig. 9). In a poor solvent, segment attraction

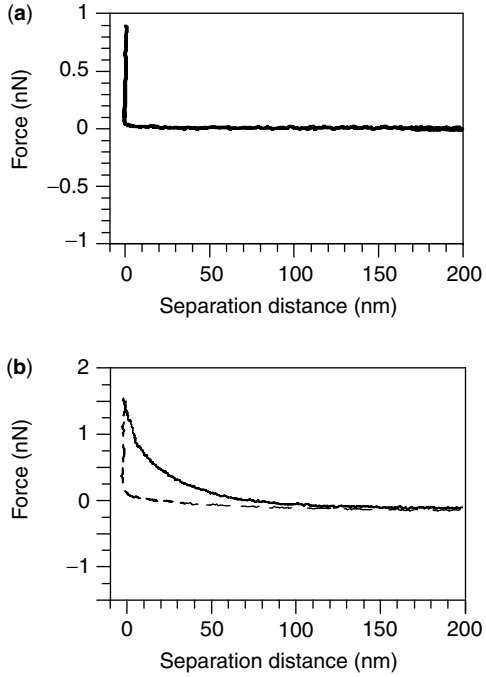

Figure 6. Representative AFM force-distance curves recorded, under water, upon approach between the silicon nitride probe and the surface of *P. chrysosporium* spores (a), *S. salivarius* HB (B; continuous line) or *S. salivarius* HBC12 (b; interrupted line) (126,128,129).

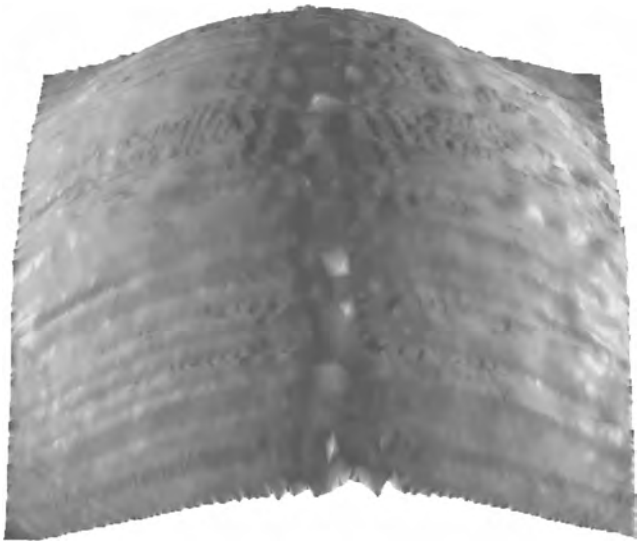

Figure 7. 3D reconstructed AFM height image (475×475 nm^2) obtained under water on *L. lactis* at an imaging force of about 7.5 nN; the groove direction was parallel to the scanning direction (127).

between molecules bound to opposite surfaces leads to overall attraction between the surfaces until a balance with steric repulsion is reached (Fig. 8b). When the degree of coverage is weak and the polymer is strongly adsorbed, the macromolecules may form bridges between the two surfaces (Fig. 8c).

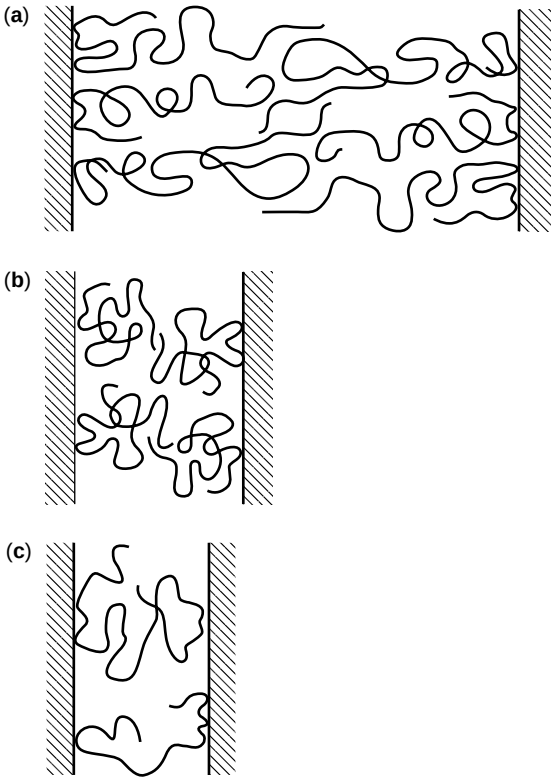

Figure 8. Illustration of steric forces generated by polymers present at an interface. Adapted from (64).

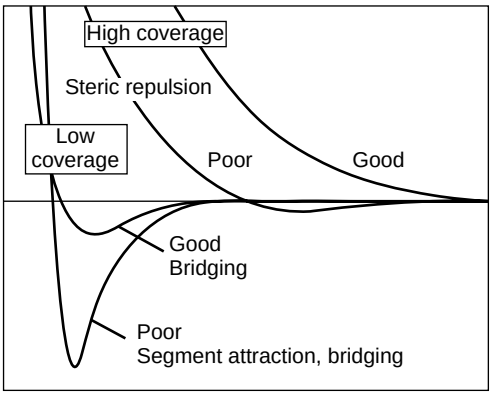

Figure 9. Variation of interaction free enthalpy as a function of the separation distance between two surfaces as a result of macromolecular interactions; influence of the polymer concentration at the surface (low or high coverage), and solvent quality (good or poor). Adapted from (64).

The influence of macromolecules at the interface will depend on the pH and on the ionic strength, which determine the electrostatic repulsion between the different partners. A microbial cell may be bound to a substratum if bridging macromolecules extend far enough from the surface to span the distance at which the electrical repulsion operates, as illustrated by Figure 10. On the left-hand side of the figure, the molecular mass or the

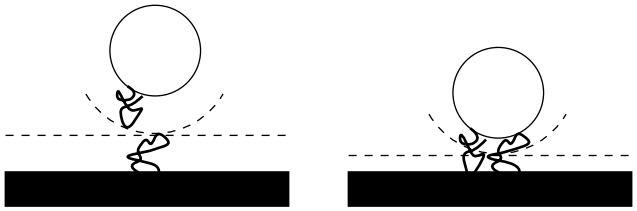

Figure 10. Illustration of the effect of ionic strength or surface potential on polymer bridging; the dashed lines represent the distance at which the electrostatic repulsion operates. The increase of ionic strength or decrease of surface potential from left to right allows polymer bridging to occur. Adapted from (130).

ionic strength are too low to allow bridging. On the right-hand side, the ionic strength is higher or the surface potential is weaker, the electrical repulsion operates at short distances compared with the thickness of the adsorbed macromolecules, and bridging occurs (130,131).

Conditioning Film

In most environments of practical relevance (natural waters, soil solution, biological fluids, industrial fluids, . . .), the substratum surface is rapidly conditioned by dissolved substances, particularly by dissolved macromolecules (proteins, polysaccharides, lipids). The formation of these conditioning films will affect both the physicochemical properties of the substratum surface and the adhesion of microorganisms. Nevertheless, explaining the change in microbial attachment is not straightforward (see CONDITIONING FILMS FROM ENVIRONMENTAL WATERS, this Encyclopedia).

The changes of hydrophobicity and electrical properties of silicone rubber, used in voice prostheses, could not be related to the systematic inhibitory effect of a salivary film on bacterial and yeast adhesion (132). The attachment (assessed after drying) of bacteria to natural (shale, sandstone, andesite) and industrial (stainless steel, polypropylene) materials was decreased or increased after the formation of a conditioning layer by dissolved compounds; however, no relation could be established with water contact angles determined on the conditioned substratum (133). The study of the influence of adsorbed milk-related products (skim milk, sodium caseinate, whey protein isolate and whey permeate) on *L. lactis* attachment revealed a beneficial effect of skim milk and whey permeate, which could not be attributed to the overall chemical composition, hydrophobicity, or electrical properties of the conditioning film. Force-distance curves recorded by AFM, combined with a study of dynamic wetting indicated that the mobility of adsorbed macromolecules play a key role in favoring attachment of *L. lactis* to skim milk-conditioned substratum (134). On the other hand, conditioning stainless steel with skim milk was found to reduce the adhesion of five food-borne pathogens; cross-linking adsorbed proteins partially reversed the inhibition of bacterial attachment (88). These two studies illustrate that adsorbed macromolecules of similar nature may condition substratum surfaces in a way that is favorable or unfavorable to attachment, depending on the partner surfaces involved. While the effect of conditioning film on attachment may be positive or negative, it appears from a recent compilation (12) that the force exerted by the liquid-air interface tends to detach a higher percentage of microorganisms attached via a conditioning film as compared with microorganisms attached to a bare substratum.

Microorganisms as Living Colloidal Particles

The study of microbial adhesion to living tissue (human or vegetal) indicated the role played by specific interactions, on the basis of highly stereochemically selective (key-lock) interactions between the microorganism and the substratum (18–20,135). The attachment of *Lactobacillus plantarum* to a human colonic cell line was shown to occur via a mannose-specific interaction (136). Another strain of *Lactobacillus*, that is, *L. crispatus*, had the capacity to attach to the collagen of human intestinal extracellular matrix via its S-layer protein (137). Specific interaction may also effect adhesion of microbial cells on vegetable surfaces. The attachment of the basidiomycetous yeast *Rhodosporidium toruloides* to barley leaf surfaces was mediated by the interaction between the mannose residues of yeast surface and a lectin (138).

Microbial cells may influence the adhesion mechanisms by modification of their surface properties or by releasing extracellular compounds into the surrounding liquid. The surface chemical composition of the soil bacterium *A. brasilense* was shown to become richer in protein and hydrocarbon-like compounds during its growth. These variations were related to an increase of both hydrophobicity and adhesion to glass and polystyrene (139). The chemical composition and/or the physicochemical properties of the surface of other bacteria were also shown to be influenced by the growth and environmental conditions (140–142). On the other hand, compounds released by microbial cells may influence in a positive or negative way their behavior at interfaces. Extracellular compounds released by *L. lactis* may affect its attachment by increasing the ionic strength locally, near the cell-substratum interface (143). Extracellular proteins released by *A. brasilense* adsorb on the substratum, allowing attachment to occur (29,30). In the latter case, the influence of cell physiology was demonstrated by the influence of temperature and of tetracycline (an inhibitor of protein synthesis) on both protein release and attachment (144).

Biosurfactants released by microorganisms have a distinct tendency to accumulate at hydrophobic-hydrophilic interfaces and to lower the interfacial tension (145) and were shown to inhibit microbial adhesion. *Streptococcus thermophilus*, regularly encountered on heat exchanger plates in dairy industry, was shown to be able to produce a biosurfactant which caused its own detachment (146). A small amount of attached oral *Streptococcus mitis* (1 to 4% of surface coverage) was able to prevent attachment of *S. mutans*, pointing to the potential protective role of *S. mitis* in the oral cavity against the cariogenic *S. mutans* (147). It may be noted that

conditioning the substratum alone with the same biosurfactant was less efficient, indicating that inhibition occurred by conditioning both substratum and cell surfaces. Attachment of *S. thermophilus* to voice prosthesis materials (silicone rubber) prevented yeast colonization by biosurfactant production, allowing the prosthesis indwelling lifetime to increase (148). Further, biosurfactants may be used to form a conditioning film that discourages microbial attachment, as for the uropathogen *Streptococcus faecalis* (149); such application presents a high potential to inhibit adhesion on catheter materials.

Are the microorganisms able to react upon contact with a solid surface by inducing a specific activity that leads to their attachment? Comparison of gene expression for *E. coli* cells, either planktonic or from a biofilm, showed that this microorganism is able both to repress the flagellum formation, which might destabilize the biofilm, as well as to activate the production of exopolysaccharide (colanic acid), which will reinforce the biofilm structure (150). However, this study does not answer the question. By comparing *E. coli* strains proficient or deficient in colanic acid production, Danese and coworkers (151) showed that exopolysaccharide production is not required for attachment, in contrast with biofilm development. The study of attachment of *P. aeruginosa* under flowing conditions revealed that the situation may be rather complex: (*1*) the biofilm development was related to the expression of the gene responsible for alginate synthesis, allowing bacteria to be retained by a glass substratum; (*2*) this expression was not a prerequisite for attachment, indicating that alginate synthesis was not necessary for attachment to glass; (*3*) in the absence of such expression, the bacteria were detached from the substratum as time passed (152). In the same way, synthesis of proteins was shown to be essential to the anchorage of *A. brasilense* to polystyrene (29,30). The production of quorum-sensing molecules (153) has been shown to be necessary to the differentiation step of *Pseudomonas* biofilm formation, but not to the primary adhesion step (154).

Heterogeneity of Cell and Substratum Surfaces

The hydrophobicity, electrical properties, and chemical composition of microbial surfaces, can be characterized by water contact angle measurement (155,156), electrophoretic mobility measurement (65) and X-ray photoelectron spectroscopy (157,158), respectively. While relevant information may thereby be obtained regarding cell behavior at interfaces, most of these techniques do not probe the cell surface in its native state. Moreover, all give information on overall surface properties and do not provide information at high lateral resolution.

Microsphere Attachment. Polystyrene latex microspheres were shown to attach preferentially to germinating tubes and hyphae compared with the parent cell, for yeast (159) and other fungal cells (160,161). The microspheres thus give information about the heterogeneity of the surface properties of these microorganisms. Nevertheless, the exact nature of the interactions (hydrophobic, electrostatic, steric) leading to the attachment of these microspheres (both negatively charged and hydrophobic) could not be specified (160). The meaning of the microsphere adhesion test must be therefore approached with caution.

In a similar way, the adhesion of gold colloidal particles (both hydrophobic and negatively charged) to a tufted streptococcal strain showed an asymmetry of surface properties (124). Electron microscopy revealed that colloidal gold did not attach to the bald part of tufted *S. sanguis* strains over the pH range 3.7 to 9.0 because of the hydrophilic nature of this portion of the cell surface. Adhesion of colloidal gold to the long tuft fibrils occurred irrespective of pH, confirming conclusions from contact angle measurements that these fibrils convey hydrophobicity to the cell surface. Adhesion of colloidal gold to short fibrils occurred at pH 3.7 but not at elevated pH, because of increased electrostatic repulsion between the gold and the negatively charged short fibrils with increasing pH. Accordingly, the short and long fibrils can be associated with carrying negative charges and hydrophobicity, respectively (67). It may be noted that, whether using polystyrene microspheres or gold particles, this approach does not account for the possible role played by macromolecular interactions.

Atomic Force Microscopy. Regarding the assessment of the heterogeneity of substratum and cell surfaces, exciting possibilities are now offered by atomic force microscopy (AFM) to investigate the molecular interactions and properties of surfaces on the nanometer scale. AFM, invented in 1986 (162) consists of measuring the forces acting between a sharp probe and the surface of a sample. It allows the nanoscale mapping of surface topography, as well as the direct measurement of mechanical properties, friction, and interaction forces (electrostatic, van der Waals, solvation, steric interactions). As opposed to more conventional surface analysis techniques, AFM can be operated in aqueous solutions, which makes it possible to study living cells under physiological conditions (125,163). A very challenging goal for future research is to directly map the surface properties of living cells in aqueous conditions.

AFM offers new perspectives concerning the nanoscale mapping of physicochemical properties (hydrophobicity, electrical properties, macromolecular interactions). Germinating spores of *P. chrysosporium* were shown to present a heterogeneous ultrastructure made of granular and smooth zones (128). Figure 11a shows a map of adhesion forces recorded on an area presenting both zones. A force-distance curve was recorded at each pixel of this map; lighter levels correspond to larger adhesion forces. The comparison of this map with the height image recorded on the same area (Fig. 11b) demonstrated the relevance of AFM to assess the heterogeneous character of microbial cell surfaces with regard to physicochemical interactions.

Recently, Dufrêne (164) described a new method for characterizing the physicochemical properties of

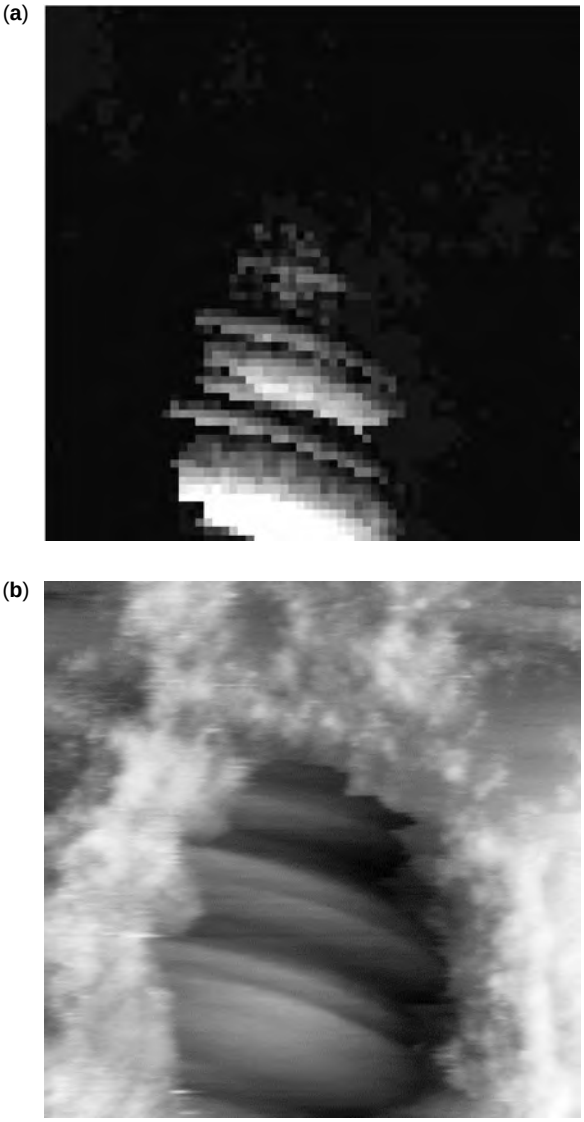

Figure 11. AFM adhesion force map (a) and height image (b) recorded with a silicon nitride probe on the same area ($2 \times 2\ \mu m^2$) of a germinating spore of *P. chrysosporium*. Each pixel of the map corresponds to a force-distance curve, the gray level corresponding to the adhesion force value (125). Z-range = 10 nN (a) and 100 nm (b).

native microbial cells by using AFM with chemically functionalized probes. Functionalization was shown to make the probe very sensitive to surface hydrophobicity, the magnitude of the adhesion forces measured between functionalized probes and substrata decreasing in the order $CH_3/CH_3 > CH_3/OH > OH/OH$. The surface of *P. chrysosporium* spores was homogeneously hydrophilic, as revealed by the lack of adhesion forces measured among the spore using CH_3- and OH-terminated probes. An AFM probe can also be functionalized to assess the specific interaction between a ligand and a receptor, as performed for streptavidin-biotin (165) or concanavalin-mannan (lectin-like) (166) interactions.

CONCLUSION

The methods used to study microbial adhesion differ according to two major characteristics that will influence the significance of the results: (i) the rate of transport of microorganisms to the surface; and (ii) the shear exerted near the substratum surface. The experimental conditions may also influence the physicochemical properties of the substratum surface, which may be affected by adsorption of substances present in the liquid or released by the cells. The choice of the methodology will differ depending on whether the interest is focused on the rate of attachment, on the strength of adhesion, on the study of the cell-substratum surface, or on the comparison of different substratum materials.

The role of electrostatic interactions and hydrophobic interactions in controlling microbial adhesion is well established. However, approaches attempting to quantify cell-substratum interactions and to predict cell attachment or adhesion strength are subject to severe limitations. The approach based on the balance of interfacial energies is limited by the impossibility to determine accurate values of the surface energy from contact angles of liquids or alternative methods.

This approach and the DLVO theory rely on hypotheses, which may be crude simplifications, particularly regarding the microbial cell surfaces. Of concern are the surface roughness, deformability, and heterogeneity. Solvated macromolecules or biosurfactants, whether present at the cell surface or adsorbed by the substratum, may also play a major role. Moreover, specific interactions may come into the play with biological substrata or substrata conditioned with compounds of biological origin. AFM offers promising perspectives regarding the possibility to probe directly interfacial interactions involving microbial cells and to map the physicochemical properties and adhesion forces over a cell surface.

Acknowledgments

The authors thank R.A. Jacob, F. Bouvy, and L. Durinckx for the preparation of the manuscript, and Prof. P. Grange for the use of the atomic force microscope. The support of the Foundation for Training in Industrial and Agricultural Research (FRIA), the National Foundation for Scientific Research (FNRS), the Research Department of Communauté Française de Belgique (Concerted Research Action), the Federal Office for Scientific, Technical, and Cultural Affairs (Interuniversity Poles of Attraction Programme), and the European Union (Research Project N° ENV4-CT97-0634; COST Action 520 Biofouling and Materials) is gratefully acknowledged.

AEROBIC ALKALIPHILES

MASAHIRO ITO
Toyo University
Gunma, Japan

Recently, it has become clear that life exists in Milieux that were earlier thought to be incompatible with growth, for example, extremely high temperatures, very low temperatures, abyssobenthic conditions, strongly alkaline pH, and strongly acid pH. The "extremophiles" that grow in such conditions are the subject of current active research. Alkaliphilic microorganisms are extremophiles that actively grow in extremely alkaline Milieux, for example, pH 10, and generally require sodium ions for growth. Alkaliphilic microorganisms are classified as either facultative or obligate alkaliphiles, depending on their capacity to grow at neutral pH (Fig. 1). Obligate alkaliphiles are restricted to alkaline pH, whereas facultative alkaliphiles can also grow at neutral pH. Microorganisms called *alkalitolerant* typically have an upper limit of pH 9 for robust growth; they grow poorly in the pH ranges of true alkaliphilic bacteria. Alkaliphilic microorganisms are distributed widely in nature and include actinomycetes, eubacteria, archaea, and fungi. There are many interesting and unresolved issues with respect to how alkaliphilic microorganisms adapt to their extremely alkaline Milieux. The mechanism of this adaptation has been most extensively studied in the *B*. species. Data have been presented for the roles of Na^+/H^+ antiporters, which are present in the cell membrane, and of a barrier of charged cell wall–associated macromolecules in the accommodation of the bacteria to the alkaline Milieux. In addition to mechanistic studies, the applications of alkaliphile biology to industry are numerous. For example, extracellular enzymes produced by alkaliphiles are used in laundry detergents (e.g., alkaline cellulase and alkaline protease) and are used in the production of cyclodextrin, which can encapsulate large compound molecules (e.g., cyclomaltodextrin glucanotransferase). Thus, alkaliphilic microorganisms are very interesting from both the viewpoints of physiology and industrial applications.

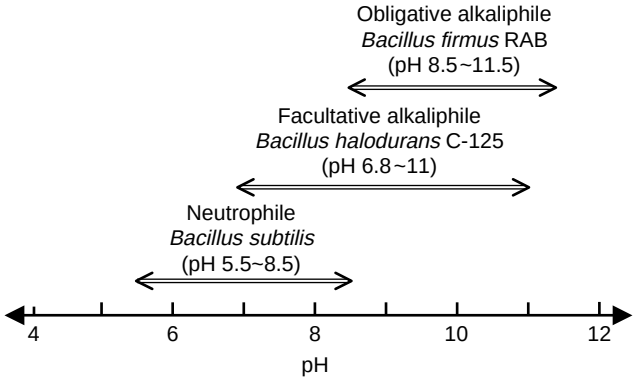

Figure 1. The relationship of pH to the growth of a typical neutrophile and two categories of alkaliphiles. The typical pH dependency of the growth of neutrophile, *B. subtilis*, and two categories of alkaliphiles, obligative alkaliphile, *B. firmus* RAB and facultative alkaliphile, *B. halodurans* C-125 is shown by two-way arrows.

In this article, I present an introduction to alkaliphilic microorganisms that includes (*1*) historical background, (*2*) diversity, and (*3*) physiology.

HISTORICAL BACKGROUND

Although alkaliphilic microorganisms are now well recognized, their existence was little noted until the 1970s. Koki Horikoshi, a leading investigator of alkaliphiles, was the first to initiate thorough studies of these bacteria, starting in the late 1960s. Horikoshi has commented that when he began these investigations, he found only 16 scientific papers referring to alkaliphilic microorganisms (1). Two of the earliest papers dealing with the growth of bacteria in alkaline environments were those of Meek and Lipman in 1922 (2) and Downie and Cruickshank in 1928 (3). However, both these reported on the growth of non-alkaliphiles when exposed to an alkaline environment. The earliest papers on true alkaliphiles were those of Gibson (4) on *B. pasteurii* growing at pH 11 and of Vedder (5) on *B. alcalophilus* growing well at pH 8.6 to 11. Early in the 1960s, Takahara and coworkers (6) demonstrated the industrial importance of alkaliphiles when he improved the process of indigo fermentation through the addition of the alkaliphilic strain *Bacillus* S-8. This was the first industrial application of alkaliphilic bacteria. Since then, more than 1,000 papers on alkaliphiles and their adaptations have been published (1).

DISTRIBUTION

Distribution of Alkaliphiles in the Extremely Alkaline Milieux in Nature

Research into the distribution of alkaliphiles in the extremely alkaline environments was developed by Grant and his colleagues (7). Natural soda lakes and soda deserts exist worldwide (e.g., Lake Magadi in Kenya (pH 10.9), Wadi Natrum in Egypt (pH 11), and Lake Sambhar in India (pH 9.0)), and they are summarized in Table 1. Some of them have NaCl concentrations of about 5% w/v, whereas others are hypersaline, with NaCl concentrations greater than 15% w/v. These lakes are strongly inhabited by prokaryotic and archaeal alkaliphiles, which prosper in these selective environments. Because Ca^{2+} and Mg^{2+} are precipitated as carbonates, the ionic concentrations of these important divalent cations are very low in these lakes. The major ions of the lake are Na^+, Cl^- and bicarbonate/carbonate. The alkaliphilic isolates from these lakes generally require Na^+ for growth. Most of them are haloalkaliphiles (7).

Artificial alkaline environments are probably selected for particular alkaliphiles from adjoining soils and waters. Isolates from such environments include *Bacillus* sp. No. S-8 from an indigo ball of indigo fermentation (6), gram-positive *Exguobacterium auratiacum* from potato processing waste (8), and a gram-positive facultatively alkaliphilic *Bacillus* sp. from the alkaline wash waters derived from the preparation of edible olives (9).

Table 1. Worldwide Distribution of Soda Lakes and Soda Deserts

North America	
Canada	Manito
United States	Alkali Valley, Albert Lake, Lake Lenore, Soap Lake, Big Soda Lake, Mono Lake, Searles Lake, Deep Springs, Rhodes, Marsh, Harney Lake, Summer Lake, Surprise Valley, Pyramid Lake, Walker Lake
Central America	
Mexico	Texcoco
South America	
Venezuela	Langunilla Valley
Chile	Antofagasta
Europe	
Hungary	Lake Feher
Yugoslavia	Pecena Slatina
Russia	Kulunda Steppe, Tanatar lakes, Karakul, Araxes plain, Chita, Barnaul, Slavgerod
Asia	
Turkey	Van
India	Lake Looner, Lake Sambhar
China	Qinhgai Hu, Sui-Yuan, Heilungkiang, Kirin, Jehol, Chahar, Shansi, Shensi, kansu
Africa	
Libya	Lake Fezzan
Egypt	Wadi Natrun
Ethiopia	Lake Aranguadi, Lake Kilotes, Lake Abiata, Lake Shala, Lake Chilu, Lake Hertale, Lake Metahara

The Distribution of Alkaliphiles in Nonalkaline Milieux in Nature

As for the broader distributions of alkaliphilic microorganisms, alkaliphiles are surprisingly distributed almost everywhere. Alkaliphiles are isolated from the soil of deep-sea trenches at 11,000-m depth (10) and from diverse soil and water samples from more conventional sites (1). Alkaliphiles can be found in soil at pH 4, but the highest frequency was observed in alkaline soil, especially above pH 8.3. The number of alkaliphiles found in soil was about 1/10 to 1/100 of that of neutrophilic bacteria. The number of organisms was to a certain extent correlated with the pH of the soil sample (Fig. 2).

Alkaliphiles Are Not Restricted to Any Taxonomic Group

Alkaliphiles are thought to change the pH of their Milieux to suit their optimum growth. In addition to prokaryotic alkaliphiles, various types of alkaliphilic microorganisms, including actinomycetes, fungi, yeast, and phages, have been isolated (1) and some of them are presented at Table 2.

A summary of the taxonomic group of prokaryotes isolated from soda lakes, an alkaline Milieux in nature, is reproduced from a review by Jones and coworkers (11). The enormous taxonomic diversity of extreme alkaliphiles is evident, and it is further reflected in the diversity of characteristics. Alkaliphilic cyanobacteria are among the primary photosynthetic organisms that produce oxygen; such organisms include *Spirulina*, *Cyanospira*, *Synechococcus*, and *Chroococcus*. Some of the soda lakes harbor many characteristic alkaliphilic phototrophic bacteria, for example, *Ectothiorhodospira* together with halophilic archaea (12). Zhilina and coworkers (13) isolated and characterized *Desulfonatronovibrio hydorogenovorans*, an alkaliphilic, sulfate-reducing bacterium, from a soda-depositing lake, Lake Magadi, Kenya.

Diversity of Alkaliphilic Bacillus Strains

Since Horikoshi and his colleagues began the screening and research of alkaliphilic microorganisms in 1968, many alkaliphilic microorganisms have been isolated. Most of them are gram-positive, spore-forming, motile, and aerobic rods, and so are classified in the genus *Bacillus*. *Bacillus* species are among the most commonly found aerobic and eubacterial alkaliphiles, both in alkaline and in nonalkaline Milieux. A very large number of

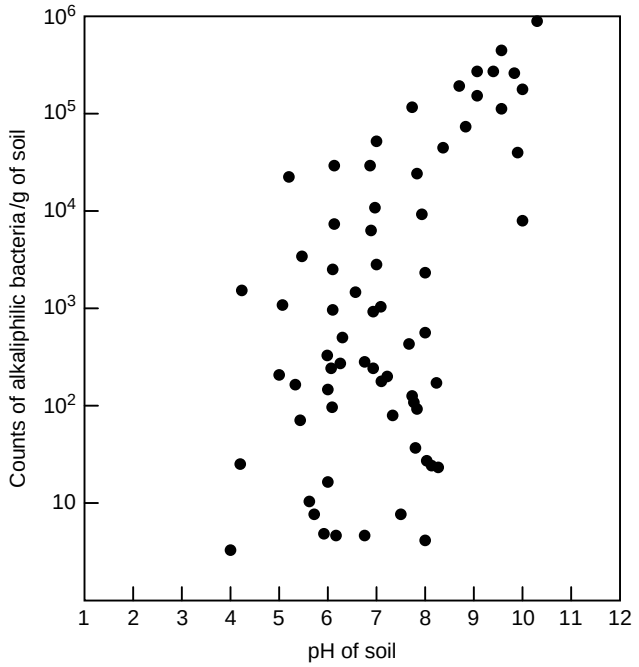

Figure 2. Distribution of alkaliphilic bacteria in soil (Reproduced with permission from Horikoshi and Akiba, *Alkalophilic Microorganisms: A New World*, p11, Japan Scientific Societies Press, Tokyo (1982)).

alkaliphilic bacilli have been isolated because of interest in the biotechnological application of useful alkali-resistant extracellular enzymes.

In the 1990s, Fritze and coworkers (14) and Nielsen and coworkers (15) classified alkaliphilic and alkali-tolerant *Bacillus*. They reported phylogenetic diversity of alkaliphilic *Bacillus* strains isolated from various sources and proposed that they were classified into 13 taxa and a number of unassigned single-membered clusters by using DNA-DNA hybridization, numerous physiological and biochemical characteristics, DNA base composition, and 16S rRNA analyses. Two taxa were equated with *B. cohnii* and *B. alcalophilus* and nine of the remainder were proposed as new species with the following names: *B. agaradhaerens*, *B. clarkii*, *B. clausii*, *B. gibsonii*, *B. halmapalus*, *B. halodurans*, *B. horikoshi*, *B. pseudoalcalophilus*, and *B. pseudofirmus*. Two taxa were insufficiently distinct to allow confident identification and these have therefore not been proposed as new species.

In a separate study, Agnew and coworkers (16) reported the isolation and characterization of novel obligate alkaliphiles from bauxite-processing waste. They are currently assigned to the new species *B. vdderi*. The new isolates appear to be members of the genus *Bacillus* but 16S rRNA sequence characters and other physiological and biochemical analysis indicate that the new isolates are not members of any validly identified *Bacillus* species.

Haloalkaliphiles

Oren (12) classified the Halobacteriaceae into six genera, *Halobacterium*, *Haloarcula*, *Haloferax*, *Halococcus*, *Natronobacterium*, and *Natronococcus*. *Natronobacterium* and *Natronococcus* are alkaliphilic archaea that grow only in specialized Milieux with the combination of extremely high salt concentrations (2.5–5.2 M NaCl) and high pH values (8.5–11.0). Such haloalkaliphiles have been isolated from soda lakes and soda deserts. The amount of glycolipid in the membrane hardly varied in haloalkaliphilic archaea when compared with that of haloneutrophilic archaea. A novel osmolyte, 2-sulfotrehalose, was discovered in several *Natronobacterium* species of haloalkaliphilic archaea (17). The concentration of sulfotrehalose increases with elevating concentrations of external NaCl, a behavior consistent with its identity as an osmolyte. Other common osmolytes (glycine betaine, glutamate, and proline) were neither accumulated nor used for osmotic balance in place of the sulfotrehalose.

Kamekura and coworkers (18) studied the diversity of haloalkaliphiles on the basis of phylogenetic tree reconstructions, signature bases specific to individual genera, and sequences of space regions between 16 and 23S rRNA genes. They proposed the following changes: *Natronobacterium pharaonis* be transferred to a new genus, *Natronomonas* as *Natronomonas pharaonis* and *Natronobacterium magadii* to be transferred to a new species of the genus *Natrialba* as *Natrialba magadii*. Xu and coworkers (19) isolated and characterized novel haloalkaliphilic archaea from a soda lake in Tibet, China. They proposed to classify their strains in a new genus *Natronorubrum*. At present, microorganisms that belong to *Halobacteriaceae* have 16 genera registered in the taxonomy section of the National Center for Biotechnology Information (NCBI) (*http://www.ncbi.nlm.nih.gov/htbin-post/Taxonomyhome.html/*). These six genera include *Haloalcalophilium* in *Halobacteriaceae*, belonging to haloalkaliphilic archaea.

Romano and coworkers (20) isolated and characterized a haloalkaliphilic microorganism from hard sand of Lake Venere on Pantelleria Island, Italy. This haloalkaliphile is a gram-negative pleomorphic rod, strictly aerobic, capable of accumulating polyhydroxybutyrate, and growing optimally at pH 9.0 in the presence of 10% NaCl at 33–35 °C. They classified this strain in a new species of the genus *Halomonas*.

Yeast and Fungi

Most species of yeasts and yeast-like fungi can grow well in the acidic to neutral pH range. It has long been assumed that yeasts cannot grow at alkaline pH except for unusual strains. A few investigators have reported that certain yeasts could grow in initially alkaline media (21,22). However, these investigations were not carried out under appropriate conditions. The media used were poorly buffered and the change in pH was not followed.

Goto and coworkers (23) examined their microbial properties and proposed a new species, *Exophiala alcalophila* Goto et Sugiyama, with an accompanying new yeast morph *Phaeococcomyces alcalophilus* Goto et Sugiyama. These strains grow between pH 5.4 and 10.4 on YM medium (5 g peptone, 3 g malt extract, 3 g yeast extract, 15 g glucose, and 15 g agar in 1,000 ml distilled water). Aono (24) studied the taxonomic distribution of alkali-tolerant yeasts in his laboratory. Yeasts and yeast-like fungi (433 strains, 296 species, 53 genera) were examined to determine the upper limit of pH for growth. Among these, 135 strains of 86 species were found to be capable of growth at a pH above 10. These alkali-tolerant species belonged to 27 genera of yeasts, of which 10 genera contained only alkali-tolerant species. Furthermore, Aono (25) measured upper pH limits for growth of yeasts belonging to the genus *Hansenula* and some related strains. As shown in Figure 3, alkali-tolerant species occupied particular positions of a phylogenetic tree proposed for the genus.

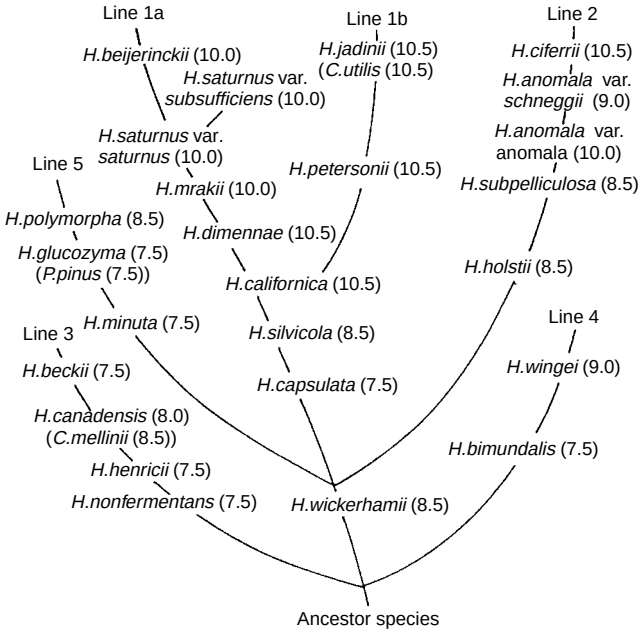

Figure 3. Alkali-tolerant yeasts on a phylogenetic tree of the genus *Hansenula*. The number in parentheses shows the upper pH limit for growth of a given strain. Species related to *Hansenula* are shown in parentheses. (Reproduced with permission from Aono, *Syst. Appl. Microbiol.* **15**, 589 (1992)).

Alkaliphilic Cyanobacteria

Gerasimenko and coworkers (26) reported the discovery of a wide variety of alkaliphilic cyanobacteria (16 genera and 34 species were found). Buck and Smith (27) reported an Na^+/H^+ electrogenic antiporter in alkaliphilic *Synechocystis* sp. Singh (28) partially purified a urease from an alkaliphilic diazotrophic cyanobacterium, *Nostoc calcicola*. Strain Z7935 (T) is an obligatory sodium-dependent alkaliphile, which grows in a sodium carbonate medium and does not grow at pH 7; the maximum pH for growth is more than pH 10, and the optimum pH is 9.5 to 9.7. The optimum NaCl concentration for growth is only 3% w/v (13).

Thermoalkaliphiles

Early work on alkaliphiles suggested that microorganisms adapted to the two extreme environmental conditions of high temperature and high alkaline pH did not exist. However, many kinds of thermoalkaliphiles have been isolated from different habitats since the 1980s. These include an obligate alkaliphilic *Clostridium* species isolated from sewage (29), an asporogenous, gram-positive ammonifying anaerobe from a soda lake deposit, *Tindallia mamadii* (30), a xylan-degrading anaerobic thermoalkaliphile designated as strain LB3A (31), and an actinomycete, *Thermoactinomyces* sp. HS682 (32). Stetter and colleagues (33) have even described a hyperthermophilic, alkaliphilic archaea, *Thermococcus alcaliphilus*, which grows on polysulfide at temperatures between 56 °C and 90 °C and with an optimum temperature around 85 °C. The pH range for growth was 6.5 to 10.5, with an optimum around 9.0.

Other Alkaliphiles

In contrast to thermoalkaliphiles, Kimura and Horikoshi (34) isolated a *Micrococcus* that was alkalipsychrotrophic in nature. This microorganism showed the highest growth rate at 0 °C and produced an amylase whose properties might be useful in food-processing circumstances.

Several alkaliphilic spirochetes were also isolated from Lake Magadi and from Lake Khatyn, Central Asia, by Zhilina and coworkers (35). Analysis of the genes encoding 16S rRNA indicated a possible fanning out of the phylogenetic tree of spirochetes.

PHYSIOLOGY

The Feature of Cell Surfaces in the Alkaliphilic *Bacillus* Species

Cell Walls. Aono and Horikoshi classified the alkaliphilic *Bacillus* species into three groups on the basis of cell wall composition and other physiological characteristics (36). As described in Table 3, the alkaliphilic *Bacillus* strains of group 1 contain large amounts of glucuronic acid and hexosamine in the cell walls and cannot grow at a neutral pH. The cell walls of group-2 strains contain large amounts of acidic amino acids and uronic acids. Na^+ is essential for their growth. The quantities of acidic compounds in the cell walls of both groups 1 and 2 are increased when cells are grown at elevated pH. In contrast, the cell walls of group-3 organisms contain phosphorus and neutral sugars in large amounts and are essentially similar to the walls of the neutrophilic *Bacillus subtilis* in chemical composition. Growth was observed in the presence of Na^+ or K^+.

The Role of the Cell Walls in Growth at Alkaline pH. Protoplasts prepared from alkaliphilic *Bacillus* are unstable at alkaline pH and regenerate only at neutral pH but not at alkaline pH (37). This suggests that some mechanisms of adaptation to high pH, "alkaliphily," might involve the cell walls, the part of the cell that is directly exposed to the extracellular environment. The cell walls of alkaliphilic *Bacillus* consist of peptidoglycan and non-peptidoglycan components. The peptidoglycan from all three groups is of the A1γ type, identical to that in the cell walls of neutrophilic *B. subtilis* (38). Cell walls groups 1 and 2 have specific acidic polymers called teichuronopeptide (TUP); TUP is a polymer in which an acidic polypeptide binds covalently to polyglucuronic acid. Cell wall concentrations of TUP increase with respect to peptidoglycan as the culture pH is elevated (39). While the mechanism is not clear, it is thought that the acidic fraction of the cell walls may act as an obstacle to the high extracellular concentrations of hydroxide ions or as a reservoir of hydrogen ions (39).

In other alkaliphilic *Bacillus* species, for example, *B. pseudofirmus* OF4, the uronic acid polymers are not found (40). Recent studies have shown that *B. pseudofirmus* OF4 has an acidic S-layer polymer produced from a gene that has strong homology with genes from neutrophilic *B. anthracis* and *B. licheniformis*. This protein was identified in studies of the 2D gel electrophoresis patterns of membrane-associated proteins of pH 10.5- and 7.5-grown cells of *B. pseudofirmus* OF4. It is a homogeneous, apparently processed, protein that is present in greater amounts at high pH. On cloning, sequencing, and disruption of the gene, the S-layer was found not to be required for alkaliphily in *B. pseudofirmus* OF4, but to confer an advantage for growth at pH 10.5. Cytoplasmic pH homeostasis, on a sudden shift from pH 8.5 to 10.5, is somewhat better in the S-layer-containing wild type than in mutant strains lacking the S-layer (41). *Bacillus pseudofirmus* OF4 may also have an acidic capsular layer partial sequence for genes that are likely to encode the synthetic enzymes for a polyglutamate capsule that were characterized in this species (42). It will be of interest to complete the characterization of the sequence and the role of this locus.

Table 3. Classification of Alkaliphilic *Bacillus* Strains

Group	Growth pH	Major Components of Cell Wall	Ion Requirement
1	No growth at pH 7	Glucuronic acid Hexosamine	Na^+ (essential)
2	Capable of growth at pH 7	Aspartic acid Glutamic acid Galacturonic acid Glucuronic acid	Na^+ (essential)
3	Capable of growth at pH 7	Phosphoric acid Glycerol Neutral sugar	Na^+ or K^+

Auxotrophy, Antibiotic Resistance

The majority of alkaliphilic microorganisms isolated from nature are apparently auxotrophic. Such alkaliphiles cannot grow in completely synthetic media (e.g., the M9 culture media in which *Escherichia coli* and *B. subtilis* can grow). However, some alkaliphilic *Bacillus* strains can; these are used for molecular biological manipulations. It is possible, in these strains, to introduce useful markers by chemical mutagenesis (1). Transformants are selected with the antibiotic resistance when plasmid DNA is incorporated into alkaliphilic microorganisms. In this case, common antibiotics such as kanamycin and tetracycline cannot be used because they are very unstable under alkaline pH (1). Chloramphenicol and erythromycin are stable at alkaline pH and can be used.

Lipid Composition

Clejan and coworkers (43,44) have reported that obligately and facultatively alkaliphilic bacteria exhibit significant differences in lipid constituents. They compared the lipid composition of several obligately and facultatively alkaliphilic Bacilli. High levels of cardiolipin were reported, that is, 13% and 25% of the polar lipids in *B. pseudofirmus* RAB and OF4, respectively. The obligately alkaliphilic *B. pseudofirmus* RAB had a much higher neutral/polar lipid ratio than the facultatively alkaliphilic *B. pseudofirmus* OF4. The *B. pseudofirmus*

RAB had 90% branched chain fatty acids as opposed to 72% in the *B. pseudofirmus* OF4. The lipids of obligate alkaliphiles contain a significant amount of unsaturated fatty acids, but these fatty acids are hardly present in the lipids of facultative alkaliphiles. Although the relationship of unsaturated fatty acid content to obligate alkaliphily has not been demonstrated, it may be hypothesized to involve membrane fluidity.

Flagella and Sodium Ion

Flagellar movement of neutrophilic, nonmarine bacteria is not caused by ATP but by H^+-driven motors (45). However, flagellar movement of alkaliphiles and marine bacteria is accomplished by Na^+-driven motors. These Na^+-driven flagellar motors are inhibited by amiloride (46). It has been reported that even on a significant shift to alkaline pH, Na^+-driven flagellar motors do not rotate without sodium ions (1). The structural difference of a flagellum motor of the H^+ type and the Na^+ type is not seen by observation at the electron microscope level. Even if there is a difference in the coupling ion between H^+- and Na^+-coupled flagella, the basal structure and the mechanism of the rotation are thought to be similar (1).

Membrane Transport

In the growing cell, nutrients can be taken up into the cell and metabolized, followed by secretion of the products. Uptake of the nutrient and secretion of the products involve passage through the cytoplasmic membrane. The cytoplasmic membrane also plays an active role in pH homeostasis (see section on Antiporters). Alkaliphiles have numerous transport systems that can take up nutrients efficiently from the highly alkaline environment (47). In bacteria, amino acids are usually taken up against a concentration gradient by active transport. Usually, the energy required for active transport is provided either by ATP or by the proton motive force. Under the high alkaline Milieux, the proton motive force decreases, and alkaliphiles tend not to utilize proton as a coupling ion. Alkaliphiles have Na^+-coupled uptake systems instead of proton as a coupling ion. Other monovalent cations such as K^+, Li^+, and NH_4^+ could not be substituted for Na^+, and different species of counteranions for Na^+ did not affect the uptake. The uptake of amino acids was stimulated by the addition of Na^+; this was especially true for glycine, L-alanine, L-serine, and L-asparagine (47).

Intracellular pH

Most alkaliphiles have an optimum growth pH at around pH 10, which is significantly different from that tolerated by well-investigated neutrophilic microorganisms. Therefore, the question arises as to how these alkaliphiles can grow in such an extreme Milieux. Are there any fundamental differences in the physiology of alkaliphilic and neutrophilic microorganisms? If intracellular pH is estimated by measuring the extra- and intra-cellular distribution of weak bases, which cells do not actively transport, the intracellular pH is found to be maintained at around 8, despite a high extracellular pH of 8 to 11, as shown in Table 4 (1). Therefore, one of the key features in alkaliphily is associated with the cell surface and its transporters, which must contribute to an intracellular neutral Milieux that is separate and distinct from the extracellular alkaline Milieux.

Na^+/H^+ Antiporters Involved in the Intracellular Acidification Relative to the Extracellular Milieux

Since alkaliphiles live in an extremely alkaline Milieux, their most challenging problem is keeping a cytoplasmic pH more acid than the outside pH, often by more than 1.5 pH units. In other words, they must actively bring protons into the cell. In contrast to research with neutrophiles, an especially strong case can be made for the acidification of the cytoplasm of alkaliphiles by Na^+/H^+ antiporters (48). When alkaliphiles are placed in a medium without Na^+ at pH 10, the intercellular pH quickly rises to the value of the outside pH. However, when Na^+ is present in the external medium, the intercellular pH does not rise on shifting to the more basic medium. Furthermore, mutants of alkaliphiles that cannot grow at pH values above 9 are defective in Na^+/H^+ antiporter activity. The antiporter is electrogenic ($H^+ > Na^+$) and driven by the membrane potential ($\Delta\Psi$), which is generated by the primary proton pumps of respiratory chains. The sodium ion circuit is completed when sodium ion enters the cell via Na^+/solute symporters that are also driven by the $\Delta\Psi$. The use of Na^+/solute symporters has the advantage that solute transport is driven by the sodium potential rather than the proton potential, the latter being low because of the inverted ΔpH (pH_{in}-pH_{out}).

Respiration-Dependent ATP Synthesis

Alkaliphiles always maintain their cytoplasmic pH lower than the outside pH, the opposite of most bacteria. This raises a serious conundrum for energy conservation. To

Table 4. Intracellular pH Values in Alkaliphilic Bacillus Strains at Different External pH Values

Microorganism	External pH	Internal pH
B. alcalophilus	8.0	8.0
	9.0	7.6
	10.0	8.6
	11.0	9.2

	7.5	7.4
	8.0	7.6
	8.5	7.8
	9.0	7.9
	9.5	8.1
	10.0	8.2
	10.5	8.4

survive in an alkaline Milieux, alkaliphiles must adjust their strategies of energy conservation. One possibility is to change the coupling ion. For example, some anaerobic alkaliphiles use Na^+-coupled ATP synthases (49). However, this is surprisingly not adopted by the alkaliphilic aerobic *Bacillus* species. These microorganisms have respiratory chains that pump H^+ ion outward and H^+-coupled ATP synthases, apparently like those of neutrophilic microorganisms. For the present, the mechanism of ATP synthesis in these microorganisms remains obscure. Krulwich (47) presented several possible models of the proton translocated outward by respiratory chains during ATP synthesis. One possibility is that the protons in electron transfer reactions are not released into free solution but extruded directly by the respiratory chains to the ATP synthase. A diagram of these elements is shown in Figure 4. An Na^+/H^+ antiporter, which is the major mechanism for extruding Na^+ and which also functions to bring protons into the cell for pH homeostasis in alkaliphilic *Bacillus* species, is shown. The Na^+/H^+ antiporter creates the sodium potential necessary for the Na^+/solute symporters because a primary Na^+ pump is not present. The antiporter uses the proton motive force (Δp) as an energy source. Also shown are Na^+/solute symporters that use the sodium electrochemical potential to accumulate solutes. The flagellar motor is drawn to turns at the expense of the sodium electrochemical potential. The respiratory chain represents a hypothesis in which protons are transferred directly from this complex to the proton coupled F_1Fo-ATP synthase in a protein–protein interaction. The cell wall–associated layer reflects the finding that, in *B. halodurans* C-125 and *B. pseudofirmus* OF4, respectively, different negatively charged polymers play at least some role in pH homeostasis (47).

Genomics

Numerous alkaliphile genes have been sequenced and physical maps have been reported from *B. pseudofirmus* OF4, *B. halodulans* C-125, and *Micrococcus* sp. Y-1 (50–52). The first whole genome sequence project for an alkaliphilic *Bacillus*, *B. halodurans* C-125, was completed in 2000 (53) and the postgenome project, especially directed toward clarifying the mechanisms of alkaliphily, has begun. The vastly increasing database on sequences of alkaliphilic proteins will provide insights into global adaptations in cytoplasmic proteins or in functional cytoplasmic assemblies, namely, ribosome, secretory particles, and so forth.

CONCLUSION

Alkaliphiles are unique microorganisms with great potential for physiology and biotechnology. The aspects that have received most attention in the late 1990s include (*1*) extracellular enzymes and genetic analysis of their production, (*2*) mechanisms of "alkaliphily," and (*3*) taxonomy of alkaliphiles. Taxonomy of haloalkaliphiles and anaerobic alkaliphiles is a very active field, and the number of microorganisms keeps increasing. So far, studies of alkaliphiles belonging to the genus *Bacillus* have led to the discovery of many alkaline enzymes and mechanisms of "alkaliphily" under extremely alkaline pH. However, new findings and an even more diverse group of applications of alkaliphiles from genome analysis, proteome studies, and novel ecological, molecular, and biophysical approaches will soon provide greatly expanded developments.

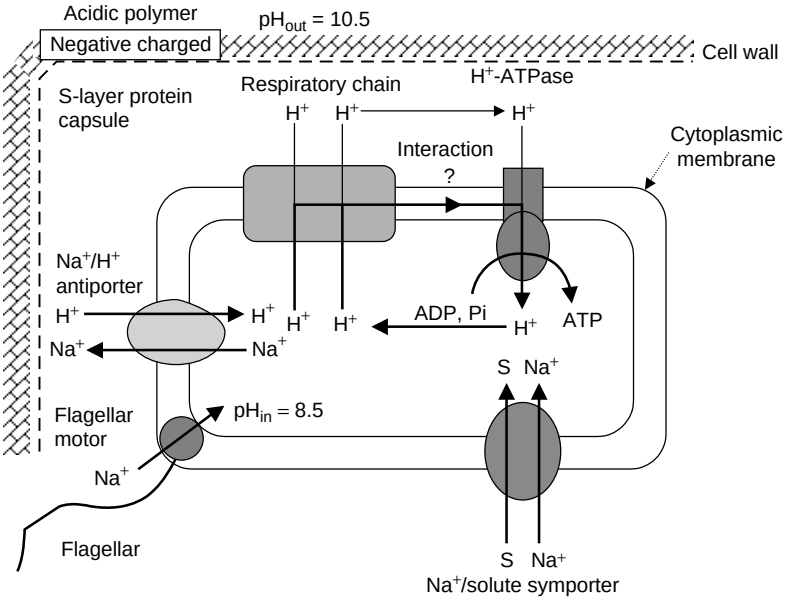

Figure 4. A model depicting the energy coupling mechanisms of alkaliphilic *Bacillus* species. The active pH homeostasis mechanism is shown as including respiration, Na^+/H^+ antiporter, and Na^+ re-entry pathway. The respiration chain extrudes H^+ (electron donors/acceptor not shown). The Na^+/H^+ antiporter is probably more Na^+-specific than those involved in pH homeostasis in neutralophilic bacteria. The Na^+ re-entry pathways are shown as a channel associated with the flagellum and Na^+/solute symporters (47). Other participants that have been suggested to function in the establishment and/or maintenance of an acidified cytoplasm relative to the medium are indicated and are discussed in the text. AEROBIC ENDOSPORES

Eva C. Nieminski
Utah Department of
Environmental Quality
Salt Lake City, Utah

Aerobic spores are not pathogenic to humans, which makes them useful as indicators of treatment effectiveness for drinking water. Because direct monitoring for waterborne pathogens such as protozoa and viruses is very inaccurate, time-consuming, and expensive, monitoring for aerobic spores can become a viable surrogate for the removal effectiveness of pathogens and parasites. Moreover, because most pathogenic organisms, even those found abundant in water sources, seldom are detected in treated drinking water, calculation of their removal through treatment is not possible. In contrast, aerobic spores are present in high concentration in most surface waters, and their presence can also be detected in treated water, thus allowing for an evaluation of treatment effectiveness.

The effectiveness of disinfection, especially the ultraviolet (UV) light treatment of both water and wastewater, can also be evaluated using aerobic spores as indicators. Being resistant to chemical disinfection and UV irradiation, aerobic spores can be used in development of disinfectant dose-response curve, thus allowing for a calibration and measurement of disinfection efficiency.

BACKGROUND

As we enter the new millennium, the drinking water industry is undergoing a major paradigm shift. This is because of increasing concerns over the potential presence of pathogens in potable waters and the large number of people with compromised immune systems. It has become clear that continuous process optimization based only on the current practice of turbidity monitoring (and to some extent particle counting) of treated water needs to be reevaluated (1). Although monitoring finished water quality is an essential step in the production of safe drinking water, traditional linkages between process monitoring and plant operation fail to provide an adequate margin of safety to enable operators to respond to temporal changes in source water quality (2). This monitoring paradox manifests itself periodically when cases of waterborne disease outbreaks occur even when finished water is in full compliance with regulatory requirements (3–5).

Water treatment regulations are becoming increasingly more stringent. However, emerging regulatory requirements do not provide utilities with a framework for optimizing treatment operations and processes to achieve finished water quality objectives. Alternative approaches for accommodating variability in source water quality are needed to provide plant operators with a sound basis for ensuring reliable plant performance.

Monitoring for microbial pathogenic contaminants presents a special challenge. Sampling and analytical methods that are available to detect *Giardia* and *Cryptosporidium* have limited sensitivity and accuracy (6). The time required for analyses does not allow for the practical use of the results in process control. Lack of "real-time" measurements of pathogens in water prevents utilities from being able to react to source water quality changes and provide proactive treatment optimization. In the absence of quick and reliable analytical methods for pathogens, pathogen indicators should be used.

The need for some measure that utility operators can use to determine how well their plants are optimized for the removal of pathogens is paramount if they are to achieve maximum treatment effectiveness. It has become clear that turbidity, as currently regulated, is an inadequate measure for this purpose. Recent waterborne outbreaks in the United States have been reported even though turbidity was within regulatory limits. Moreover, research has shown the presence of *Giardia* and *Cryptosporidium* even at turbidities of less than 0.1 NTU (4,7,8). A further complication to the turbidity issue is that optical turbidimeters are not accurate at readings less than 0.1 NTU (9).

In recent years, the use of on-line measurements by utilities to supplement routine sampling and analysis has increased substantially. Currently, the major types of on-line monitors in use at water treatment facilities include turbidity, pH, and ion-specific electrodes. Other options include particle counting and streaming current monitors. Relationships between on-line measurements and other monitoring parameters have not been developed. Correlation between suspended solids, particle counting, turbidity, and microbial content are highly source-specific (7), and most likely depend on the fraction of organic matter contained in the colloidal and suspended solids (10).

Common indicators are needed to establish a platform for comparison of water quality of various sources and their treatability, as well as to evaluate the efficiency of treatment achieved at various plants. Some indicators can be selected from the commonly used water quality parameters, such as turbidity, particle counts, and coliform bacteria (10–12). A critical assessment of microbiological parameters that could serve as surrogates for pathogenic microorganisms is needed to identify readily measurable analytes that can be quickly incorporated into the decisions made about water treatment plant operation.

The need for a surrogate has become increasingly apparent in the water industry in light of well-documented cases of disease outbreaks traced to drinking water as the route of transmission. Although the causative agent for a number of these outbreaks was identified as *Giardia* or *Cryptosporidium*, the affected water treatment plants did not have an effective way to monitor for the presence of the pathogen or to judge the treatment efficiency in eliminating the organisms from the finished water. Since these outbreaks, it has become even more apparent that the current methods for analyzing for *Giardia* and *Cryptosporidium* in watersheds and in finished water are inadequate. Besides, the reliability and reproducibility of the existing methods being an issue, there is a serious time lag between sample collection and data availability. Therefore, it is impossible to use even these flawed methods as a means to optimize treatment processes. Despite the water industry and the U.S. Environmental Protection Agency's (EPA's) attempts to improve this analytical method, the problems with its use remain. Although research into innovative and more rapid methods using such techniques as polymerase chain reaction and flow cytometry is promising, additional research is required before practical monitoring tools are available to the water industry.

SURROGATES FOR PROTOZOA IN DRINKING WATER

In recent years, a substantial effort has been focused on investigating the use of surrogates for optimizing treatment of drinking water and pathogen removal. Generally, it is agreed that an ideal surrogate would be abundant in water but not multiplying in treatment plant basins, resistant to treatment, and easy to detect and enumerate with cost-effective methods. The search for the surrogate includes both microbial and nonmicrobial parameters.

A research project on biological particle surrogates for filtration performance, performed at Colorado State University in 1995–1998 (13), has addressed the need for indicators that would serve as tools in plant optimization and was designed to evaluate a wide spectrum of microorganisms and their potential to serve as surrogates for monitoring of pathogen removal through filtration. This effort indicated that some bacteria, bacterial phages, and algae could represent *Giardia* and *Cryptosporidium* in removal mechanisms. In pilot tests, the use of various microbial surrogates was tested through seeding experiments. Significant correlation was established between the removal of *Giardia* and *Cryptosporidium* and some of the surrogates tested. However, because of a lack of supportive data, the significance of these correlations may be suspect. One suggested conclusion was that the strength of the correlations was dependent on the quality of measurements or enumeration of the surrogates. In fact, the strongest correlation was found with those surrogates that had the smallest deviation within the data set. A conclusion was also suggested that the deviation observed was due to error in measurement—the smaller the error, the more apparent the "true" relationship between pathogen and surrogate removal. The study demonstrated the difficulty in finding a reliable surrogate when there is so much uncertainty in the analytical methods for enumerating the pathogens.

Optical particle counting and sizing ("particle counting") has been considered a good candidate for a surrogate measure for pathogen occurrence in watersheds and treatment processes. Importantly, many utility operators and consulting engineers have begun to use this analytical technique in water production. A project evaluating data from 100 drinking water plants across the United States was initiated to assess particle removals by filtration (8). Specific objectives of this study included: distribution of

particle counts, factors that affect finished water particle counts, evaluation of the relationship between particle counts and pathogen concentrations in source and filtered water. Some relevant findings of this project indicated that particle counting can be used by utilities to optimize treatment for particulate removal, but a relationship between the two parameters is not straightforward. In full-scale sampling, a correlation between the occurrence of pathogens and the number and distribution of particles in watersheds was not substantial. Particle count was not found to be a good indicator of pathogen occurrence in watersheds. An exception to this observation was noted during storm and run-off events that resulted in higher levels of particles and in pathogens entering the source water intake. These data indicated that particle-counting measurement could be used as an alarm for unusual events, but not as a reliable indicator of the presence or absence of pathogens in a watershed. The uncertainty in the method used in enumerating the pathogen was indicated as a factor preventing the accurate comparison of particles and pathogen concentrations.

One of the important caveats when looking for a surrogate, however, is that the concept of log removal as a measure of filtration effectiveness is somewhat limiting in that the maximum log removal is governed by the detection limit of the analytical methods. Therefore, the maximum log removal that could have been obtained when considering the pathogen data is governed by the source water pathogen levels. Much higher levels of particles occurring in source water allowed calculation of higher removal effectiveness. It is almost numerically impossible to obtain similar log removals for particles and pathogens. However, because pathogens are "particles," it stands to reason that measuring particulate concentrations through a treatment process and optimizing the performance of that process to reduce particles will result in lower levels of pathogens. Particle counting is a good measure of these particulate changes. Measurements of finished water concentrations of particles or any microbial indicator of water quality could provide the assurance of consistency of plant operations. Water treatment systems should focus on the consistency of providing very good water quality, even during changes in source water quality. Consistently low concentration of particulates (and therefore microbial contaminants) in finished water may present a higher confidence in high water quality than the assurance of a specified log removal of these particulates. The direct monitoring of finished water quality may therefore be in conflict with the concept of log removal because when source water concentrations increase, so could the log removal increase even if the finished water quality deteriorates.

The database of the U.S. EPA's Information Collection Rule (ICR), (14), is an additional source of information about presence and removal of pathogens in treatment plants across the United States. The ICR data were collected and made available as a result of monthly monitoring for *Giardia*, *Cryptosporidium*, and enteric viruses conducted for 18 months (July 1997–January 1988) at more than 500 plants. Although samples were analyzed at various laboratories, making data comparison difficult, the resulting database concerning removal of these pathogens could be a valuable source of information concerning pathogen occurrence. The *Giardia* and *Cryptosporidium* occurrence data, collected during the ICR, show an overwhelming majority of sample results falling below the analytical detection limit, making the evaluation of national occurrence of these pathogens and an assessment of their treatment effectiveness more difficult and stressing a need for their surrogate more than before.

AEROBIC SPORES AS SURROGATES FOR REMOVAL OF PROTOZOAN PARASITES

A research effort, sponsored in 1995 by the U.S. EPA in Cincinnati, Ohio, focused on comparison between occurrence and removal of indigenous aerobic bacterial spores and particle counts (15). The project findings indicated that spores of spore-forming aerobic bacteria such as *Bacillus* could serve as a good surrogate of pathogen removal. Naturally occurring *Bacillus* spores can be easily and quickly detected in both the source and the treated water. The spores did not propagate in the various treatment processes. Removal of *Bacillus* spores correlated highly with removal of particles. The working relationship between the project team at EPA and the team involved in this proposed project allowed for an exchange of information and a continuation of efforts undertaken by other researchers.

In July 1994, the State of Utah and five major Utah water utilities organized the Utah Water Quality Alliance and initiated a Water Quality Enhancement Study to evaluate treatment effectiveness based on an increasing need to provide protection against pathogenic microorganisms (16). In this study, 10 water treatment plants were sampled for *Giardia*, *Cryptosporidium*, total aerobic spores, *Bacillus* spores, turbidity, and particle count. The project tasks included source and finished water quality data collection, development of water quality standards, search for surrogate analytical tools, and treatment optimization. A major conclusion of the study was that conventional monitoring practices do not provide sufficient information on source water quality variations to provide plant personnel with adequate response time to adjust plant operations. Thus, the ability to ensure a consistently reliable treated water quality, free of pathogenic organisms, is handicapped by inadequate linkages between monitoring and operating practices. A key issue that resulted from the study is the need for improved integration of source water quality parameters into strategies for operation of treatment unit processes.

To evaluate potential pathogen surrogates for treatment plant performance optimization, log removals for all measured parameters (*Giardia*, *Cryptosporidium*, total aerobic spores, *Bacillus*, particle count, and turbidity) were compared. The best correlation was seen between either total aerobic spores or *Bacillus* and *Cryptosporidium* followed by *Giardia*, particle counts, and turbidity. It was concluded that with lack of detectable amounts of *Giardia* and *Cryptosporidium* in filtered water, either total aerobic

spores or *Bacillus* spores proved to be a reliable measure for assessing plant performance effectiveness.

In 1996, the American Water Works Association Research Foundation sponsored a study to evaluate the applicability of pathogen surrogates to be used by treatment plant operators as a tool in continuous plant performance optimization (17,18). The target pathogens were *Giardia*, *Cryptosporidium*, and enteric viruses. Pathogen surrogates were selected among indigenous, nonpathogenic microorganisms that represent the target pathogens in removal through treatment. In undertaking this project, it was assumed that the detection of the surrogate should be quick, simple, and inexpensive. The selected surrogate could then become a tool to integrate source and finished water quality information with treatment plant operations. The implementation of a representative surrogate as a monitoring and operational tool should improve overall treatment process reliability and provide a sound basis for reducing the likelihood of microbial pathogen breakthrough. The project findings provided information on the source water occurrence of *Giardia*, *Cryptosporidium*, enteric viruses, total aerobic bacterial spores, *Bacillus* spores, total anaerobic bacterial spores, *Clostridium* spores, heterotrophic plate-count bacteria (HPC), *Escherichia coli*, fecal and total coliforms, bacterial phage, turbidity, and total particle count. The corresponding source water concentrations of *Giardia*, *Cryptosporidium*, and viruses were compared to these of other organisms to evaluate the potential of using surrogates to estimate the pathogen occurrence. Removal of the potential surrogates through treatment was examined, and compared to the removal of *Giardia*, *Cryptosporidium*, and viruses to evaluate the potential of using surrogates to estimate treatment plant performance. The effects of variables such as water source type, source water quality, and seasonal changes on the effectiveness of using surrogates to assess source water occurrence of pathogens were evaluated. Finally, the effects of treatment type, filter type, disinfectant type and application point, filtered water pH, as well as source water quality (turbidity and pathogen concentration) on the effectiveness of using surrogates to evaluate treatment plant performance were assessed.

Aerobic Spores Versus Other Surrogate Parameters for Protozoa in Drinking Water

Among possible microbial indicators of the removal of protozoa in drinking water treatment plants, aerobic spores could serve best because they meet most of the requirements of a surrogate measure. Surrogate parameters used in evaluating and improving water treatment plant performance should meet the following requirements: First, the organisms should be indigenous, nonpathogenic, and ubiquitous in an aquatic environment, especially in surface waters. They should be occurring naturally at concentrations greater than but corresponding to those of target pathogens. Next, their removal through treatment processes should be at levels comparable with removal of target pathogens. The surrogate parameters should be easy to analyze through techniques that are simple, quick, and economically feasible.

Table 1 contains a list of candidate surrogates and their capability to meet these criteria (19–26).

ANALYSIS OF WATER SAMPLES FOR AEROBIC SPORES

The twentieth edition of the *Standard Methods for the Examination of Water and Wastewater* (27) does not contain methodology for analysis of aerobic spores in water. Analysis of total aerobic spores and their major representative, *Bacillus*, is based on methods adopted by Rice and coworkers (14) from the dairy industry (28). The method has been further modified (18) to facilitate the adoption of the method by drinking water laboratories. On

Table 1. Candidate Surrogate Parameters for *Giardia* and *Cryptosporidium* in Water

Potential Surrogate	Natural Occurrence in Surface Waters	Removal Similar to Pathogens	Analysis Turn-Around Time, Simplicity, and Costs	Candidate Surrogate
Turbidity	Yes	Site- specific	Quick, simple, inexpensive	Yes
Particles >2 μm	Yes	Yes?	Quick, simple, relatively inexpensive	Yes
Streaming current potential	Yes	Treatment specific	Quick, simple, relatively inexpensive	Used only as baseline
Total and fecal coliform, and *Escherichia coli*	Yes	No	Quick, simple, inexpensive	Used only as baseline
Heterotrophic plate count	Yes	Treatment specific	Quick, simple, inexpensive	Yes
Micrococcus luteus	Yes, very low	?	Quick, simple, inexpensive	No
Anaerobic bacterial spores and *Clostridium perfringens*	Yes, very low	?	Quick, complicated, inexpensive	Yes
Aerobic bacterial spores and *Bacillus subtilis*	Yes	Yes	Quick, simple, inexpensive	Yes

the basis of the results of a study on methods comparison, the incubation temperature and time needed to kill all vegetative cells and to induce the spores to germinate were set at 60 °C for 15 minutes in a shaking water bath (150 rpm), (following pretreatment in a water bath at 37 °C for 30 minutes). The germinated spores in water samples should be filtered through 47-mm diameter, 0.45-μm pore-size membrane filters and plated on a nonselective nutrient agar also containing soluble starch (0.1%) and trypan blue dye (0.01 μg/L) and incubated for 21 hours at 35 °C in a humid environment. The total number of colonies on that agar represented the number of aerobic spores present in the sample. The number of colonies that have cleared zones around them (indicating the presence of amylase, an enzyme produced by *Bacillus* spores that degrades starch) was a presumptive representation of the number of *Bacillus* spores present in the sample.

OCCURRENCE OF PATHOGENS, AEROBIC SPORES, AND OTHER SURROGATES IN SURFACE WATERS

An example of the relative concentration of *Giardia* and *Cryptosporidium* and their microbial indicators, including aerobic spores, as well as some nonmicrobial indicators, is presented in Table 2, which was developed, based on the source water analytical results collected over one year of sampling at 24 water treatment utilities in the United States and Canada (17,18). Typically, the microbial content of surface source waters varies dramatically. Results of microbial analysis revealed that *Cryptosporidium* and *Giardia* are usually found in the least number of samples, whereas aerobic spore-forming bacteria were found in all source water samples tested. With the frequently observed exception of coliform bacteria and anaerobic spores, all the potential surrogate organisms occur more consistently in source waters than the pathogenic organisms, and at orders of magnitude greater concentration than those of the pathogenic organisms.

An example of the distribution of pathogens and their potential surrogates in source waters, based on the number of samples given in Table 2, is presented in Table 3.

Typically, *Giardia* and *Cryptosporidium* were detected in surface water samples at concentrations ranging from 1 to 10 per liter. In this study, only one sample revealed concentrations of *Giardia* in excess of 10 per liter. Anaerobic spores were usually detected at concentrations ranging from 1 to 10,000 per liter (0.1 to 1,000/100 mL). Aerobic spores were found to be more abundant, with typical concentrations ranging from 100 to 1,000,000 per liter (10 to 100,000/100 mL). Heterotrophic bacteria were found in a wide range of high concentrations as well, that is, from 1,000 to 10,000,000 per liter (100 to 1,000,000/100 mL). The physical surrogates (turbidity and particle count) vary significantly in various source waters.

It is very difficult, if not impossible, to establish a relationship between the *Giardia* and *Cryptosporidium* measurements and any of their potential surrogates, including aerobic spores. Figure 1 presents an example of the lack of correlation found between aerobic spores and the pathogens (17). Correlation coefficients (R^2) for occurrence among these pathogens to any of the intended surrogates in the source waters were less than 0.2 and showed no statistical significance. These results support a recommendation that the search for a *Giardia* and *Cryptosporidium* surrogate in natural waters should be put on hold pending the development of more sensitive and accurate analytical methods for these pathogens.

Factors Influencing Occurrence of Aerobic Spores in Surface Waters

Several factors can influence the concentration of aerobic spores found in waters. Because aerobic spores are soil-based organisms, their presence in water is associated with the presence of solids. Major factors responsible for the presence of spores in water are water quality (turbidity and particle concentrations), source water type (river

Table 2. Example of the Surface Water Microbial Quality Results (18)

Pathogen or Surrogate	Number of Samples	Percent Detection in All Samples	Median Concentr.	Twenty-Fifth Percentile Conc.	Ninety-Fifth Percentile Conc.

or flowing stream and lake or reservoir), and seasonal changes.

A relationship between increasing aerobic spore concentrations and turbidity is presented in Figure 2.

PRESENCE OF AEROBIC SPORES IN TREATED DRINKING WATER

Aerobic spores can be found in treated drinking water samples. The median value, calculated after sampling at 24 drinking water plant effluents for 12 months (17,18) was 1,820 spores per 100 mL (the ninety-fifth percentile was 25,280 spores per 100 mL). Aerobic spores were detected in 84% of the filtered water samples. Because aerobic spores are not human pathogens, their presence in treated drinking water samples is an indicator of

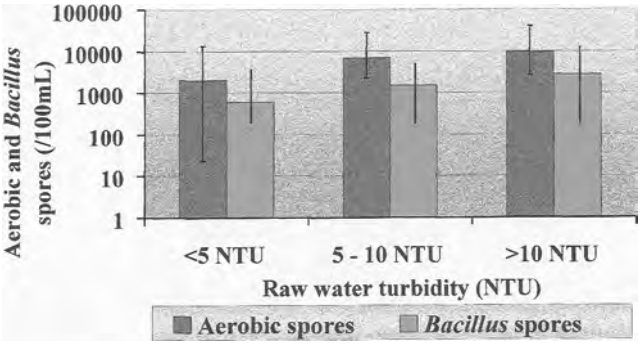

Figure 2. Comparison of aerobic and *Bacillus* spore occurrence to source water turbidity (18). See color insert.

a presence of particles that are soil-based, and not an indicator of water contamination that would pose a human health concern. They were found in sufficient concentrations in many of the source waters to be used as a direct indicator of treatment performance. Even for those waters with lower concentrations, aerobic spores can be used as relative indicators of treatment performance.

USING AEROBIC SPORES IN THE ASSESSMENT OF TREATMENT PLANT EFFECTIVENESS IN REMOVING PARTICULATES AND MICROBIAL CONTAMINANTS

The calculation of removal of microbial contaminants through treatment, and thus the ability to directly assess treatment plant performance, is controlled (or constrained) by the following factors:

1. The source water concentrations of microorganisms, or
2. The detection limits for microorganisms in finished water.

It has been documented that a well-operated water treatment plant can reliably remove more than 3 log of microorganisms and particles 2 μm in size (1,8–10,16). Therefore, it is necessary for the source water concentration and the filter water detection limit to be separated by at least 3 orders of magnitude to accurately assess a 3-log removal. Since most treatment plants are capable of greater than 3-log removal, even this range in source water occurrence and filtered water detection level limits an accurate assessment of performance.

To illustrate the relationship between source and finished water concentrations of *Giardia*, *Cryptosporidium* and aerobic spores, data in Figure 3 are plotted to show the frequency distribution of the organisms.

It can be noted that the range of concentrations of organisms in source water is significantly wider than the range of their observed concentration in filtered water. It can also be observed that the range between the median concentration of *Giardia* and *Cryptosporidium* in filtered water and the source water spans between 0.001 per liter and 0.1 per liter. The respective difference of median concentrations of aerobic spores in filtered and in source water ranges from 10 per liter to 100,000 per liter. This observation leads to an estimation of "a theoretically

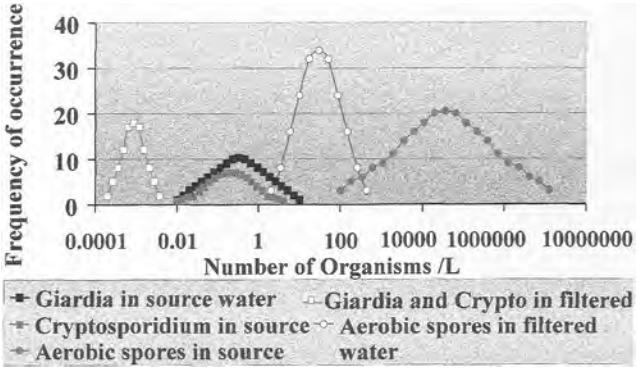

Figure 3. Distribution of aerobic spores and protozoan cysts in source and filtered water (18). See color insert.

probable removal capacity" that could be documented at a water treatment plant. Using naturally occurring aerobic spores detected in both the source and filtered water, up to 4-log removal can be documented at a majority of treatment plants. The removal of aerobic spores has been found to result from their physical removal through water treatment rather than inactivation (18). Inactivation of these organisms contributes little to their overall reduction in treated waters. In contrast, monitoring of *Giardia* and *Cryptosporidium* would only allow for documentation of 2-log removal through treatment in a typical plant.

Because of the limitations of the analytical procedures for *Giardia* and *Cryptosporidium*, no reasonable method has been found to date to develop a surrogate to predict treatment performance characterizing the removal of these pathogens. Thus, the search for a surrogate that correlates directly to pathogen treatment should be put on hold pending the development of sensitive and accurate analytical methods for the target organisms.

Practical Application of Aerobic Spores in Drinking Water Treatment

Aerobic spores and particle counts can be used as surrogate measures to evaluate or improve treatment plant performance. The spores present a more sensitive tool than particle counting as they maintain their size and shape, remaining intact through the treatment process. In contrast, particle counting does not reflect changes in the size of particles as they enter the plant, undergo coagulation into larger particles, and break apart when passing through the filters.

Among known indicators, only aerobic spores and particles are found in sufficient quantities in the source waters to provide a basis for assessing treatment plant performance, (i.e., removal through water treatment plant processes). HPC bacteria can also be found in abundance but cannot normally be used as a surrogate to directly evaluate treatment efficiency because they multiply in filters.

Limitations to Aerobic Spores as Microbial Surrogates

No "ideal" surrogate for predicting occurrence of protozoan pathogens (i.e., *Giardia* and *Cryptosporidium*) in source water was found to date due to the lack of accuracy in defining occurrence of these pathogens. The best relationship was found between turbidity and the pathogens. Even this relationship is only indicative of trends and not predictive in nature. All other comparisons had no perceptible relationship.

No correlation between surrogates and pathogens for removal could be derived in treated drinking water samples because it is not possible to calculate true pathogen removal. However, it is possible to use aerobic spores and particles to evaluate treatment performance based on direct removal calculations or on relative measurements of filtered water concentrations.

Benefits of Aerobic Spore Analyses to Water Treatment Plant Operations

Aerobic spores are sufficiently plentiful in the majority of source waters to allow for removal calculations that will demonstrate from 3- to 4-log treatment efficiency. In contrast, in most source waters only 1- to 3-log pathogen removal can be demonstrated. Future method development suggested that the sensitivity of the aerobic spore analysis can be improved, and its use as a monitoring technique could be extended.

In addition to calculating removal, evaluating finished water microbial quality could be performed by aerobic spore analysis. This type of microbial monitoring complements the physical measurements of turbidity and particles.

Efficiency of drinking water treatment will continue to be evaluated based on surrogates until a full range of pathogen analyses are developed that can easily test for all of the waterborne pathogens of concern. Even though an ideal pathogen surrogate has not been found, surrogates can and will continue to be needed to assist in assessing treatment efficiency. Several studies and drinking water utility practices have identified a number of factors that should be considered when selecting surrogates as predictors of treatment efficiency for pathogen removal.

The most important issue when selecting a surrogate is an understanding of the site-specific source water characteristics and treatment impacts on the surrogates. The surrogate parameter must be present in sufficient concentration to allow for an assessment of treatment efficiency. The concentration of the surrogate will dictate whether it can be used as a "direct indicator" of performance (e.g., removal of >3-log aerobic spores) or a "relative indicator" of performance (e.g., absolute value such as a turbidity value of 0.1 NTU).

Finally, understanding the impact of treatment on the surrogate concentration also is very important. For example, concentration of HPC bacteria may increase in a filter and obscure the actual removal efficiency of the process.

Using Aerobic Spores in Monitoring for Minimum Required Removal of Pathogens. To be used as a direct indicator of performance, the concentration of a surrogate in the source water must be greater than the detection limit in the filtered water by a factor equivalent to the removal to

be demonstrated and a safety factor. When this occurs, it is possible to monitor directly for the minimum required log removal by the treatment process.

For example, if aerobic spores are to be used as a direct indicator of performance for 3-log removal and the filtered water detection limit is 0.1 spores per 100 mL, the source water concentration must be at least 100 spores per 100 mL. A testing safety factor should be applied to assure reasonable accuracy, typically a factor of 2 (or 200 spores/100 mL should be satisfactory). Of the 24 utilities studied in the United States and Canada (18), more than 75% can use aerobic spores as a direct indicator of performance for 3-log removal. Over 50% of these utilities can use aerobic spores to demonstrate 4-log removal.

Particles greater than 2 μm are present in sufficient quantities in a number of source waters to allow for direct log removal determinations. More than 75% of the observed values were greater than 5,000 particles per milliliter. This allows for a 3-log removal calculation.

Probably the most important issue associated with monitoring to demonstrate minimum required assurance of log removal is an understanding that log removal is not appropriately assessed if the source water concentration is insufficient to calculate the desired log removal. As greater physical removal is achieved during treatment and there is a need to demonstrate better removal capabilities, it will be more difficult to demonstrate direct removal.

Monitoring of Treated Water Quality Through Monitoring of Aerobic Spores. Often, a surrogate is present in source water at a concentration below that necessary to allow for a direct determination of removal at a level that actually is achievable by the treatment process. A less than adequate source water concentration of the intended surrogate should not preclude its use as a parameter to assist in determining treatment plant performance. If this occurs, the surrogate might be used as a relative indicator of performance.

For example, source water may have variable particle concentrations from 1,000 to greater than 10,000 particles per milliliter. If the filtered water quality remains at 1 to 2 particles per milliliter, the actual log removal will be calculated at approximately 3 to 4 log. However, both calculations, and especially the 3-log removal calculation, are constrained by the source water concentration or the filtered water detection limit. It is not reasonable to imply that the calculated log removals are the true treatment efficiency of the facility. It is more reasonable to assign a given treatment efficiency for a given filtered water quality. This approach is being used to assure a 2-log *Cryptosporidium* removal in the U.S. EPA's Interim Enhanced Surface Water Treatment Rule. A 2-log removal will be credited to any facility achieving a filtered water turbidity of 0.3 NTU 95% of the time. Pilot-scale or demonstration-scale studies can be used to show that an absolute value for a surrogate in the filtered water indicates a predetermined level of treatment efficiency for pathogen removal.

A single surrogate measurement should not be considered sufficient to assess treatment. By measuring a number of surrogates in the filtered water (both physical and biological), it is reasonable to conclude that a specified level of treatment is being achieved. For example, a turbidity of less than 0.1 NTU 95% of the time, particles greater than 2 μm below 50 particles per milliliter, and aerobic spores below 2 per 100 mL may reliably indicate absence of pathogens. The actual level of treatment must be determined based on site-specific criteria and studies. Additional research in this area may lead to more universally applied treated water quality parameters.

Using Aerobic Spores in Challenge Studies. Challenge studies can be used to relate surrogate removal efficiency or a filtered water quality value to pathogen removal performance in a treatment facility. This is the basic approach that was used to produce the background data to support the establishment of a 0.3 NTU filter effluent quality being equivalent to a minimum of a 2-log *Cryptosporidium* removal.

Challenge studies can be conducted at pilot-, demonstration-, or full-scale. The studies can use viable pathogens, inactivated pathogens, bacterial spores, or other proven nonmicrobial pathogen surrogates such as microspheres. The selection of the appropriate constituent to use for the challenge study is site-specific.

The premise for a challenge study is that the surrogate and challenge constituent will be present in the source water at a concentration sufficient to measure the removal efficiency desired. Thus, seeding of the challenge constituent at a concentration sufficient to demonstrate the desired removal, and then comparing this to the surrogate treatment efficiency, can lead to the establishment of a treated water quality goal based on the surrogate measurement.

When there is a sufficient concentration of the intended surrogate in the source water supply, the challenge study can directly relate the removal efficiency of the surrogate to that of the pathogen. The treatment plant performance can then be determined based on the removal efficiency of the surrogate.

Where the concentration of the surrogate(s) in the source water is not sufficient, it will be necessary to relate the pathogen treatment efficiency to a filter water quality value, for example, aerobic spores. The result can be a set performance value that will relate to the level of pathogen performance desired. For example, it could be demonstrated that an aerobic spore concentration in the filtered water of less than 2 per 100 mL will assure a 3-log removal of Cryptosporidium oocysts. Turbidity and particle counts can be set in much the same way. The end result is the establishment of filtered water quality values for the surrogate(s) that relate to a desired pathogen removal.

For those source waters with highly variable surrogate concentrations, it may be desirable to establish both a filtered water value and a removal value. When the concentration in the source water is sufficient, a calculated removal can provide the desired treatment information. As the source water concentration drops below the value necessary to calculate the removal directly, a finished

water value may be sufficient to verify appropriate treatment. In most cases, there will be a maximum set for the finished water value, regardless of the source water concentration.

Each utility needs to determine which surrogates to develop and how the surrogates will be evaluated to verify the treatment efficiency of the treatment plant. The goal is to establish a number of surrogate measures that will assure appropriate treatment. Selection of the correct surrogates and verification of the surrogate measures as indicators of pathogen treatment will accomplish this goal.

CONCLUSION

Because removal calculations and the ability to directly assess water treatment plant performance is controlled (or constrained) by the concentration of pathogens in the source water and the detection limits for pathogens in finished water, it is difficult to accurately determine the rate of removal of parasitic protozoa such as *Giardia* and *Cryptosporidium* using the current analytical methods. Although sampling and processing significantly larger sample volumes results in lowering method detection limits and allows for calculation of higher log removals, it is very expensive and time consuming and not practical from the analytical standpoint. Aerobic spores are sufficiently plentiful in the majority of source waters to allow for removal calculations that would demonstrate from 3- to 5-log treatment efficiency. In contrast, only 1- to 3-log pathogen removal can be demonstrated based on natural occurrence of pathogens and analytical sensitivity. Aerobic spores can be used as effective surrogate measures to improve treatment plant performance. They cannot be considered, however, as direct surrogate measures of pathogen removal.

Because aerobic pores are nonpathogenic to humans and are not associated with fecal contamination, they could be used in challenge studies, being applied in a slug or at a step dose to water treatment plant unit processes and measured in the effluent to establish log removal. The analysis of aerobic spores is simple (using plate-count agar), quick (less than one day), and inexpensive ($25 per sample).

Evaluating finished water microbial quality can be performed by aerobic spore analysis. This type of microbial monitoring complements the physical measurements of turbidity and particles. The filtered water spore monitoring could be used as plant performance verification.

JAMES P. SHAPLEIGH
Cornell University
Ithaca, New York

Aerobic respiration is by definition the transfer of electrons from a donor compound through a series of carriers to molecular oxygen (O_2), which is reduced to water. Molecular oxygen serves as the terminal acceptor of electrons or terminal oxidant in this process. An oxidant is a compound that brings about the oxidation of other compounds and is therefore an acceptor of electrons. Likewise, a reductant is a compound that brings about the reduction of other compounds and is therefore an electron donor. Reactions involving the transfer of electrons are frequently termed redox reactions because they involve both oxidation and reduction reactions. An oxidation is the loss of electrons by an atom or molecule, whereas a reduction is the gain of electrons by an atom or molecule. The use of O_2 as a terminal electron acceptor differentiates aerobic respiration from "anaerobic" respiration reactions that use alternative oxidants such as nitrate, sulfate, or oxidized metals. Aerobic respiration is also distinct from fermentation in that carbohydrates serve as the terminal electron acceptors during fermentation. This article will focus on the mechanisms organisms have evolved to use O_2 as a terminal oxidant. A basic description of the structure and function of the components involved in aerobic respiration will be included. The organization of these complexes into functional respiratory chains will then be discussed. Examples of aerobic respiratory chains from well-studied model systems, along with a brief description of some of the mechanisms used by organisms to regulate the make-up of these chains, will also be provided. The primary focus will be on aerobic respiration in bacteria. However, the information discussed here is applicable to respiration by higher organisms because the mechanisms used by all organisms to couple respiration with energy production are essentially the same. Aerobic bacteria use a much broader range of respiratory strategies than higher organisms, so it is useful to discuss these strategies to help understand how bacteria can adapt to many different physiological niches.

BASIC FUNCTIONS OF AEROBIC RESPIRATION

Conservation of Energy

The most important function of respiration is energy conservation via the formation of ATP. This is termed *oxidative phosphorylation* because the oxidation of reduced substrates leads to the phosphorylation of ADP to produce ATP. The hydrolysis of phosphate from ATP, which is part of numerous reactions in the cell, releases a relatively large amount of Gibbs free energy (ΔG), a measure of the energy available for work. The "standard" value (ΔG^o) of the free energy available from the hydrolysis of ATP is approximately -7.7 kcal/mol. (Standard free energy values (ΔG^o) are calculated by setting the concentrations of both the products and the reactants at 1 M, and, according to convention, the larger the negative value of the Gibbs energy change the greater the energy available.) Because actively growing cells maintain a high concentration of ATP relative to that of ADP, the actual free energy (ΔG) of ATP hydrolysis is greater (more negative) than the standard free energy value. For example, it may be -10 kcal/mol. The biosynthesis of ATP requires the input of an amount of energy equal to that of the actual free energy of hydrolysis, ΔG. Respiration can provide this energy because the flow of electrons through the carriers that make up the respiratory chain to the terminal oxidant is energetically favorable. One form of the Nernst equation (Eq. 1) relates the amount of energy in electrons flowing through the electron transport chain to the amount of Gibbs free energy available to do work. In this equation, ΔG is the Gibbs energy change, n is the number of electrons transferred, F is the Faraday constant (23.06 kcal/V/mol) and ΔE_m is the difference between the redox potentials of the oxidation and reduction half-reactions of the reaction of interest.

$$\Delta G = -nF\Delta E_m \quad (1)$$

It can be seen from Equation (1) that, as long as mechanisms are available, cells can maximize energy production by transferring electrons from donors of low potential to terminal acceptors of high potential. The larger the overall voltage drop the greater the energy available, similar to a battery. The redox potential of the reduction of O_2 to H_2O is $+0.82$ V, which is one of the highest redox potentials of any biologically useful oxidant. This is one of the principal reasons O_2 is preferred as a terminal oxidant. This high midpoint potential also makes it possible to use a wide range of compounds as electron donors while maintaining an energetically favorable ΔE_m. The most common electron donor is the enzyme cofactor NADH, which is produced by the reduction of NAD^+ during many reactions in the cell involved in the oxidation of reduced carbon compounds. The redox potential of the NAD^+/NADH couple is -0.32 V. Using equation (1), the transfer of two electrons from NADH to O_2 yields a ΔG of -53 kcal/mol, which is sufficient free energy to drive the synthesis of several molecules of ATP.

Peter Mitchell first elucidated the mechanism, by which energetically favorable electron flow is coupled with energy requiring biosynthesis of ATP; the Mitchell theory of energy production and conservation is termed *chemiosmosis* (1,2). In the now proven chemiosmotic mechanism, the energy of electron transfer to O_2, via the respiratory electron transfer chain, is used to move a few negative and positive charges to opposite surfaces of a membrane, either by pumping protons to the positive surface or electrons to the negative surface (Fig. 1). The protein components of the respiratory chain are oriented with specific topology in the membrane to drive such charge separation events (Fig. 2). Lipid bilayers are relatively impermeable to charged species; this allows the transmembrane charge separation to persist as long as

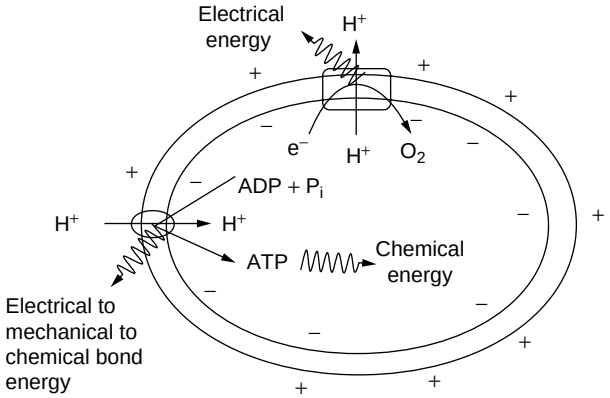

Figure 1. Schematic representation of the chemiosmotic circuit in a bacterial cell. The membrane bilayer is shown with the positive (+) and negative (−) charges that are closely associated with each face of the membrane during aerobic respiration. The redox energy of electron flow to oxygen within a terminal oxidase is used to pump protons through the oxidase to the outer face of the cytoplasmic membrane, thus establishing the separation of charges that is termed the transmembrane voltage gradient, or $\Delta\Psi$. $\Delta\Psi$ provides the driving force for proton flow through the F_0 portion of the F_1F_0-type ATP synthase, where the proton flow initiates a carousel-like rotation of a ring of proteins within the membrane. This rotary motion leads to the rotation of a protein spindle within the F_1 portion of the ATP synthase. Rotation of this spindle forces the active sites in F_1 that bind ADP and phosphate (Pi) to change shape, with the result being the formation of a chemical bond between ADP and Pi and the release of the product, ATP.

electron transfer continues. The charge separations create a transmembrane voltage gradient and this gradient attracts positively charged ions to the negative surface of the membrane. In fact, it is the flow of protons through the ATP synthase in the bacterial membrane, from the positive surface to the negative surface, which provides the energy for ATP synthesis (this is discussed in more detail later). Because only protons move through the ATP synthase, the transmembrane voltage gradient is also termed the *proton motive force* (PMF). A more detailed explanation of chemiosmosis can be found in (3).

Those components of the respiratory electron transfer chain that use some of the energy of electron flow to generate PMF via charge separations are termed *electrogenic protein complexes*. The respiratory electron transfer chain in all mitochondria contains three electrogenic complexes (4). The situation in bacteria, however, is considerably more complicated. Some bacteria modulate the number of electrogenic complexes in their electron transport chain depending on the environmental conditions as well as their physiological requirements. Moreover, many bacteria synthesize fewer electrogenic complexes than do mitochondria, although they use the same reductants and terminal oxidants.

Aerobic bacteria can also use a much wider variety of compounds as electron donors than higher organisms. In addition to carbon containing compounds, many inorganic compounds can serve as sources of electrons. Bacteria that can use inorganic compounds as sources of energy

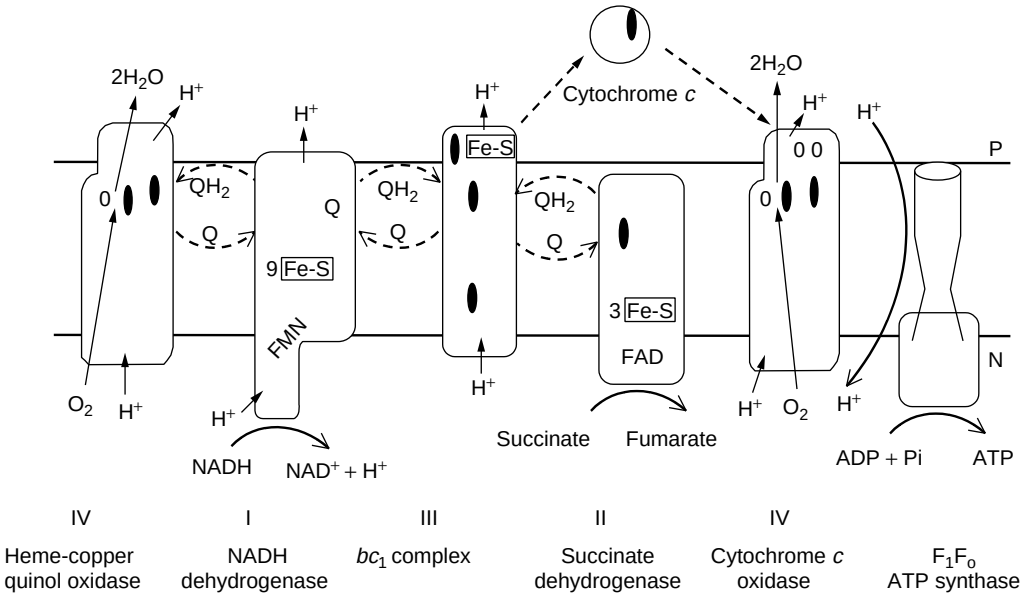

Figure 2. Representation of some of the protein complexes involved in aerobic respiration and the reactions they catalyze. The name of each complex is indicated below the complex along with its shorthand designation as a Roman numeral. Solid ovals represent heme centers and open circles represent copper. P and N represent the positive and negative surfaces of the membrane. Fe–S indicates complexes containing iron-sulfur centers and FAD and FMN represent flavin moieties. Dashed arrows within the membrane indicate the redox cycling of the quinone pool that occurs as NADH dehydrogenase and succinate dehydrogenase reduce quinone (Q), while the bc_1 complex and quinol oxidases oxidize quinol (QH_2). Redox cycling of the cytochrome *c* pool in the periplasmic space of the cell also occurs as cytochrome *c* is reduced by the bc_1 complex and oxidized by cytochrome c oxidases. The ability of four of the five electron transfer complexes shown to function as proton pumps is indicated by the entry and exit of H^+ from each complex.

are known as *lithotrophs*. For example, there are bacteria termed *nitrifiers* that use nitrite as their energy source by oxidizing it to nitrate. The relatively high midpoint potential of this reaction (+0.41 V) decreases the ΔE_h of electron transfer to O_2, as compared with the oxidation of NADH, thus reducing the amount of the Gibbs free energy that can be recovered (Eq. 1). Consequently, these bacteria must oxidize more reductant than is oxidized by bacteria that use NADH to produce an equivalent amount of ATP. The benefit of this strategy is that the development of an aerobic respiratory chain that oxidizes inorganic compounds allows lithotrophs to occupy a unique environmental niche.

The high concentration of O_2 in the atmosphere, along with the energetic efficiency of the aerobic respiratory chain, makes aerobic respiration the preferred mode of energy conservation for those organisms that can switch between aerobic and anaerobic modes of growth. Other modes of energy conservation, such as fermentation, are not as efficient in the production of ATP. In addition, fermentation and anaerobic respiration may result in the buildup of products that can be toxic at modest concentrations. Aerobic respiration by most organisms generates CO_2 and H_2O as its end products, neither of which is particularly cytotoxic. Accordingly, the regulatory circuitry of aerobic bacteria is designed to preferentially express those genes required for O_2 respiration at the expense of alternative modes of energy conservation whenever O_2 is present (5).

Detoxification

Aerobic respiration can fulfill other physiological functions besides ATP production. One of these alternative functions is to protect O_2-sensitive components of the cell. For example, the bacterium *Azotobacter vinelandii* uses the O_2-sensitive enzyme nitrogenase to fix nitrogen even under aerobic conditions. *Azotobacter* minimizes O_2 damage to nitrogenase by maintaining high rates of aerobic respiration (6). This results in low intracellular concentrations of O_2. Because these bacteria want to maximize O_2 consumption, they must also maximize electron flow through the respiratory chain. This can be accomplished by modifying the components of the respiratory chain. By definition, the processes of electron transfer and charge separation are linked, or coupled, in the electrogenic complexes of respiratory electron transfer. As a result of this situation, it becomes energetically more difficult to pump additional charges (protons or electrons) against the transmembrane voltage gradient as the magnitude of the gradient increases. This results in a slowing of electron transport. However, bacteria can adjust the components of the respiratory chain to include complexes that are less efficient at coupling electron flow to the generation of a voltage gradient. This makes it possible to maintain higher rates of electron transfer to O_2. As discussed later, *Azotobacter* uses a particular terminal oxidase that is less efficient at coupling electron flow to the generation of PMF.

Consume Reducing Equivalents

Another possible use for electron transfer to O_2 is to replenish the supply of NAD^+. Bacteria growing on highly reduced carbon sources, such as fatty acids or aliphatic hydrocarbons, produce NADH at such a rate that the supply of NAD^+ may become limiting for the metabolism of the cell. Under such conditions, a cell might modify its respiratory chain to ensure that NADH oxidation can keep pace with NAD^+ reduction. Some bacteria have been shown to reduce nitrate to nitrite in order to oxidize the NADH pool (7). Although never directly shown, it seems likely that O_2 also serves as a sink for excess reducing equivalents under certain conditions and may help explain the diversity of aerobic respiratory chains in many aerobes.

COMPONENTS INVOLVED IN AEROBIC RESPIRATION AND THEIR FUNCTION

Electron Transfer and Charge Separation

The process of oxidative phosphorylation can be viewed as a series of energy transformations (Fig. 1). The function of the components of the electron transport chain is to take high-energy electrons (those with a more negative redox potential) and transfer them stepwise to O_2, which is reduced to water. Proper arrangement of the respiratory components allows some of the redox energy released in the stepwise transfer of electrons to O_2 to drive charge separation events across the cytoplasmic membrane (Figs. 1 and 2). Charge separation is accomplished by moving a positive charge (a proton) to the outer, positively charged surface of the membrane or by moving a negative charge (an electron) to the cytoplasmic, negatively charged surface of the membrane. Thus, a transmembrane voltage gradient is created and maintained, which is another form of electrical energy (Fig. 1). The voltage gradient is used to pull protons through the membrane-bound ATP synthase, which is a nanomachine that converts the energy of the voltage gradient into mechanical energy. As the ATP synthase couples phosphate to ADP and forms ATP, mechanical energy is transformed into chemical bond energy. A good deal of Gibb's free energy is made available upon the hydrolysis of ATP to ADP and phosphate; for this reason the hydrolysis of ATP is incorporated into the mechanisms of numerous reactions in the cell to make them thermodynamically favorable.

Description of Basic Components of the Respiratory Chain

For aerobes that use carbon compounds as electron donors, the flow of electrons during respiration centers on a pool of lipid-soluble quinone (Q); each quinone molecule is a two-electron (and two-proton) carrier. In these bacteria, all of the possible electron transfer pathways of aerobic respiration can be described by defining which membrane-bound electron transfer proteins are adding electrons to the Q-pool and which protein complexes are removing electrons from the Q-pool (Fig. 2). The chemical structure of Q varies somewhat throughout the eubacteria and the archea, but all contain a simple quinone headgroup coupled to a long hydrocarbon tail that restricts the

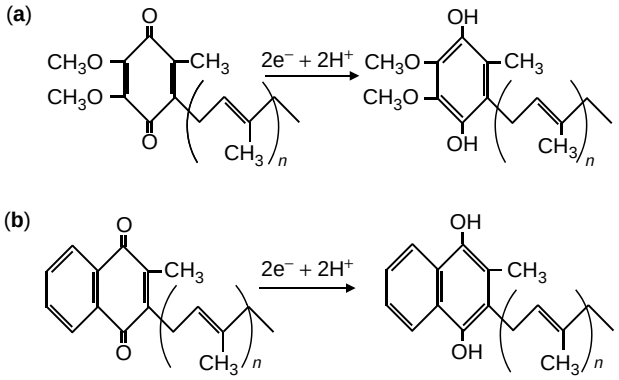

Figure 3. Structure of common quinones found in *E. coli* in their reduced and oxidized forms. Ubiquinol is shown in (**a**) and menaquinone is shown in (**b**). The length of the hydrophobic side chain (n) is variable but is typically 8 in *E. coli*.

quinone to the lipid bilayer (Fig. 3). Fully oxidized quinone and fully reduced quinol diffuse rapidly in the bacterial membrane to shuttle electrons between the membrane-bound electron transfer complexes. During the actual reduction or oxidation of each quinone, its headgroup binds to a specific site on the electron transfer complex. In this manner, the one-electron reduced quinone intermediates, which may be negatively charged, are sequestered from the hydrophobic lipid bilayer.

Eectrons enter the Q-pool in two ways: via the oxidation of NADH or via the direct oxidation of reduced metabolic intermediates, such as succinate. NAD^+ is a small, water-soluble two-electron carrier that is reduced to NADH in numerous cellular oxidations of reduced carbon substrates (see Table 1 for listing of respiratory complexes). When NADH is the source of electrons for respiration, it is oxidized by a NADH dehydrogenase. Many aerobic bacteria use a NADH dehydrogenase that is very similar to the mitochondrial enzyme (4). This enzyme is the largest of the membrane-bound electron transfer complexes of aerobic respiration, being composed of 13 to 14 separate protein subunits (8–11). NADH binds at a site on the internal extramembrane domain of the complex, where its electrons are transferred to a flavin prosthetic group (Fig. 2). Flavins are two-electron, two-proton carriers derived from riboflavin; they are always bound within proteins. The electrons then travel through a series of electron carriers known as *iron-sulfur centers* ([Fe–S]) spaced throughout the protein complex, and finally to a quinone that is transiently bound at a site accessible to the lipid bilayer. [Fe–S] centers are complexes of non-heme iron and acid-labile sulfur bound to particular residues in the protein complex (Fig. 4). These [Fe–S] clusters are of variable iron and sulfur stoichiometry and variable redox potential but are all one-electron carriers. The quinone reduced by the NADH dehydrogenase enters the lipid-soluble Q-pool. NADH dehydrogenase is one of

[b]Different hemes are present in various versions of these oxidases.

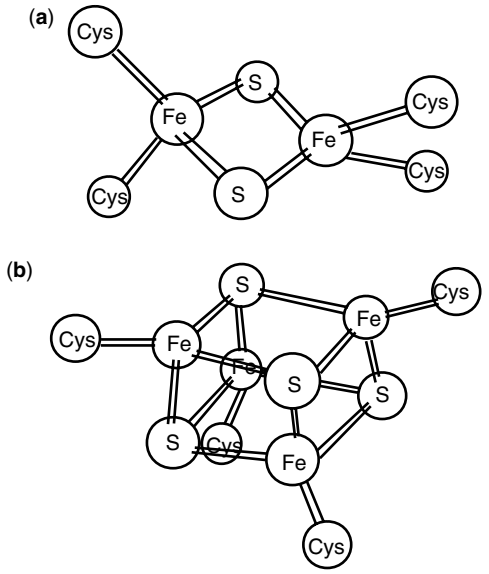

Figure 4. Examples of a [2Fe−2S] cluster (**a**) and a [4Fe−4S] cluster (**b**). The S represents acid-labile sulfur. One of the sulfur ligands for each iron (Fe) comes from a cysteine residue in the protein.

the three-electrogenic complexes that are used by aerobes, meaning that the enzyme contributes to the maintenance of the transmembrane voltage gradient. It does this by using a portion of the redox energy released during electron transfer from NADH to Q to pump protons from the negative surface of the cytoplasmic membrane to the positive surface. The mechanism of this proton pumping process is not fully understood (12,13).

Succinate dehydrogenase is a membrane-bound protein complex of three to four subunits that also transfers electrons from succinate to the Q-pool (Table 1, Fig. 2). This protein can be an important part of the respiratory chain of some aerobes if the cultures contain succinate or significant concentrations of tricarboxylic acid cycle intermediates. Like NADH dehydrogenase, the electrons flow through a flavin cofactor and a series of [Fe−S] centers to reach a lipid-accessible quinone-binding site (4,14,15). The energy released during electron transfer from succinate to Q falls short of that required to drive a charge separation event across the cytoplasmic membrane. Thus, the reaction catalyzed by succinate dehydrogenase is not electrogenic.

Electrons flow out of the Q-pool via two paths, both of which terminate with the reduction of O_2 to water through the activity of a terminal oxidase (Fig. 2). The first path requires a single membrane-protein complex that oxidizes quinol and reduces O_2; this type of terminal oxidase is referred to as a *quinol oxidase* (16,17). The second path from Q to O_2, commonly referred to as the *cytochrome c pathway*, involves two electron transfer complexes in the bacterial membrane. In the two-step pathway, quinol is oxidized by the bc_1 complex (18,19), which then reduces a mobile cytochrome *c*, a small electron transfer protein containing a single *c*-type heme (Fig. 2). Cytochrome *c* then shuttles its electron to a cytochrome *c* oxidase, another type of terminal oxidase that uses the electrons donated by successive cytochrome *c* molecules to reduce O_2 to water.

[Heme is composed of a conjugated ring of four pyrrole groups, termed *porphyrin*, with a central iron atom bound by one nitrogen from each pyrrole (Fig. 5). Hemes can be used as one-electron carriers; proteins that bind redox-active heme are termed *cytochromes*. Bacteria modify substituent groups of the porphyrin ring to produce at least four chemically distinct forms of heme, hemes B, O, A, or D. More than one type of heme may be present in multi-heme cytochromes.]

Electron transfer from reduced quinol to cytochrome *c* in the bc_1 complex occurs through a complicated dance that has been termed the *Q-loop* (18,20,21). The bc_1 complex is composed of three to four subunits (Table 1). One subunit contains two quinone-binding sites and two *b*-type hemes that are oriented perpendicular to the plane of the bilayer and span the membrane. A second subunit contains a *c*-type heme, and a third contains an [Fe−S] center in an extramembrane domain that moves back and forth on a flexible tether between the quinol oxidation site and the *c*-type heme (19,21). Some of the redox energy released by electron transfer from quinol to cytochrome *c* is used to push electrons through the *b*-type hemes from the positive surface of the cytoplasmic membrane (outside) to the negative surface (inside). Thus, electron transfer through the bc_1 complex is electrogenic, that is, it contributes to the transmembrane voltage gradient.

The third electrogenic component, present in all of the possible electron transfer pathways to O_2, is the terminal oxidase (4). Although the terminal oxidases of bacteria show the greatest level of diversity of any of the respiratory components (discussed later), basic structural and mechanistic similarities are shared by all of these enzymes (Fig. 6). All of the terminal oxidases are composed of two to four integral membrane proteins (16,22) (Table 1). Electrons from quinol or from reduced cytochrome *c* are passed by various means to a six-coordinate heme in the largest subunit of the complex. This heme transfers electrons, one at a time, to a nearby five-coordinate heme in the same subunit. Being five-coordinate, as opposed to the fully occupied six-coordinate geometry, allows one of the ligand binding sites of this heme's iron to serve as the O_2 binding site (23,24). Once O_2 binds, it is reduced by four successive electrons to two water molecules (25,26). The O_2 reduction site, or active site, of the oxidases is buried within the transmembrane region of the large subunit. The four electrons required to reduce O_2 follow a path from the outside to the buried active site (27,28); this path carries the electrons part of the way across the membrane toward its negative surface. Simultaneously, the four protons required to convert O_2 to $2H_2O$ are transferred from the cytoplasm to the buried active site; this path carries the protons part of the way toward the positive surface of the membrane (29–32). Because these electrons and protons combine at the active site to form H_2O, a neutral molecule, the partial electron and proton transfers add up to one charge separation event (i.e., the movement of one charge completely across the membrane) for each electron transferred to O_2. All

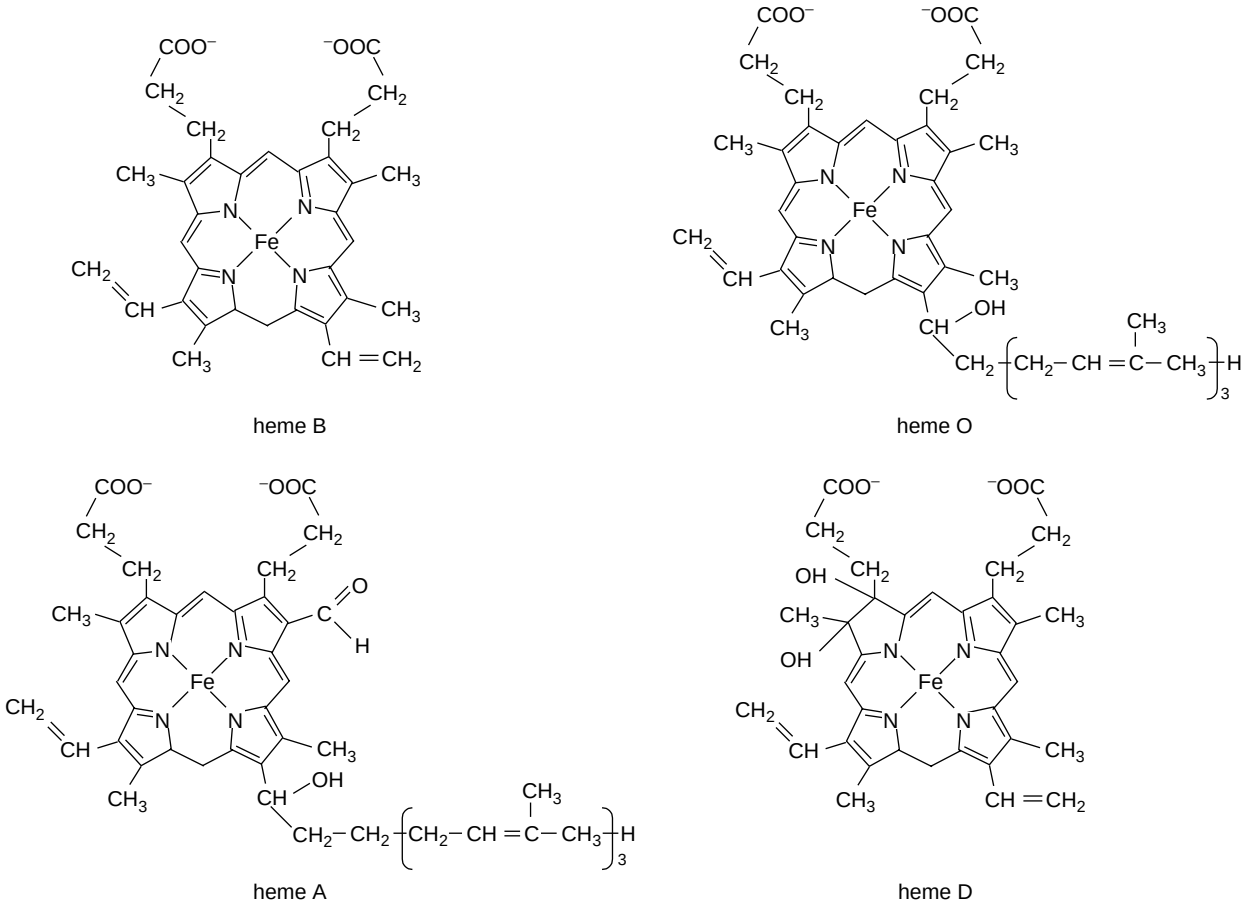

Figure 5. The different structures of the hemes found in common cytochromes of aerobic bacteria.

terminal oxidases are electrogenic in this fashion. The redox energy available in the oxidation of either quinol or cytochrome *c* by O_2 is substantial, however, and most terminal oxidases have evolved a second mechanism to convert more of this redox energy into the energy of the transmembrane voltage gradient. This is accomplished by pumping one proton, through the protein, from the negative to the positive surface of the membrane, for each electron transferred to O_2 (29). This proton is in addition to the charge separation achieved through the chemistry of O_2 reduction. It is not clear how the proton is transferred through the protein, but its transfer is obligatorily linked to electron flow through the oxidase complex (33,34).

Structural Diversity of the Essential Respiratory Complexes

The degree of structural diversity, as far as is currently known, varies considerably for each of the principal protein complexes. The structures and mechanisms of the bc_1 complex, succinate dehydrogenase, and the ATP synthase appear to be largely similar throughout the eubacteria and the archaea. Perhaps the greatest diversion known to date is the ability of certain marine bacteria, for example, *Vibrio alginolyticus*, to synthesize a NADH dehydrogenase, a terminal oxidase, and an ATP synthase that pump and use Na^+ rather than protons (35).

In addition to the proton-pumping NADH dehydrogenase, numerous eubacteria synthesize a simpler enzyme that oxidizes NADH and reduces Q (36). This simpler dehydrogenase consists of a single integral membrane protein containing a flavin prosthetic group; it does not use the energy of its electron transfer reaction to contribute to the transmembrane voltage gradient (Table 1).

The greatest degree of structural diversity is found in the terminal oxidases. Terminal oxidases are first divided into two groups on the basis of the structures of their active sites, in which O_2 is reduced to water. The first of these groups is composed of a family of quinol oxidases, the prototype of which is the *bd*-type quinol oxidase (Fig. 6). The *bd*-designation derives from the types of hemes associated with the complex. The *bd*-type oxidases are composed of two integral membrane subunits, one of which contains three hemes (26) (Table 1). Electrons from quinol are first transferred to a heme *b*, and then to the active site, which consists of a second *b*-type heme and a closely associated *d*-type heme. This two-heme center forms the active site. The *bd*-type oxidases have a high affinity for O_2 and thus allow respiration to continue under low ambient O_2 concentrations (37). This high affinity for O_2 allows some bacteria to use this oxidase for detoxification. For example, *Azotobacter* species use rapid electron flow through a

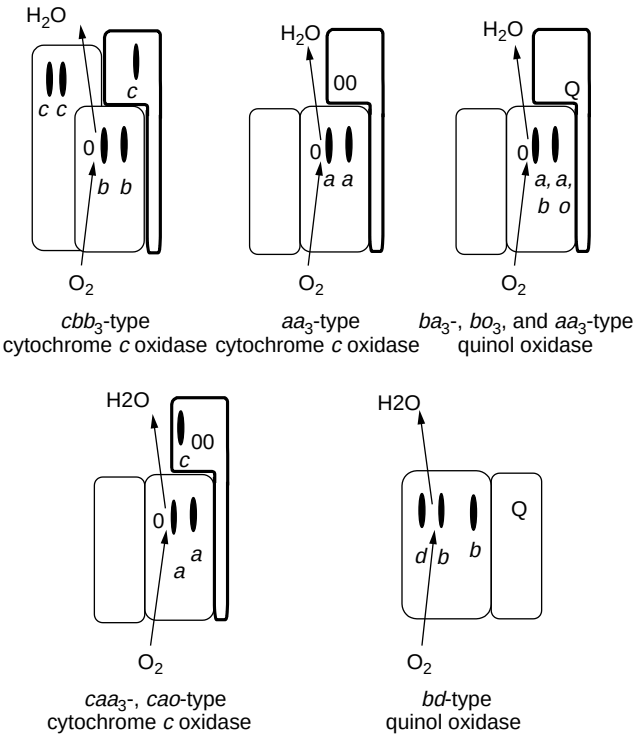

Figure 6. Schematic representation of the structural organization of the different type of bacterial terminal oxidases. Each complex is drawn such that the top of the figure would face the periplasmic side of the cytoplasmic membrane and the bottom would face the cytoplasmic side of the membrane. Closed ovals represent hemes and open circles represent copper. Q indicates the likely quinone-binding site in the quinol oxidases. The letters below the hemes indicate the possible hemes found in a particular type of oxidase. The subscript 3 is used to indicate those hemes that bind oxygen. This form of designation was developed to differentiate between the two chemically identical, but functionally distinct, a hemes in the aa_3 type cytochrome c oxidase. As additional variants of the heme- copper oxidase have been found the subscript 3 designation has been used primarily in those complexes that have chemically identical, but functionally distinct hemes. The catalytic site is indicated by the arrows indicating where O_2 is bound and water is produced.

bd-type oxidase to maintain the low intracellular O_2 concentrations required for nitrogenase activity (38). As discussed earlier. It appears that the *bd*-type oxidases do not pump protons, although their O_2 reduction mechanism is electrogenic.

The second, and more diverse, group of terminal oxidases is that of the heme-copper oxidase superfamily (39) (Table 1). In these enzymes, electrons are transferred from a six-coordinate heme to an active site composed of a five-coordinate heme, where O_2 binds, and a closely associated copper atom, termed Cu_B (Fig. 6). It appears that all of the heme-copper oxidases are capable of pumping protons. Because the heme-copper oxidases consume one cytoplasmic proton per electron as part of the O_2 reduction mechanism, as do all terminal oxidases, their additional ability to pump one proton per electron (as described earlier) makes them twice as efficient at energy conservation as the *bd*-type oxidases.

A wide degree of structural variation is found within the heme-copper oxidase superfamily (39,40). Some of these enzymes oxidize quinol, and thus bypass the bc_1 complex, whereas others oxidize cytochrome *c*. The hemes that are present vary considerably. In different enzymes, heme B, O, or A (Fig. 5) may be present in the heme-Cu_B active site, whereas heme B or A may be present as the six-coordinate heme that transfers electrons to the active site. There are no obvious mechanistic differences associated with the type of heme found in different heme-copper oxidases.

The oxidases of the heme-copper superfamily can be further divided into two groups. One group contains three core subunits that have obvious structural homology between species. In this group, electrons from quinol or cytochrome *c* enter through a protein designated subunit II; as in all of the heme-copper oxidases the six-coordinate heme and the heme-Cu_B active site are located in the subunit designated subunit I (39). Those enzymes of this group that oxidize cytochrome *c* contain an additional copper center in subunit II, termed Cu_A, close to the cytochrome *c* binding site. The quinol oxidases of this group appear to have evolved from the cytochrome *c* oxidases by losing the residues that bind Cu_A and cytochrome *c* and by gaining a quinone-binding site (40). One subset of this first group, the heme aa_3-type cytochrome *c* oxidases of the α subgroup of the proteobacteria (including *Rhodobacter* sp. and *Paracoccus* sp.), are the progenitors of the aa_3-type cytochrome *c* oxidase of mitochondria (40).

The second group of the heme-copper oxidases consists of the more "primitive" cbb_3-type (or FixN) cytochrome *c* oxidases (41) (Table 1). Only the largest subunit of this enzyme, containing the active site, is structurally homologous to the first group of heme-copper oxidases. Although this enzyme oxidizes cytochrome *c*, it does not contain Cu_A (42). The cbb_3-type oxidase has a higher affinity for O_2 than the other heme-copper oxidases, possibly because this enzyme arose when the O_2 concentration in earth's atmosphere was low (41,43).

Diversity of Respiratory Chains

Not surprisingly, given the diversity of respiratory enzymes, aerobes also exhibit a diversity of respiratory chains. Not only is there diversity between species, but because most aerobes are capable of synthesizing multiple terminal oxidases, the components of the respiratory chain of a single bacterium often changes in response to environmental conditions. Only a few well-studied examples of aerobic respiratory chains will be discussed. It should be emphasized, however, that the diversity of aerobic respiratory chains is a hallmark of bacteria. The presence of multiple respiratory complexes having similar functions allows electrons that are being transferred from reductant to oxidant to potentially flow through more than one path (Fig. 7). This "branched chain" structure of respiratory chains is common in bacteria. There are few examples of branched chain respiratory chains in higher organisms.

In some sense, the *Escherichia coli* aerobic respiratory chain is relatively simple (Table 1, Fig. 7). *Escherichia coli* encodes both a mitochondrial-type NADH dehydrogenase

and a single subunit, nonelectrogenic NADH dehydrogenase (44,45). Electrons from the dehydrogenase flow to one of the three types of quinones, ubiquinone, or either of two napthoquinones, menaquinone, or demethylmenaquinone (46). The quinones transfer electrons to either a *bo*-type heme-copper oxidase or a *bd*-type oxidase (16). The regulation of the expression of the various components of the *E. coli* chain is complex and not completely understood. In general, ubiquinone and the *bo*-type oxidase are preferentially expressed if O_2 levels are high (47). Menaquinone and the *bd*-type oxidase are more highly expressed under limiting O_2 concentrations (47). Regulation of the statement of the NADH dehydrogenases is not so clear-cut (48). The single subunit enzyme is apparently expressed aerobically and repressed during fermentation. Expression of the electrogenic enzyme is apparently stimulated by O_2 and nitrate.

The aerobic respiratory chain of *Paracoccus denitrificans* is similar to the mitochondrial respiratory chain and both more complicated than the *E. coli* chain (Table 1, Fig. 7). *Paracoccus denitrificans* apparently only encodes the mitochondrial-type NADH dehydrogenase (49). Ubiquinone is the major quinone. As in *E. coli*, there is a quinol oxidase of the heme-copper family that can directly oxidize quinol. This oxidase is designated the ba_3-type oxidase because of its heme content (50). Unlike *E. coli*, electrons can also flow from reduced quinol to the bc_1 complex. Electrons then flow from the bc_1 complex to one of the several *c*-type cytochromes that can either be located in the periplasm or are membrane-bound (49). *Paracoccus denitrificans* has two terminal oxidases that use reduced cytochrome *c* as a source of electrons. One of these oxidases is the aa_3-type oxidase, which has significant sequence similarity with the mitochondrial aa_3-type oxidase, consistent with the proposal that the bacterial progenitor of the mitochondria was closely related to *P. denitrificans* (23,51). The other oxidase is the cbb_3-type oxidase (52). The aa_3-type oxidase is preferentially expressed when O_2 concentrations are high. The cbb_3-type oxidase, consistent with it being a high-affinity oxidase, is more highly expressed when O_2 concentrations are limiting (53). The expression of the ba_3-type quinol oxidase is more complex and its role in the physiology of *P. denitrificans* is unclear (54).

In addition to multiple terminal oxidases, some bacteria also have the capacity to use electrons from

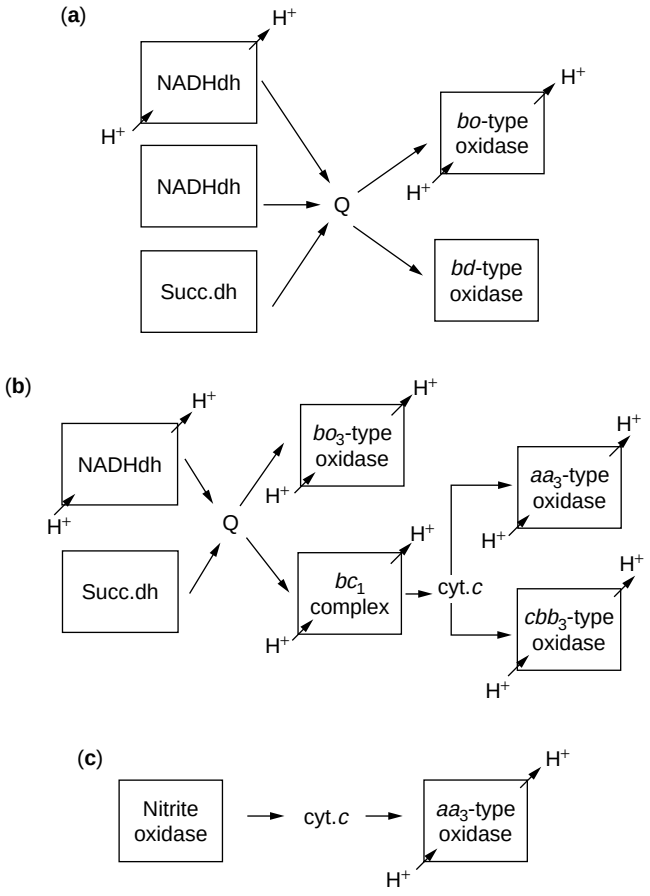

Figure 7. Representation of the aerobic respiratory chain of (**a**) *E. coli*, (**b**) *P. denitrificans* and (**c**) *Nitrobacter* species. Abbreviations are: Q, quinone pool, cyt. c, soluble cytochrome c, NADHdh, NADH dehydrogenase, Succ.dh, succinate dehydrogenase. Arrows indicate the direction of electron flow, and H^+ entering and exiting the boxes indicate electron transfer complexes that pump protons.

multiple substrates during aerobic growth. For example, some, including *P. denitrificans*, can use thiosulfate as an energy source (55). Others use the single carbon compounds methanol and methylamine as both a source of carbon and high-energy electrons (49,56). Oxidation of thiosulfate involves a periplasmic thiosufate-cytochrome *c* oxidoreductase, a periplasmic cytochrome *c*, and the aa_3-type terminal oxidase. Similarly, the oxidation of methanol or methylamine requires periplasmic dehydrogenases that feed electrons to the aa_3-type oxidase via periplasmic cytochrome *c*'s. In these pathways, the only electrogenic component contributing to the PMF is the terminal oxidase, because electron flow through the NADH dehydrogenase, the Q-pool and the bc_1 complex is bypassed. However, the oxidation of formaldehyde, one of the end products of methanol and methylamine oxidation, produces NADH (49,56). Because the oxidation of this NADH involves the entire respiratory chain, cells growing on methanol and methylamine still synthesize the NADH dehydrogenase and the bc_1 complex.

The lithotroph *Nitrobacter* provides another example of the versatility of bacterial aerobic respiration (Fig. 7). *Nitrobacter* obtains electrons from the oxidation of nitrite to nitrate; the redox potential of the nitrite/nitrate couple is about +0.4 V. This is too high a potential for the direct reduction of cytochrome *c*, as occurs in the examples given earlier. Thus, *Nitrobacter* places a nitrite-cytochrome *c* oxidoreductase within the cytoplasmic membrane in which it can take advantage of the PMF to help drive the transfer of electrons to the positive surface of the membrane in order to reduce a periplasmic cytochrome *c*. The reduced cytochrome *c* then transfers its electrons to an aa_3-type terminal oxidase (57). The entire PMF is generated through the electrogenic activity of the aa_3-type oxidase (3). The situation is further complicated by the fact that *Nitrobacter*, as an obligate autotroph, must generate NADH for CO_2 reduction. Using more of the PMF to drive electron transfer in reverse, such that the NADH dehydrogenase oxidizes quinol and reduces NAD^+ to NADH, does this. This strategy allows the cell to generate high-energy (low potential) electrons in the form of NADH from lower energy (higher potential) electrons from nitrite. To accomplish this, the cell must oxidize several nitrite molecules for each molecule of NADH produced.

As shown by the examples discussed earlier, aerobes can use many compounds as reductants and, by expressing a variety of oxidases, can grow over a wide range of O_2 concentrations. However, genomic sequence information suggests that some aerobes have an even larger respiratory repertoire than currently available biochemical evidence demonstrates. For example, it is known that the bacterium *Rhodobacter sphaeroides* expresses three terminal oxidases. These include an aa_3-type cytochrome *c* oxidase, a cbb_3-type cytochrome *c* oxidase, and an uncharacterized quinol oxidase (58–60) (Table 1). However, recent genomic analyses indicate that *R. sphaeroides* encodes at least five terminal oxidases: a *bd*-type quinol oxidase, a heme-copper quinol oxidase, and the three-cytochrome *c* oxidases. The quinol oxidase that is expressed is likely to be the *bd*-type quinol oxidase, in a modified form (58). It seems likely that *R. sphaeroides* encounters conditions in the environment in which the heme-copper quinol oxidase is functional, although it is not yet obvious what these conditions would be. Another example is provided by *E. coli,* which contains a set of genes that encode an alternative *bd*-type oxidase (61). The role of this oxidase is not clear, but it has been shown to be functional (62). It is likely that as more genomic sequences become available they will show that the true diversity of aerobic respiratory chains has been underestimated because standard laboratory culture conditions do not induce expression of the full set of respiratory enzymes.

The F_1F_O ATP Synthase

The protein complex that allows the electrochemical gradient to be coupled to ATP synthesis is termed the F_1F_O ATP synthase. Recent structural and mutagenesis studies have shown that the ATP synthase of the bacterial membrane is actually a molecular motor (63–66). The ATP synthase complex is composed of two domains: a transmembrane domain that contains a ring of small protein subunits and an extramembrane domain that is shaped like a mushroom (Table 1, Fig. 8). The stalk of the extramembrane domain consists of one elongated subunit (γ), which extends through the cap of the complex. The cap is a ring of six large subunits (3α and 3β); an active site where ATP is synthesized from ADP and phosphate is present in each of the three β-subunits. The proposed mechanism of this machine is as follows. Protons are pulled through the transmembrane domain, toward the inner, negatively charged surface of the membrane, using

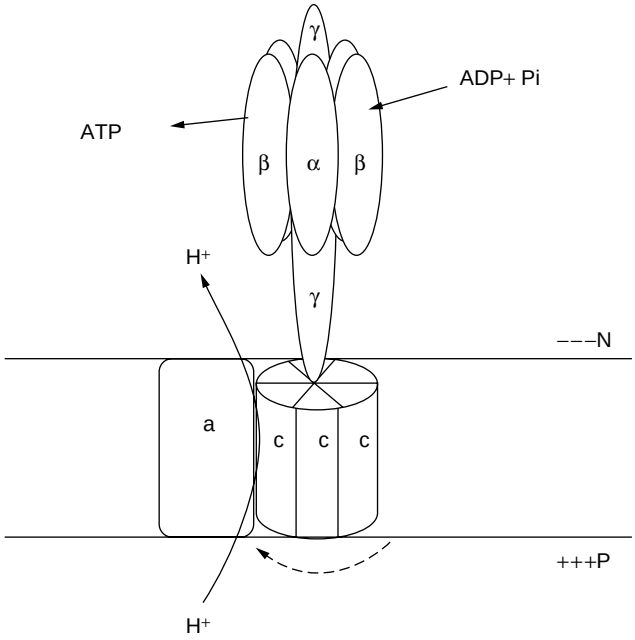

Figure 8. Structural organization of the F_1F_o-type ATPase. Not all subunits making up the complete complex are present. The F_o part of the complex resides in the membrane and is indicated by the a and c subunits. The F_1 part lies on the cytoplasmic side of the membrane. The dashed arrow indicates direction of rotation of the F_o complex during ATP synthesis.

the energy of the transmembrane voltage gradient or PMF. Through an electrostatic mechanism, the flow of protons causes the ring of small subunits in the membrane to rotate in a clockwise direction (64,67–69). This ring is connected to the γ-subunit, which also rotates, and the extramembrane ring of α- and β-subunits is prevented from rotating by additional subunits that act as a stator. As the γ-subunit rotates within the cap structure it forms different associations with each β-subunit, much the same way as a camshaft in a multicylinder engine forms different associations with each cylinder at any given second. As γ rotates, the active site on each β-subunit moves successively through three conformations: one that loosely binds ADP and phosphate, one that binds these substrates tightly and catalyzes the condensation reaction to form ATP, and a third conformation that opens the active site to release ATP. Thus, the overall result of continued proton transfer through the transmembrane domain of the synthase is constant consumption of ADP and phosphate by the extramembrane headgroup and the constant release of ATP.

REGULATION OF AEROBIC METABOLISM

As stated earlier, O_2 is the preferred oxidant for aerobic bacteria, and when it is available, aerobes will adjust their physiology to preferentially use this oxidant over all others. Bacteria have developed complicated regulatory circuitry to assess O_2 concentrations. A few of these have been studied in some detail and will be briefly described. These proteins are found in many aerobic bacteria; however, it should not be assumed that every protein would have the same function in every aerobe. Each species of bacteria has its own regulatory circuitry and physiological set points making it difficult to extrapolate from one organism to the next. One common theme among the regulatory proteins studied so far is that they are active when O_2 is absent. That is, they are used to activate genes whose products are required when O_2 is limiting. Regulatory proteins that are activated by increases in O_2 have not been studied in bacteria.

Oxygen Sensing Regulatory Proteins

The prototype of this type of regulatory protein is Fnr. Fnr apparently senses O_2 directly and binds to DNA when O_2 concentrations are low (Fig. 9). This is because Fnr contains an O_2 labile [Fe–S] center (70). When O_2 concentrations are high the [Fe–S] center is not completely assembled. Consequently, the protein does not dimerize and this prevents it from binding to its target sequence (71). As O_2 concentrations decline, conditions become more favorable for assembly of a stable [Fe–S] center. Once the [Fe–S] is formed, Fnr can dimerize and interact with its target sequence. In most cases, Fnr is a positive activator of gene expression. This protein is found in a wide range of bacteria and is responsible for the expression of many genes. It is now evident that Fnr is member of a large family of transcriptional regulators termed the *Fnr/Crp* family (72). All of these regulators have similar structural organization, with a

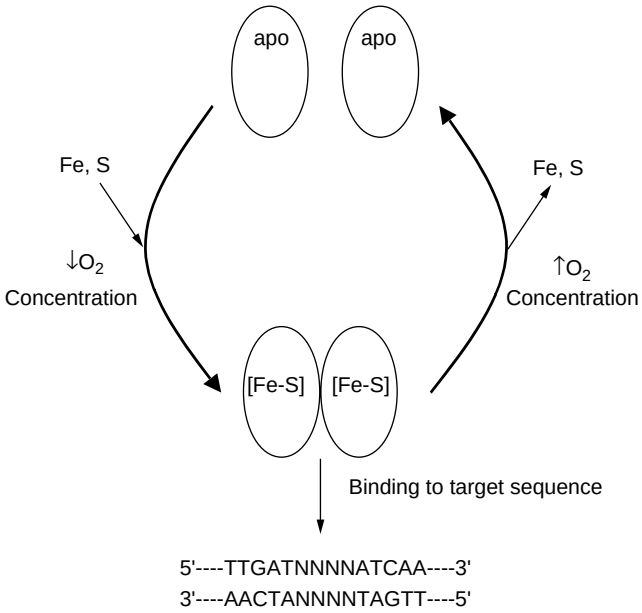

Figure 9. Model of how the transcriptional regulator Fnr responds to changes in O_2 concentration in the cell. [Fe–S] represent O_2 labile iron-sulfur centers found in Fnr. The consensus Fnr target sequence is given below the active [Fe–S]-containing Fnr.

DNA-binding domain at the C-terminus and an effector-binding domain at the N-terminus. There is little sequence similarity among the N-terminal domains among the various members of this family of proteins. However, most seem to be designed to use small molecules as effectors. For example, there are members of the family that detect the gas carbon monoxide and other members that respond to changes in cyclic AMP (73,74).

In *E. coli*, Fnr has been shown to repress the expression of the genes encoding the cytochrome *bd*-type oxidase under anaerobic conditions (75). A similar role for Fnr occurs in *A. vinelandii*, with Fnr repressing synthesis expression of the *bd*-type oxidase used to protect nitrogenase from O_2 (76). In *Pseudomonas aeruginosa*, inactivation of the gene encoding Fnr caused increased expression of an oxidase with high affinity for O_2, probably a cbb_3-type oxidase, along with a cyanide-insensitive oxidase that is probably a *bd*-type enzyme (77). Inactivation of a gene encoding an Fnr homologue in *P. denitrificans* also caused increased expression of a quinol oxidase, but repressed expression of the cbb_3-type oxidase (53). Expression of the genes encoding cbb_3-type oxidase in *R. sphaeroides* also requires Fnr (78).

Regulators That Indirectly Sense Changes in O_2 Concentration

Although Fnr appears to interact directly with O_2, other proteins appear to sense changes in O_2 concentration by indirect mechanisms. One of these systems is termed the *Arc system*, which has been extensively studied in *E. coli* and its relatives. The Arc system consists of two proteins, ArcB, which is a membrane-associated histidine kinase, and ArcA, which is its associated response

regulator (79). Together, these two proteins form a two-component regulatory system. ArcB apparently senses some aspect of respiration, perhaps the redox state of an intermediate in the respiratory chain. There is no evidence that ArcB directly senses O_2. When conditions limit electron flow through the aerobic respiratory chain, ArcB phosphorylates ArcA (80). ArcA then acts as either an activator or a repressor of its target genes. The activity of ArcB also seems to be influenced by the presence of metabolic intermediates that indicate O_2 is limiting, such as pyruvate and D-lactate (81). The ArcAB system functions as a positive activator of expression of the genes encoding the *bd*-type oxidase in *E. coli* (82).

A second example of a regulatory system that regulates anaerobically expressed genes, but does not directly sense O_2, is the PrrA/PrrB system (also termed *RegA*/*RegB*) in *Rhodobacter* species and related bacteria. Like the ArcBA system, the PrrBA system is a two-component sensor-regulator system, with PrrB being the membrane-associated histidine kinase and PrrA the associated response regulator (79). Recent work in *R. sphaeroides* indicates that PrrBA interacts with the cbb_3-type oxidase (83). When O_2 is present, the cbb_3-type oxidase is active and PrrB does not phosphorylate PrrA. However, when electron flow through the oxidase decreases because of O_2 limitation, PrrB phosphorylates PrrA, causing it to activate transcription of a number of genes. In this case, the activity of the oxidase is the gauge the regulator uses to determine ambient O_2 levels.

TAXIS RESPONSE TO O_2

In addition to using their regulatory systems to monitor environmental conditions, cells can use taxis to move themselves to positions that optimize aerobic respiration. Taxis toward terminal oxidants such as O_2 has been observed for many years. This taxis response to O_2, termed *aerotaxis*, has been extensively studied in *E. coli* and its relatives (84). Taxis toward O_2 is dependent on the ability of the cells to respire O_2, which suggests that O_2 is not directly sensed by cellular receptors. Rather, the cell appears to respond to electron flow to a particular oxidant. In *E. coli*, a membrane-bound flavoprotein termed *Aer* has been shown to be involved in the aerobic taxis response (85). It is likely that the redox status of the flavin allows Aer to monitor electron flow to O_2 (86). In the bacteria in which aerotaxis has been studied, O_2 is always the preferred oxidant and its presence will prevent taxis to alternative oxidants.

AGGREGATES AND CONSORTIA, MICROBIAL

HANS W. PAERL

JORMA KUPARINEN
Finnish Institute of Marine Research
Helsinki, Finland

Nearly a century of microbiological research indicates that structurally and functionally complex microbial communities commonly inhabit surface-associated environments in aquatic ecosystems. Surficial microbial communities often show higher metabolic activities and growth rates than their freely suspended counterparts. This has been linked to surfaces facilitating close metabolic coupling among community members, leading to enhancement of growth and nutrient cycling that exceeds what is achievable at the single species level. These synergistic, mutually beneficial associations are termed *consortia*. Consortia are common to aggregate and other surficial communities broadly distributed along geographic and trophic gradients, ranging from the tropics to the poles. Consortial activity, growth, and diversity are enhanced by biogeochemical (i.e., oxygen, E_h, pH, nutrients) gradients in surficial microenvironments, or microzones. In part, consortia themselves promote biogeochemical zonation and microbial diversification through localized production and mineralization of organic matter. This positive interaction is a requisite for biodiversification, which in turn enhances microzonal productivity and nutrient cycling. For these reasons, consortia are viewed as the functional units of biocomplexity in aquatic ecosystems.

The consortial "lifestyle" also appears to be a highly effective strategy for colonizing and exploiting nutrient and energy resources under environmentally extreme conditions at "the edge of life." Examples from oligotrophic planktonic, hypersaline, and lithifying benthic, Baltic Sea and Antarctic lake ice communities are used to exemplify the important roles aggregate and surface microbial

communities play in ecosystem, regional and global biogeochemical cycling and production dynamics. Because they are highly sensitive, exhibit rapid community growth, and compositional responses to environmental change and extremes, microbial consortia are excellent indicators of climatic and geochemical changes, as well as human pollutants and other perturbations in aquatic ecosystems.

SUSPENDED AND SOLID SURFACES AS MICROENVIRONMENTS

Microorganisms are the dominant producers and cyclers of organic and inorganic compounds in the biosphere. In aquatic environments, at least two-thirds of primary production is mediated by microorganisms, including bacteria (cyanobacteria and photosynthetic bacteria) and microalgae (1). A vast percentage of aquatic production is either sedimented or recycled via microbial mineralization (2,3). Therefore, environmental controls of microbial production, mineralization, and associated nutrient transformations are key determinants of aquatic ecosystem structure, function, and material flux. A vast proportion of the Earth's marine and freshwater ecosystems is nutrient- and energy-poor, and as such production and mineralization are tightly controlled by nutrient and energy availability. In natural waters, nutrient resources are heterogeneously distributed in time and space (4), with relatively high concentrations associated with particles and submersed surfaces (2,5), which can act as sources or concentration sites of nutrients. Microbial biomass and activities are generally higher on surfaces than in the free-floating state (2,5,6). As a result, microbial growth and nutrient transformation are often stimulated by surfaces (5,7). This has been attributed to the nutrient-rich "oasis" that surficial microenvironments provide in an otherwise dilute "desert" macroenvironment (2,8).

Relatively high rates of primary productivity and respiration associated with surfaces lead to localized regions of elevated organic-matter enrichment and consumption, accompanied by the development of oxygen gradients (2,9,10), which provide conditions for species enrichment along the resultant biogeochemical continuum. These are the essential ingredients for intensification and diversification of surficial biogeochemical cycling.

Owing to their rapid growth rates and small size (i.e., $\sim\mu$m), microorganisms are excellent exploiters of nutrient-enriched surficial microenvironments. Small cell size enables large numbers of cells to colonize these microenvironments. Small cell size also provides high surface to volume ratios, facilitating nutrient uptake at low concentrations. The metabolic activities (i.e., oxygen production and consumption, pH changes) associated with metabolically active microbial communities further enhance biogeochemical zonation, promoting microbial diversification. However, there is a price to pay for being small. The small cell size and prokaryotic (lack of organelles and nucleus) nature of bacteria restricts cellular biochemical specialization. This metabolic "packaging problem" is particularly problematic when considering the need for harboring aerobic (oxidized) and anaerobic (reduced) processes on the cellular level. Both types of processes are often required to fully metabolize and derive energy from organic and inorganic compounds. For example, cyanobacteria utilize oxygenic photosynthesis to obtain energy and carbon compounds to support growth. However, cyanobacteria also rely on highly reduced processes, such as nitrogen (N_2) fixation to obtain biologically available nitrogen in nitrogen-deplete waters. The oxygen evolved from photosynthesis is inhibitory to N_2 fixation; it can also exert a strong negative feedback control on photosynthesis itself (i.e., the Warburg effect, see Refs. 11,12). Some filamentous cyanobacteria are able to separate these cross-inhibitory processes by cellular specialization (e.g., the formation of heterocysts to which N_2 fixation is confined) (12,13). Such specialization requires multicellular compartmentalization, a luxury that may not be practical within the confines of micron-scale surficial habitats.

To circumvent the "packaging problem," physiologically distinct prokaryotes, eukaryotic microalgae, protozoans, and fungi participate in metabolically coupled associations (13–16), enabling them to colonize, optimize growth, establish redox gradients, and maintain effective nutrient cycling within the confines of a microenvironment. Under these conditions, smallness, metabolic specialization, and close proximity along micron-scale biogeochemical gradients are advantageous for (*1*) survival, (*2*) obtaining nutrient and energy sources, (*3*) establishing high biodiversity, (*4*) facilitating nutrient and genetic exchange, and (*5*) exploiting environmentally "extreme" habitats not colonizable by single species acting alone (14,17).

Microorganisms participating in the "lifestyle" described earlier operate as consortia. That is, populations have evolved to functionally specialize and diversify along micron-scale biogeochemical (redox, nutrients, organic matter supply, etc.) gradients, or "microzones," where effective exchange of metabolites leads to "one organism's trash being another's treasure." Consortia are defined as the operational units of biocomplexity in nature, as *several species or populations that function in a complementary fashion such that production and growth are enhanced above that which a single species or loosely-knit collection of populations (i.e., assemblage) can achieve independently* (14,17). On regional and global scales, consortial associations in aggregates, biofilms, and microbial mats play basic roles in production and nutrient cycling dynamics. The "microbial loop" in trophodynamics, energy flow, and biogeochemical cycling highlights the central role consortia play in ecosystem processes (3). Clarification and quantification of consortial components and their exchange rates are essential for developing process-based models linking biocomplexity to function in aquatic and terrestrial ecosystems.

Consortia develop within, and as a consequence of, an interactive matrix of geological, physical, and chemical parameters. Over time, consortia develop by interactions at some quasi "steady-state" whose determinants arise from the prevailing interplay of system parameters (Fig. 1). We will explore this operational definition of consortial life in aggregates and surficial microzones and its role in production and biogeochemical cycling dynamics in planktonic and benthic habitats.

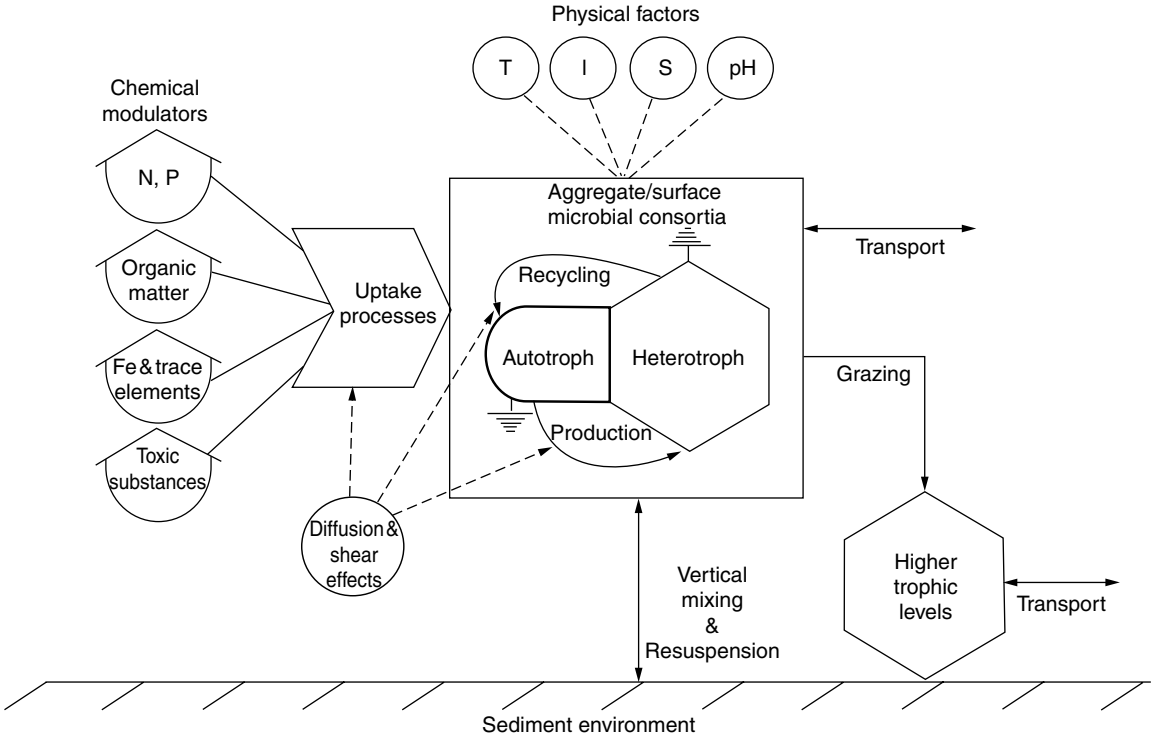

Figure 1. Conceptual diagram depicting influence of natural and anthropogenic environmental factors, and physical modulators and biotic interactions on aggregate/surface microbial consortial assemblages. Physical modulators include temperature (*T*), irradiance (*I*), salinity (*S*), and pH (pH).

FORMATION OF AGGREGATES AND CONSORTIA

Suspended Aggregates

Formation of visible, suspended macroscopic aggregates composed of microscopic particles is a common phenomenon in aquatic ecosystems (18–23). Microscopic particulate matter in surface waters consists of living organisms, inorganic particles, and nonliving organic matter, or detritus. Aggregation of these "particles" is a complex process involving physical, chemical, and biological interactions on different spatial and temporal scales (Fig. 1). Physical processes, such as shear (difference in fluid movements on small scales), Brownian motion (thermal movement of one particle toward another), and differential settlement (one particle sinking faster than the other, overtaking and colliding with it) bring particles together (Fig. 2) (24). The number of particles per unit volume of water is crucial for encountering other particles and forming aggregates. Frequently, physical discontinuities in the water column, such as the pycnocline, act as sites for enhanced aggregation.

Chemical and biological properties of colliding particles ("stickiness") determine whether they adhere and aggregate. The mucus sheaths and other organic surface materials, especially polysaccharide particles known as transparent exopolymer particles surrounding organisms, act as adsorption surfaces for additional particles (19,25,26). Attachment to surfaces stimulates bacterial exopolysaccharide synthesis, which further enhances aggregation (27). Aging microaggregates collide with each other and form visible macroaggregates, such as "marine snow" and "lake snow."

A two-state coagulation theory, in which coagulation is insignificant at low, but significant at high algal concentrations with a rapid transition between the two states has been suggested for diatom blooms (28–30). The critical cell concentration is dependent on cell size, cell surface stickiness, and turbulence, and may be reached rapidly, with the entire sequence of aggregation and sedimentation completed in 24 hours (31). In the Baltic Sea, such rapid transition from diatom growth to aggregation and sedimentation has been recorded during spring blooms (32–35). Nutrient depletion at the end of a bloom has been shown to increase diatom cell stickiness, enhancing aggregation (30,36,37). Despite its episodic nature, aggregation is significant and widespread enough to control ecosystem-level annual energy flow and nutrient dynamics owing to the transport of organic matter to the benthos by sedimentation.

Physical and biological processes may also decrease aggregate size (Fig. 2). Turbulence may tear particles apart or bring them together (38,39). Biological disaggregation by microorganisms or consumption by zooplankton can, at times, be an important factor regulating aggregate size (25,40). Grazing of aggregates by fish and zooplankton is an important shortcut in the food web, transferring organic carbon to higher trophic levels more efficiently

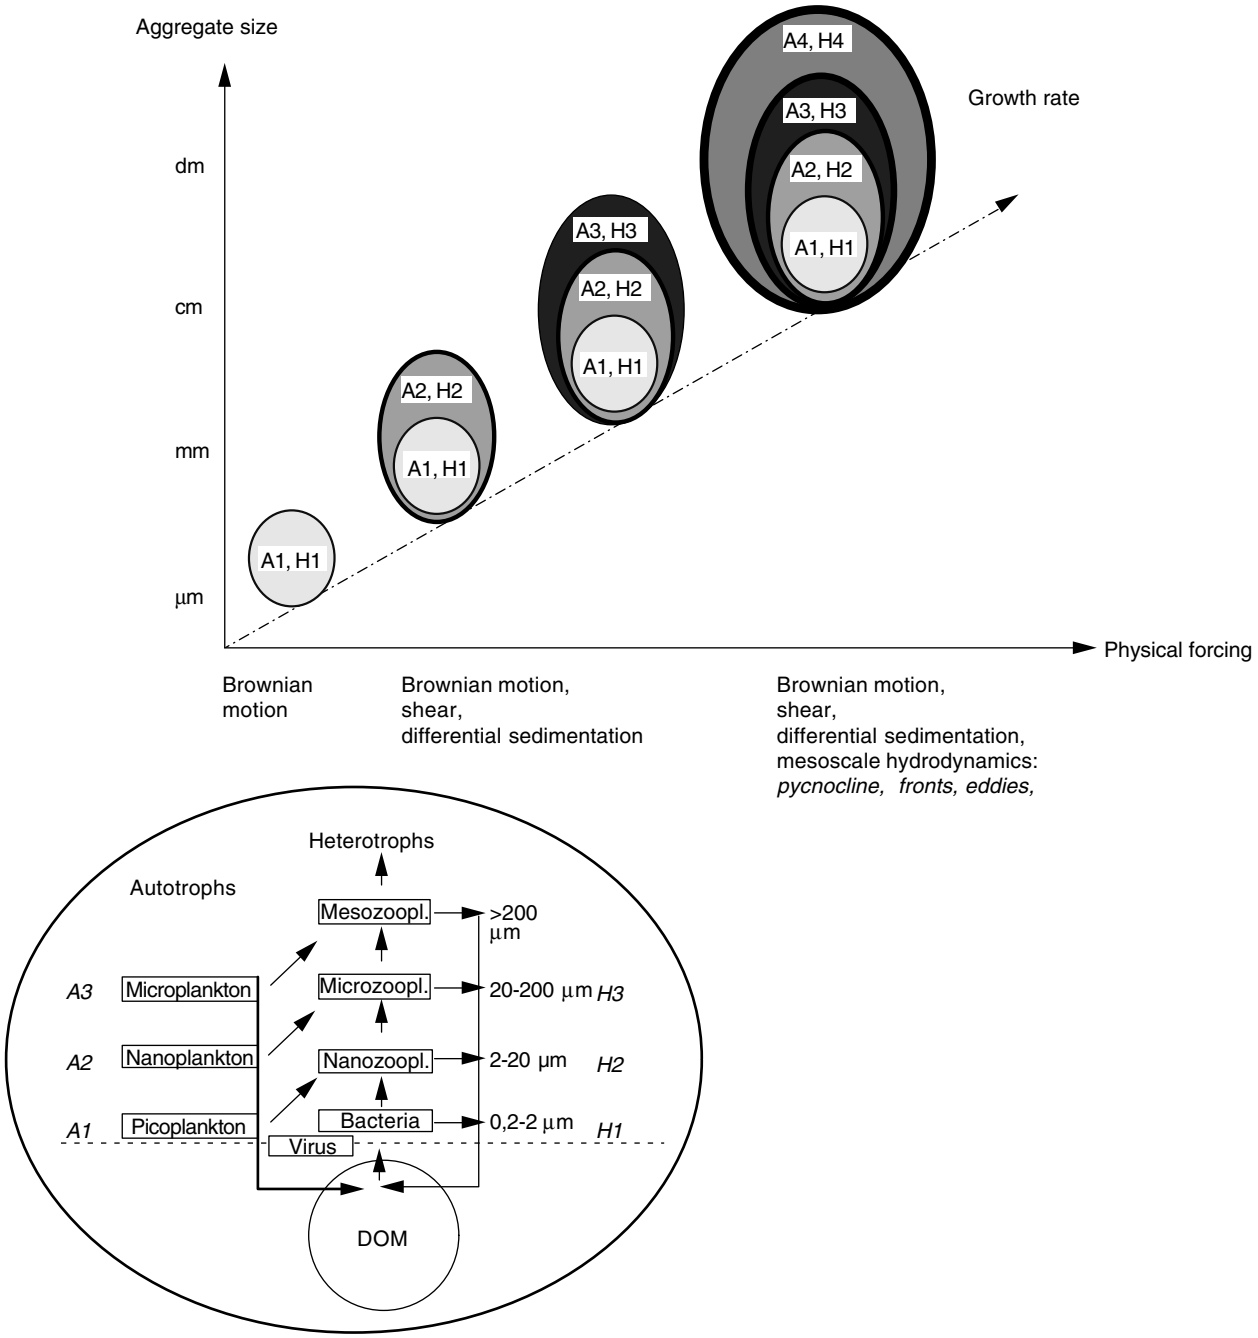

Figure 2. Aggregate size development in relation to physical forcing and time. A1-H3 and H1-H3 represent autotrophic (A) and heterotrophic (H) plankton in the classical size structured pelagial food web. Dashed line represents the artificial partitioning between DOM and particulate organic matter. Brownian motion is a relevant collision mechanism with particles smaller than 1 µm (A1, H1 particles) (38). Shear contact from laminar or turbulent processes is a common collision mechanism for particles larger than 1 µm (A2, H2, and above). The third collision mechanism is differential sedimentation (A2, H2, and above). The critical cell concentration for aggregation depends on cell size, cell surface properties, and environmental shear. Spherical particles have upper limits to their size as large particles become vulnerable to break up by the same shear that brings them together. Large aggregates (>cm A4, H4 particles) are formed when organisms have appendages, hairy structures, or grow in filaments. The physiological status of the cell adds to the "stickiness" of the particle.

than via the microbial loop (23,41). The relative importance of these mechanisms in aggregate dynamics depends on the origin and age of the aggregates (28,42,43).

Sea and Lake Ice Aggregates

Seasonal formation of sea ice traps organisms in organic-matter rich aggregates. Ice-associated microbial assemblages in the brackish Baltic Sea resemble those found in Antarctic and Arctic sea ice (44–46). The biotic assemblages in the Baltic Sea ice consist of diatoms, photo- and heterotrophic flagellates, cyanobacteria, heterotrophic bacteria, and metazoa (44–48). Diatoms and various autotrophic flagellates are the most important algal groups; hetero- and mixotrophic organisms (flagellates and ciliates) compose 2 to 10% of carbon-based biomass (49). The accumulation of inorganic nutrients and abundant heterotrophic organisms seasonally found in the Baltic Sea is indicative of active carbon mineralization in the interior parts of the ice. The interior layers of 2- to 3-month-old ice are also active sites for nitrogen transformations. The enrichment of denitrifying organisms in the middle layers of thick ice, together with elevated nitrite concentrations, indicate active nitrate reduction and potentially denitrification, that is, microbial reduction of NO_3^- to N_2 gas (50). Despite the low rates of N_2O and N_2 production from seasonal ice (50), the large aerial expanse of seasonal ice on the global scale renders sea ice microbial processes of high significance.

Microbial aggregates may also be embedded in the ice cover of lakes and marine systems for many years. The permanent ice cover of the glacial lakes in the McMurdo Dry Valley region of Antarctica is one example (51–53). Here, aggregates originate as windblown soil particles (originating in the surrounding exposed desert soils) harboring desiccated phototrophic (cyanobacteria) and heterotrophic microflora that are deposited on the ice cover. Solar heating of the soil particles enables them to melt into the ice cover, where they remain for several years. The ecophysiology of these "entombed" aggregates is discussed in detail later. As with sea ice, lake ice primary production and nutrient cycling rates are extremely low; however, on the ecosystem-scale, the aggregates are a major source of "new" production and nutrient input to these lakes (51).

Surficial and Benthic Habitats

The bottom (benthos) and other surficial attached environments provide diverse colonization sites for metabolically complex microbial consortia. These include, biofilms on submersed inorganic and organic nonliving substrates, including rocks, metals, glass, wood, plastics, and other synthetic materials (5,54). Consortia also inhabit the surfaces of living plants (epiphytic) and animals (epizoic). Benthic habitats supporting microbial consortia include submersed and intertidal mud- and sandflats, hard (rock) and soft (mud-silt) bottoms, marshes, reef, and shelf environments (55–57). Consortia inhabiting these environments range from ephemeral, loosely organized, flocculent, accumulations of microalgae, and associated bacteria, fungi, and metazoans, to well-developed laminated microbial mat communities (55). Microbial communities may physically modify the attachment substrates. Examples include, complex biofilms on submersed surfaces (54,58), adhesive mats that consolidate sediments (55), beach sands and lagoonal environments (55), providing protection against erosion from storm surges, and calcifying mats that form permanent lithified, layered deposits called stromatolites, the oldest known evidence (2 billion years ago) for microbial consortial life on Earth (59,60).

Microbial Modification of Aggregates and Biofilms

Once attached, microbial communities can physically and chemically modify the substrate. Recently divided "young" phytoplankton cells usually show the least amount of bacterial colonization (61,62). As the cells age, they are more readily colonized by microorganisms. Bacterial colonization may be quite intense along algal filaments surrounded by mucilage (23,62,63) and cyanobacterial heterocysts (61) (Fig. 3). These bacterial epibionts represent a key food source for protozoan grazers, leading to complex microbial food webs (19,21,39,62,64–66). Among aging aggregates, senescent algae provide degradable organic matter for large numbers of attached bacteria. The role of the recycling of organic matter via microzooplankton back to bacteria is enhanced as the aggregates mature (39,41,62).

Cyanobacterial aggregates that avoid sedimentation and grazing can maintain "steady-state" aggregation conditions for long periods owing to recycling of organic matter and mineral nutrients by attached microflora within the phycosphere (62,67,68). Under these conditions, "host" cyanobacteria can reveal high growth rates, frequently exceeding rates obtainable under axenic conditions (10). In fact, some bloom-forming cyanobacterial species are only culturable when bacterial epibionts are present (13). Among other cyanobacterial genera (e.g., *Oscillatoria, Lyngbya, Nodularia*), bacterially colonized strains revealed higher growth rates and were easier to maintain in culture than axenic strains. Gibson and Smith (69) reported that both axenic *Oscillatoria redekei* and *Oscillatoria agardhii* isolates "always appeared to grow better in the presence of contaminant heterotrophic bacteria." Similar findings were reported by Meffert (70), Herbst and Overbeck (71), Caldwell (72), and Lehtimäki and coworkers (73), suggesting consortial interactions.

Cyanobacteria excrete organic compounds, including organic and amino acids, peptides, alkaloids, carbohydrates, and lipopolysaccharides (74–76). Diverse excretion products chemotactically attract and support the growth of phycosphere-associated bacteria (77,78). In N_2 fixation and fate experiments, some of the ^{15}N-labeled N_2 fixed by host *A. oscillarioides* was rapidly transferred to heterocyst-associated *Pseudomonas aeruginosa* (79). Axenic isolates of *A. oscillarioides* exhibited optimal growth and N_2 fixation rates when reinoculated with *P. aeruginosa* (16). When released in axenic *A. oscillarioides* cultures, *P. aeruginosa* reestablished the heterocyst-specific association. These findings suggest close metabolic coupling and mutually beneficial relationships in cyanobacterial-bacterial aggregates.

Aggregation into large flocculates by filamentous cyanobacteria may be of major importance for prolongation

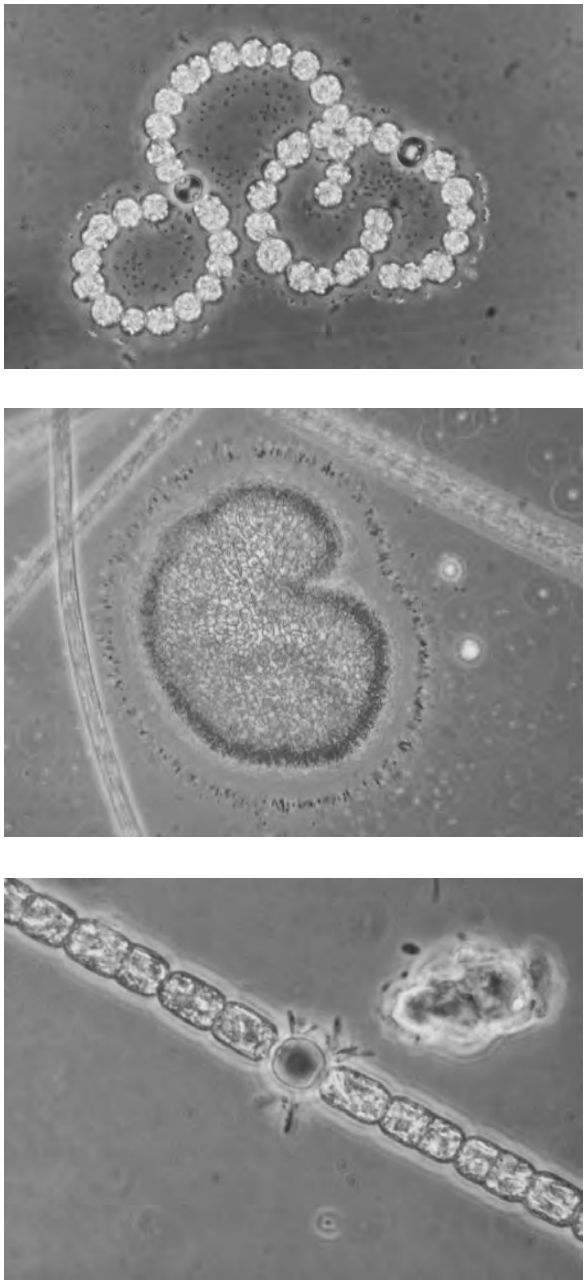

Figure 3. Microbial associations with bloom-forming cyanobacteria: (**a**) bacteria inside *Anabaeana spiroides* coils; (**b**) bacteria around *Gomphosphaeria* colonies; (**c**) bacteria on heterocyst of *Anabaeana oscillarioides*. See color insert.

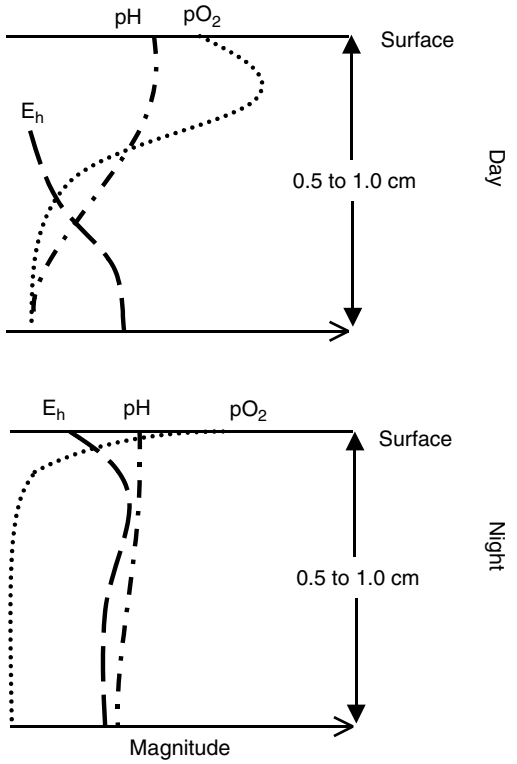

Figure 4. Idealized set of vertical profiles of redox potential (E_h), pH, and percent saturation of dissolved oxygen (pO_2) in a microbial mat. The differences among relative values for each parameter are shown for daytime (upper frame) and nighttime. Typically, the biogeochemical gradients show strongest vertical zonation in the upper 0.5 to 1.0 cm of the mat where light can potentially penetrate and photosynthesis takes place.

of bloom events. Further, the interior of these large flocculates can become anaerobic (80) like the microbial mats, support denitrification (81) and sulfate reduction (82), biogeochemical transformations not predicted by models that assume random distribution of organic matter and microbes in the pelagic environment.

Microbial Mats

Microbial mats are laminated microbial communities associated with a variety of benthic substrates, including sands, muds, rocks, metals, glass, concrete, wood, even plastics, and other synthetic substances. Mats are morphologically complex microecosystems that possess a high degree of phylogenetic and functional (metabolic) diversity compressed into only a few millimeters (55,83). Mats are widely distributed, with their range including polar deserts, glacial lakes and streams, lakes and marine ecosystems, the deep-sea, polar to tropical shallow seas, reefs, mud- and sandflats, saltmarshes, hypersaline, and hyperthermal ecosystems. In many of these systems, mats are among the most productive and diverse biotic communities. Mats are composed of microbial phototrophs (anoxygenic and cyanobacterial), heterotrophs, and chemoautotrophs (55,84–87). Characteristically, mats exhibit vertical biogeochemical zonation (10,88,89), which usually includes an upper oxic and lower anoxic zone (Fig. 4). In aphotic regions (i.e., deep sea), or under anaerobic (i.e., sulfidic hot springs) conditions, anaerobic processes prevail. In euphotic, oxygenated environments, photosynthetic production is usually conducted by a phylogenetically diverse assemblage of cyanobacteria and diatoms that dominate the upper oxic layer. Lower regions of well-developed mats are often O_2 subsaturated or anoxic, leading to sulfide accumulation generated by heterotrophic sulfate-reducing bacteria (SRB). These mats also have

steep vertical redox (E_h) and pH gradients. Gradients create a range of microzonal (micron to millimeter scale) habitats, in which metabolically diverse microbial consortia are located according to energetic, nutrient, and ecological needs and limitations. Consortia closely interact by exchange of metabolites, enabling major biochemical processes with different environmental requirements (e.g., oxygenic photosynthesis, N_2 fixation, denitrification, nitrification, sulfate reduction, methanogenesis) to function contiguously and contemporaneously (9,10,90–92).

Depending on environmental conditions, critical energy and nutrient transformation processes oriented along these gradients may be cross-inhibitory. For example, during sunny days, rates of oxygenic photosynthesis may be high, leading to a buildup of oxygen-saturated conditions in the mat matrix. This could prove inhibitory to anaerobic carbon, nitrogen, and sulfur transformation processes, especially near the mat surface. For example, daytime O_2 supersaturation presents a problem for N_2 fixation, denitrification, sulfate reduction, and other anaerobic processes (e.g., methanogenesis) that are reliant on photosynthetically produced organic matter as an energy source, yet are inhibited by even low ambient O_2 concentrations (91–93). Sulfate reducers account for a large fraction of the heterotrophs in some mats (90), and are also suspected of being significant contributors of fixed nitrogen (94). Although N_2 fixation can be observed during daytime, rates often increase at night or in the early morning when pO_2 is low. It is suspected that sulfate reducers may contribute to N_2 fixation at this time.

Denitrification can be an important process mediating nitrogen availability in microbial mats (95). Denitrifying bacteria include taxonomically diverse heterotrophs that are either facultatively anaerobic (*Pseudomonas* and *Thiobacillus*) or obligate anaerobic (*Bacillus* and *Spirillum*) genera. Molecular O_2 strongly inhibits denitrification because O_2 can outcompete NO_3^- as a respiratory electron acceptor. Oxygen can also be directly toxic to some denitrifiers. Therefore, denitrifiers are often most effective in anoxic zones near NO_3^- sources. Organically enriched surface sediments and mats harboring anoxic microzones overlain by NO_3^- rich bottom water are optimal conditions for denitrifiers (96,97).

Even though sulfate reduction, N_2 fixation, and denitrification are all inhibited by even low pO_2, they can co-occur during peak photosynthetic (i.e., high O_2 evolving) periods (56,90,97,98). Consortial syntrophic associations between presumed metabolically incompatible organisms, such as oxygenic cyanobacteria and obligate anaerobic purple sulfur bacteria, sulfate reducers and facultative aerobes (99,100), and sulfate reducers and methanogens (101) have been demonstrated. These results can be reconciled with the observation of small-scale (i.e., 1 to 100 μm) anoxic microzones in an oxygenated matrix (i.e., mats) as determined by localized reduction of tetrazolium salts (79,102) and the presence of active photosynthetic bacteria (103).

In mats, anoxic microzones are promoted and maintained by abundant supplies of organic matter (via sedimentation and high rates of primary production), which support high rates of respiration. If respiratory O_2 consumption exceeds inward O_2 diffusion, anoxic microzones can be formed even in the upper layers of mats. In addition, facultative anaerobic and aerobic bacteria associated with anaerobic bacteria provide removal of potentially toxic O_2 (79). Microscopic observations of mats treated with redox (tetrazolium) dyes reveal a highly heterogeneous matrix supporting anoxic microzones even within largely oxic regions (determined by microelectrodes) (103). This heterogeneity promotes high genetic and physiological diversity, needed to fully optimize production and nutrient cycling processes requiring a range of oxygen conditions. The production of mucilaginous exopolysaccharides (EPS) by resident cyanobacteria and associated bacteria promotes sediment stabilization and cohesion of the mat, acts as diffusional barrier, provides surfaces and substrates for growth (104), and selectively binds potential toxins such as heavy metals (105).

ECOLOGICAL AND BIOGEOCHEMICAL ROLES OF AGGREGATES AND CONSORTIA

By virtue of ensuring quasi-stable, small-scale biogeochemical gradients, planktonic aggregates and surficial microzonal habitats provide a protective set of niches for complex, highly interactive microbial production and nutrient cycling processes. These microzones harbor metabolically diverse microbes even in the face of severe environmental constraints. As a result, life in some of the most extreme environments on Earth largely operates in a consortial mode. We will explore the consortial "players," their metabolic and structural strategies for survival and growth in a range of environments, including extreme ones. We will also examine the implications for aquatic production and biogeochemical cycling in physically, geochemically, and ecologically diverse planktonic and benthic habitats. These include

1. Cyanobacterial aggregates in lakes, oceans, and in the brackish Baltic Sea
2. Nitrogen-fixing cyanobacterial (*Trichodesmium*) aggregates in the open ocean
3. Microbial mats in temperate and tropical ecosystems
4. Microbial mats in hypersaline waters
5. Aggregates embedded in the permanent ice cover of Antarctic lakes.

CYANOBACTERIAL AGGREGATES IN LAKES, OCEANS, AND IN THE BRACKISH BALTIC SEA

Planktonic diazotrophic cyanobacteria are common in eutrophic lakes, rare in oceans, and nearly absent in estuaries and coastal seas (106). Exceptions are the Baltic Sea and the Peel-Harvey estuary in Australia (107). Cyanobacteria are responsible for most of the planktonic N_2 fixation, but rates are high only when these organisms make up a majority of the biomass (107). In eutrophic lakes, planktonic N_2 fixation may account for 6 to 82% of the nitrogen input into the system. In the surface waters of the world's oceans and estuaries, including eutrophic estuaries, N_2 fixation provides a far lower percentage of nitrogen input (107). In the Baltic Sea,

however, planktonic N_2 fixation provides at least 15% of the nitrogen input (108).

The mass appearance of N_2 fixing cyanobacteria in eutrophic lakes has been linked to the ratio of nitrogen to phosphorus loading. An N/P ratio near or below the Redfield ratio of 16 : 1 provides a selective advantage for N_2 fixing phytoplankton species. However, planktonic N_2 fixation is low in many estuaries despite low N/P input ratios. One explanation for this conspicuous absence is iron or possibly trace element limitation (109,110). Another explanation is that persistent high turbulence negatively impacts N_2 fixing cyanobacterial growth and hence reduces their dominance (111). Lastly, organic matter enrichment may be a prerequisite for bloom formation (112,113). The cyanobacterial blooms in the Baltic Sea and Peel-Harvey estuary have been linked to high concentrations of dissolved organic matter, which increase the availability of iron and possibly other metals through chelation (114,115). With the exception of iron (discussed later), none of these factors appear to explain large blooms of the pelagic marine N_2 fixer *Trichodesmium*, which inhabit some of the most nutrient-deprived waters on Earth (116).

Nodularia spumigena is the dominant cyanobacterium in the Peel-Harvey estuary, Australia (117). In the Baltic Sea, *N. spumigena* is also abundant but other heterocystous cyanobacteria, such as *Aphanizomenon flos-aquae* and *Anabena* spp. coexist in blooms (118–121). *Nodularia spumigena* and *A. flos-aquae* blooms may be initiated in the open Baltic following deep-water phosphorus intrusions to the warm surface layer, providing a competitive advantage for N_2 fixers (121).

In the open sea, contrary to many enclosed coastal bays, hydrodynamically induced nutrient additions to the phytoplankton community are pulsed, episodic events. As shown by Rothhaupt and Güde (122) and Thingstad and coworkers (123), even minor amounts of nutrients may cause a shift from picoplanktonic (less than 2 μm) to larger organisms. The cyanobacterial blooms occurring in the open Baltic often start with *A. flos-aquae*, which, owing to high phosphorus storage ability, is favored by pulsed phosphorus inputs (124). Once the blooms are established, *N. spumigena* may cover large areas of the open Baltic Sea (Fig. 5) (121).

During their initiation, *N. spumigena* blooms start as straight filaments. During this early stage, phosphorus intrusions from deeper water can occur (121), enabling *Nodularia* to experience unrestricted growth conditions when it fixes N_2 (125,126). If phosphorus inputs to the planktonic community are intermittent, the development and persistence of a bloom must rely on regeneration of the stored phosphorus. In later growth stages, when *Nodularia* dominates over *Aphanizomenon*, formation of large aggregates of coiled *Nodularia* filaments has been observed (Fig. 5).

As a proposed survival strategy, coiling provides a means to engulf and support the development of an active microbial food web promoting phosphorus recycling within the confines of the aggregate. In contrast, *A. flos-aquae* forms tight flake-like aggregates that are not penetrated by other microbes. Rather, bacteria attach to the outside of these aggregates (127,128). In the absence of additional phosphorus pulses, *A. flos-aquae* loses its

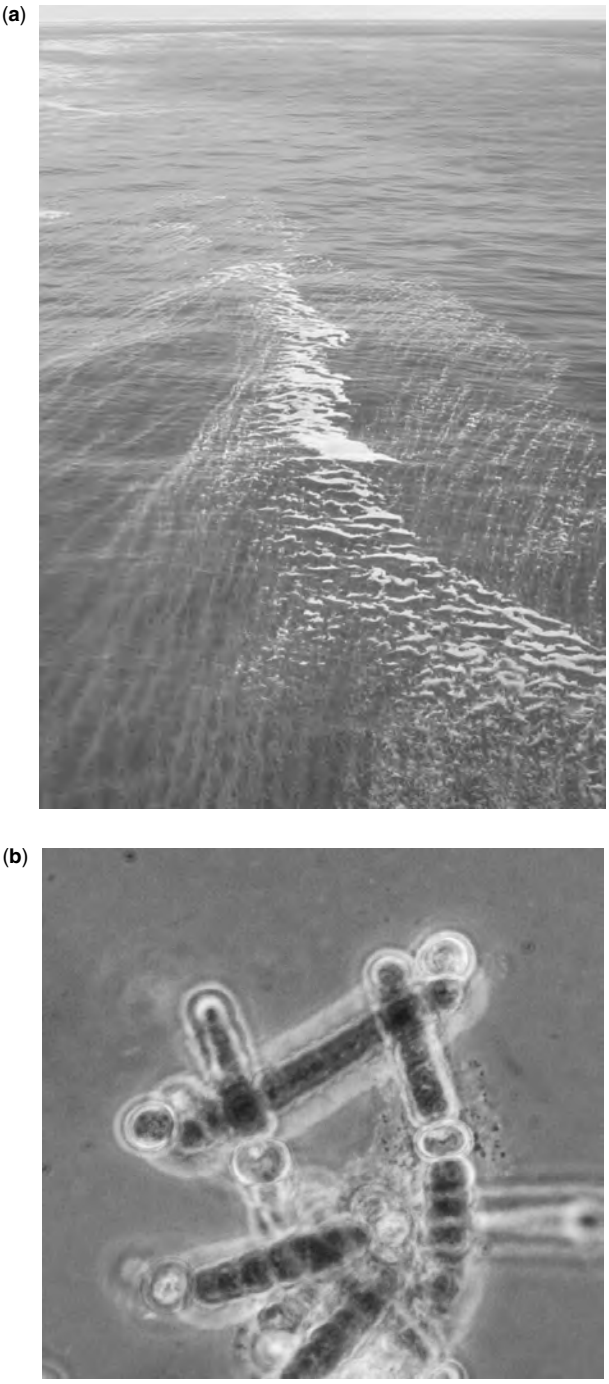

Figure 5. Observations of a bloom of the N_2 fixing cyanobacteria *Nodularia* spp. Left-hand side: a *Nodularia*-dominated cyanobacterial bloom observed in the Gulf of Finland, Baltic Sea (photo courtesy of Pia Moisander). Upper right-hand side: photomicrograph (400x) of several *Nodularia* sp. filaments, showing the nitrogen fixing heterocysts (round, light green cells), neighboring heavily (green) pigmented vegetative (photosynthetically active) cells, as well as associated bacteria. Lower right: coiled *N. spumigena* aggregates with associated bacteria and protozoans present inside the coils (400x). See color insert.

(C)

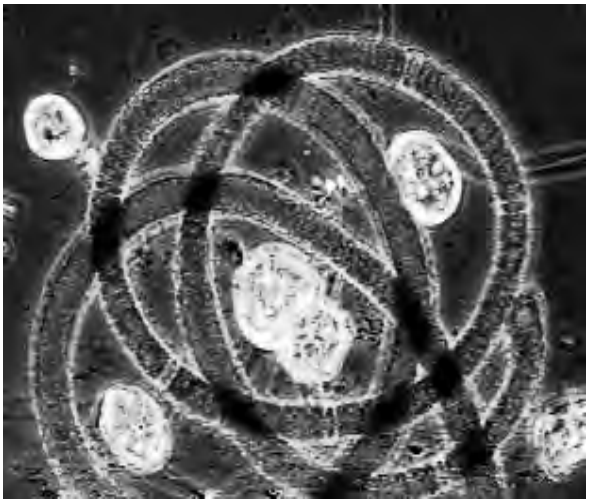

Figure 5. (*Continued*)

dominance owing to its reliance on this phosphorous supply mechanism. Under these circumstances, *N. spumigena* can persist because it is able to maintain effective phosphorus regeneration mediated by the microbial consortia in its coiled matrix. Thus, coiling-based aggregate formation provides a competitive advantage to *N. spumigena*, in part owing to its ability to "win the battle" against diffusive loss of nutrients. In addition, *N. spumigena* has a higher overall affinity for phosphorus than *A. flos-aquae*, which helps explain the successional sequence of the two species (129).

What is the biogeochemical contribution of cyanobacterial blooms to the Baltic ecosystem? Apart from the toxicity aspect of the cyanobacterial blooms, little is known about the contribution of blooms to, for example, carbon flux. Although visually impressive, the cyanobacteria may contribute only little to the pelagic food web in terms of carbon as the two dominant cyanobacterial species *N. spumigena* and *A. flos-aquae* are poorly eaten (only a few percentage of the biomass) by mesozooplankton (130,131). Little or no sedimentation of the summer plankton (including cyanobacteria) has been recorded in various basins (132–134). During the cyanobacterial bloom period, less than 1% of the suspended concentrations settled daily (133), which led the authors to conclude that the cyanobacterial bloom had disintegrated into dissolved and particulate organic pools incorporated into the food web via the microbial loop. Nevertheless, in *N. spumigena*-dominated blooms, a highly active microbial food web may develop within aggregates and thus contribute to pelagic planktonic production (135). In terms of the Baltic Sea's nitrogen budget, cyanobacterial aggregates appear to be important nitrogen transformation sites. N_2 fixation by cyanobacterial bloom-formers is a significant source of externally supplied or "new" nitrogen (108,136). It is suspected that aggregates may also be sites of denitrification (137); however, rates and overall contributions to nitrogen losses via this process have not been adequately assessed. It is possible that N_2 fixation and denitrification may co-occur in aggregates, complicating their roles in the nitrogen budget.

NITROGEN-FIXING CYANOBACTERIAL (*TRICHODESMIUM* SPP.) AGGREGATES IN THE SUBTROPICAL AND TROPICAL OCEAN

Among planktonic cyanobacterial aggregate-formers, the filamentous nonheterocystous N_2 fixing genus *Trichodesmium* is the most widespread and biogeochemically important contributor of "new" nitrogen to nitrogen-depleted subtropical and tropical oligotrophic oceans (138,139). *Trichodesmium* occurs as buoyant macroscopic (a few millimeters in length) radial (puff) or fusiform (tuft) aggregates (Fig. 6), which exhibit high rates of primary production and N_2 fixation, as well as associated microbial (bacterial, microalgal, and protozoan) and crustacean grazer populations (140,141). When calm seas prevail, buoyant aggregates accumulate as large (sometimes greater than 100 km^2) yellow-brown slicks covering the ocean's surface (139,142). *Trichodesmium* is one of the few planktonic nonheterocystous genera that can fix N_2 and CO_2 (and hence evolve O_2) simultaneously, exhibiting parallel maxima of these processes during daytime. Capone and coworkers (143) showed that even when supplied with light during nighttime, N_2 fixation (but not CO_2 fixation) ceased, suggesting strong daytime dependence and a diel "rhythm" in its diazotrophic behavior. Molecular studies indicate that the nitrogenase enzyme complex of *Trichodesmium* is structurally (i.e., amino acid sequence) conserved and similar to that found in other diazotrophs (144,145). As with all other diazotrophs, *Trichodesmium*'s nitrogenase is O_2 sensitive. However, unlike heterocystous cyanobacteria (e.g., *Nodularia*, *Aphanizomenon*), in which nitrogenase is protected in O_2-devoid heterocysts, *Trichodesmium* reveals no obvious cellular differentiation. A great deal of research and speculation has been directed toward clarifying how this enigmatic diazotroph manages to optimize these potentially cross-inhibitory processes in the open ocean. *Trichodesmium* fixes N_2 at highest cellular rates when present as surface-dwelling aggregates as opposed to single filaments (116,142,146,147). When viewed in situ, aggregates reveal highly-compacted, dense, dark-pigmented central cores, while their peripheral regions are often more diffuse and less compacted (148,149) (Fig. 6). Fogg (13) hypothesized that CO_2 and N_2 fixation were spatially segregated, with CO_2 fixation confined to high irradiance external regions and N_2 fixation confined to optically dense internal regions. Carpenter and Price (150) and Paerl (149) provided support of Fogg's hypothesis by microautoradiographically showing that external regions of individual trichomes were photosynthetically much more active than internal regions. Furthermore, numerous studies (148–151) have shown a positive relationship between calm sea state (facilitating aggregation) and rates of N_2 fixation in natural Caribbean Sea, Indian, and Pacific Ocean *Trichodesmium* populations. Bryceson and Fay (148) also showed a strong direct correlation between aggregate shape, size, and N_2 fixation potentials in *Trichodesmium* sampled off the east African coast.

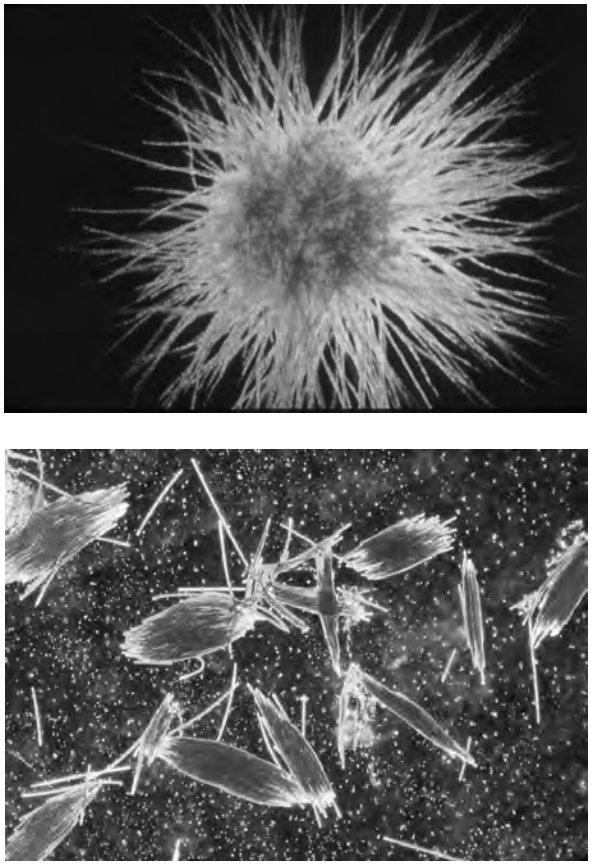

Figure 6. Surface-dwelling aggregates of the filamentous marine planktonic N_2 fixing cyanobacteria *Trichodesmium* spp. Upper frame: radial, or "puff"-shaped aggregates, sampled during a bloom in the Gulf Stream, W. Atlantic Ocean, off the coast of North Carolina. Lower frame: fusiform "tuft"-shaped aggregates sampled in the W. Atlantic Ocean near San Salvador Island, Bahamas. For more details on the N_2 fixing characteristics, and microbial ecology of these aggregates see Paerl (149). See color insert.

Paerl and Bland (102) demonstrated, using tetrazolium dye reduction, that highly reduced (O_2 depleted) regions were present in actively N_2 fixing *Trichodesmium* aggregates obtained from the western Atlantic Ocean (Gulf Stream). Using O_2 microelectrodes, Paerl and Bebout (147) directly measured small (μm) O_2-deplete internal regions in *Trichodesmium* aggregates. Collectively, these studies showed that photosynthetically active *Trichodesmium* aggregates could simultaneously exhibit high and low pO_2 microzones.

Recently, Fredricksen and coworkers (152) showed partitioning of nitrogenase and photosynthetic activities within single filaments of both naturally occurring and cultured *Trichodesmium* populations, suggesting spatial segregation of these processes without the aid of heterocysts. Microautoradiographic examinations of $^{14}C-CO_2$ fixation under both natural and artificial irradiance conditions (149) showed internal regions of aggregated filaments to be far less photosynthetically-active (and hence having low O_2 evolution rates) than the external regions. One explanation for this partitioning is self-shading, imposed by the dense aggregates. It is also possible that respiration is heterogeneously distributed in aggregates. Immunological studies did not show similar partitioning for nitrogenase, with this enzyme being scattered, possibly as groups of cells, throughout aggregates (140,153). These studies indicate a widespread potential for N_2 fixation throughout aggregates. Thus, while photosynthesis appears to be strongly partitioned between inner and outer regions, nitrogenase is not. The implications are that when inner regions of aggregates are photosynthetically inactive (and hence O_2 subsaturated), N_2 fixation can proceed there. Energy needed for supporting N_2 fixation would be supplied by photosynthetically active cells near the outer regions transporting reductant to the inner regions along the filaments, which was shown by autoradiography (149). These studies provide evidence for spatial partitioning of these processes, which is promoted by aggregation. Interestingly, Paerl (149) demonstrated that even single *Trichodesmium* filaments were able to partition photosynthesis along their length, with central regions having lowest rates. However, N_2 fixation and photosynthesis only co-occurred at very low irradiance levels (less than 100 $\mu E\,m^{-2}$ second) in single filaments, while aggregates were able to simultaneously conduct these processes at irradiances exceeding 500 $\mu E\,m^{-2}$ second. Aggregation therefore appears advantageous by enabling this genus to optimize these essential processes in radiant energy-rich, oligotrophic surface waters.

As observed among *Nodularia* aggregates in the Baltic Sea, *Trichodesmium* aggregates host diverse bacterial, microalgal, and protozoan epibionts (154,155). Bacteria associated with *Trichodesmium* are actively engaged in assimilating organic compounds, including amino acids and sugars known to be excreted by the "host" cyanobactria (139,155). Bacteria isolated from naturally occurring *Trichodesmium* aggregates are mostly aerobic heterotrophs. Some reveal chemotactic behavior, being attracted to nitrogen-containing amino acids (155), reflecting *Trichodesmium* excretion products (139). Culturing experiments show high *Trichodesmium* growth and N_2 fixation rates in the presence of these bacteria. These findings suggest mutualistic consortial associations, in which organic excretion products from *Trichodesmium* support the growth of associated bacteria, while these bacteria may promote *Trichodesmium* growth. Factors potentially involved in stimulating "host" *Trichodesmium* growth include localized respiratory O_2 consumption, nutrient (phosphorus, CO_2 recycling), and exchange of beneficial bioactive compounds, such as vitamins and chelators.

An additional functional role of surface-dwelling *Trichodesmium* aggregates is their possible ability to intercept atmospheric nutrient inputs. Iron (Fe) is a nutrient required as a cofactor in enzymes and energy transferring molecular mediating the synthesis and activities of the photosynthetic and nitrogen fixing machinery. This metal is known to be in short supply (i.e., limiting) in the tropical open oceans (156). Field and laboratory studies (116) indicated that iron supply controlled N_2 fixation

and growth in *Trichodesmium* blooms off the North Carolina coast (Gulf Stream). The dominant source of new iron in these as well as open ocean waters is atmospheric, either via dry or wet deposition (157,158). Rueter and coworkers (159) hypothesized that, by forming surface-dwelling aggregates, *Trichodesmium* enhances its ability to intercept iron associated with small particles (dust, aerosols) deposited on the ocean surface. Indeed, there appears to be geographic overlap between relatively high frequencies and densities of *Trichodesmium* blooms and areas of iron deposition downwind of iron-enriched African Saharan dust storms the Atlantic Ocean between 20°N and the equator (160). Alternatively, the concentrated blooms may simply arise from lengthy periods of calm seas state (i.e., "horse latitudes") periodically encountered in this region (160).

CYANOBACTERIAL MATS IN A TEMPERATE MARINE ECOSYSTEM: BIRD SHOAL, NORTH CAROLINA

Microbial mats are common features of shallow water marine environments. Coastal (Atlantic Ocean) North Carolina is blessed with expansive lagoonal, intertidal mud- and sandflat habitats supporting mats. Bird Shoal (~220 ha), located near Beaufort, NC (34°40′ N, 74°42′ W) forms the southern edge of the Outer Banks barrier island system ringing the major estuaries and Pamlico Sound, the second largest estuarine complex in the United States. Microbial mats on Bird Shoal are mainly located in the high intertidal on a protected, siliclastic sandflat. They are inundated twice daily with coastal Atlantic Ocean water. The climate is temperate to subtropical, with air temperatures ranging from an extreme low of −5 °C in the winter to temperatures often exceeding 30 °C in the summer. Water temperature ranges from 12 to 30 °C. Irradiance can reach up to 2,000 $\mu E\,m^{-2}\,s^{-1}$ during summer, when extended periods of low tide occur at midday, and evaporation greatly elevates the porewater salinity. Owing to this evaporation, mats may also experience desiccation. Mats in the supratidal may become desiccated for extended periods (days to weeks). The mats go through a dramatic diel cycle of O_2 supersaturation during the day to anoxia at night. Ambient waters are nitrogen-limited year-round (161). The impact of major storms such as hurricanes and nor'easters is unknown, but is likely to have a strong structuring effect.

The Bird Shoal mats are highly laminated, with resultant strong vertical biogeochemical (i.e., pO_2, E_h) zonation (91–93) (Figs. 4 and 7). The upper layers of the mat are dominated by non-heterocystous, filamentous cyanobacterial genera, including *Microcoleus*, *Lyngbya*, and *Oscillatoria*, and coccoid forms (e.g., *Synechocystis*, *Synechococcus*) (91,93). Other filamentous, nonheterocystous cyanobacterial genera, including *Phormidium*, *Arthrospira*, and unicellular morphotypes are present to a lesser extent. Diatoms are present in the surface layer, but they comprise less than 15% of total microalgal biomass (162). Purple sulfur bacteria are occasionally observed below the green cyanobacterial layer and pigment analyses indicate the presence of bacteriochlorophyll *a* (163,164). Ambient waters are nitrogen-deplete, leading to year-round nitrogen-limitation of planktonic and benthic primary production (93,161). Therefore, mats must rely on N_2 fixation to satisfy microbial nitrogen requirements (91,165). Recent estimates of nitrogen inputs by microbial N_2 fixation indicate that this process meets at least half of the phototrophic community's demand for nitrogen, the remaining nitrogen being supplied through efficient nitrogen recycling within the mat (166). *NifH* phylogenetic analysis of genomic DNA extracted directly from the mats and from cultured mat isolates has demonstrated

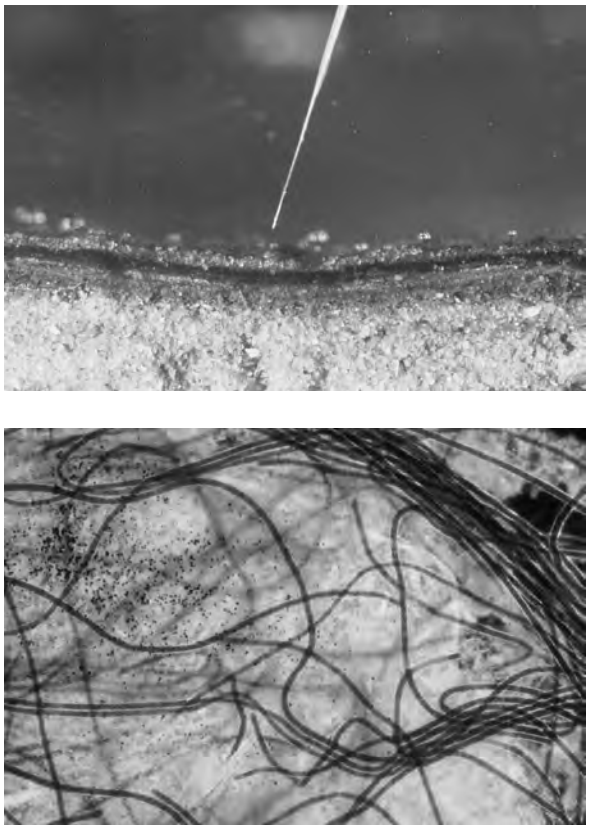

Figure 7. Laminated microbial mat obtained from the Bird Shoal, coastal North Carolina. As is the case with most marine intertidal mats, microalgal biomass and production are dominated by cyanobacteria. The cyanobacteria are concentrated in the upper, illuminated segment of the mat. The mat thickness is approximately 0.5 cm. Upper frame: cross-section of the mat, showing distinct microbial laminations. Phototrophic cyanobacteria dominate the upper, euphotic zone of the mat. Below that is a layer composed of photosynthetic bacteria, cyanobacteria, and heterotrophic bacteria. The lowest layer contains obligate anaerobic heterotrophs, including sulfate-reducing bacteria. Methanogenic bacteria can also be found in this layer. The mat is situated on highly porous sands, which allow for rapid exchange of sweater and oxygen. Hence, the lighter oxygenated appearance of the lower sand layer. The tip (~100 μm diameter) of an oxygen microelectrode is shown for size reference. Lower frame: photomicrograph of the mat matrix. Shown are nonheterocystous filamentous cyanobacteria (*Microcoleus chthonoplastes*) and a variety of bacteria, including microcolonies of purple photosynthetic bacteria (*Chromatium* sp.). See color insert.

a diverse assemblage of diazotrophs (86,167). These organisms include filamentous nonheterocystous cyanobacteria, microaerophilic beta/gamma proteobacteria, and anaerobic bacteria similar to delta SRB. The diazotrophic cyanobacteria genera include *Lyngbya* and *Oscillatoria*.

Interestingly, the numerically dominant filamentous cyanobacterium *M. chthonoplastes* does not appear to possess the genetic (*nifH*) ability to fix N_2 (87). Instead, it supports bacterial N_2 fixing epibionts that most likely utilize organic matter excreted by this cyanobacterial "host". In addition to being a major source of organic matter supporting consortial N_2 fixation, *Microcoleus* forms the "fabric" that consolidates the mats and maintains structural integrity, while providing numerous microaerophilic and anaerobic niches for metabolically diverse bacteria involved in nutrient cycling. In this manner, the presence of a highly productive non-N_2 fixer provides adequate organic carbon to support consortial N_2 fixation and complete nutrient cycling (regeneration of existing nitrogen and other nutrients), thereby enabling the mat to remain highly self-sufficient in a nutrient deplete, periodically hostile and environmentally extreme environment. The major N_2 fixing taxa in these mats can be found in other temperate shallow-water intertidal marine habitats having mats (Tomales Bay, California; Sippewisett Marsh, Massachusetts) (167). In coastal North Carolina, mats are present year-around, but reveal distinct seasonal patterns in community composition, photosynthetic performance, and diel patterns of N_2 fixation, indicative of both taxonomic and metabolic diversity (87,93).

The observed rates and patterns of N_2 fixation (nitrogenase activity) appear to be dependent on complex interactions between seasonality, mat development, and community structure. In the winter, NA rates are low, but exhibit maximum activity during the day. In the summer, average rates increase greatly. In less developed mats during the summer, substantial daytime NA may be observed, with maximum rates observed just after sunrise (93,166). In more developed mats during the summer, daytime NA is greatly repressed and maximum rates occur sometime during the night (Fig. 8). Results from the experiments designed to assess the inhibition of total photosynthesis, oxygenic photosynthesis, and protein synthesis suggest that different physiological strategies translate into contrasting diel NA patterns. Additionally, the results infer that multiple physiological strategies are utilized to sustain daytime NA during the summer. The inhibitory effect of O_2 on NA occurs very early. Evidence suggests that de novo protein synthesis is required to sustain daytime NA. Reverse transcriptase-polymerase chain reaction (RT-PCR) results demonstrate that organisms other than cyanobacteria are at least actively transcribing the functional genes for N_2 fixation (166). They further imply that transcription of nitrogenase for different organisms may occur as environmental conditions within the mat change.

Mats are an important source of organic matter (i.e., primary production) and fixed nitrogen in what

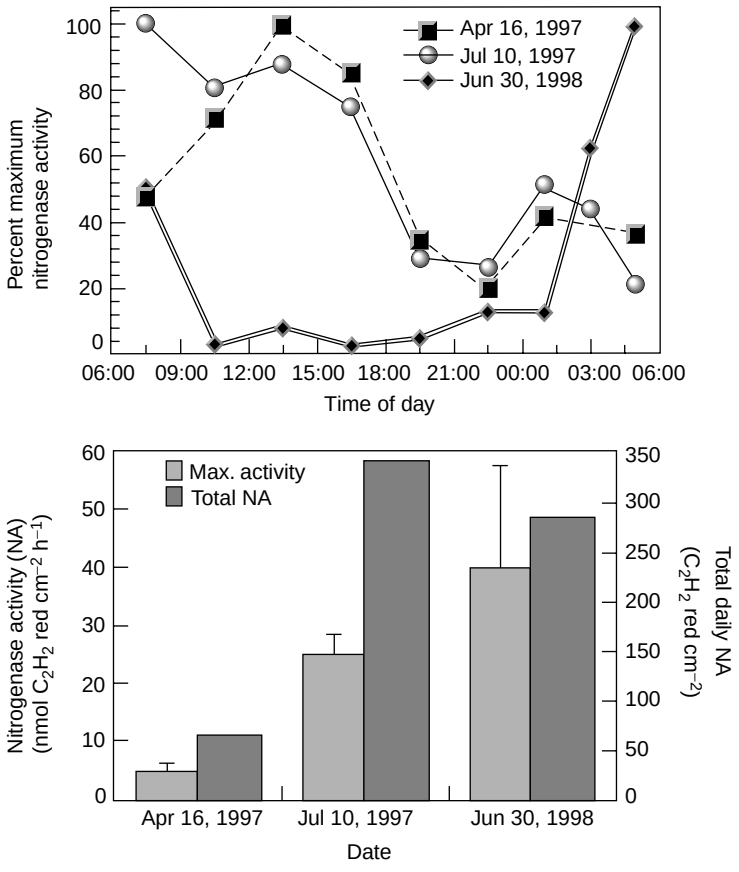

Figure 8. Observed diel variation in N_2 fixation (nitrogenase activity) in the Bird shoal microbial mats, Beaufort, North Carolina. The diel variation observed on April 16, 1997 depicts typical late wintertime observations. Highest specific nitrogenase activity is generally observed during midday. Diel variations observed on July 10, 1997 and June 30, 1998 depict diel nitrogenase activity variations observed from late spring through fall. Highest specific nitrogenase activity is generally observed during very low light periods near sunrise. Values are shown as percentage of maximum nitrogenase activity that was observed during diel experiments. (Data from 166)

are often very nutrient-deprived (oligotrophic) coastal regions (91,113,165). They represent an important nutritional source for micro- and macroinvertebrates that are critical food sources for a variety of fish species that utilize lagoonal marsh environments as nurseries and refugia from predators. The full biogeochemical and trophic importance of microbial mats is only now beginning to be understood.

STROMATOLITIC MATS OF HIGHBORNE CAY, EXUMA SOUND, BAHAMAS

Stromatolites are highly laminated, lithified ($CaCO_3$) rock formations that are at least partially formed by microbially mediated $CaCO_3$ precipitation (60). Fossil stromatolites, dating back 2.5 billion years, are among the oldest evidence for organized life on Earth (59). The stromatolites of Highborne Cay are subtidal along 2.5 km of an eastward-facing beach facing Exuma Sound, Bahamas. They form as ridges and columnar heads up to a half a meter height. The ambient waters range in salinity from 35 to 37 psu and are saturated with respect to calcite and aragonite (60). Surface irradiance can exceed 2,200 $\mu E\, m^{-2}\, s^{-1}$. Their depth at low tide is approximately one and a half meters. Water temperature ranges from 21 to 30 °C. The stromatolites are protected by a fringing reef complex, but are still subjected to substantial wave energy. Ambient nutrient levels (nitrogen, phosphorus, trace metals) are extremely very low. Laminated cyanobacteria-dominated mats cover the surface of the stromatolites (Fig. 9) and their metabolic activity is thought to be responsible for the formation of lithified laminae and subsequent buildup of the stromatolites (60). These mats constitute the dominant source of "new" production and nitrogen input to this nutrient deprived ecosystem. The internal microenvironment is characterized by vertical O_2 concentration gradients that are typical of microbial mats (168,169).

The phototrophic community is dominated by nonheterocystous, filamentous cyanobacteria *Schizothrix* spp., but the biomass is very low (Pinckney, unpublished). Other prevalent nonheterocystous cyanobacterial genera include *Phormidium*, *Lyngbya*, and *Microcoleus*. Unicellular cyanobacteria, such as *Solentia* spp. are also commonly observed. Diatoms are present, but not abundant. *NifH* phylogenetic analysis has yielded sequences most similar to unicellular cyanobacteria, filamentous, nonheterocystous cyanobacteria, including *Lyngbya* sp. and *Phormidium* sp., alpha proteobacteria, and anaerobic bacteria similar to SRB.

Rates of N_2 fixation show seasonality, but diel patterns do not. In both late winter and summer, most N_2 fixation is confined to nighttime, but summertime rates are much higher. However, the ratio of N_2 fixed to net primary production (CO_2 fixation) is relatively low. Net production values in Highborne Cay stromatolites for comparable times of the year range from one-third to a little over half the values for temperate Bird Shoal mats. Maximum N_2 fixation values are an order of a magnitude less than what has been observed in the Bird Shoal mats. Inhibition of protein synthesis by chloramphenicol had different effects on N_2 fixation rates depending on the season, suggesting contrasting physiological controls on this process at different times of the year.

Figure 9. Stromatolitic mat communities on the Exuma Islands, Bahamas. Upper frame: view of the subtidal stromatolites situated off a beach at Highborne Cay, Exumas. Middle frame: cross-sectional view of a laminated ($CaCO_3$) stromatolite, showing the cyanobacteria-dominated mat residing on the surface of the stromatolite. Lower frame: photomicrograph, showing the aggregated filamentous cyanobacteria (*Schizothrix* sp.) comprising a bulk of the surface mat (from 104). See color insert.

There are close associations between cyanobacteria and bacterial epibionts that appear to play an important role in the layered deposition of $CaCO_3$ that characterizes stromatolites. Microscopic and microautoradiographic observations indicate that the dominant cyanobacterial

taxa (most notably *Schizothrix* and *Lyngbya*) produce copious amounts of sheath and exopolysaccharide (EPS) materials (60,105). These materials can strongly bind calcium ions and by doing so prevent $CaCO_3$ precipitation and lithification (60). Bacteria that are embedded in the sheath and EPS decompose this material, thereby liberating Ca^{++} ions into solution. These Ca^{++} ions are then rapidly precipitated, allowing lithification to proceed. Microscopic investigation reveals bacteria encapsulated in $CaCO_3$ (aragonite), while the filamentous cyanobacteria remain free of precipitates as long as they are covered by sheaths and EPS (104). Thus, rather than being directly mediated by cyanobacterial precipitation, the lithification of stromatolitic mats is indirectly controlled by cyanobacteria, which produce organic matter that is mineralized by bacteria mediating precipitation (104). The ecological and biogeochemical significance (and underlying physiological mechanisms) of this consortially mediated lithification process require further clarification.

MICROBIAL MATS IN HYPERSALINE LAKES: CONSORTIA "AT THE EDGE OF LIFE"

The Bahamian hypersaline lakes are among the most extreme aquatic environments on Earth. These lagoonal ponds are isolated from the nearby oligotrophic oceans (Atlantic and Caribbean) by narrow dunes and carbonate ridges. They are exposed to hot (sometimes exceeding 40 °C), arid and extremely high irradiance (greater than 2,200 $\mu E\, m^{-2}\, s^{-1}$) conditions throughout much of the year. Annually, evaporative water loss greatly exceeds rainfall input, leading to persistent hypersaline conditions exceeding 150 psu (seawater salinity is ~35 psu). Because rainfall is extremely low and restricted to tropical storms of oceanic origin and surrounding carbonate soils are highly leached, nutrient (nitrogen, phosphorus, iron, and trace metal) inputs to these lakes are very small and restricted to aeolian sources (i.e., dust). As a result, the lakes exhibit a broad spectrum of environmental extremes and limitations. Despite these hostile conditions, the lakes support an abundant microbial community, largely confined to microbial mats lining the lake bottoms (164). The nitrogen requirements of these mats are largely met by N_2 fixation and nitrogen regeneration in the mat matrix (166). San Salvador Island, Bahamas (24°00′ N, 72°05′ W) has numerous hypersaline lagoonal systems, including: (*1*) Storr's lake (45 → 90 psu), which supports calcifying, stromatolitic mats dominated by the heterocystous cyanobacterial genus *Scytonema*, nonheterocystous *Schizothrix*, and coccoid forms *Synechocystis, Synechococcus*; and (*2*) Salt Pond (45 → 100 psu), which contain a highly laminated, noncalcified cyanobacterial mat dominated by nonheterocystous filamentous *Microcoleus, Lyngbya*, and *Oscillatoria* species (Fig. 10).

The hypersalinity is inhibitory to both photosynthesis and N_2 fixation (164,170), and may play a role in selecting for cyanobacterial species, because eukaryotic microalgae are confined to only a few diatom species that constitute less than 10% of the total microalgal biomass. Cyanobacterial biomass often exceeds 50 nmol Chl *a* cm^{-2}, which is very high by benthic microalgal standards (164,170). Biomass is highly compacted in the surface layer of the mat, causing rapid light extinction with depth. Photosynthetically active radiation (400 to 800 nm) decreases from greater than 2,200 $\mu E\, m^{-2}\, s^{-1}$ at the surface to undetectable levels at 4 to 5 mm depth. This leads to a highly compressed euphotic zone with strong vertical biogeochemical (O_2, E_h) zonation; typically, during daylight the upper 1 to 2 mm of the mat is O_2 supersaturated, while the lower 3 to 10 mm is permanently anoxic and sulfidic. A layer of anoxic photosynthetic bacteria (*Chromatium, Rhodopseudomonas*) is present at the oxic–anoxic interface. The O_2 gradients spanning oxic and anoxic zones are dynamic and light attenuation-dependent, varying with time of day and season.

Both light- and dark-mediated N_2 fixation occur in these mats. Rates are generally high (relative to photosynthesis (162,166,170). Both oxygenic (cyanobacterial) and anoxygenic (photosynthetic bacteria) photosynthesis contribute significantly to mat primary production, and are a dominant source of "new" carbon supporting the lake's unusual (extensive microbial loop and invertebrate grazing, but no fish) food web (170).

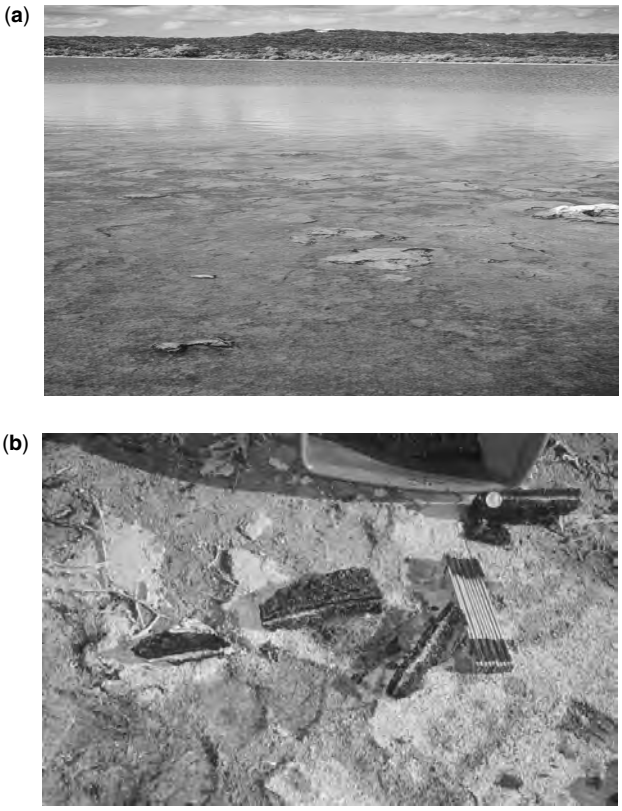

Figure 10. Upper frame: hypersaline (100 to >160 psu) Salt Pond, located on San Salvador Island, Bahamas. The entire bottom of this lake is dominated by laminated mats dominated by filamentous, nonheterocystous cyanobacteria (*Microcoleus* sp., *Lyngbya* sp., and *Oscillatoria* sp.). Lower frame: close-up side view pieces of laminated mat excised from the pond. See color insert.

AGGREGATES AND MATS IN THE PERMANENT ICE COVER OF LAKE BONNEY, MCMURDO DRY VALLEYS, ANTARCTICA

The McMurdo dry valleys of Southern Victorialand, Antarctica (160–164° E, 76°30′–78°20′ S) contain a series of glacial lakes having permanent ice covers varying in thickness from approximately 3 to over 6 m. The dry valleys are among the highest, driest, coldest, and most nutrient-deprived habitats on Earth, with wintertime air temperatures ranging from −40 to less than −60 °C, and summer temperatures ranging from −20 °C to near 0 °C. Because the dry valleys are surrounded by greater than 3,000 m mountains, they are in a "snow shadow," resulting in annual snowfall of only 2 to 4 cm. Under these conditions, evaporation (sublimation) greatly exceeds precipitation, leaving the soils of the valley floor exposed (51). As a result, the dry valley area forms the largest expanse of ice free soils (~4,000 km^2) on Antarctica. Liquid water is confined to a short summer period (December to early February), when air temperatures and solar heating are high enough to generate meltwater from permanent glaciers that reach the valley floor. Meltwater enters the lakes via narrow streams, which flow for only about 2 to 3 months. However, much of the rest of the valley floor is frozen, desiccated desert soil. Under these extremely cold, water-stressed conditions, prokaryotic life largely exists as cyanobacterial-bacterial aggregates and mats associated with the ice cover surface and embedded in the ice matrix (51–53).

Microbial consortia associated with the ice cover include desiccated mats around the edge of the ice cover, and aggregates associated with desert soil particles that are periodically dispersed over the ice surface by strong adiabatic and catabatic winds sweeping this region (42,43). Soil particles are very dark and absorb enough radiant energy to warm and melt their way down into the ice matrix during the austral summer (Fig. 11). These particles aggregate and tend to accumulate in distinct layers in the ice cover. The depths of the layers depend on the extent to which solar heating can maintain molten conditions around the particles. During relatively clear periods, more extensive melting and deeper layers result. A cyanobacterial community is associated with the soil particles (Fig. 11). This includes nonheterocystous genera (*Phormidium, Oscillatoria*), at least one heterocystous genus (*Nostoc*) and coccoid forms (*Synechococcus* spp.) (52,171). During at least nine months of the year (fall through late spring), ice-embedded aggregates exist in a desiccated, "freeze dried" state. Rehydration occurs during the summer period (late November to February) when localized solar heating of aggregates leads to localized melting, followed by activation of metabolic processes and growth (51,52). When desiccated aggregates are experimentally rehydrated, photosynthesis, heterotrophic activity, and N_2 fixation can be detected within a few hours.

The cyanobacterial-bacterial consortia that are associated with aggregates physically and chemically modify the aggregate microenvironment. Following rehydration, exudation of organic matter takes place and redox gradients

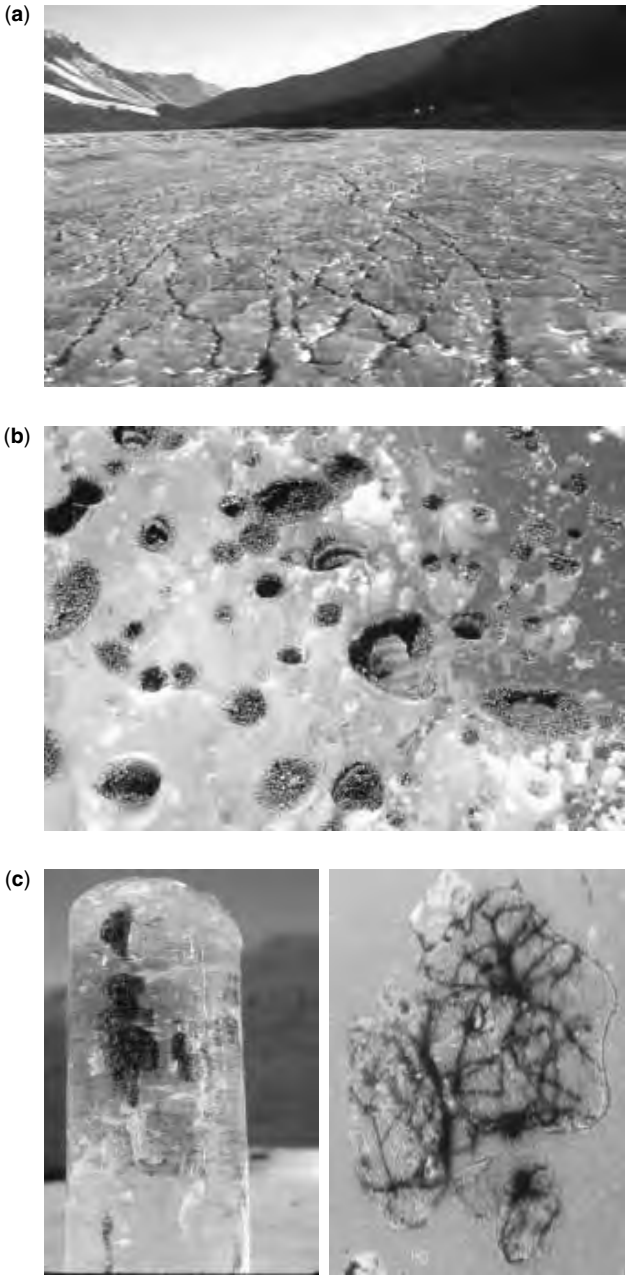

Figure 11. Soil-based microbial aggregates in the permanent ice cover of Lake Bonney, McMurdo Dry Valley, Antarctica. Upper frame: surface view of the ice cover, showing the cracks in which windblown soil accumulates. Middle frame: close-up view of the ice surface, showing localized melting of ice by dark soil aggregates. Eventually, this melting activity causes soil aggregates to settle into the ice matrix. Lower left frame: a core taken from the ice cover, showing soil aggregates embedded in the ice matrix. Lower right frame: microautoradiograph of $^{14}CO_2$ uptake by microorganisms associated with a soil aggregate sampled from the ice matrix. The darkened filaments are photosynthetically active cyanobacteria attached to a soil particle (from 52 and 103). See color insert.

are established in response to microbial photosynthetic O_2 production and heterotrophic O_2 consumption along microscale nutrient, light, and organic matter gradients. Ice aggregates represent structural and functional biocomplexity in the form of interactive production and nutrient cycling consortia ensuring microbial self-sustenance at the "edge of life" on Earth. Molecular studies of aggregate consortia (171,172) indicate a diverse assemblage, including some of the most ancient (i.e., Precambrian) known forms of life on Earth.

CHARACTERIZING AGGREGATE AND MAT CONSORTIAL STRUCTURE AND FUNCTION

Ecophysiological Approaches

The past two decades have seen significant developments and improvements in aggregate and mat consortial rate measurement techniques that are both appropriately scaled and sensitive. There have been breakthroughs in the areas of microsensing (i.e., microelectrodes), microchemical, and molecular techniques that have greatly expanded the "toolbox" microbial ecologists, chemists, hydrobiologists, geologists, and molecular biologists can deploy for examining aggregate and consortial structure and function. Consortial structure and function are most commonly analyzed in terms of (*1*) production and transformation rates (and their interactions), (*2*) community composition and structure, and (*3*) biogeochemical gradient and localization studies. Establishing diurnal and seasonal rate patterns of key production and nutrient cycling processes, such as CO_2 and N_2 fixation, denitrification, and sulfate reduction reveal how carbon, nitrogen, sulfur, and other essential elements are cycled and allocated in aggregates and mats in response to long- and short-term physicochemical influences. Microscale sensing and chemical characterization techniques are detailed by Jørgensen (9), Revsbech and coworkers (168), Canfield and Des Marais (90), Rysgaard coworkers (173), and Stal and Caumette (55), while molecular applications have recently been reviewed by Amann (174), Nielsen and coworkers (175), Zehr and Paerl (145), and Paerl and Zehr (113).

Aggregates and mats reflect broad taxonomic and physiological diversity and plasticity, which interacts with biogeochemical gradients. Gradients in large part reflect the combined product of O_2 production (P) versus consumption via respiration (R) in time and space (10). Gradients are controlled by the concentrations of dissolved O_2 and salinity in water surrounding aggregates and mats and the internally generated P/R ratios. O_2 gradients can be experimentally manipulated, allowing for examinations of the impacts of pO_2 on aggregate and mat structure and function.

Oxygen, pH, and H_2S gradient fluctuations can occur on temporal scales of seconds to minutes and spatial scales of microns to millimeters; spatial scales reflecting consortial dimensions. Microelectrode analyses and tetrazolium redox salt assays have been used to determine chemical gradients on these scales (89,92,102). In addition, microautoradiography allows visualization of those organisms responsible for primary production (CO_2 fixation) and dissolved organic matter (DOM) uptake (of radiolabeled compounds) at individual microorganism and biogeochemical gradient levels (57). Complementary techniques, such as process-specific (i.e., CO_2 and N_2 fixation, nitrification, denitrification) immunofluorescence assays can be used to visualize those cells actively expressing the structural genes (nitrogenase; *NifH*, ribulose 1,5-diphosphate carboxylase; *RubisCo*, nitrate reductase; *Nir*) and hence capacities for enzyme function (176–178).

Experimental approaches to examining the in situ impacts of O_2 tension on aggregate and mat production and nutrient cycling processes include the use of inhibitors of oxygenic photosynthesis (photosystem II). Among these, 3-(3,4-dichlorophenyl)-1,1-dimethylurea (DCMU) at greater than 10^{-5} M effectively blocks PS II activity, leading to a cessation of O_2 evolution (and CO_2 fixation) without altering respiration (i.e., O_2 consumption) (91,114). Studies (57,58,92,93) have shown that when mats are photosynthetically active (i.e., high rates of O_2 evolution), DCMU additions arrest O_2 production and CO_2 fixation (93), with concurrent stimulation of N_2 fixation rates, indicating that, within the aggregate and mat matrix, in situ O_2 evolution rates are high enough to negatively impact O_2-sensitive N_2 fixation. However, when photosynthetic rates are low (i.e., wintertime), or at nighttime when photosynthesis ceases, DCMU has little impact on diazotrophy. These results indicate N_2 fixation may be restricted by increased O_2 levels accompanying periods of active photosynthesis.

To compensate for this metabolic incompatibility, diazotrophs have evolved various morphological and physiological adaptations, including (*1*) temporally separating photosynthesis from N_2 fixation, by confining the former to daytime and the latter to nighttime; (*2*) spatial separation of the two processes, with photosynthesis concentrated near the illuminated surface of aggregates and mats and diazotrophy taking place in deeper, aphotic layers; (*3*) formation of localized O_2 deplete microzones throughout the matrix, in which R exceeds P; and (*4*) confinement of the N_2 fixation to O_2 devoid cells (heterocysts) or nonphotosynthetic regions of filaments and colonies. Despite the obvious advantage of forming heterocysts, many aggregate and mat systems in nitrogen deplete waters are devoid of heterocystous cyanobacteria (e.g., *Trichodesmium* aggregates, many intertidal mat systems) (55,113). This ironic situation is a puzzling aspect of cyanobacterial evolution, that is, why do microbial mats, biofilms, aggregates, and other surficial communities in nitrogen limited oxic waters and soils not contain more heterocystous genera? The resolution to this dilemma should yield key insights into ecophysiological controls of microbial N_2 fixing consortia.

Consortial composition has recently been assessed by bulk community analysis (DNA and photopigment) and specific gene expression (mRNA) (discussed later). Chemosystematic carotenoids and chlorophylls, quantified using high-performance liquid chromatography have been used as indicators of relative abundance of major phototrophic groups (162,179). 16S rRNA or rDNA sequences are considered accurate measures of microbial diversity (180). Genes encoding for biogeochemically important

and evolutionarily conserved processes, including N_2 fixation, nitrification, and denitrification are receiving increasing scrutiny for phylogenetic and physiological studies. Their application is discussed later. In the case of primary production (CO_2 fixation), the ribulose-1,5-carboxylase gene (RubisCo) is responsible for virtually all primary production in the world and the large subunit, *rbcL*, is evolutionarily well conserved (181). Examining *rbcL, nifH, amoA*, and *nirSK* expression and then correlating the expression with patterns of CO_2 fixation, N_2 fixation, denitrification, and nitrification will allow us to identify consortial members responsible for these processes, environmental factors controlling genetic expression of key functional genes, and how they are manifested in terms of community compositional or physiological responses (Fig. 12).

Molecular Approaches

A serious limitation to an improved understanding of the "players" involved in microbial consortia has been the lack of availability of quantitative identification and characterization techniques. Standard microbiological approaches to the identification of individual populations within microbial consortia, such as selective culturing, require the extensive knowledge of microzonal environmental conditions. This information is not easily determined along a natural gradient. Furthermore, environmental conditions are often transient, depending on the balance between oxygen production and consumption, nutrient uptake and release, and physical control processes, such as turbulence and diffusion, all of which operate on highly variable temporal and spatial scales. As a consequence, only a small portion (less than 1%) of microorganisms from the environment can be grown using routine culturing techniques (182–185).

Determination of functions, including rates of basic metabolic processes, such as photosynthesis, respiration, utilization of organic matter, and nutrient uptake/assimilation have traditionally been limited by the small scales and sample sizes needed to adequately assess microzonal consortial processes.

Small subunit rRNA (16S) sequence analysis is routinely used for the identification and phylogenetic placement of microorganisms without the need for cultivation. Members of the bacterioplankton that have not been previously described have been identified (186,187), and their diversity and distribution have been investigated (188–190). New members of the Archaea have also been identified in the water column (191,192) and in sediments (193,194), and their spatiotemporal variability has also been assessed (190,195). Functional genes encoding for enzymes directly involved in the transformation processes have also been used to characterize natural microbial assemblages. Target genes involved in denitrification (*nosZ*) (185), nitrification (*amoA*) (196), nitrogen fixation (nifH) (197,198), and the oxidation of methane (*pmoA*) (199) have been successfully used. Moreover, the sequences for the dissimilatory sulfate reductase genes (*dsr*) have been recently obtained from different organisms (200,201), and *dsr*-specific PCR primers have been developed to track sulfate-reducing microorganisms, which play a central role in the global sulfur cycle. Detection of target genes such as 16S, *amoA, nosZ*, and *nifH* can be coupled with high throughput techniques, such as terminal restriction length polymorphism analysis (TRFLP) to characterize consortia in a timely, quantitative, and unequivocal manner.

The utility of highly conserved functional genes for microbial consortial characterization studies can be readily demonstrated for *nifH*. Because studies of *nifH*-based diversity and phylogeny have been underway for at least a decade, a substantial database on taxa-specific sequence regions of interest has been established (86,87,145,167,172,197,198). This database can then be used to establish phylogenetic trees, which serve as references against which established as well as novel sequences derived from N_2 fixing consortia can be compared and characterized according to specific functional groups (i.e., heterotrophs, such as

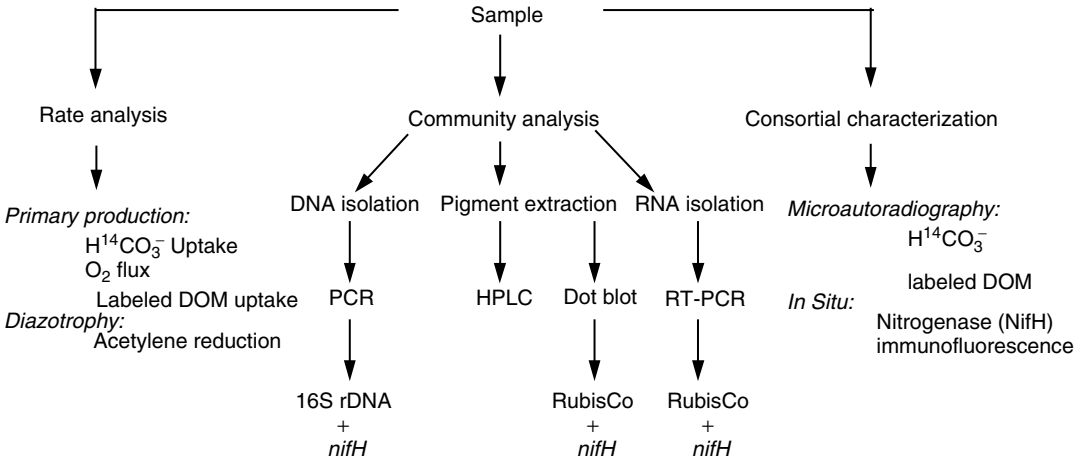

Figure 12. Schematic diagram showing complementation of rate measurements, diagnostic indicators of microalgal community composition with nucleic acid determinations of functional (i.e., *nifH*), phylogenically important (16s rRNA) genes for determining the structure and function of microbial consortia in natural samples.

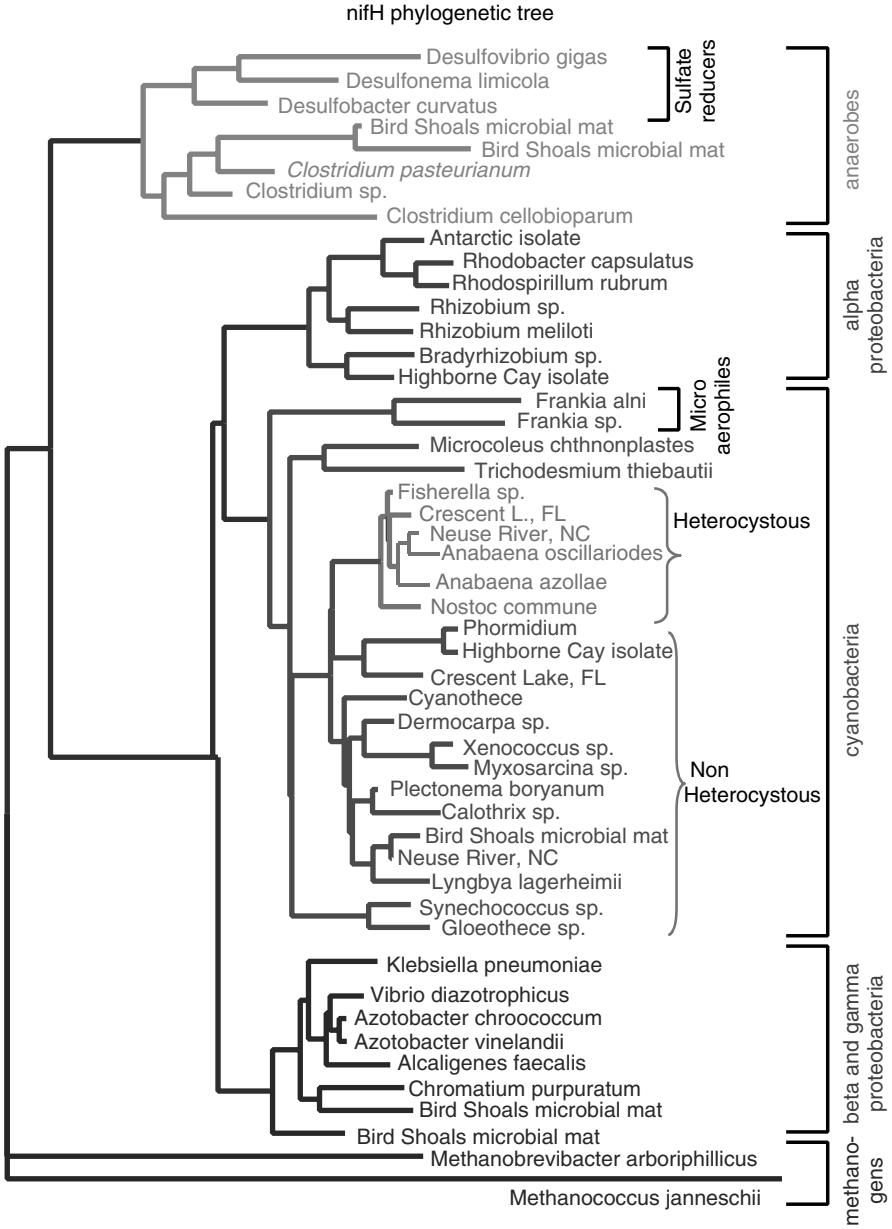

Figure 13. Phylogenetic tree of nitrogen fixing microbial groups, many of which participate in consortial associations. The tree was based on analysis of a 326 base pair nucleotide fragment of the *nifH* gene, which encodes for the highly conserved dinitrogenase reductase subunit of nitrogenase, the N_2 fixing enzyme complex. The tree was constructed by the neighbor-joining method and bootstrap values greater than 50% are given above or beside the corresponding nodes. See color insert.

sulfate reducers, chemolithotrophs, coccoid, filamentous-heterocystous, heterocystous cyanobacteria) (Fig. 13).

While molecular characterization of target genes, such as *nifH* and 16S rRNA, is a routine procedure in many microbial ecology laboratories, the procedure is slow, laborious, and potentially prone to biases. These biases are being overcome by developing highly reproducible extraction procedures (202) and quantitative nucleic acid characterization methods (202–204). Recently, rapid "fingerprinting" methods, utilizing fluorescent end-labeling of PCR product (target genes) and screening by terminal restriction length polymorphism (TRFLP; see Refs. 205,206) have greatly streamlined and improved the accuracy of these methods. Highly reproducible fingerprints can be obtained from complex samples. It is now possible to rapidly identify target genes for specific nutrient transformations using TRFLP analysis of clonal libraries to minimize the time necessary to identify specific target gene clones. For example, TRFLP analyses have been used to screen for denitrifying bacteria in sediments from salt marshes, fresh water marshes, and coastal sediments (207).

Specific target genes (and the nutrient transformations they catalyze) are available for characterizing aquatic microbial consortia. These biomarkers can be used to assess the numbers and activity of various consortial members, using TRFLP analysis. For example, one way to ascertain whether bacteria involved in denitrification are indeed active in an environment involves determining if a functional gene (like *nosZ*) is being transcribed (i.e., mRNA synthesis) (207). Rate measurements can then accompany transcript information to elucidate

consortia members that are actively growing and hence participating in nutrient transformations of interest (in this case denitrification).

CONCLUSION

Aggregates and other surficial microzones are ecophysiological, environmental, and evolutionary units of microbial biodiversity (i.e., community structure) and biocomplexity (i.e., community function) in aquatic and terrestrial habitats. There are commonalities and redundancies embodied in microzonal structure and function among the myriad aquatic and soil habitats. Using a variety of examples from geographically and geochemically distinct environments, we have shown that prokaryotic consortia, able to develop and colonize microscale biogeochemical gradients, are a common feature of these environments. Aggregate, mat, biofilm systems can be used as "models" to identify and functionally understand a basic set of process-level requirements or "ground rules" for microbial life to establish, maintain, and proliferate itself on a community organizational level.

Research on diverse marine, estuarine, and freshwater habitats points to aggregates and surficial microbial communities as biogeochemically and ecologically important nutrient transformation and trophic transfer sites. These sites are particularly significant in nutrient-poor and otherwise extreme environments, in which microbial production and nutrient cycling are severely restricted by nutrient and energy availability, as well as other environmental constraints (i.e., extremely low or high temperatures, desiccation, hypersalinity, high UV light). Changes in these conditions are likely to have a cascading effect on the structure, function, and overall production and nutrient cycling characteristics of these microzonal communities, with ramifications for biogeochemical cycling on larger ecosystem, regional and global scales. In particular, the biocomplexity and productivity of oligotrophic open ocean waters are likely to be affected. Contemporary issues of global change, including warming, altered amounts and patterns of rainfall and (conversely) drought, resultant changes in runoff and riverine discharge of nutrients and sediments, coupled to human land-use changes and associated nutrient and other pollutant loading patterns, will have profound impacts on the structure and function of aggregate/surficial microbial consortia.

Microzonal communities as described here are sensitive, metabolically active, and hence responsive indicators of environmental change, in essence serving as the microbial equivalent of the "canary in the mine." As such, microzonal communities may serve as excellent indices of environmental change spanning the size spectrum from specific habitat, ecosystem, regional-coastal to oceanic scales. Standard microbiological, molecular, physiological, and analytic assessments of aggregate and surficial genetic composition, function, and rates of relevant processes serve as the parameters of change. The advantage of using this suite of parameters for gauging environmental change over more conventional descriptive approaches (i.e., inventories of biotic diversity at higher organismal levels) is multifold. These microbial parameters: (*1*) simultaneously allow for measures of community structure (biodiversity) and function (rates of relevant processes, including primary production, mineralization, specific nutrient transformations, etc.); (*2*) can be coupled to large-scale survey and remote sensing tools, including aircraft and satellite imagery (of ocean color, turbidity, photopigments diagnostic of certain microalgal groups); (*3*) are amenable to microchip and other molecular-based, multiparameter indices of carbon, nitrogen, and other nutrient cycling processes, (*4*) have a role in the detection and characterization of microbial pathogens, harmful bloom algae, and other indices of environmental degradation of ecosystem and human health.

Now, at the beginning of the third millennium, we are facing unprecedented changes in Earth's biotic resources. One of the greatest and most important challenges is being able to detect, quantify, and differentiate human impacts form natural climatic and geological and geochemical changes facing our planet. For better or worse, microbially mediated changes are among the most fundamental and important in the biosphere. We have the opportunity and responsibility to judiciously apply the tools of microbiology, molecular biology, and ecology to gauge anthropogenic and natural change, using microbial consortia as key indicators.

AIRBORNE TOXIGENIC MOLDS

BRUCE B. JARVIS
University of Maryland
College Park, Maryland

In the past 20 years, there is increasing recognition that an important factor in the health of people in indoor environments is the dampness of the buildings in which they live and work (1). Furthermore, it is now appreciated that the principal nonpathogenic biologics responsible for the health problems in such buildings are fungi rather than bacteria or viruses (2,3). Although traditionally fungi in this context have been viewed as allergens (and in some circumstances, pathogens), data have accumulated to show that the adverse health effects resulting from inhalation of fungal spores are due to multiple factors. One factor associated with certain fungi is the small molecular weight toxin (mycotoxin) produced by these fungi (1). Mycotoxins are held to be important in human and animal health because of their production by toxigenic fungi associated with food and feed (4). However, mycotoxins tend to concentrate in fungal spores (5,6) and thus present a potential hazard to those inhaling airborne spores. There are well documented cases of mycotoxicosis resulting from inhalation of toxigenic spores by agricultural workers handling moldy farm material (7,8), but until recently there have been few reports of such toxicoses in an urban setting (9).

MYCOTOXINS

The most potent toxin known is that produced by *Clostridium botulinum*, the bacterium responsible for botulism. Fungi also produce toxins that, like the botulism toxin, can enter our food and livestock feed. These fungal toxins are called mycotoxins, and they present both medical and economic problems to the community. Exposure to mycotoxin-producing (toxigenic) fungi has a long history and is a continuing threat to human and animal health (10), especially in developing countries where people do not often have the luxury of good agricultural practices. But even in more developed countries, contamination of food products results in significant economic losses, prompting governments to monitor levels of certain mycotoxins (e.g., aflatoxins) in food products to ensure that people do not consume unacceptable levels of these fungal toxins.

Mycotoxins are low molecular weight (generally $<1,000$ Daltons) and nonvolatile compounds; the odors associated with moldy buildings are due to microbial volatile organic compounds (mVOCs) that are typically low molecular weight alcohols, ketones, esters, and hydrocarbons of low inherent toxicity (11). Importantly, most mycotoxins are fairly stable compounds that can survive unchanged for long periods of time after the fungi are no longer viable. Thus, information obtained from culturing air samples (e.g., CFUs/m^3) needs to be evaluated with this in mind because low levels of viable (culturable) fungi do not necessarily reflect low levels of toxigenic fungi in the air. Furthermore, some airborne toxigenic fungal spores (e.g., *Stachybotrys*) have much shorter lifetimes in the dry state than do others, complicating the interpretation of CFU data from air sampling (12).

There is a great deal of information available on mycotoxins (4,13,14). In brief, mycotoxins are fungal secondary metabolites (15) that pose a risk to both human and animals that come into contact with these natural products, principally through ingestion of food and feed. They span an enormous range of chemical structures (Fig. 1), with diverse biological activities and are produced by a wide variety of fungal genera (16). Mycotoxins, like other secondary metabolites in general, tend to be idiosyncratic in that specific mycotoxins are often restricted in their production to a small number of fungal genera or even single species. Although some classes of mycotoxins may be restricted to a small number of species in a single genus (e.g., the aflatoxins to *Aspergillus*), some fungi are notorious for producing many different classes of mycotoxins within their genus (e.g., *Penicillium*). Additionally, there may be great variation in toxigenic potential within a single species. Most isolates of *Aspergillus flavus* are aflatoxin producers (although the percentage varies between areas of the country) (17), but only one-third of *Stachybotrys chartarum* isolates produce the satratoxins, highly toxic members of the trichothecene class of mycotoxins (18). Furthermore, there is a general lack of knowledge about the long-term chronic effects of most mycotoxins, especially in humans. With all this diversity in the biology, chemistry, and toxicology of mycotoxins, it is not surprising that there are no general methods available for mycotoxin analysis. The only useful analyses for mycotoxins are those for specific ones for which the analytical chemistry has been established.

From an agricultural view, the three most important genera of toxigenic fungi are *Fusarium, Aspergillus*, and *Penicillium*. The principal classes of mycotoxins of concern from ingestion are (fungal genera): the trichothecenes and fumonisins *(Fusarium)*, aflatoxins *(Aspergillus)*, and the ochratoxins (*Aspergillus* and *Penicillium*). Also, there are numerous other mycotoxins that intermittently cause problems. Some trichothecenes are acutely toxic (e.g., the

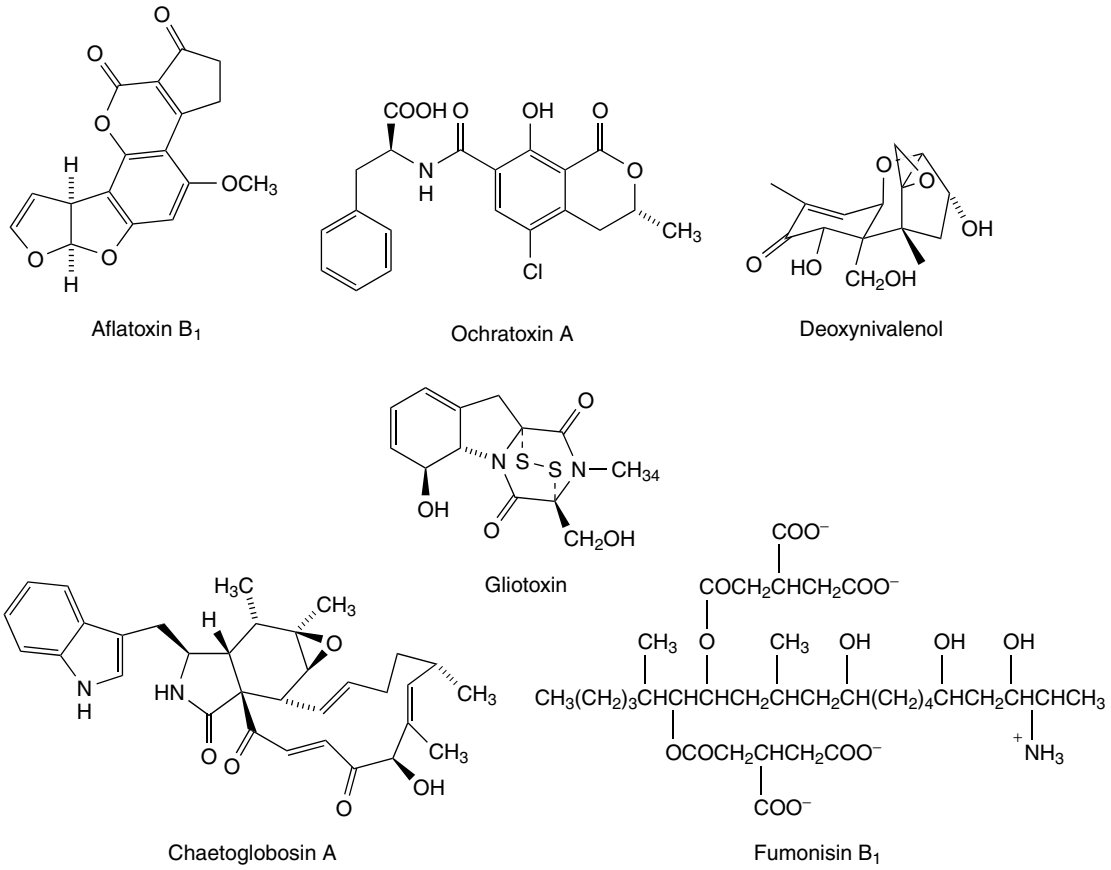

Figure 1. Selected mycotoxins.

satratoxins), whereas others are considerably less acutely toxic but are immunosuppressant or cause feed refusal in livestock (e.g., deoxynivalenol). Fumonisins, and especially some of the aflatoxins (e.g., B_1), are carcinogenic (10). There is now overwhelming epidemiological evidence that aflatoxin B_1 in the diet contributes significantly to the high incidence of liver cancer in many developing countries (10). Ochratoxin A is nephrotoxic and a possible cause of urinary tract tumors and Balkan-endemic nephropathy (10).

In an indoor environment, the toxigenic molds of most concern are *Penicillium, Aspergillus Chaetomium*, and *Stachybotrys*. However, the specific species of *Penicillium* and *Aspergillus* in indoor environments differ from those of an agricultural concern. For agricultural-based mycotoxicoses, *P. verrucosum, P. cyclopium, A. flavus*, and *A. parasiticus* (the latter two are aflatoxin producers) are of most concern; whereas, indoors, *P. aurantiogriseum, P. brevicompactum, P. chrysogenum, A. versicolor*, and the *A. nidulans* group are the most important toxigenic species (19). *Stachybotrys chartarum* (Ehrenb. ex Link) Hughes (*S. atra* Corda) has been focused on in recent years because of its association with acute bleeding in the lungs of infants (idiopathic pulmonary hemosiderosis, IPH), several of whom have died (20,21). However, the *Penicillium* spp. and *A. versicolor* are far more commonly encountered in water-damaged buildings than is *S. chartarum*. The basic reason for this is that the former species grow well on building material with water activities (a_w) in the range of 0.8; whereas *S. chartarum* requires a_w of 0.9 and higher and greater than 0.96 on building material to grow well (22). Generally, moisture levels this high are the result of local leakage (e.g., from a broken pipe) and are confined to a small area, but with leaking roofs, water intrusion can be quite extensive. Like all fungi, the growth of toxigenic fungi depends on substrate, temperature, and water activity (23).

AIRBORNE FUNGAL SPORES

The mycotoxins found in indoor air are most likely confined to the aerosolized spores (or more correctly referred to as *conidia*) of the toxigenic fungi (and building material on which these fungi grow) (24), with levels unlikely to approach those encountered in animal feed intoxications. However, mycotoxins are considerably more toxic when inhaled than when ingested (25,26). Furthermore, the effects of these toxins are multiple, and in particular, the immunosuppressant effects of these toxins on alveolar macrophage function is very pronounced (27,28). Studies of the effects of fungal spores on rat pulmonary alveolar macrophage cells have shown variability probably mediated by spore-borne toxins (29). Spores of five *Aspergillus, Penicillium spinulosum*, and *Cladosporium*

cladosporioides caused the release of leukotriene B4 and increased superoxide anion production and activation of complement. Several species of *Aspergillus* inhibited LPS-stimulated IL-1; whereas the other species had no effect (30). Data are available to support the role of the immunosuppressant mycotoxin, gliotoxin (Fig. 1), in the pathogenicity of *A. fumigatus* in animal lungs (31). Jakab and coworkers (32) demonstrated that inhalation exposure of aflatoxin in rats led to persistent reductions in phagocytosis, among other effects. In rats, inhalation exposure to aflatoxin-containing spores of *Aspergillus* has been demonstrated to be an effective route of exposure (33). Damage to clearance mechanisms would affect processing of antigen and lead to accumulation of material in granulomatous matter, leading to an immunotoxic effect (34–36). Low exposure to spores of toxigenic *S. chartarum* affects lung surfactant production in laboratory animals (37).

Toxigenic spores that strongly affect alveolar macrophage function pose a threat to workers handling mycotoxin-contaminated material. Occupational exposures to spores of *A. flavus*, a producer of the potent carcinogenic aflatoxins, have been shown to correlate to increased risk of liver cancer (7,8). A female agricultural worker suffered acute renal failure following exposure to grain dust in an enclosed granary, whose wheat was shown to be contaminated by *A. ochraceous* and its mycotoxin metabolite, ochratoxin A (Fig. 1). Although ochratoxin A was not demonstrated to be in air samples from the granary, caged experimental animals (guinea pigs and rabbits) experienced acute renal failure when exposed for eight hours to aerosols generated by their movement on moldy wheat (38). In this regard, a recent report of high concentrations (1,500 ppb) of ochratoxin A in dust from a home air-handling system in which occupants had complained of recurring health problems is noteworthy (39). Other reports have indicated that *S. chartarum* (40–42), *A. versicolor*, and several toxigenic species of *Penicillium* are potentially hazardous, especially when the air-handling systems have become heavily contaminated (28,43).

Epidemiological studies have connected the increased incidence of premature births in Norwegian farmers to their exposure to grain-borne toxigenic fungi (44). Researchers have shown that Finnish farmers are commonly exposed to relatively high levels of airborne spores (10^3–10^6 CFU/m^3), and that low to moderate (0.00–11 ppm) levels of *Fusarium* toxins (e.g., deoxynivalenol, see Fig. 1) are commonly found in the grain, although less commonly in air samples (45).

The literature on the growth characteristics of fungi in damp buildings is extensive (1–3,23,28). However, with respect to the production of organic compounds by these fungi, most of the literature has focused on the microbial-generated mVOCs (11). Although some of the mVOCs might be of health concern from a chronic perspective (e.g., styrene), mVOCs are not considered an acute toxic hazard (although the associated odors can present problems) (11). However, confounding factors such as the co-occurrence of ozone with mVOCs may result in a significant increase in volatile irritants (46).

MYCOTOXINS IN THE AIR

Although a great deal is known about the spectrum of mycotoxins produced by the relevant toxigenic fungi found indoors (20,21,47), there are few data available on the presence of the mycotoxins themselves in mold-contaminated buildings. In those few cases where mycotoxins have been found in mold-contaminated buildings (47–55), they have been found in bulk samples rather than in air samples. Following from this, there remains the critical question of the exposure of people in these buildings to the airborne toxigenic fungal spores, a problem that merits further discussion.

As noted earlier, many studies report the presence of toxigenic fungi in mold-contaminated buildings, but few actually determine the presence of the mycotoxins in the buildings. Nielsen and coworkers (47) showed that bulk samples from mold-contaminated building materials from water-damaged domestic residence contained both toxigenic fungi and the specific mycotoxins produced by these fungi. Although their data are complicated by these natural cultures being mixtures of two or more fungal species growing together (mixed cultures are the rule rather than the exception under natural conditions), the mycotoxins found are those expected from the fungi observed. Thus, the sterigmatocystin (an IARC 2A carcinogen i.e., a probable human carcinogen) and 5-methoxysterigmatocystin found in the bulk samples most certainly came from *A. versicolor* (which in fact produces these mycotoxins when grown on building materials) (54), and the chaetoglobosins from the *Chaetomium* sp. *P. chrysogenum* were commonly observed in these bulk samples, but no mycotoxins were found that could be ascribed to this fungus. In a similar study of mold-contaminated homes in Finland, workers showed that 34 of 79 bulk dust samples contained one or more of the 17 mycotoxins for which analyses were conducted. Of the 79 samples, 24% contained sterigmatocystin and 19% contained one or more of the trichothecene mycotoxins (55).

STACHYBOTRYS CHARTARUM — A MODEL?

As noted earlier, *S. chartarum* is less commonly encountered indoors than other toxigenic fungi (e.g., *A. versicolor*) but has nonetheless garnered more attention than the others because of its association with acute bleeding in the lungs of infants in Cleveland (20,21). This fungus was held responsible for serious health problems of a family living in a water-damaged home in Chicago (40) and has been implicated in several cases of building-related illness (39–41,56,57). A cluster of cases of acute bleeding in the lungs of infants was reported in Cleveland, Ohio where over 30 infants from homes that suffered flood damage became sick (12 deaths) with the illness beginning in January 1993 (21).

Stachybotrys chartarum was first described more than 150 years ago by Corda in 1837, who isolated the mold from damp wallpaper in a home in Prague. Although *S. chartarum*-related animal intoxications have no doubt existed for some time, it was not until 1931 that this

toxicosis was described and not until the late 1930s was the condition recognized as a mycotoxicosis: stachybotryotoxicosis (58). Horses are particularly sensitive to this mold that is a common contaminant of damp hay and straw (58). However, there are intermittent reports where major portions of a livestock herd have been killed following ingestion of *S. chartarum*–contaminated hay (58,59).

Stachybotryotoxicosis in humans is rare and has been reported most commonly in workers who handle moldy straw and hay (60). Workers handling *S. chartarum*–contaminated hay experienced bloody nose and nasal secretions, dyspnea, sore throats, and inflammation of the skin (61). More recently, severe dermatitis appeared on the hands of those workers who were handling decomposable flower pots made of recycled paper that had a heavy growth of *S. chartarum*; however, no respiratory distress was noted, although viable spore levels of *S. chartarum* up to 7,500 CFUs were found during the handling of the pots (62). Until 1986, there were no reports in the literature of stachybotryotoxicosis in North America. The first report of a toxicosis in North America attributed to *S. chartarum* occurred in a Chicago household where the home had suffered significant water intrusion from a leaky roof over a period of several years (40). The occupants of the home had suffered recurring maladies, including cold and flu symptoms, diarrhea, headaches, fatigue, dermatitis, sore throats, intermittent loss of hair, and general malaise. Examination of the home revealed extensive growth of *S. chartarum* on the ceiling of a bedroom and, more significantly, in the air-handling system. Ethanol extracts of the contaminated material were lethal (injected *per os*) to mice and rats within 24 hours. From these extracts were isolated a series of potent cytotoxic trichothecenes (40). After the home was thoroughly cleaned (protective clothing was necessary to prevent severe dermatitis in the workers), the residents returned, and their symptoms abated and within a few weeks, their health returned to normal.

The rare occurrence of *S. chartarum*–induced toxicosis in humans stems from the specific conditions this fungus requires for significant growth (e.g., this fungus is never found growing on food products). In damp buildings, high cellulose and fibrous surfaces are favored for growth if the moisture level is sufficient ($a_w > 0.9$). For example, if sufficiently moist, *S. chartarum* readily grows on gypsum board (63,64), wood fiberboard, wall paper, and dust-lined air-conditioning ducting (40,43,45–49,54). In the laboratory, *S. chartarum* is commonly grown on rice although toxin production is observed when the fungus is grown on building material as well (48,54,63,64).

Chemical investigation of *S. chartarum* has provided many highly toxic and novel compounds (65). *Stachybotrys chartarum* is known to produce the very potent cytotoxic macrocyclic trichothecenes (e.g., satratoxin H) along with a variety of immunosuppressants (65–67) and endothelin receptor antagonists (68–70). In fact, some of the most cytotoxic fungal metabolites ever discovered are products of *S. chartarum* fermentation (71), and by no means have all the active constituents been isolated and identified — there remains an uncharacterized hemolytic agent(s) found in several *S. chartarum* isolates from the Cleveland study (72). *Stachybotrys chartarum* can produce a diverse array of compounds, and the variation in individual and overall metabolite levels from one isolate to the next is remarkable — and troublesome to any who wish to draw toxicological inferences from levels of airborne *S. chartarum* spores. Similarly, the toxicity of two isolates of *S. chartarum* recovered from almost identical environmental conditions, and then grown in the laboratory, may exhibit widely different biological activity profiles (73).

It is instructive to see how chemically complex the profile of toxin production by this fungus is. Figure 2 illustrates members of the classes of mycotoxins reported to be produced by isolates *S. chartarum* and *Memnoniella echinata*, obtained from Cleveland homes involved in the IPH study (20,21,73–75). The latter fungus is closely related taxonomically to *Stachybotrys* (76) and is often found growing on the same substrates indoors with *S. chartarum*. The spectrum of compounds produced by *S. chartarum* in the laboratory depends not only on the particular isolate but also on the substrate. There are more than 10 each of the trichothecene (71) and atranone (77,78) classes of compounds produced by *S. chartarum* and they are the minor secondary metabolites. The major mycotoxins produced by *S. chartarum* and *M. echinata* are the benzodrimanes (Fig. 2: stachybotrylactone, stachybotrydialdehyde, and memnobotrin A), which are the "signature" compounds of this fungus (65,73). There are more than 20 members of this class, and unless steps are taken to separate these compounds from the others before chemical analysis by high performance liquid chromatography (HPLC), it is very difficult to even observe the presence of the other classes of mycotoxins (79). In addition, the more highly immunosuppressant dialdehydes (80), such as stachybotrydialdehyde (Fig. 2), are unstable and tend to readily rearrange to the corresponding significantly less active (80) stachybotrylactones (79,81).

As noted earlier, isolates of toxigenic fungi may differ significantly in their toxigenic potential. In the laboratory, isolates (approximately 40) of *S. chartarum*, grown on rice, from the Cleveland study (73), display cytotoxicities of their crude extracts that vary by five orders of magnitude. The most toxic isolates (about 1/3) are those that produce the macrocyclic trichothecene mycotoxins (e.g., satratoxin H). Of the remaining two-thirds of the isolates, some produce the considerably less toxic trichothecenes, trichodermol, and trichodermin; and most isolates yield the considerably less biologically active atranones (Fig. 2) (77,78). Although we have yet to find any significant biological activity associated with the atranones, these compounds are related in structure to the diterpenoid dolabellanes (two of whom have been isolated from *S. chartarum* cultures) (78), several of which do have appreciable biological activity (82). Others also have noted great variation in various biological activities of *S. chartarum* isolated from indoor environments (83), and thus this is no doubt a general characteristic of *S. chartarum*.

The cluster of cases of acute lung bleeding (idiopathic pulmonary hemosiderosis, IPH) in infants (two weeks to

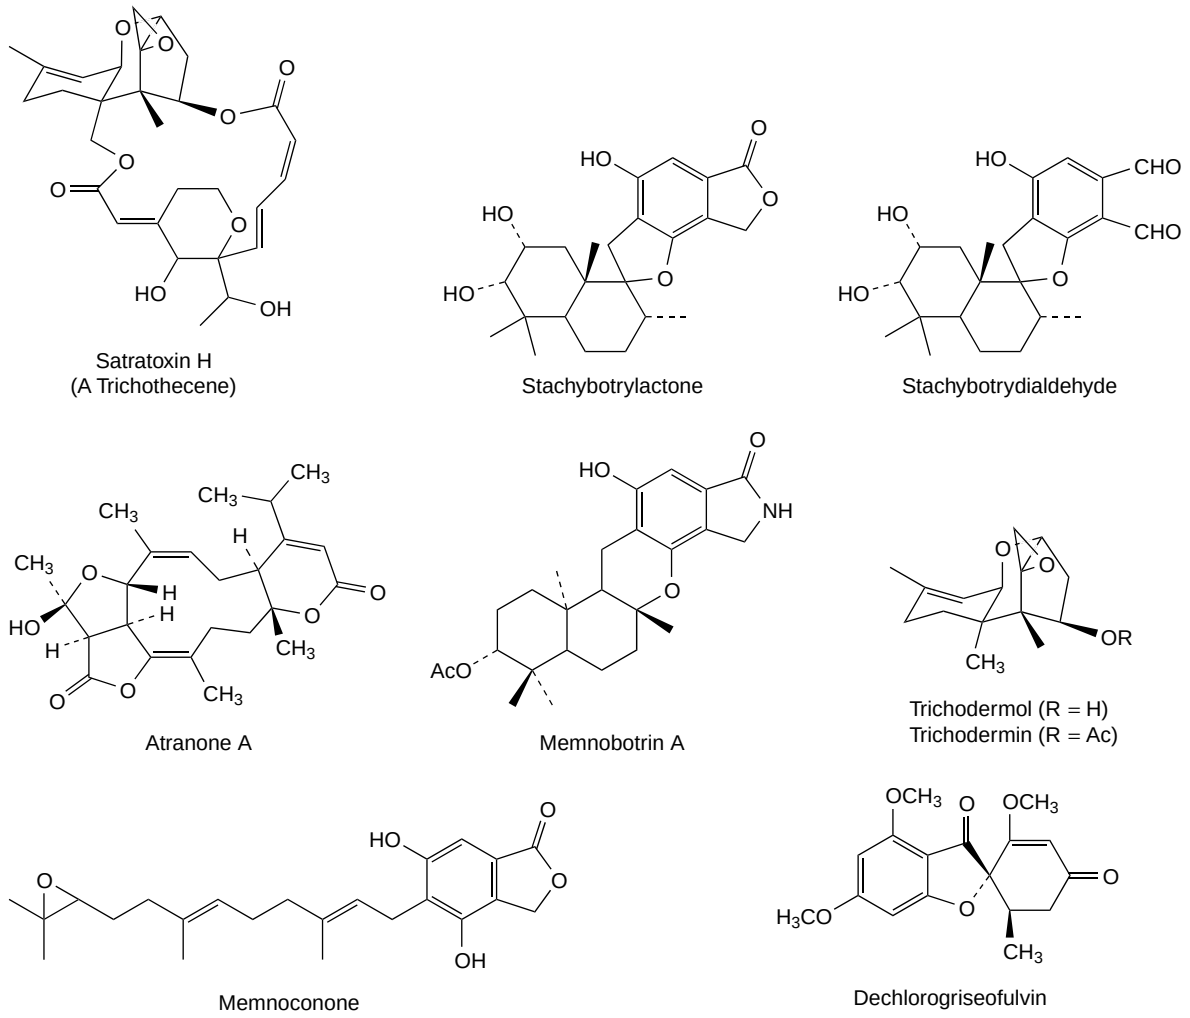

Figure 2. Mycotoxins isolated from *S. chartarum* and *M. echinata*.

six months of age) from Cleveland, Ohio has garnered a good deal of public attention. Between 1993 and 1998, there were 37 cases of IPH reported in the Cleveland area, a normally rare syndrome (20,21). Twelve of the cases resulted in deaths, including seven that had originally been diagnosed as sudden infant death syndrome. The researchers reported that all the case homes in the study had varying degrees of water damage and that *S. chartarum* was significantly more commonly found and at higher levels than in control homes (20,21). However, a strange observation in these cases is that occupants of the IPH homes older than six months of age appear not to suffer from any undue adverse health effects, although the investigators have offered a rationale for the hypersensitivity of infants to the effects of *S. chartarum* spores. In addition to the Cleveland IPH studies, there have been several recent reports of individual cases of IPH apparently associated with the presence of *S. chartarum* in homes (51,84), including one where culturable spores of *S. chartarum* were isolated from the bronchoalveolar lavage fluid of a child with pulmonary hemorrhage (85). However, "association" is not the same as cause and effect, and workers in this area (21) have taken some care in pointing out that other environmental factors (e.g., second-hand cigarette smoke) also may play important roles in the etiology of IPH. Nonetheless, others (86–90) have emphasized that the epidemiology of IPH vis a vis *Stachybotrys* is tenuous, and that reports such as the Cleveland studies may raise undue concern in the public mind. It is worth noting that it took 30 years (with hundreds of time-consuming and expensive studies) before the medical community accepted as fact the causal relationship between the consumption of aflatoxin-contaminated food and an increased incidence of liver cancer in humans.

THE FUTURE

There are presently a number of serious limitations in our ability to assess the role played by mycotoxins in the health of those exposed to toxigenic fungi in water-damaged buildings. Toxicologists prefer to study pure toxins, but mycotoxicoses always involve mixtures of chemicals and usually mixed fungal cultures as well. Furthermore, the spores appear to have noticeable

effects themselves apart from their mycotoxins. Intranasal exposure of mice to spores of a highly toxigenic strain of *S. chartarum* resulted in a remarkable deterioration of the lung tissue of the animals (91,92). In the case where animals inhaled pure trichothecene mycotoxins (25,26), little or no damage was observed in their lung tissue, even though the trichothecene toxin (T-2 toxin) administered in this manner was more than an order of magnitude more toxic relative to iv or ip injection. But spores in which toxins have been extracted are considerably less deleterious to lung tissue than are the spores prior to extraction of their toxins (93). Thus, it appears that the spores themselves play an important role in the responses observed in the lung tissue of animals who inhale the spores, strongly reinforcing data on the disregulation of pulmonary macrophages caused by toxigenic spores.

The critical question to be answered is that of the level of exposure. Without a reliable assessment of exposure, the risks to human health cannot be properly ascertained in individual cases. Although the epidemiological data clearly show that heightened exposure to indoor molds compromises the general health of those exposed (1), what cannot be gleaned from these data is the role played by mycotoxins. At present, few good methods for measuring exposure of individuals to indoor molds are available. The measurements of airborne mold levels indoors is problematic for a variety of reasons (12) and tend to be meaningful only when careful comparisons are made to the concurrent levels of molds in outdoor air. Indoor air sampling may be useful to demonstrate unacceptable amplification of indoor molds, but beyond that, these data are usually not statistically reliable (12).

Except for a small number of allergenic molds, no direct way of determining whether an individual has been exposed to a particular mold is currently available. In fact, the biochemical markers for general exposure to heightened levels of fungal spores are presently only of limited use, and certainly are such that one cannot distinguish exposure to toxigenic molds from exposure to nontoxigenic molds (12), let alone exposure to specific mycotoxins. What are needed are biological markers for exposure to both specific fungi and for their specific toxins. A few mycotoxins (e.g., ochratoxin A) are metabolically stable enough to give sustainable and measurable levels in blood (94), but most metabolize readily and few give metabolic products that have been characterized. An exception to this is aflatoxin B_1 that conjugates to genomic DNA and can be assayed as the guanine adduct, giving a measure of exposure to the mycotoxin (10).

Future advances in analytical chemistry coupled with the identification of biological markers for specific mycotoxins will be a great aid in addressing the fundamental questions of exposure to airborne toxigenic molds and their risk to people living and working in mold-contaminated buildings.

ALGAE BIOTECHNOLOGY

Bonnie K. Lustigman
Lee H. Lee
Montclair State University
Upper Montclair, New Jersey

In recent years there has been increased interest in the use of algae for biotechnology. Algal biotechnology represents an area of current and future development as new sources for products are being explored. Algae require minimal substances for growth and provide a rich source for bioproducts. Traditionally, seaweeds were harvested and used as a source of complex carbohydrates such as agar and carrageenan. People in several countries, particularly in Asia, have used algae as a food source for centuries. Yet, of more than 30,000 species of algae known, only a small number have been exploited for commercial purposes. *Spirulina* has been cultivated for several years as a health food product. Biotechnology for valuable biochemicals from algae is currently a reality, and growth of algae through aquaculture has developed into an important industry. Several countries produce carotenoids by growing *Dunaliella* and *Haematococcus* and harvesting the pigments. With the search for new natural products for use in pharmaceuticals, food materials, cosmetics, and other uses increasing, algae represent a likely resource to be explored for future development.

Algae, both micro- and macro-, are increasingly being sought as a means of bioremediation that can compete with other technologies in terms of efficiency, cost, and reliability. The application for bioremediation and for natural products derived from algae is even being combined, with algae being grown on wastewater and their proteins harvested for industrial use. Algal biotechnology represents an important area for current and future research.

COMMERCIALLY IMPORTANT ALGAE

Among the thousands of marine, freshwater, and soil microalgae, about 100 species have been shown to produce valuable compounds (1), a few of which have gained considerable significance commercially. *Spirulina, Chlorella, Dunaliella, Haematococcus*, and *Porphyridium* are five genera of microalgae with great economic relevance. Cultivation of these species is important for the health and pharmaceutical industries, and for the manufacturers of animal feed.

Spirulina is the most widely cultivated cyanobacteria (Fig. 1). It is a prokaryotic organism containing blue phycocyanin in addition to chlorophyll. It is found in lakes that are rich in salts in Central and South America and in Africa. It is characterized by forming helical strands of cells in aqueous environments and grows in alkaline media, surviving pH of 11. It can grow in temperatures as low as 18 °C, but the optimum is 35 to 37 °C. It grows well in mass cultivation in open, shallow racetrack ponds, or in closed tube systems. The media for growth was developed by Zarouk (2) but was modified to reduce the costs by substituting cheaper substances, such as ammonia or urea for nitrate. *Spirulina* is grown for its high protein content (71%) and is widely marketed as a health food product and for animal feed. In addition to its high protein content, it has essential fatty acids, minerals, and vitamins. Most health benefits to humans claimed for supplementation come from anecdotes and not scientific research. In vitro and animal tests have demonstrated a wide range of healthful benefits including anticancer (3), lipid lowering (4), and blood-iron status enhancing (5).

Chlorella vulgaris was the first microalgae to be isolated. It is a unicellular green algae and does not have flagella (Fig. 2). All strains have a cell wall, and asexual reproduction occurs within the parent cell wall producing four to 16 new cells. The cell wall then breaks to release the offspring. *Chlorella* has high tolerance for acidic pH ranging from 2.0 to 6.0. Its salinity tolerance ranges from 0 to 5%. Optimum temperature varies depending on the strain, ranging from 25 to 38 °C (2). Maximum growth rate can be induced by the use of mixotrophic cultures (supplementation with acetic acid), rather than strict reliance on autotrophic growth (6). *Chlorella* is grown commercially for its chlorophyll and protein content. It is used as a health-food supplement and for animal feed. *Chlorella* can be used for bioremediation of heavy metals in wastewater (Fig. 3).

Dunaliella are unicellular, flagellated, green algae that lack a cell wall (Fig. 4). There are halotolerant and

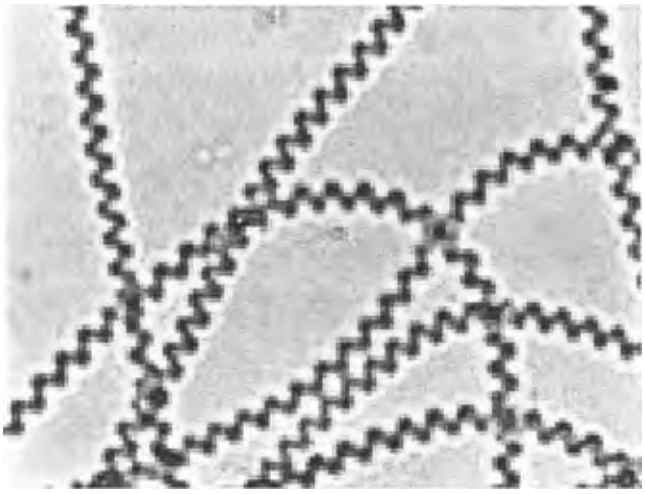

Figure 1. Cyanobacteria-*Spirulina* sp. *http://vis-pc.plantbio.ohiou.edu/algaeimage/pages/spirulina.html* See color insert.

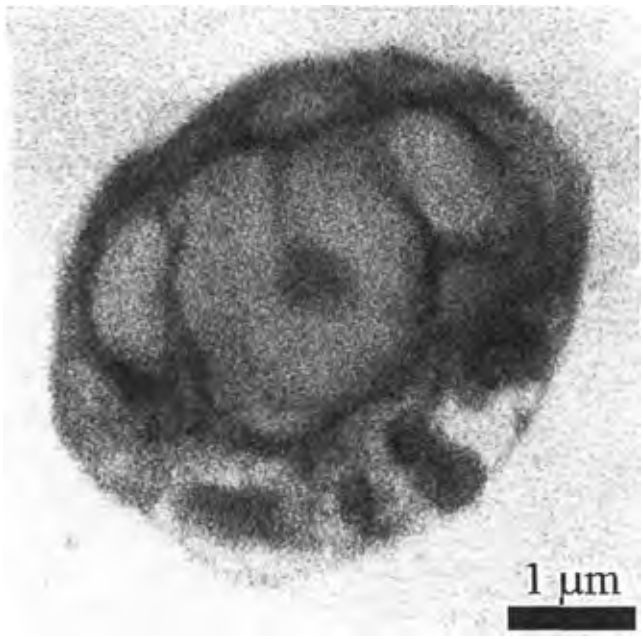

Figure 2. *Chlorella vulgaris*, *http://www.ifa.au.dk/~jabraham/algae.htm* See color insert.

halophilic strains; the species grows in a range from brackish to hypersaline waters. Optimum conditions for growth vary depending on the strain involved, and the interaction between the physical and chemical growth conditions. Several different media have been developed for growth, with commercially important strains adapted to high salt concentrations. These strains were isolated from environments such as the Dead Sea. Temperature requirements vary depending on the light intensity and salinity. With high salt concentrations, high temperatures, and intense light, halophilic varieties of *Dunaliella* produce significant quantities of beta-carotene. This is harvested for use in health-food supplements and as coloration in foods and cosmetics. In response to increasing osmotic pressure, *Dunaliella* produces glycerol to maintain osmotic balance, and this is also harvested for commercial distribution (2).

Haematococcus pluvialis is a unicellular green algae that has two anterior flagella (Fig. 5). It grows in coastal rock pools, water holes, and other similar small bodies of water. Its optimum temperature is between 15 and 25°C. *Haematococcus pluvialis* is able to respond to environmental stress by changing from the motile, vegetative green cell form to red stationary aplanospores. This occurs when nutrients become scarce or under hypersaline conditions, high temperature, or intense light. In the cyst phase, it produces high amounts of carotenoids and astaxanthin, 4 to 6% or more of their dry weight (7). Astaxanthin is a red pigment that is valued commercially for cosmetics and as an antioxidant. It is also used as a color additive in feed for salmon to enhance the pink color (Food and Drug Administration 21 CFR Part 73

Figure 3. Bioremediation of heavy metals in wastewater, *http://zobell.biol.tsukuba.ac.jp/~inouye/ino/g/chl/chl_picl.html* See color insert.

[Docket No. 98C-0212]). These characteristics have led to increased interest in developing culture methods for commercial exploitation.

Porphyridium is a unicellular red algae (Fig. 6). *Porphyridium* has been isolated from a wide range of environments, freshwater streams, brackish and marine water, and damp soils. It is characterized by a single large stellate chloroplast. It lacks a true cell wall, but is surrounded by a gel polysaccharide layer that causes clumping of the cells so that they form loose colonies. Its pigment, phycoerythrin, has commercial significance for cosmetics, medical diagnostics, and food coloring. *Porphyridium* is grown in large-scale open ponds and in closed tube systems in marine media.

CULTURE TECHNOLOGY

To produce sufficient quantities of algae for industrial purposes, methodologies for mass cultivation and harvest have been developed. Considerable technological research has been undertaken to determine the optimum conditions for growth and to remove problems with contamination.

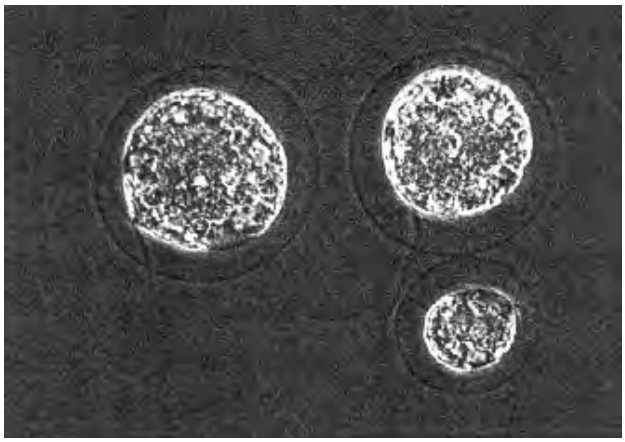

Figure 5. *Haematococcus*, *http://www.microscopy-uk.org.uk/mag/wimsmall/extra/haema.html* See color insert.

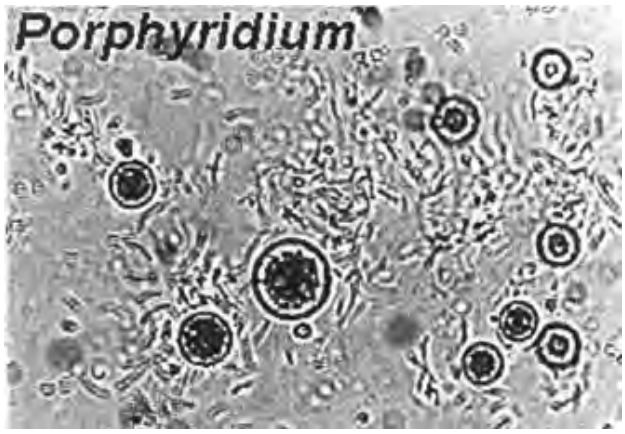

Figure 6. Rhodophyta-*Porphyridium purpureum http://vis-pc.plantbio.ohiou.edu/algaeimage/pages/Porphyridium.html* See color insert.

Cultivation of algae can occur in areas that are not suitable for conventional agriculture, but have high light availability and warm temperatures, making this suitable to thirdworld nations. Many species can be grown in saline water or in marine environments. All systems for mass production must include supply systems, culture systems, harvesters, and processing equipment (Fig. 7). Special technology is needed for each of the phases of the growing process: cultivation, enrichment of the required product, harvesting, and extraction of the products. The phases are dependent on each other and the process varies depending on the algae grown and the product to be harvested.

The standard method used for large-scale production is shallow ponds, 10 to 20 cm deep that are open or covered. The ponds are circular or oval and are stirred by paddle wheels to provide an even suspension and prevent the algae from settling out. The most common commercial structure is an open raceway, which is stirred by paddle wheels. There are several problems with large-scale cultivation, mainly concerned with low productivity and contamination by microorganisms and chemicals (8). Guterman and Ben-Yaakov proposed application of modified, simple, mathematical algorithms to computerized control systems to provide for optimum operating conditions by automatic systems in which the parameters of light intensity, optical density, pH, and temperature are included in the formula to calculate the conditions needed to increase yield (9).

Closed, long, polyethylene sleeves, first proposed by Trotta in 1980 (10), have been used to limit the problems found with open ponds. There are various types of horizontal or vertical closed systems including horizontally arranged glass or polyethylene tubes (11). The tube photobioreactors are arranged as vertical closed bioreactors that have limited contact with the external environment, especially compared to open ponds. These systems reduce the problems of contamination and increase control over temperature, evaporation, and light availability (12). Comparison of near horizontal straight tubular reactors and near horizontal flat panels in outdoor cultivation of *Spirulina* showed that the photosynthetic efficiency in the tubular systems was significantly higher because the curved surface reduced the light saturation

Figure 7. *http://members.nbci.com/_XMCM/rekel/ushn/helo/photo_daphnia.htm* See color insert.

effect (13). Comparison of curved versus straight tubes indicates that curved tubes are superior to straight ones (14) (Fig. 8).

Water is added by a system of tubes that connect the sleeves to a control center where the temperature and the densities of the materials are controlled and harvesting begins. Models have been developed to estimate the biomass productivity depending on the solar irradiance on the culture surface (15). The determination of the final product is subject to the environment present (16). Thus, changes in the composition of the medium, light intensity, and gas flow will affect the productivity of the algal cultures (17). Low-dose ultrasonic treatment can affect the growth rate and biomass yield of algae depending on the species of algae cultivated; the ultrasonic treatment either increasing or decreasing growth rates (18).

Microalgae can be grown by various technological means that are dependent on the needs and economics of the environment. Algae exist primarily in freshwater and marine habitats. They acquire the substances they need for growth and metabolism (water, carbon dioxide, and nutrients) directly from this environment. In Israel, *Dunaliella* and *Porphyridium* are grown in vertical sleeves in which the growth conditions are closely monitored and controlled. In these rows of vertical plastic sleeves, they are separated from the external environment, except for the sun (12). The advantage of the closed system is to limit contamination and fluctuations in environmental conditions. In other localities, where the growth of algae is linked to remediation of agricultural wastewater or similar environments, other technologies may be applicable (19,20). It is easier to commercially grow hardy organisms, such as *Chlorella, Spirulina*, and *Dunaliella* than *Haematococcus*, which cannot compete with contaminant organisms in open outdoor systems. *Haematococcus*, which produces the pigment astaxanthin in the cyst phase, is grown in a combination of enclosed outdoor photobioreactors and pond-culture systems (1) as well as other culture methods intended to increase yield (21).

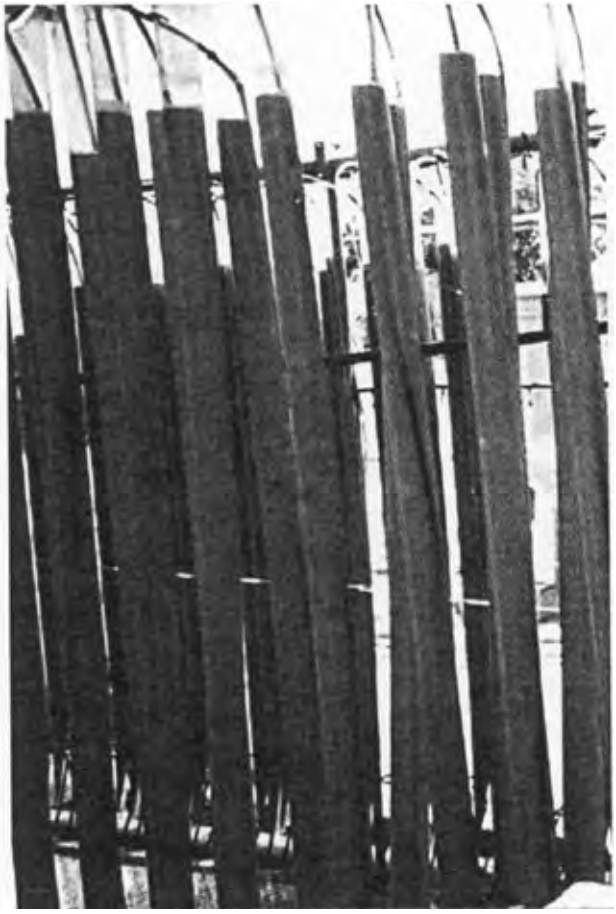

Figure 8. Polyethylene culture sleeves from Ben–Gurion University. Provided by Dr. Lustigman and Dr. Lee. See color insert.

The yield and type of product can vary depending on the nutrients and other growth conditions supplied to the algae. Nitrogen deprivation can increase the yield of polysaccharides of *Porphyridium* (22), but higher nutrient availability will increase lipid content of *Dunaliella tertiolecta* (23). High biomass protein production can be achieved by growth with high nitrogen content, such as swine wastewater (19). Temperature can be an important factor affecting the productivity and biomass in *Spirulina* grown outdoors (24). The growth stage can be followed by an enrichment stage aimed at the concentration of the desired product (25,26). The algae must be harvested from the culture medium, concentrated, and dried. The harvesting technique employed depends on the algae. For microalgae, harvesting occurs by centrifugation, filtration, flocculation and settling, or flotation, depending on the organism involved. Degradation of the product, as with beta-carotene, can occur because of exposure to light and air (27). Irradiation can change the proportions of the stereoisomers of beta-carotene in *Dunaliella* (28).

With the high costs involved in the cultivation of microalgae and harvesting the bioproducts, it is probable that in the future the identification of the genes responsible for the production of these products will take place. Genetic manipulation will then be used for enhancement of these products in organisms, not necessarily algae. Identification of some of the genes responsible for production of astaxanthin (29,30) and their transfer into tobacco plants has taken place (31).

NATURAL PRODUCTS FROM ALGAE

It is in the area of natural products that algae have become increasingly important as sources for the health and pharmaceutical industry and for use in animal feed. Algae have long been used as a source of commercial products, particularly for the food and pharmaceutical industry. These products such as agar, sodium alginate, and carrageenan are complex polysaccharides whose usage is well established. They are used as thickening agents, emulsifiers, and gelling agents in food products and paints, photographic films, and drug formulations. With increased consumer interest in natural products as opposed to synthetic ones, attention has been focused on algae as a source of these substances. Marine organisms including algae have been an important source of natural products with biomedical potential (32).

Protein

Although other algae also have high protein content, *Spirulina* is probably the most widely known algae grown for its natural products. Because its protein is complete, *Spirulina* is raised for use in protein supplements and for animal feed. In addition to protein, it produces essential fatty acids, minerals, and vitamins.

Pigments

Carotenoids. One of the most widely used products derived from algae are the pigments that are harvested from mass cultures. Microalgae are frequently grown for their pigments, particularly the lipid-soluble carotenoids. These are used for food coloration, cosmetics, and medicinal purposes. Carotenoids are found in a large number of organisms including bacteria, algae, higher plants, and animals. Carotenoids are lipid-soluble pigments made of isoprene units with a yellow-orange-red coloration. Beta-carotene is the most abundant of the carotenoids making up 10% of the dry weight of *Dunaliella bardawil* and *D. salina* (33).

In plants, carotenoids are secondary photosynthetic pigments that serve to absorb additional light energy for the photosynthetic process. They increase in concentration when the plant is undergoing stress such as high light intensity or high osmotic stress. This is true particularly for microalgae such as *Dunaliella*, which has been cultivated commercially for several years. Extensive cultivation of *Dunaliella* occurs in Israel, Australia, United States, Spain, and China (34–36). The amount of beta-carotene produced is directly related to the amount of light absorbed by the algae. Therefore this is a mechanism to protect against high light intensity (37). Increased salinity also increased the concentration of carotenoids, particularly beta-carotene (38).

Industrially, carotenoids have been used for food coloration, cosmetics, and as a health-food product (39). Beta-carotene is a vitamin A precursor and acts as an antioxidant (40). Exposure of algal cells to various environmental stresses causes an increase in the presence of antioxidative enzymes and beta-carotene production (41). Beta-carotene has been shown to scavenge reactive oxygen species generated in vitro (42) and to cause slight lowering of spontaneous and X-ray-induced chromosomal damage in bone marrow cells (43). Beta-carotene has long been considered as an anticarcinogen (44,45). Because of its antioxidant properties, it has been studied as a means of chemoprevention to prevent development of gastric carcinoma in high-risk populations with precancerous lesions (46). However, two large-scale studies, the Physicians' Health Study (PHS) and the Beta-Carotene and Retinol Efficacy Trial (CARET), question the benefit against heart disease or cancer (47). In fact, an increase in the risk of lung cancer among smokers who took beta-carotene supplements was reported in the alpha tocopherol, beta-carotene cancer prevention study (48), and among smokers and asbestos workers in CARET (49), but not among male physicians in the Physicians' Health Study (50). Studies using ferrets supplemented with high and low doses of beta-carotene show that high supplementary doses leads to precancerous lesions in ferrets exposed to tobacco smoke, whereas low levels were antiproliferative (51).

The pathway for biosynthesis of beta-carotene in *Dunaliella* has shown that several intermediates are produced, terminating as two stereoisomers (all-*trans* and 9-*cis*) found in equal concentration. The synthetic variety consists of the all-*trans* stereoisomer. In view of the question as to the possible greater value of natural versus synthetic beta-carotene, studies have been performed comparing serum and tissue concentrations of the all-*trans* and 9-*cis* isomers. The steroisometric mixture of beta-carotene in *Dunaliella* has been shown to be preferentially absorbed in animal tissues (34), but much of the 9-*cis* molecules are converted to all-*trans* (52,53). Serum analysis in humans shows that 9-*cis*-beta-carotene is more efficient as an in vivo lipophilic antioxidant than all-*trans*-beta-carotene, indicating that natural sources may be superior to synthetic ones (54). Comparative studies of natural and synthetic beta-carotene using in vitro tests indicate that natural, or a mixture of natural and synthetic beta-carotene, was more effective in antigenotoxicity than synthetic, and may be of value as a supplementary treatment in cancer prevention (55). Other carotenoids used commercially are xanthophylls, which are yellow-orange in color, used as food dyes for poultry skin, egg yolk, and salmon (56).

Astaxanthin. Another carotenoid is the red pigment astaxanthin produced almost exclusively by *Haematococcus pluvialis* cysts (Fig. 9). It has commercial value as a red colorant in cosmetics and foods, and enhances the pink color of salmon (57). The gene *CrtO*, responsible for the production of astaxanthin has been transferred to tobacco plants imparting red color in the manipulated plants (31). Astaxanthin present in cyst cells appears to function as an antioxidizing agent against oxidative stress (58). It increases in oxidative stress along with superoxide dismutase, an antioxidative enzyme (59). It is being evaluated for presumed cancer prevention (60). The development of methods for increased production and purification of astaxanthin is currently a very active area of commercial interest in several locations including Iceland, Israel, and Hawaii (1,61).

Phycobiliproteins. The water-soluble phycobiliproteins, produced by the cyanobacteria and red algae, are other important pigments. These pigments create the blue-green and deep red color, respectively. They have potential as food dyes and application in the cosmetic industry (62). Phycocyanin, which is the blue-green pigment obtained from cyanobacteria, has been patented and is commercially available as Linablue (Dainippon Ink and Chemicals Inc. 1980. Jap. Patent 8077890). It is used in the food industry for coloring dairy products, candy, and soft drinks. *Spirulina platensis* has been suggested for phycocyanin production (63). It has also been shown to have hepatoprotective effects against toxic substances (64). The red fluorescent phycobiliprotein, phycoerythrin, gives the red algae, Rhodophyta, their name and coloration. The phycobiliprotein from the red alga, *Rhodella reticulata*

Figure 9. Astaxanthin, *http://www.bioprocess.is/product.html* See color insert.

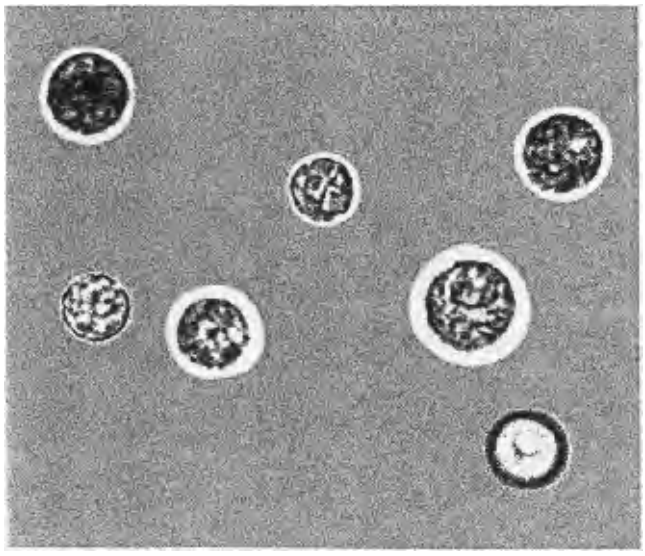

Figure 10. *Rhodella reticulata*, *http://www.cibnor.org/malgas/ifotrhr.html* See color insert.

(Fig. 10), have been purified and could be considered as a potential source of these substances for commercial purposes (65). They are also found in several microalgae including *Porphyridium* (66) and *Synechococcus*. The purification of phycoerythrin from *Synechococcus* sp. DC-2 has shown that two forms of phycoerythrin are produced (67). Heat-resistant C-phycocyanin has been purified from the red alga *Cyanidium caldarium*, and has potential for use in industrial processes because it does not denature up to 60 °C (68).

These pigments are used for diagnostic purposes in multiple-color-flow cytofluorimetric analysis. The phycobiliproteins and molecules with specific biological activity bind to target molecules forming fluorescent conjugates. The phycoerythrin conjugates are soluble in water, have a long shelf life, and are not affected by most natural molecules (69). Glazer and Stryer developed markers, phycoprobes, made of fluorescent phycobiliproteins covalently bound to biologically active molecules (70). These include phycoerythrin-immunoglobulins, phycoerythrin-biotin, phycoerythrin-avidin, and phycoerythrin-protein (71). The use of phycoerythrin-antibody conjugates allow for early detection of leukemia and other blood disorders (72).

Fatty Acids

Algae are also used commercially to obtain unsaturated fatty acids (73). Although fish oils are considered to be the source of unsaturated fatty acids, these acids are actually produced by the marine algae that the fish consume (74). Algae and cyanobacteria are rich in ω-3 fatty acid homologs (75), and if the fatty acids are harvested directly from the algae, the undesirable components, like the fishy smell and cholesterol, will not be present (76). These fatty acids are suggested to be of value in prevention of heart disease by reducing levels of plasma lipids and lipoproteins. They act to decrease serum cholesterol and triglyceride levels (77). High quantities of essential fatty acids such as arachidonic and docosahexaenoic acids are found in marine algae. Greater variation exists in the quantities of fatty acids in different algae than in the class of fatty acid produced, although within the class unique metabolites may exist (78). The Phaeophyta and Rhodophyta generally produce more fatty acids than the Chlorophyta, including eicosatetraenoic and eicosapentaenoic, and less linolenic acids (79). Arachidonic acid (5,8,11,14-eicosatetraenoic acid) is a natural precursor of a large family of structurally related C-20 compounds including prostaglandins, leukotrienes, and prostacyclins. Arachidonic acid and docosahexaenoic acid are important for neurological development in newborns (80). The tropical red marine alga, *Murrayella periclados* has been shown to produce high quantities of eicosanoids, including a leukotriene, usually found in animal sources (81). Other red algae including *Porphyridium*, are also rich in high unsaturated fatty acids, which is considered as a potential source of arachidonic acid (82,83). The green microalgae, *Chlorella* has been suggested for the commercial production of gamma-linolenic acid (84) as has *Spirulina* (85). Commercial fish feed enriched with fatty acids derived from algae produces better growth of fish larvae (86,87) and juvenile scallops (88). There is considerable difference in the success of the juvenile scallops, depending on the species of algae fed. There was greater growth when those species having high levels of ω-3 and ω-6 polyunsaturated fatty acids and carbohydrates were used (89).

Polysaccharides

The Rhodophyta are the traditional source of complex polysaccharides used commercially as gelling agents, stabilizers, thickeners, and emulsifiers for dairy products and other foods. They are also used in paints, photographic films, and pharmaceuticals. The most widely used are agar-agar and carregeenan. The insoluble carrageenan fraction extracted from *Stenogramme interrupta* has also shown antiviral and anticoagulant properties (90).

Polysaccharides derived from seaweeds are frequently used as fiber for nutritional supplements. Seaweeds such as *Ulva*, an edible green algae, have been raised in aquaculture for its polysaccharides and used as dietary fiber (91). For several years there has been an increase in the development of additional marine algal polysaccharides for pharmaceutical purposes (92). The polysaccharide derivative, calcium spirulan, from *Spirulina* has been shown to limit tumor metastasis (3).

Antimicrobials

Antibacterial. Because of the increase in the number of strains of bacteria that are resistant to antibiotics, there has been increased interest in the development of antimicrobial substances produced by algae. Most of the antibiotics currently used clinically are derived from substances produced by fungi or actinomycetes. However, the production of antibiotic substances from marine algae has long been known, dating back to Pratt in 1942 (93). Since the 1960s, many studies have been undertaken on the growth-inhibitory substances produced by marine algae (94,95). Several reviews have been published (32,96–98) on this topic.

Among the seaweeds, the Chlorophyta, Phaeophyta, and Rhodophyta have been surveyed for their activity. It has been shown that activity may be present, but it is species specific and varies depending on the season (99–102). Cyanobacteria have been found to produce antibiotic substances and other potentially pharmacologically active products (103,104). Green algae including Chlorococcum (Fig. 11; 95) and *Dunaliella* (105,106), have also been shown to produce antibacterial substances.

Many of the substances produced by marine microorganisms show a high degree of toxicity. The toxic nature of these substances, which include acrylic acid, phenols, terpenoids, and halogenated compounds, has made them unfit for, or have limited use in, commercial exploitation (107). However, the need to develop new antibiotics because of increasing resistance by clinical bacteria to traditional ones has led to renewed interest in the search for antibiotics from algal sources (108,109). A survey of 100 strains of marine microalgae from Japan determined that several strains showed activity, with a species of *Chlorella* displaying the greatest results, producing a light-induced substance (84). In a similar survey of 84 marine algae, *Dunaliella primolecta* showed the highest antibiotic activity (106). Nine extracts made from 16 marine algae from the Atlantic coast of Brittany, France, showed activity against isolates of marine fungi, bacteria, and yeasts (110).

Antiviral. Development of substances that show activity against viruses is another active area of research.

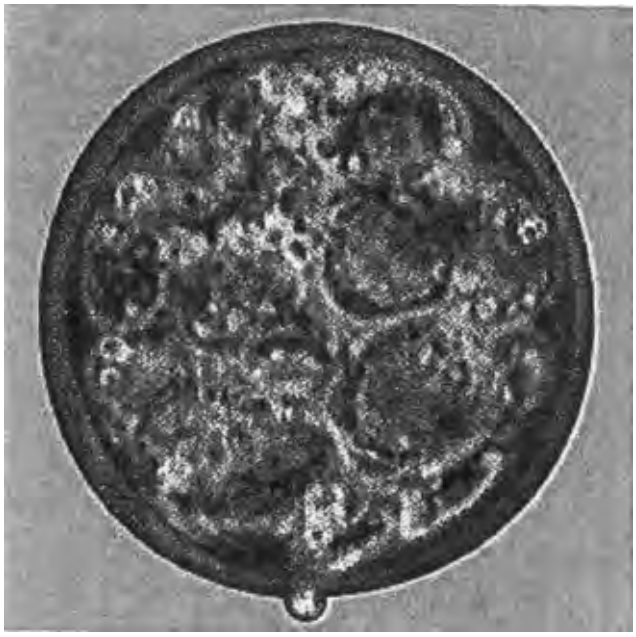

Figure 11. *Chlorococcum oleofaciens*, *http://www.cibnor.mx/malgas/efotcho.html* See color insert.

Screening of 89 seaweeds from British Columbia, Canada, and Korea for substances with antiviral activity has shown that 37% of the species tested were able to inhibit viruses (111).

Natural substances derived from algae that were active against HIV include terpenoids, xanthones, alkaloids, flavenoids, polyphenols, and polysaccharides and appear to be active against reverse transcriptase, protease, and integrase (112). In particular, the sulfated polysaccharides, such as dextran sulfate, are known to interfere with the adsorption and penetration of retro- and other viruses (113,114). Such substances have been extracted from *Spirulina* and *Cochlodinium polykrikoides* (115–117). Two mechanisms have been proposed: (*1*) Inhibition of retroviral reverse transcriptase (118) and (*2*) binding to CD4 receptors (119). The sulfated polysaccharide of *Porphyridium* (120) and that of *Spriulina* (116) have shown activity against *Herpes simplex* virus types 1 and 2 and *Varicella zoster* virus. The mechanism for action is the inhibition of production of new viral particles within host cells and/or prevention of adsorption of the virus into host cells (120).

The potential for the identification and development of antimicrobial substances from algae is an area of great potential for future development. With the increasing proliferation of resistant bacteria and the need for antiviral drugs, the exploitation of substances from algae is sure to increase.

Additional uses for algal products are the proposal of development for use as natural oral deodorants by members of the brown algae belonging to the Laminariales (121). Algae and other marine organisms have been suggested as a source of substances that are environmentally safe to control barnacles that live on ships' hulls, oil platforms, and pipelines (122). Methods, such as new assay gels containing extracts from these

organisms, are being developed to assist in the screening of such substances (123).

ALGAE AS FOOD SOURCES

As we search for new, safe, and less costly sources of feed for animals and humans, and for supplementary dietary products like protein, vitamins, and minerals, algae provide an important source for these substances. Algae have long been used as human food sources in cultures with access to the marine environment, especially in Asian cultures.

There is increased awareness of the potential for use of agar by consumers in countries outside of Japan (124). Aquaculture has become an important source of food for humans and animals. Technological advances have provided the ability to raise and harvest algae grown in controlled environments, with specialized media formulated to increase yield. The blue-green alga, *Spirulina*, has been effectively marketed as a healthfood supplement because of its high protein content (125). Although other species, including *Chlorella, Dunaliella*, and *Scenedesmus*, are also suggested to be used for their protein content (126), *Spirulina*, in particular, has been proposed for use in poultry feed, fish meal, and as a supplement in other animal feed (127–129). Since the cost of traditional protein sources such as fish, groundnuts, and soybean meals is expensive, especially for developing nations, the search for less expensive alternative sources such as algae, has increased (130,131).

Algae provide a source of high protein, comparable to those from conventional sources. *Dunaliella*, grown under optimum conditions, can produce up to 70% protein content (23). However, production costs are high and this limits use as animal feed, although many third world nations are exploring the cultivation of microalgae for protein and other biochemicals. This, in conjunction with wastewater treatment (128), or to clean liquid manure (129), provides dual benefits in terms of production and is ecologically sound.

TOXICOLOGY

Algae, as simple microorganisms, can be used as indicator species for environmental contamination and ecotoxicology (130). Large quantities of heavy metals are released into the environment mainly through industrial discharges. Agricultural runoff and sewage treatment are also sources of environmental contamination. The effect of these substances on algae will reflect in the entire ecosystem because they are the world's largest group of primary producers. Heavy metals exert their toxic effects by competing with essential metals for active enzyme or membrane protein sites, and by reacting with biologically active groups, thereby disrupting normal cell processing. The Environmental Protection Agency (EPA) has listed major toxic target contaminants including 13 heavy metals. Of these contaminants, the ones that have received the most attention are mercury(Hg), lead(Pb), and cadmium(Cd), although several others are of important environmental significance.

Because of the environment they inhabit, sediment microorganisms exhibit a higher level of tolerance to high heavy-metal concentrations. Aquatic microorganisms display the lowest tolerance to heavy-metal concentrations because the heavy-metal suspension in water is generally very low (132).

A microorganism's ability to tolerate specific heavy-metal toxicities is because of the organism's exposure to that substance. Thus, many bacterial strains show high tolerance to zinc (Zn) and copper (Cu), and few to silver and arsenic because of the greater percentage of Zn and Cu in the environment compared to silver and arsenic (133).

Collard and Matagne (134) showed that most tolerance appears to be physiological rather than genetic, but genetically caused tolerance to heavy metals was present in *Euglena gracilis* (Fig. 12), *Stigioclonium* (Fig. 13), *Chlorella vulgaris* (Fig. 2), and *Chlamydomonas reinhardtii* (Fig. 14). Cd tolerance in *Chlamydomonas* is achieved by alteration in the metabolic pathways associated with the chloroplast, causing reduced chlorophyll content and not by increased efficiency of a detoxification system (135). Pretreatment provides for increased tolerance. Preexposure of *Euglena gracilis* to low concentrations of Hg protected cells to concentrations up to 5 μM. Hg pretreatment also conferred tolerance against Cd exposure and vice versa. These algae were able to tolerate higher levels of Pb as well (136). Some algal species display cotolerance in which they can tolerate one or more additional metals to which they were not previously exposed (137). Exposure of *Dunaliella minuta* to Cu or Cd led to the acquisition of tolerance toward both Cu and Cd (138).

Anacystis nidulans, (Fig. 15) a unicellular cyanobacteria, and *Chlamydomonas reinhardtii*, a unicellular green algae, have served as indicator species for a long-term project that was undertaken to determine the inhibitory concentrations of the heavy metals identified by the EPA. In these studies, *Anacystis* with *A. nidulans* was treated with the heavy metals in media with and without the chelator, ethylene diamine tetraacetic acid (EDTA) (139). The results of this survey indicate a wide range of inhibitory concentrations of the heavy metals. These studies show the following order of inhibitory concentrations: Hg > Tl > Al = Cu > Ni > Co > Se = Zn > Cd > Mn > Ba = Pb with EDTA. A similar, but not identical pattern was seen when EDTA was not used in the medium. Without EDTA the results were: Hg > Cu > Tl > Ni > Co > Se = Zn > Cd > Mn > Ba. In this series, Pb was not studied and the results with manganese show a long lag period at lower concentrations before the onset of log phase (140–148).

There does not appear to be consistency based on toxicity. Matulova, working with the green alga *Scenedesmus quadricauda* (Fig. 16), and using lethality as the measurement found that the order was: Ni > Cr = Zn ≫ Pb (149). Rosko and Rachlin using *Chlorella vulgaris* cultures with EDTA found toxicity to heavy metals in the following order: Cd > Cu > Hg > Zn ≫ Pb (150) and Raichlin and colleagues using *Chlorella saccharophila* found that the order was Cd > Cu ≫ Zn ≫ Pb (151). However, Raichlin and colleagues using the freshwater

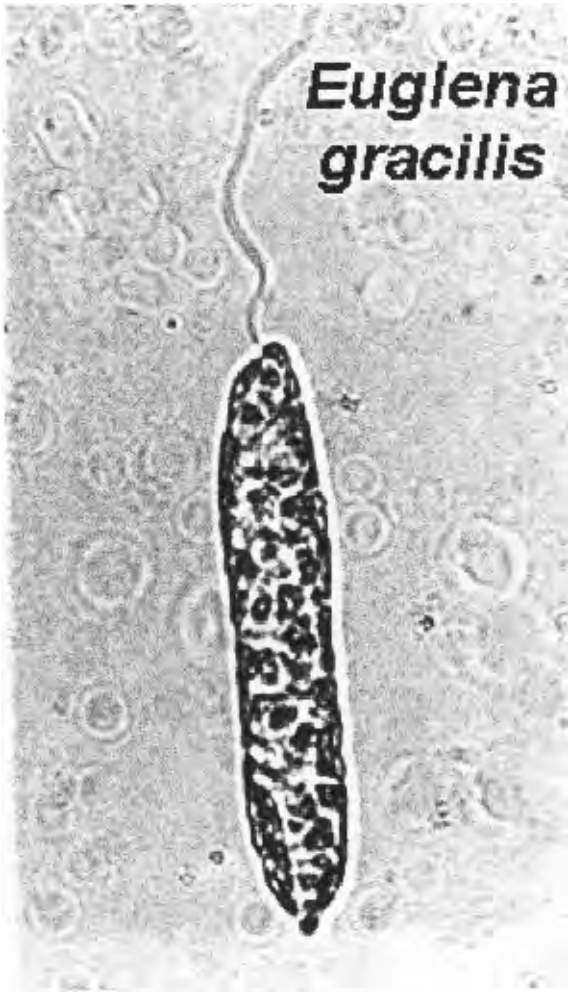

Figure 12. Euglenophyta-*Euglena gracilis http://vis-pc.plant-bio.ohiou.edu/algaeimage/pages/Euglena.html* See color insert.

diatom *Navicula incerta* (Fig. 17) found the toxic hierarchy to be Cd > Pb ≫ Zn > Cu (152). Comparison in terms of toxicity to thallium shows a wide difference between *Anacysitis nidulans* and *Chlamydomonas reinhardtii*, with inhibitory concentrations at 10 mg/L and 0.25 mg/L, respectively (148).

These results contrast to environmental studies that contain a mixed phytoplankton population. Studies of the Saanich inlet showed the order of toxicity to be: Hg ≫ Cu = Pb > Cd > Ni = Cr in two experiments (153). Krock and Mason found the order of toxicity based on inhibition of photosynthesis in phytoplankton communities of San Francisco Bay to be: Hg > Cu ≫ Cd = Cr = Ni = Pb (154). It appears that the results depend largely on the type of algae used, and this constitutes an important factor in determining the effects of heavy metal toxicity.

Pb is the most abundant and widely used heavy metal, although recent use has declined with lead-free gasoline. It exerts its toxicity more in terms of chlorophyll a content than on cell division (150) and binds strongly to cell membranes (155). It appears to be the most widely tolerated of the major heavy-metal contaminants for phytoplankton (140–151).

On the other hand, phytoplankton appear to be highly sensitive to Hg; most organisms display greatest sensitivity to this metallic ion (153–156). Hg is one of the most lethal heavy metals studied, with no known biological function. There are three forms of Hg, elemental, inorganic, and organic compounds. Inorganic Hg is far less dangerous than organic methyl Hg. Because of limited solubility, Hg compounds are deposited in bottom mud of rivers, lakes, and so on. Through biological processes Hg compounds are converted into dimethyl and methyl Hg and thereby enter the food chain (157).

Cd has widespread industrial usage and is capable of bioaccumulation (158). It is released as a result of electroplating and alloy preparation. Plants absorb Cd more readily than Pb. Cd binds to organic molecules through sulfur and nitrogen (159), thereby inactivating proteins. The degree of toxicity to Cd appears to vary depending on the algae used as a model (150–154).

Resistance of algae to toxicants has significance for bioremediation. Elucidation of the mechanisms for resistance may produce more efficient means to remediate contaminated waters or reclaim the metals involved. Algal resistance to heavy metals may be due to several mechanisms. These include production of extracellular chelating factors (160), the presence of heavy metal–resistant genes present in plasmids, or as part of the genome (134,161,162). Specific enzymes have been identified that are capable of reducing toxic heavy metals to forms that are nontoxic (163,164). Metallothionein-like compounds have been identified in several types of microorganisms that function in reducing the toxicity

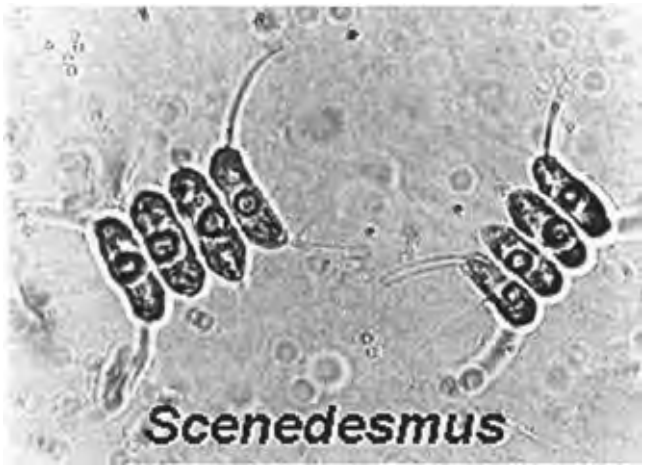

Figure 16. Chlorophyta-*Scenedesmus* sp. *http://vis-pc.plantbio.ohiou.edu/algaeimage/pages/Scenedesmus.html* See color insert.

of heavy metals. These compounds act by binding cysteine and lysine to heavy metals (165) thereby providing a mechanism by which the ions are incapable of adversely interacting with essential metabolic enzymes. Another detoxification mechanism is conformational changes in the cell wall that will trap the heavy-metal ions and prevent them from entering the cell (133). Most metals, when absorbed into the cytosol are concentrated in the vacuole and excluded from vital portions of the cell, such as the nucleus and chloroplast (166). Nassiri and colleagues showed that microalgae could develop a tolerance toward metallic pollutants by exclusion or by internal trapping (159). *Skeletonema costatum*, when exposed to Cd, Hg, or Zn forms electron-dense inclusions, multivesiculate bodies, and cytoplasmic tubules. Several trace metals including Cu, Pb, Hg, and Zn retard the flow of electrons in electron-transfer reactions of plant mitochondria and chloroplasts (167). It is currently possible to make use of some of these resistance mechanisms in products derived from algae. Thus dried biomass produced from *Chlorella* has been proposed for bioremediation (168) and polysaccharides from *Ascophyllum* can be used to remove

heavy metals (169). Similarly, genetic engineering may be used to produce strains of microalgae with greater resistance and ability to adsorb pollutants than those currently in use.

REMEDIATION

In view of increasing environmental protection control, the use of microorganisms has received attention in recent years as a means of removing soluble metallic ions from wastewaters. Existing treatment technologies may have problems with removal of the ions; therefore, alternative treatment techniques have been explored (170). Absorption of heavy metals by microbial cells has become recognized as an alternative to existing methods such as precipitation methods or use of synthetic ion exchangers. Several microorganisms have been studied, including bacteria (171), fungi (172), and algae.

Algae, like other aquatic microorganisms, have the ability to take up dissolved metals and other contaminants from the environment. Biooxidation by Cryptophyceae in lake water showed processes that can detoxify organic contaminants such as resorcinol (173). Polycyclic aromatic amines are promutagenic/procarcinogenic. Because they can accumulate and metabolize promutagenic pollutants, algae, in combination with other microorganisms, can be used in aquatic environments for the detection and conversion of environmental promutagens (174). Microalgae such as *Botryococcus-braunii*, can be used for hydrocarbon recovery, but results in lower cell viability (175,176). Bacteria and microalgae act symbiotically in wastewater treatment to provide for removal/metabolism of materials (177). The process, microalgae use the end-products of bacterial metabolism (carbon dioxide, ammonia, etc.,) and in turn, supply bacteria with oxygen for total degradation of organic compounds. The algae serve for reoxidation and mineralization, and contribute to the food chain (178). Filamentous *Oscillatoria* has been proposed as an agent to remove nutrients from secondary activated sludge effluent, and the proteins produced could be utilized commercially (179). *Spirulina maxima* grown in seawater has been suggested as a means of controlling pollution from anaerobic effluents of animal wastes and for harvest for high protein (19). Cultures of algae and *Daphnia* are raised in Holland on sewage effluent (Fig. 18).

Algal cell walls contain polysaccharides and proteins having amino, carboxyl, phosphate, and sulphate groups. The amino and carboxyl groups, and the nitrogen and oxygen of the peptide bond could be used for coordination bonding with metallic ions (180). Algae need not be living to act for biosorption. *Heterosigma akashiwo (hada) Hada*, which was inactivated by steam sterilization, showed biosorption of bivalent metal ions owing to binding to carboxylic- and phosphatic sites (181). Modification of carboxyl and amino surface functional groups has been shown to decrease the adsorption capacity of Cd (II) and Zn (II) binding with *Chlorella* (182) indicating the role these groups play with regard to metallic ion absorption. Carboxyl groups are considered to be the major metal-sequestering sites (104).

Figure 18. *Oscillatoria http://vis-pc.plantbio.ohiou.edu/algaeimage/pages/oscillatoria.html* See color insert.

pH plays an important role in the removal of metallic ions. The pH for optimum adsorption depends on the physiochemical conditions of the metal ions and the algae (168,180). The pH will affect the bond formation of the algal cell wall, particularly the amino groups, to the metallic ions. It has been found that higher pH provides for greater adsorption of Pb and (Ni) with *Chlorella* (168), and with the brown algae, *Fucus, Ascophyllum*, and *Sargassum* (183). However, at pH values above 5.0 for Pb and Cu, and 6.7 for Ni, the ions precipitate out of solution. pH may also affect the ionic form of the ions and therefore plays a role with regard to toxicity.

Many algae are known to be able to absorb and concentrate metal ions from dilute solutions and to accumulate them within the structure of the cells. The accumulation of trace metals can be of particular importance from several perspectives. Although accumulation of trace metals may not be of sufficient toxicity to the algae, magnification can occur up the food chain, disrupting the metabolism of higher organisms, thereby causing biomagnification. Similarly, absorption and accumulation can be used for metal reclamation with gold (Au), cobalt, and other ions (184–186) and remediation of industrial wastewaters (187,188). Use of algae for the biosorption of radioactive Strontium 90 and Yttrium 90 allows for concentrating and removal of these radionuclides (189). Acidophilic microorganisms including *Euglena* sp., have been proposed for the treatment of highly acidic minetailing waste to remove Ni–Cu sulphide minerals and other toxic heavy metals (190). Use of microorganisms including algae for the removal of Hg is less satisfactory because whereas the cells absorb the Hg, volatilization of significant quantities occurs (191).

Metal uptake by intact algal cells has been found to consist of two processes: (*1*) A rapid passive adsorption to the cell surface and (*2*) a slower metabolism-dependent uptake into the cytosol. Dead cells accumulate heavy-metal ions

to the same or greater extent as living cells. The passive process of adsorption is called biosorption (192). The sorption phenomenon is most frequently expressed by the Freundlich adsorption isotherm and is used for calculating the residual or adsorbed metal-ion concentration with application in wastewater treatment (180). The Langmuir isotherm is used to quantitatively determine sorption performance and reflects the attraction between the sorbent and the sorbate (168). The biopolymers involved include Na/Ca alginate, agarose, and cellulose-acetate. These biopolymers are nontoxic, selective, efficient, and inexpensive (193). When heavy metals are accumulated intracellularly, toxicity can occur that is not present in cell surface adsorption (194). Wehrheim and Wettern (195) compared dry weight of whole cells and isolated cell walls rather than definite surface area and found that isolated cell walls have 10-fold higher accumulation rates than whole cells for Cd, Cu, and Pb. Similar rates have been observed with *Vaucheria* (Fig. 19) (196), fungi, and bacteria (197–199). However, the amount of uptake varies depending on microbial biomass employed and the type of metal ion (200).

As a result, biosorption processes, which are the passive accumulation of metals by biomass, have been proposed as an efficient and cost-effective way of removing toxic heavy metals from industrial effluents (201). For cost-effectiveness, they can be manipulated for better efficiency and multiple reuse (202). Biosorption processes can be

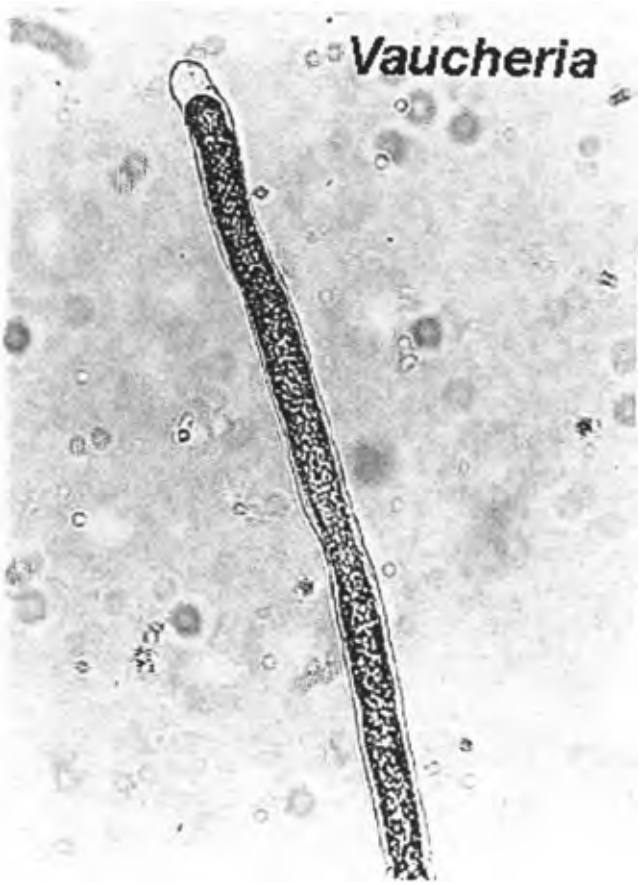

Figure 19. Xanthophyceae-*Vaucheria http://vis-pc.plantbio.ohiou.edu/algaeimage/pages/Vaucheria.html* See color insert.

produced from a wide range of algal and nonalgal sources, including dried biomass of *Chlorella* (168). Similarly, screening of 191 strains of marine microalgae showed that 24 of these were able to remove Cd from their growth media. *Chlorella* showed the highest rate of removal. Six strains out of 19 green algae and one out of five cyanobacteria removed more than 10% of total Cd from the medium. Although 12 days of incubation showed that most of the Cd was accumulated intracellularly, dried cells adsorb the ions more quickly than living cells (203). *Ascophyllum nodosum* produces a polysaccharide that provides it with the ability to remove and sequester high levels of Cd/g dry weight (169).

Biosorption of metals is not based on only one mechanism. It consists of several mechanisms that vary according to the species used, the origin of the biomass, and its processing (197). The mechanisms involve chelation, adsorption by physical forces, and binding to cell wall polysaccharides and amino, phosphate, sulfhydryl, and carboxyl groups in proteins. Within cells, heavy metals adsorbed strongly to biological membranes or to cytoplasmic polyphosphate bodies (152,204).

Combinations of ions can have a variety of effects in biosorption. Combination of Cr VI and Fe III indicate that these ions can act antagonistically with regard to levels of adsorption of Cr and Fe in *Chorella vulgaris* (205). Studies with reinforced *Ascophyllum nodosum* using two and three metal sorption systems containing Cd, Cu, and Zn have shown that Zn and Cu solutions showed an antagonistic effect on the uptake of Cd (197). Combinations of Cd, Cu, and Zn with formaldehyde cross-linked *Ascophyllum* showed that the total metal sorption increases at low concentrations, but each metal can inhibit the sorption of the others. At high metal concentrations the total metal sorption uptake is either constant or slightly decreases (206). However, there was little effect on uptake of Au by *Sargassum* biomass by other metal ions (207).

Chlorella has been found to be effective in adsorbing metallic ions (203). Dried cells showed high capacity for Pb adsorption and reached saturation within 10–15 minutes, with pH 5.0 being optimum (168). Comparison of whole cells and isolated cell walls indicated that whole cells accumulated more metal ions than cell walls using Cd, Cu, and Pb (195). Similarly, *Chlorella* was shown to have a stronger affinity for Cd II than Zn in uptake studies (182).

CONCLUSION

It is expected that future trends in algal biotechnology will involve the commercial development of additional products derived from algae. With improvements in culture methodology and harvesting of natural products, the cost for production of bioproducts from algae should make them competitive compared to production from synthetic sources. Similarly, the need for cheap, safe, animal feed will bring about increased aquaculture of algae for feed. Fish farming is increasing and therefore the need for high-quality feed. The search for antimicrobials, especially those that have antiviral properties or new

antibiotics to fight resistant bacterial strains represents an important area for future development.

Genetic engineering provides for a new area of biotechnology of algae. As genes are isolated and their functions determined, transfer of valuable genes from algae to other species will provide another avenue for bioproducts to be produced for commercial exploitation. Algal biotechnology is a field that has only begun to be developed and one with much promise for the future.

ALGAL BLOOMS — IMPACT ON TREATMENT, TASTE, AND ODOR PROBLEMS

GARY A. BURLINGAME
Philadelphia Water Department
Philadelphia, Pennsylvania

Algae are not regulated in drinking water. However, algae can cause water quality to exceed secondary maximum contaminant levels (SMCLs) such as color, taste, and odor. Algae can increase the pH above the SMCL limit of 8.5 and they can increase the threshold odor number above the limit of three. SMCLs are nonenforceable guidelines under the Safe Drinking Water Act as set by the U.S. EPA; however, in some states they have been adopted as enforceable standards. In most cases, algae are a nuisance. They affect the water's aesthetics or the water's usability. Algae are also known for their interference with the treatment of water. More recently, concern has been raised over the production of toxins by cyanobacteria (blue-green algae).

Although algae themselves do not typically pass into drinking water, their by-products often do. These by-products can be (*1*) chemicals released upon death or cell lysis, (*2*) chemicals formed by treatment, that is, chemical reactions with algae materials, or (*3*) chemicals released by the active algae before treatment.

WHAT ARE ALGAE?

The terminology is alga for the singular form and algae for the plural form of the word. The study of algae is called algology or phycology. Algae are related to plants because they contain pigments that cause photosynthesis to take place. They are eukaryotic organisms (their cells have a true nucleus as do plant and animal cells). But algae have no roots or leaves like plants. (There is an exception with the blue-green algae or cyanobacteria, and they will be mentioned in more detail later.) The cell wall of most algae is made of cellulose. The diatoms have an outer protective shell made of silica. When dead diatoms accumulate they form deposits called diatomaceous earth.

Algae are typically photoautotrophic: they only require light, water, and carbon dioxide to produce their own food source. Photosynthesis is the process in which light is absorbed by chlorophylls (green photosynthetic pigments) and converted to chemical energy (sugars). Chlorophyll *a* and *b* and *c* are common pigments, giving algae their green color. Other carotenoids are also present, such as those, which give rise to the color of the golden-brown algae.

Algae in water can be found in a variety of places: benthic algae are found in sediments, planktonic are free-floating, and periphyton are attached to aquatic plants, rocks, submerged debris, and walls. They can be found in

various waters, from salt water to freshwater and from swamps to hot springs. Planktonic algae are most often associated with taste and odor and filter-clogging problems at water treatment plants.

Algae also vary in physical structure, which makes them relatively easy to identify and differentiate. Algae vary in size from microscopic forms to aquatic seaweeds or kelp:

- Picoplankton are of the size 0.2 to 2.0 μm.
- Nanoplankton are of size 2 to 20 μm.
- Microplankton are of the size 20 to 200 μm and are the types involved directly in water-treatment problems.

Finally, algae differ in the ways their cells associate with each other. For example, they can be unicellular (Fig. 1), filamentous (Fig. 2), or colonial (Fig. 3).

In clear or slightly polluted water, diatoms are often found as planktonic algae. They are an important source of food for fish and wildlife. Increasing the nutrient pollution load (nitrogen and phosphorus) to the water causes a shift in the predominant forms of planktonic algae to filamentous green algae, colonial green algae, unicellular green algae, and blue-green algae. There are many variations and many other secondary factors also affect algal growth and predominance. Blue-green algae are often indicators of organic pollution or excessive nutrient loading. They can form blooms that, upon death of the cells, cause a depletion in dissolved oxygen, which in turn can result in fish mortality.

Figure 1. An example of a unicellular green alga (*Closterium* sp.). See color insert.

Figure 2. An example of a filamentous blue-green alga (*Oscillatoria* sp.) surrounding a single strand of a green alga (*Spirogyra* sp.). See color insert.

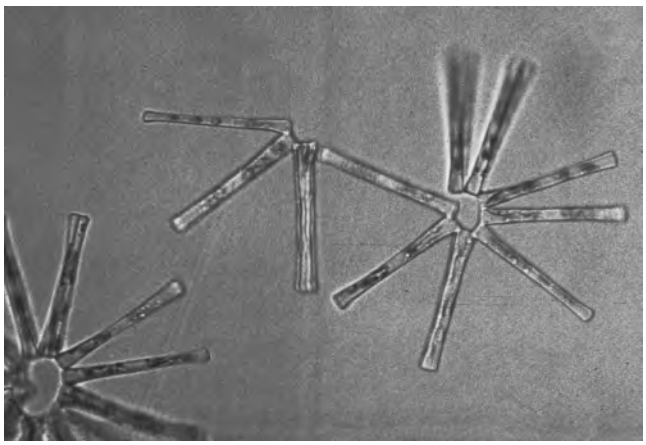

Figure 3. An example of a colonial diatom (*Asterionella* sp.). See color insert.

COMMON ALGAE THAT AFFECT DRINKING WATER

Waters in which algae are present are either surface waters (such as rivers, lakes, and reservoirs) or groundwaters under the influence of surface waters. These waters are required, in most cases, to be filtered to remove particulate matter such as algae. If treatment is insufficient, algae can pass into finished drinking water and have been found in water distribution systems. In general, water never contains a single alga specie, but always consists of some combination of algae species. Sometimes the alga of greatest dominance in water is not the alga causing the problem. Palmer's Guide to Algae (1) provided an empirical classification of algae according to their impacts on water supplies and treatment. Table 1 provides an overview of Palmer's guide. The following divisions of algae are of common concern for drinking water and its treatment (2).

Green Algae

Chlorophyta or the green algae are the largest and most diverse division of algae, which range from microscopic single-celled algae to colonial and filamentous algae (examples include the genera *Chlorella*, *Scenesdesmus*, *Spirogyra*, *Cladophora*, and *Ankistrodesmus*).

Dinoflagellates

Pyrrhophyta or the dinoflagellates are important components of plankton. They have flagella and, therefore, are motile and are typically single-celled in occurrence (examples include the genera *Peridinium* and *Ceratium*).

Table 1. Algae Associated with Certain Source Water and Treatment Conditions Based on Palmer's Guide (1)

Association:	Taste & Odor Problems in Tap Water	Clogging of Filters in Water Treatment	Nutrient Pollution of Natural Waters
Most often	Blue-green algae	Diatoms	Blue-green algae
Common	Pigmented flagellates	Blue-green algae	Pigmented flagellates
Infrequent	Diatoms	Green algae	Green algae
Least often	Green algae		Diatoms

Yellow-Green or Golden-Brown Algae

Chrysophyta or golden-brown algae include two classes of algae, which are important in drinking water treatment. The *Chrysophyceae* are pigmented flagellates (examples include the genera *Volvox*, *Pandorina*, *Synura*, *Peridinium*, *Chlamydomonas*). The *Bacillariophyceae* are the diatoms (examples include the genera *Cyclotella*, *Asterionella*, *Navicula*, *Melosira Diatoma*, *Fragillaria*, and *Synedra*).

Blue-Green Algae

Cyanophyta or blue-green algae are also known as cyanobacteria (examples include the genera *Oscillatoria*, *Microcystis*, *Anabaena*, *Aphanizomenon*). These algae are more closely related to bacteria than algae. They can be single-celled, colonial, or filamentous in occurrence, and can appear as floating scum or benthic mats, in eutrophic waters or stratified reservoirs. Blue-green algae are not plantlike in their cellular structure as are the other algae. They exhibit a gliding motility, have resting spores or endospores, have gas vacuoles to regulate their buoyancy, and can have a sheath surrounding the cells. They are diverse in their metabolism and are oxygenic photosynthetic bacteria. Some fix nitrogen and develop heterocysts for nitrogen storage. Some are found in symbiotic relationships in lichens.

Figure 4. Example of visible abundance of a blue-green alga as a surface scum on water. See color insert.

WHAT IS A BLOOM AND WHERE DOES IT OCCUR?

A bloom of an alga is commonly considered a visible abundance of plankton at the surface of water (Fig. 4). Algal blooms can also appear as carpetlike mats of algae attached to the bottom of a water body or to submerged matter (Fig. 5). Perhaps more accurately, in the context of water treatment, a bloom is a significant increase in the density of an alga to the point where the use of the water is negatively affected. For some algae a bloom could translate into a density of 100,000 cells per milliliter, whereas for others it could mean only 10,000 cells per milliliter of water or less.

An accepted cause of an algal bloom is the excess availability of nutrients such as phosphorus and nitrogen (3). Nutrients are considered very important in determining the types of algae that will grow. Nutrients can come from sources external to the body of water (farm runoff and wastewater discharges) or within the body of water (recycling from the sediment, aquatic vegetation). The three primary nutrients are carbon, nitrogen, and phosphorus. In most cases, there is no limit to the availability of carbon since carbon is derived by algae through photosynthesis from dissolved carbon dioxide. Phosphorus is most often the limiting nutrient. Sediments can contain insoluble phosphorus bound to iron, calcium, or aluminum. Under anaerobic or elevated pH conditions the bound phosphorus can become soluble and fuel an algal bloom. When phosphorus becomes the limiting nutrient, any addition of phosphorus can lead to green algae blooms. When nitrogen is limiting, this can select for blue-green algae, which can fix nitrogen from other sources. When a bloom occurs, an alga can deplete the nutrient that fueled the bloom and can, in turn, limit the bloom.

Although algal blooms occur most often during the warmer months of the year, clear lakes, which are enriched with nitrogen, during the late winter to early spring, can experience blooms of pigmented flagellates, diatoms, and green algae.

Depending on the characteristics of the lake or reservoir, the distribution both vertically and horizontally

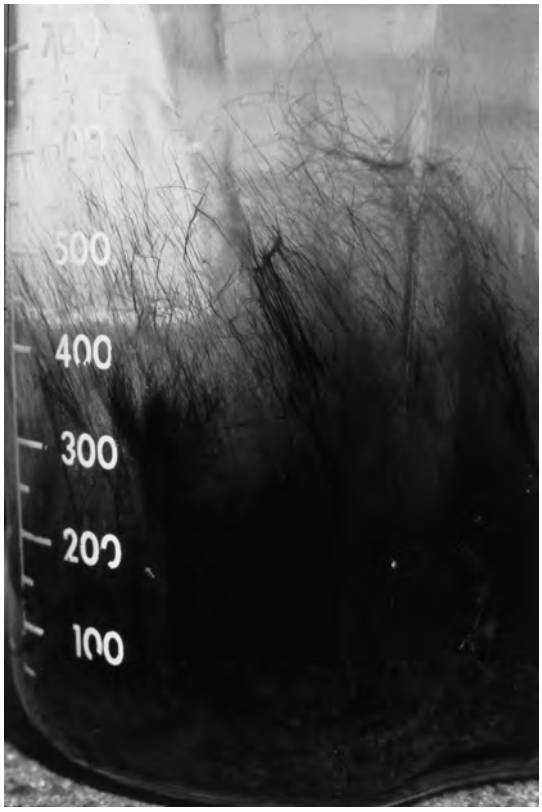

Figure 5. Example of how filamentous blue-green algae appear attached to bottom sediment. See color insert.

of nutrients, temperature, pH, light, and oxygen can result in different types of algae in different concentrations at different depths. As a result, the depth at which a treatment plant withdraws water from a reservoir can affect the types of algae that must be treated. It is important that a treatment plant manager develop an understanding of the source water. The ability to predict algal blooms to provide an early warning to water treatment operators depends on sanitary surveys of the watershed and measurements of nutrients such as total phosphate, nitrate, ammonia, total organic carbon, dissolved silica, dissolved oxygen, pH, water temperature, available light, and water turbidity.

OVERVIEW OF IMPACTS FROM ALGAL BLOOMS

There are two categories of impacts that algae can have on water treatment (2): direct impacts caused by presence of algae cells, and indirect impacts caused by cellular by-products. The direct impacts of algal blooms include filter clogging, surface scums, and change in color of the water. Indirect impacts include the production of odors, consumption of oxygen in the water when algae decompose, and change in the pH of the water.

Algae convert inorganic matter (carbon dioxide, nitrogen, phosphorus) to organic matter through photosynthesis. This organic matter makes up the algal cells. It can contribute to extracellular organic matter, which is excreted outside the cells. When algae cells are lysed, as by chemical treatment or stress, they release intracellular organic matter, which can affect water-treatment processes.

Perhaps the most dramatic impact caused by algal cellular products are caused by toxins (4,5). Freshwater blue-green algae or cyanobacteria can produce two important human and animal toxins. Hepatotoxins inhibit enzyme activity and can cause acute liver damage. Animal poisoning has resulted in animal mortality in one hour because of liver failure. They are produced by species of *Microcystis* (*M. aeruginosa* and *M. flos-aquae*), *Anabaena*, *Nostoc*, *Oscillatoria*. *Microcystis aeruginosa* is a commonly implicated cyanobacterium. Neurotoxins are nerve poisons and can cause death by respiratory distress. They are produced by such algae as *Anabaena flos-aquae* and *Aphanizomenon flos-aquae*. *Microcystis aeruginosa* can also produce a neurotoxin.

Toxins can have effects in two ways. Direct effects are where algae release their toxins into water, which is ingested, or the toxin is released after ingestion of the algal cells. Mediated effects are where the algae or toxin accumulate in a vector organism, such as shellfish, which is unaffected by the poison but causes illness when the vector is consumed. Human contact, rather than ingestion, can cause skin and eye irritation, whereas the ingestion of very low levels of toxin can cause gastrointestinal illness such as vomitting, cramps, and fever. (See also CYANOBACTERIA-TOXINS IN DRINKING WATER.)

OVERVIEW OF TREATMENT PROCESSES AFFECTED BY ALGAE

The following discussion explains the treatment stages of a conventional drinking water treatment system (6) (Fig. 6):

Presedimentation Basin

Some treatment works contain a presedimentation basin where treatment is achieved by gravity settling in a large basin at the head of the treatment plant. The primary purpose is for the removal of silt and sand and debris, which can damage pumps and processes. This basin also provides for additional emergency storage. Generally, presedimentation basins are ineffective at removing algal cells and may serve to increase algal production because of their long detention times.

Preoxidation

In the presedimentation basin or in the conduits that deliver water to the plant, an oxidant such as potassium permanganate, chlorine dioxide, or chlorine might be used to precondition the water or satisfy the oxidant demand. The demand can be caused by organic matter (algae, decaying plant matter, suspended natural organic matter) and inorganic matter (ammonia, iron, manganese). The achieving of this oxidant demand helps the plant operators achieve disinfection and produce stable water before it leaves the treatment plant. Aeration has at times been used to oxidize dissolved metals such as iron and manganese. Preoxidation can be effective at inactivating algal cells and at improving their removal in subsequent treatment processes.

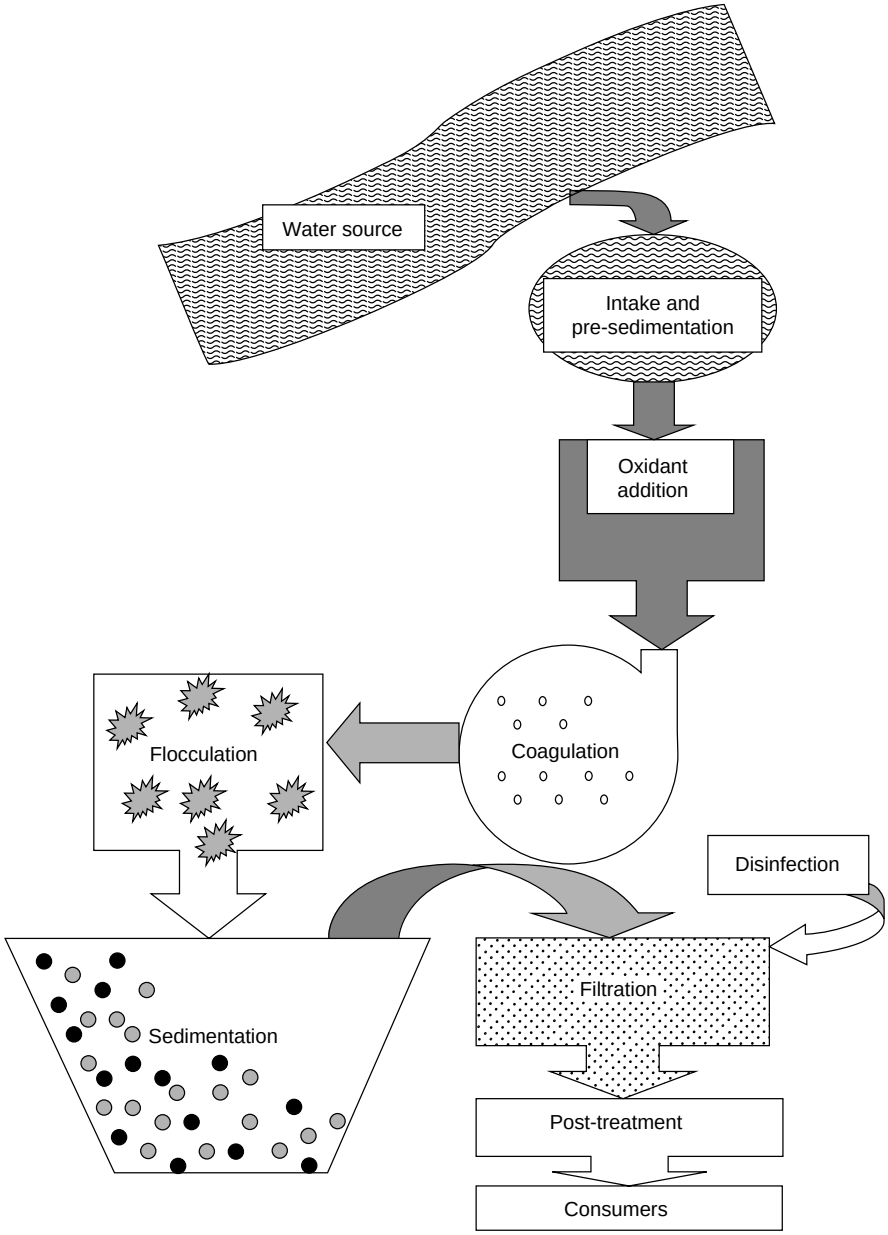

Figure 6. Stages of a conventional water treatment plant.

Coagulation/Flocculation/Sedimentation

Coagulation is the addition into water of coagulant chemicals to neutralize the surface charges of the remaining suspended matter. Aluminum salts (alum), and ferric salts such as ferric chloride and ferric sulfate, when added to water form hydroxide complexes in water. These positively charged complexes neutralize the negative surface charges of particles in the water, allowing them to stick together. This is followed by flocculation, which is the gentle mixing of water to cause the floc particles to collide and form larger particles that will settle out by gravity (sedimentation). Coagulation and flocculation are often followed by sedimentation and filtration. The combination of these processes constitutes a treatment train by which dissolved inorganic and organic matter, biological particulates, and suspended inorganic matter are removed from the water. This sequence of coagulant addition, rapid mixing, flocculation, and sedimentation has been commonly used in the treatment of surface waters and is effective at removing a large percentage of algal cells.

Filtration

Filtration by sand media, or a combined bed of sand and coal (dual media) has been commonly applied for the removal of suspended microscopic particulates and floc, which did not settle. Typical turbidity levels in well-run filter effluents can range from 0.1 to 0.3 nephelometric turbidity units or less. Turbidity is a measure of the light-scattering properties of water and, thus, is a relative measure of the suspended particulate matter in water. At

low turbidity levels, such as these, very few algal cells will have penetrated the filters.

Disinfection

Disinfection using chlorine, chloramines, or ozone is common. Disinfection renders the water free of microbial pathogens. Once the water has been adequately pretreated, the addition of a disinfectant to the water can effectively remove or inactivate most disease-causing organisms without interference from other organic and inorganic substances. Disinfection should also ensure that no viable algal cells are transmitted to the distribution system.

Posttreatment

Posttreatment can include fluoride addition, pH adjustment, corrosion control, and the addition of a disinfectant residual to make the water acceptable for distribution and storage in reservoirs. Posttreatment has little or no effect on the control of algal cells.

SUMMARY OF NEGATIVE IMPACTS FROM ALGAE ON TREATMENT

There are sources of information on the negative impacts of algae on water treatment processes (1,2). The size, shape, motility of algae, release of extracellular organic matter (EOM), and aggregation of algae affect the treatability of the algae. For example, algae that associate as dense rafts will more readily clog filters. Smaller, singly occurring algal cells can more readily break through the filters. Algae that have cell structures that prevent the proper formation of floc will interfere with the flocculation and settling processes. Motile algae can stay near the surface of settling basins and avoid getting caught in the floc that is settling out.

Control of Coagulant Demand

The amount of coagulant that must be added to water to achieve the process goal for coagulation, flocculation, and sedimentation is termed *the coagulant demand*. The process goal could be charge neutralization for the suspended particulates or it could be a reduction in total organic carbon or turbidity. Algae or their extracellular organic matter can induce an additional coagulant demand and interfere with the efficiency of the process.

Maintenance of Coagulation pH

The pH of the water is important for determining the actual mechanism by which particles settle out and the efficiency of the coagulation and flocculation processes. Algal blooms can increase the pH of the water above 9. Optimum coagulation pH is usually from 5.0 to 8.5 units. Treatment plants may not be able to counteract the pH increase. Water with an elevated pH then enters the coagulation and flocculation processes, thereby affecting the efficiency of the processes.

Performance of Settling and Clarification

Although algae can be effectively incorporated into the floc, the presence of the algae and their by-products such as extracellular organic matter and cellular oils may impair the settling of the floc. One effect is the carryover of algal cells and floc to the filters. The size and shape of the algae are two important factors in determining the extent of these effects to occur. It is generally believed that coagulation and flocculation should be preceded by oxidation to inactivate the algae.

Performance of Filtration

Algae that pass through the treatment processes and make their way onto the filters can cause the clogging of the filters. This requires more frequent filter backwashing, which increases turbidity and the quantity of wasted water. For example, rapid sand filters that are normally backwashed every forty hours into operation might have to be backwashed every twelve hours. Along with this effect on the filters comes a reduction in water quality. Increased backwashing of the filters and the penetration of algal cells through the filters can increase the turbidity of the finished water, but the largest effect of clogging is to limit the amount of water that the treatment plant can produce.

Disinfectant Demand and By-Product Formation

Algal cell products such as extracellular organic matter or products released upon cell lysis may constitute sufficient organic matter to react with oxidants such as chlorine to form disinfection by-products. The oxidation of algae cells causes cell lysis, which releases organic matter that itself will get oxidized and exert an oxidant demand. Chlorination by-products (trihalomethanes and haloacetic acids) are regulated under the Safe Drinking Water Act. Aldehydes are one other group of by-products. Sufficient levels of aldehydes can alter the odor quality of the finished water. Algae and their extracellular organic matter impart a chlorine demand, thus requiring increased use of chlorine in the treatment process, which increases disinfection by-product formation in general.

Overall Control of the Treatment Process

The treatment plant operator and manager must adjust chemical dosages and other process controls according to changes in water quality (such as during a rainstorm that washes excessive sediment into the source water and decreases alkalinity). Algal blooms that cause changes in chlorine demand, pH, coagulant demand, and filter operations require the plant operator to adjust treatment processes. Such changes impact other processes such as sludge management, storage of treatment chemicals as more chemical might have to be used, or the recycling of filter backwash water. In addition, adjustments to treatment to offset the direct and indirect effects of the algae can in turn increase turbidity, disinfection by-product formation, and change the chemical quality of the water. All of these issues must be carefully balanced.

Quality of Water Passed into Distribution and onto Customers

Changes in treatment or the inability of treatment to control the impacts of algal blooms can result in increased turbidity, lower chlorine residuals, increased disinfection by-products, and tastes and odors. These can negatively affect compliance with regulatory standards along with customer relations.

TASTE AND ODOR OF DRINKING WATER

One goal of the treatment process is to produce a drinking water that has minimal taste and odor (or flavor). One consequence is that customers become accustomed to the flavor of their tap water. Customers will complain if they detect a change in tap water flavor irrespective of whether that change is an improvement or not. Therefore, the flavor of water must be consistent. In the United States, the Safe Drinking Water Act requires that tap water contain a detectable residual of chlorine to control microbiological quality. Thus, the minimal flavor of tap water is a chlorinous flavor.

There are only four basic tastes (sweet, sour, salty, bitter). There are innumerable odor qualities (such as musty, earthy, fishy, grassy, rotten eggs, swampy, chlorinous) and their names are usually representative of associations or experiences (smells like fresh cut grass). Feeling sensations, produced at free nerve endings in the nasal and oral regions by chemical reactions, include drying, slick, metallic, and astringent. Changes in the inorganic and organic chemistry of drinking water have caused such off-tastes, off-odors and off-feeling-factor sensations.

IMPACTS ALGAE HAVE ON TASTE AND ODOR

There has been much research into the taste and odor of drinking water and the impacts that algae have on that quality (7–9). Findings of this research are summarized in the following section. Odors that have occurred in source waters include grassy, fishy, earthy, musty, cucumber, geranium-flowery, rancid, sulfide-like, decaying vegetation, aquarium, rotting hay, tobacco, and septic odors. The most common odors that affect drinking waters and cause customer complaints come from two naturally produced, compounds known as geosmin and 2-MIB. They impart earthy or musty odors to the water.

Geosmin ("earth odor") is an abbreviated name for trans-1,10-dimethyl-trans,9-decalol. This compound has been known since the 1960s. It is naturally produced, and blue-green algae are a common source, although not the only source. The odor of geosmin has been likened to earth, dirt, corn silk, and beets. It can be smelled at levels as low as about 5 nanograms per liter. Analytical detection methods exist for detection of this compound in water at these low levels. Typical levels in source waters are around 5 to 200 nanograms per liter.

2-MIB is an abbreviated name for 2-methylisoborneol. This compound has been known since the 1960s. It is naturally produced and blue-green algae are a common source though not the only source. The odor of 2-MIB is likened to earth, damp musty soil, and peat. It can be noticed as an odor at levels around 5 nanograms per liter. Analytical detection methods exist for detection of such low levels in water. Typical levels in water are around 5 to 100 nanograms per liter.

Cyanobacteria that have been reported to produce geosmin include *Anabaena*, *Aphanizomenon*, *Lyngbya*, *Oscillatoria*, *Phormidium*, *Schizothrix*, *Symploca*, and *Fischerella*. Cyanobacteria reported to produce 2-MIB include *Oscillatoria*, *Pseudanabaena*, *Synechococcus*, and *Phormidium* (8).

The decay of algae can produce sulfurous odors such as from dimethyldi- and dimethyltrisulfides (decaying vegetation, septic and fishy odors). The sulfides are decomposition products of proteins and amino acids. Other decay products include isovaleric and butyric acids, which give off rancid, sour milk, and dirty sock odors.

Grassy odors have been noticed during algal blooms and have been associated with *cis*-3-hexen-1-ol and *cis*-3-hexenyl acetate. The grassy odors sometimes are more noticeable after oxidation of the algae. Algae can produce linolenic acid, which has a watermelon type of odor, and this can degrade microbially to the grassy odorants *cis*-3-hexenal and *t*-2-hexenal.

A cucumber odor has been found to be produced by alga such as *Synura*. The responsible compound is *trans*,2-*cis*,6-nonadienal. This chemical is naturally produced and is also found in cucumbers and melons. The cucumber odorant can be detected as an odor down to levels under 10 nanograms per liter.

Fishy odors have been noticed during algal blooms. Fishy odors have been related to the compounds n-hexanal, n-heptanal, decadienal, and heptadienal. Some of these same compounds also produce fishy odor problems in fish oils and related products.

A hay-woody-tobacco-like or fruity-fragrant odor can be produced by other alga such as *Microcystis*. The odor comes from the chemical beta-cyclocitral. It is a degradation product of carotenes (which are cellular pigments).

The diatoms (*Asterionella*, *Tabellaria*, *Synedra*, *Melosira*) that bloom during the spring and fall, have been associated with grassy and fishy odors. The yellow-brown algae or pigmented flagellates that bloom sometimes in winter (*Dinobryon*, *Mallomonas*, and *Synura*) have been associated with cucumber and fishy odors depending on the stage of the bloom such as during the exponential stage of growth or during the death of the bloom. The green algae that bloom more typically during the summer have also been associated with grassy and fishy odors.

IMPACTS ON TAP WATER CONSUMERS

Consumers of tap water rely on their senses of taste and smell and sight to detect changes in water quality. Consumers can choose to install point-of-use treatment systems (such as faucet filters) or purchase bottled water to avoid consumption of water they do not trust or find

acceptable. Consumers can choose to register complaints with the water provider or with the local health agency and regulatory authority. Depending on the response they receive from the water provider and the attention given to the problem by the local media, their trust of the water provider can be greatly challenged.

EVIDENCE OF THE OCCURRENCE OF TASTE AND ODOR PROBLEMS

It is an unacceptable, but often unavoidable practice to wait until customers complain to know that an algae bloom has affected the taste and odor quality of the drinking water. There do exist some means by which to better predict the occurrence of algal blooms and better prepare for changes in treatment. For example, algal photosynthesis requires pigments such as chlorophyll. There are analytical techniques for measuring the chlorophyll content of water. On-line analyzers are available to help operators monitor trends in algal growths before the water turns green in color. Other predictors of algal blooms include water temperature, light transmittance, light availability, orthophosphate, ammonium nitrogen, nitrate nitrogen, dissolved silica, and pH. Finally, the odorous chemicals produced by algae can be monitored for increasing trends over time.

The actual source of a taste-and-odor problem may not be easy to find. The algal growth that is releasing an odorous compound could be in one of many coves of a reservoir, only in a certain bottom area of a body of water, only at a certain depth of a reservoir, or many miles up river from a treatment plant's intake.

OVERVIEW OF CONTROL OPTIONS

There are sufficient sources of information from treatment chemical manufacturers to treatment handbooks, which cover the options for control of algae and their associated problems (3,5,6–9). The following is a summary of these options.

Source Controls

Controls include chemical oxidation or inactivation, nutrient reduction, alteration of the ecological balance (in smaller reservoirs), and aeration or mixing. The average cost per year for algae control by treatment works ranged from 1,000 to 25,000 dollars during the 1980s (9). Controls are often initiated according to time of year, start of a taste or odor problem, occurrence of certain algae, and the temperature of the water.

If phosphorus is the limiting nutrient for a reservoir or slow moving river, it is possible that when the sediment becomes anoxic the bound phosphorus that had precipitated out redissolves into the water. With mixing or reservoir turnover this bottom concentration of dissolved phosphorus then becomes available to the algae. Attempts have been made to precipitate out the phosphorus with aluminum sulfate, aluminum silicate, and ferric chloride because phosphorus is tightly bound to aluminum hydroxides. The floc lays a blanket over the sediment and prevents recycling for a period of time.

Hypolimnetic aeration is the process of adding oxygen to the hypolimnion (colder bottom layer of water) without upsetting the stratification of the reservoir. This aeration is used in deep reservoirs that develop anoxic bottom layers. The aeration maintains the water density layers in the reservoir and helps prevent the recycling of phosphorus and the release of other nutrients, such as iron and manganese, from the sediment into the photic areas where algae thrive.

Artificial destratification is used in the late spring or early summer when reservoirs stratify. It attempts to mix the layers of water to prevent the bottom layer from becoming anoxic. It can be accomplished by hydraulically mixing the waters and by injecting air across the bottom. The objective is to keep the water uniform in temperature throughout the whole body of water. Mixing can also stir together the various types of algae growing at different levels, and thereby cause a shift to more favorable algae types. Other reservoir control options include removing sediment; harvesting aquatic vegetation; draining and cleaning the reservoir.

Algicides are chemical agents, which are toxic to algae. Copper sulfate has been the most common reservoir control option since about 1905. It is less effective for lakes, which have a high pH or high alkalinity or water temperatures below 15 °C. Algae vary in sensitivity and some can be quite resistant to copper sulfate such that its use can even encourage the growth of more problematic algae. Copper sulfate-type algicides can be fed to a reservoir as small crystals such as in a burlap bag filled with crystals and pulled behind a boat to dissolve the chemical into the water. Helicopters and boats can also apply larger crystals, which dissolve slowly and sink to reach the algae at lower depths or on the bottom of the reservoir.

Potassium permanganate has been used to control algae in the water source as well as algae coming into the treatment plant. However, it seems to work best as a pre-oxidant in the treatment plant. Potassium permanganate, in all cases, must be applied at a sufficient dosage and given sufficient time of contact.

Another control option is watershed management. This includes land use management, control of runoff and land development, use of agricultural practices that capture runoff, waterway preservation, and control of the use of chemicals in the watershed. Included is the reduction of nutrients by upgrading wastewater treatment plants to achieve better nitrogen and phosphorus removals.

A final option is avoidance of the source of water containing the nuisance algae. This includes providing multiple intakes in a reservoir, which allow the draw off of water from different depths, where algal blooms are not found. This also includes changing source waters.

Inplant Treatment Controls

Treatment can either physically remove or kill the algal cells. It is preferable to capture and settle out the algae, avoiding cell lysis and the release of intracellular toxins or organic matter, which could increase taste and odor,

chlorine demand, coagulant demand, or disinfection by-products. Chemical oxidation can kill the algal cells, or at lower dosages, immobilize motile algae so that they can be more readily trapped in floc. Oxidation also changes the surface of the cells, which can enhance or impede charge neutralization. This may aid or interfere with the removal of algal cells during flocculation.

Conventional particle removal treatment (coagulation, sedimentation, rapid sand filtration) is ineffective for soluble algal toxins. Adsorption onto activated carbon or oxidation can be effective in controlling the toxins. Lysed cells can release high levels of toxins, which may require the use of large chemical dosages. Therefore, it is preferable for treatment to remove the cells before cell lysis.

Jar testing is often used by treatment plant operators to determine the optimum dosages of treatment chemicals. The amount of coagulant added, the mixing energy, the settling time, the water temperature and the pH of the water all affect the efficiency of settling of the floc.

Treatment plant operators can measure charge neutralization with a streaming current detector, which gives a relative measure of the surface charge on particles in the water. One would, in the lab, add increasing amounts of coagulant until charge neutralization is achieved. Cationic, anionic, and nonionic polymers (flocculant aids) have been used to improve floc formation and settleability to get charge neutralization. Microsand enhanced flocculation and dissolved air flotation are other options for improving the physical removal of algal cells. This is important in preventing the loading of the filters with algae. The algal cells must be inactivated or immobilized and physically captured in floc and removal by sedimentation. The goal is to accomplish 90 to 99 percentage removal of algae before filtration without producing other negative side effects.

The predominant algae species in the surface water supply might not be the same species that cause filter clogging or that break through filtration into the drinking water. Algae vary in their propensity to resist different stages of treatment and even low counts of certain species can cause treatment or water quality problems.

Chemical oxidation attempts to accomplish a variety of tasks for algae control: inactivate the algae; oxidize taste and odor compounds; and prevent the biological formation of other odor compounds. Chlorine has been commonly used at dosages from 1 to 5 milligrams per liter and is effective for most algae and many algae odorants but causes formation of disinfection by-products. Chlorine dioxide has been used at dosages from 1 to 3 milligrams per liter in place of chlorine to reduce the formation of disinfection by-products. Ozone has been used at dosages from 1 to 3 milligrams per liter and has been effective for the control of geosmin or 2-MIB, which are not affected by other oxidants. Potassium permanganate at dosages from 1 to 5 milligrams per liter, though a relatively weak disinfectant, has been found to be effective for certain algae and certain odorants. For example, it works more effectively for the cucumber odor and does not form disinfection by-products.

Adsorption of By-Products

Although treatment can effectively remove algae from the water, algal intracellular and extracellular chemicals can still pass through into the treated water. Carbon has been used to adsorb algal by-products from the water. Carbon can be added to water in an activated powdered form (as a slurry that settles or filters out) or a filter can be made of granular activated carbon to adsorb the organic materials from the water. Since many algal blooms are infrequent or episodic in nature, powdered activated carbon has been the most commonly used form. Geosmin and 2-MIB have been removed up to 40 to 90 percentage of their initial levels. However, different types of carbon are more or less effective on different odorous compounds depending on the chemical quality of the water being treated.

CONCLUSION

Algae in source waters can affect drinking water quality. Typically, they affect the aesthetic quality of water (color, taste, odor) but some algae can impart toxins that have human health impacts.

Algae in source waters can affect drinking water treatment processes in a treatment plant. They can exert an oxidant demand, interfere with the removal of particulate matter, and clog filters.

The treatment of drinking water can be optimized to reduce the effects of algae on the treatment processes and the finished water quality. However, at times, source water treatments, watershed controls, selection of alternative water supplies, and advanced treatments have to be used because the problems caused by algae cannot be mitigated using existing treatment.

Much is known about algae, their impacts on drinking water quality and its treatment, and their control. Algal impacts can be documented and, at times, even predicted by water quality testing and algae monitoring. However, the solutions to problems caused by algae remain site-specific. Each water quality manager and treatment plant engineer must effectively apply existing experience and knowledge to secure a high quality drinking water for their consumers.

ALGAL TURF SCRUBBING: POTENTIAL USE FOR WASTEWATER TREATMENT

RUPERT CRAGGS
National Institute of Water and Atmospheric Research
Hamilton, New Zealand

Algal turf scrubbing (ATS) is a novel algal technology that has been designed and engineered to promote natural wastewater treatment processes. Algal turf scrubbing improves water quality by passing a shallow stream of water over the surface of a gently sloped floway in a series of pulses. The floway is colonized by a natural heterogeneous assemblage of periphyton consisting of filamentous algae and symbiotic aerobic bacteria and fungi. Algal photosynthesis provides oxygen for aerobic breakdown of wastewater by heterotrophic bacteria. Pollutants are extracted from the wastewater by several processes including assimilation, adsorption, filtration, and precipitation. The algal turf is periodically harvested to remove the accumulated periphyton biomass and associated pollutants from the system.

DEVELOPMENT

ATS was developed by Adey and coworkers at the Smithsonian Institution, Washington, D.C., during their research on coral reef ecosystems (1–4). Adey found that the algal turfs growing on coral reefs have very high growth rates despite the low nutrient concentrations ($mg\,m^{-3}$) in the surrounding seawater (3). The high growth rates were attributed to two main factors. First, the constant surging of seawater across the turf, which by turbulent mixing breaks down boundary layers and provides a constant supply of nutrients to the algae. Second, the efficient grazing of the algal turf by herbivorous invertebrates and fish maintains the turf species growth in exponential phase.

By using a screen to mimic the reef surface, a dump bucket to provide a wave of turbulent mixing, artificial lighting, and periodic manual scrapping of the screen to remove accumulated turf biomass, the algal turf scrubber can simulate these natural conditions (Fig. 1). Adey and Hackney (3) found that ATS provides a much more natural means of maintaining water quality and community structure in model coral reef ecosystems than bacterial filters and protein skimmers that are traditionally used in aquarium systems. Bacterial filters and protein skimmers are not suitable for use in ecosystem models as they filter out the zooplankton and larval stages of many aquatic organisms.

Following the success of the ATS system as part of the coral reef ecosystem model, ATS was used in several other ecosystem models at the Smithsonian Institution, including a salt marsh estuary, a northern temperate littoral system, and a tropical mangrove (2,5,6). ATS was used as an integral part of the 3,400 m^{-3} mesocosm of the Space Biosphere 2 project in Arizona (4,7). Algal turf scrubbers have been used to remove nutrients and maintain water quality in the aquarium systems of several cities in the United States, including Indianapolis, Pittsburgh, and St. Louis, and in the 2,500 m^3 Great Barrier Reef Aquarium in Townsville, Australia (4).

The use of ATS systems to treat aquaculture wastewater at pilot-scale has been demonstrated (3,4) and a full-scale Tilapia aquaculture facility is now operating in San Antonio, Texas. The system uses 1.6 hectares of parallel algal turf scrubber floways to treat the aquaculture wastewater, and the harvested algae biomass is used as a feed supplement for the fish (8).

In terms of wastewater treatment, small-scale laboratory experiments have indicated the potential of ATS systems to remove both refractory organic compounds and heavy metals from polluted water (9). The capability of

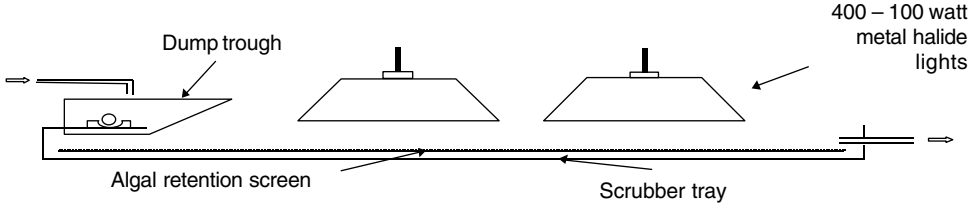

Figure 1. Schematic diagram of the component of ATS.

ATS to remove nutrients from agricultural runoff has also been demonstrated at pilot-scale using a 15.0-m long, 0.75-m wide algal turf scrubber floway (10).

The first large-scale ATS system for the treatment of domestic wastewater was constructed in Patterson, California (Plate 1). The capability of ATS to polish secondary treated wastewater at several influent flow rates (ranging from 108.9 $m^3 d^{-1}$ to 1,336 $m^3 d^{-1}$) was evaluated over a three-year period (1994–1996) (11,12). The system consisted of a single floway that was 152.4 m long, 6.5 m wide, and had a surface area of 1,012 m^2.

A second trial to assess the potential of an ATS floway to polish domestic wastewater was conducted at Fruitland, Maryland. The system consisted of 10 parallel, 91.4-m long floways, which were connected so that the effluent from the first floway was pumped to the top of the second and so on, until the wastewater was treated by all 10 floways. The system was evaluated over a one-year period (1998–1999) for its ability to treat secondarily treated wastewater at a flow rate of 284 $m^3 d^{-1}$ (8).

At the time of writing, the United States Department of Agriculture (USDA) in Beltsville, Maryland in association with the University of Florida, is evaluating ATS systems for treatment of cow manure. The systems consist of 200-m long, 1-m wide floways. Their ability to remove nitrogen and phosphorus from raw or anaerobically digested cow manure diluted with water is being determined. Two pairs of 50-m by 1-m floways (one pair at a 1% slope and the other at a 2% slope) are also under construction and will be used to study seasonal variation in algal growth and nutrient uptake rates (8).

Plate 1. The ATS pilot system at Patterson, California. See color insert.

ATS WASTEWATER TREATMENT SYSTEMS

Algal turf scrubbers are low-cost treatment systems, which are simple in design and construction (Fig. 2). The floway is formed from graded (0.25% to 2.0% slope), compacted earth covered with an impervious liner and an overlying biomass retention screen between two raised sidewalls. The liner may be constructed from any impervious material including concrete, asphalt, high-density polyethylene, polyvinyl chloride, or sprayed on asphalt rubber surfaces. Geomembranes with low thermal expansion are particularly suitable as they do not wrinkle or retain manufacturing creases.

Pulsed Influent

The influent is normally delivered to the ATS by a surging device, which releases the wastewater in a series of waves. Various techniques have been tested to produce pulsed wastewater application including pulsed pumping, counter weighted dump troughs, and displacement troughs. Pulsed application was found to be important in maintaining the treatment efficiency of marine ATS systems (3,4,13). However, research at Patterson showed that surged flow may not be necessary for freshwater and wastewater treatment systems (12). Freshwater algae may be better adapted to the continuous turbulent flow that naturally occurs in streams and rivers.

Water Depth

Algal growth on ATS systems declines with increased water depth (3). Vymazal (14) found that periphyton growth was much higher at shallow depth of 6 cm than at 64 cm. Therefore, the water depth of ATS systems is maintained between 2 and 4 cm to allow optimum exposure of the algal turf to sunlight.

Residence Time

One factor influencing the treatment efficiency of ATS systems is the time that the wastewater is in contact with the algal turf (the hydraulic residence time). A simple

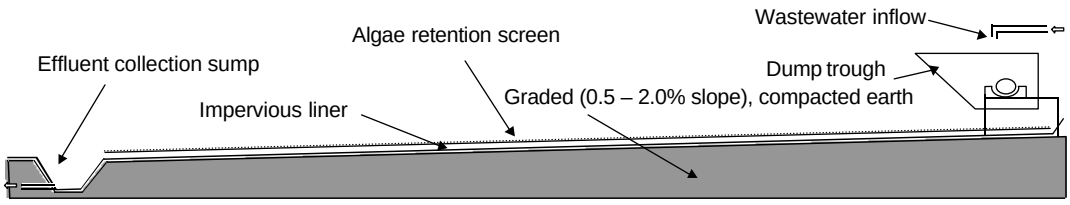

Figure 2. Schematic diagram of an ATS for the treatment of wastewater.

means of optimizing treatment is by controlling residence time, by changing the hydraulic loading velocity, or by passing the wastewater down a floway of variable length.

Hydraulic Loading Velocity. Reducing the hydraulic loading velocity of the Patterson ATS system from $1.36\ m\,d^{-1}$ to $0.44\ m\,d^{-1}$ increased removal efficiency and produced an effluent with lower concentrations of nutrients, total suspended solids (TSS), and biochemical oxygen demand (BOD) (11).

Floway Length. For a particular hydraulic loading velocity, a minimum length of floway is required for efficient treatment to be achieved. Some parameters (e.g., dissolved oxygen (DO), temperature and concentrations of all forms of nitrogen) have a linear correlation with floway length. Other parameters (particularly, pH, soluble reactive phosphorus concentration, hardness, and conductivity) change more rapidly at or after a particular floway length.

Algal Species

The algal species that typically occur on algal turf scrubbers can be divided into three ecological types: the mat-forming species consisting primarily of Cyanophyta, the green filamentous periphyton that grow through the mat to form a canopy (Plate 2), and the diatomaceous epiphytes that grow on the surface of the periphyton or are embedded within the mat (Fig. 3). The population density and algal species diversity of algal turfs in wastewater treatment systems are much lower than in systems treating agricultural drainage water and seawater (3,4,10,12). The dominant algal species is also strongly influenced by season. For much of the year they are cyanobacteria (specifically, *Oscillatoria* sp.) and diatoms (including *Navicula* sp., *Nitzschia* sp., and *Cyclotella* sp.). It is only in the summer that the green filamentous periphyton *Ulothrix* sp. and *Stigeoclonium* sp. are dominant with *Cladophora* sp., *Spyrogyra* sp., *Tribonema* sp., *Oedogonium* sp., and *Rhizoclonium* sp. present to a lesser extent.

The low population density and species diversity of algal turfs in wastewater treatment systems probably is due to the absence of algal spores in secondary treated wastewater compared to agricultural drainage water to seed the system (10) and the lack of recirculation, which

Plate 2. ATS filamentous algae canopy. See color insert.

provided a source of algal spores in the mesocosm and ecosystem model systems (4).

Seeding and Recirculation. Algal turf development and species diversity are much improved by seeding the floway with periphyton from nearby streams and rivers. This can be done either by placing the biomass retention screens in natural waterways and transferring them to the top of the floway once a turf has established or by collecting algal turf, breaking it up, and evenly distributing it over the floway surface. The latter method can bring a floway into full productivity after only a few weeks (12). Species diversity may also be maintained by recirculating a portion of the algal turf scrubber effluent to introduce algal spores with the influent.

Invertebrates

Several invertebrate species are found in wastewater algal turfs. The most abundant are amphipods and chironomid midge larvae. Chironomid infestation can be a significant problem because the larvae, which live in cocoons on the floway surface, dislodge the surrounding algal turf causing a reduction in algal turf standing crop. Chironomid problems have been observed in several other periphyton growth systems (15–17). A simple method of controlling chironomid populations on algal turf scrubber floways is by drying out the floway following harvest of the turf, especially as the productivity of the turf can be quickly restored by seeding.

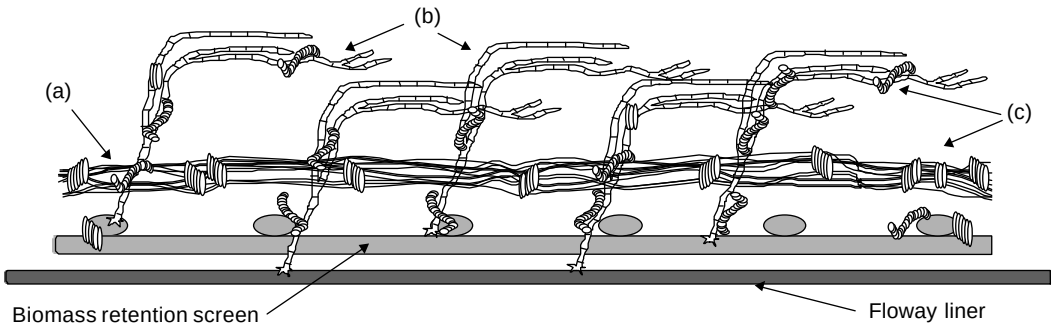

Figure 3. Schematic drawing of algal turf species growing on an ATS screen: (**a**) cyanobacterial mat, (**b**) green filamentous algae, (**c**) epiphytic diatoms.

Algal Standing Crop

Self-shading by accumulated turf biomass is one major factor limiting the growth rate and productivity of the turf algae. This can be prevented by frequent harvest, although a sufficient standing crop of algal biomass is required to maintain regrowth of the turf and effective treatment immediately following harvest. Several operational parameters influence the standing crop of ATS systems, and these are harvest technique and interval, and growth surface texture.

Harvest Technique. Harvesting the floway has several roles. It physically removes all the pollutants accumulated by the algal turf from the system before they naturally slough off. It simulates heavy grazing of the plant community, which has been shown to stimulate algal growth and nutrient removal (4,17,18). Harvesting also controls the population densities of most invertebrate grazers so that pollutants remain entrapped in the turf community and are not reintroduced into the water. Harvest is achieved by initially stopping the flow of wastewater and allowing the water to drain from the floway. Several harvest methods have been successfully employed, including both manual scraping or vacuum suction of the screen surface on the floway as well as removal and scrapping of a screen that is rolled up off the floway. Vacuum harvest, which was found to reduce the population density of filamentous algae, is not as suitable as harvest by scraping (12).

Harvest Interval. Because the growth rate of algal turf varies with season, treatment performance can be improved by varying the harvest interval over the year to maintain sufficient biomass on the ATS floway. A harvest interval of less than one week may be appropriate when the highest productivity is achieved during summer, whereas intervals of up to a month may be required during winter when productivity is at its lowest.

Growth Surface Texture. The texture of the floway liner seems to be of particular importance for the maintenance of algal species diversity and the promotion of turf productivity. Particularly, the addition of a biomass retention screen to the floway surface improves treatment performance by increasing the surface area available for turf colonization and retaining a larger standing crop of filamentous algae beneath the screen following harvest (Plate 3). Biomass retention screens were used in much of the original research conducted on ATS (3,4,9,13). The mesh becomes impregnated with algal holdfasts and rhizoids, which are not removed during harvest (4,19). Algal productivity has been found to vary with screen mesh size (optimum mesh size appears to be between 1 mm and 5 mm) and color (3). The lower turf productivity of black screens is possibly due to its greater absorbance of heat than white screens, which may inhibit algal growth.

Algal Turf Productivity

There is a gradual decline in the productivity of the algal turf down the length of the floway. Algal turf productivity (total solids dry weight) averaged for the whole floway can attain values of up to 61 $g\,m^{-2}\,d^{-1}$, although the annual mean productivity (24 $g\,m^{-2}\,d^{-1}$) is similar to that previously reported for periphyton water treatment systems (10,12,17). Sedimentation, filtration, and precipitation of particulates on the floway surface contribute to the accumulation of algal turf solids, such that nearly 50% of turf dry weight is nonvolatile and contains high concentrations of calcium (Ca) and magnesium (Mg).

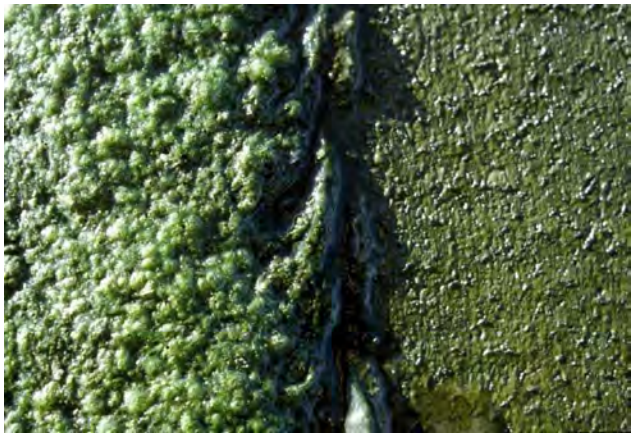

Plate 3. Unharvested (left) and harvested turf biomass (right) on an ATS floway without a biomass retention screen. See color insert.

WASTEWATER TREATMENT CAPABILITIES

Algal turf scrubber wastewater treatment systems have been demonstrated to improve water quality in many ways. They increase dissolved oxygen concentrations to between 100% and 300% saturation during the day and reduce alkalinity, conductivity, and hardness (11).

BOD, TSS, and turbidity of wastewater can be removed by ATS treatment. Removal is due to filtration of particulates by filamentous algae and bacterial oxidation. Particulate filtration is increased when the predominant turf algae are filamentous rather than the mat-forming cyanobacteria and diatoms (12). Bacterial oxidation of BOD varies diurnally, correlating with dissolved oxygen concentration. Mean annual concentrations in Patterson secondary treated wastewater, BOD (10 $g\,m^{-3}$), chemical oxygen demand (COD) (45 $g\,m^{-3}$), and total organic carbon(TOC) (10 $g\,m^{-3}$) were minimally affected and are probably close to background levels for ATS systems. Removal of BOD and COD by ATS systems was shown by Adey and coworkers (9) although the operational parameters of the recirculating mesocosm system used in that study are very different from those of a single pass wastewater treatment floway. The capability of ATS floways to significantly remove BOD remains to be evaluated.

Pathogen and Indicator Removal by ATS

Because of the shallow water depth and large surface area of ATS systems, wastewater is exposed to high amounts of

solar-ultraviolet (UV) radiation, which can result in a high removal rate of the fecal indicator bacteria *Escherichia coli* (11). However, because of the very short residence time (typically 20 to 40 minutes) of wastewater on the ATS floway, there is little (<1 log) overall reduction in fecal coliform bacteria concentrations by this system.

Nutrient Removal

ATS systems have been shown to reduce nutrient concentrations to low levels in agricultural runoff and marine systems. In coral reef mesocosms, nitrate can be maintained at levels between 7 and 14 $mg\,m^{-3}$ (4). This level is limited by the nitrogen fixation of cyanobacteria present in the system. Phosphorus can be reduced to levels below limits of detection.

ATS wastewater treatment systems are effective at removing nitrogen and phosphorus from secondary treated wastewater, with greater removal achieved at higher influent concentrations. Nutrient removal is a result of several microbiological and physical processes (Fig. 4) that are affected by a number of parameters, including hydraulic loading, the seasonal change in turf growth and species, and attainment of a pH greater than 9.0 in the floway effluent. Reduction of nutrient concentrations to $mg\,m^{-3}$ levels is limited in wastewater treatment systems as there is not enough available organic carbon to enable the nutrients to be assimilated into algal turf biomass. Addition of a carbon source to the wastewater on the floway when carbon is limiting may enhance nutrient removal by the system.

Nitrogen Removal

(see also ACTIVATED SLUDGE — MICROBIOLOGY OF NITROGEN REMOVAL.)

All forms of nitrogen can be removed by ATS wastewater treatment systems. Particulate nitrogen removal is related to the dominance of filamentous species on the floway. The simultaneous removal of both ammoniacal-nitrogen and nitrate is due to the mixed assemblage of algal species including both cyanobacteria that generally prefer nitrate and filamentous green algae that prefer ammonium as a nitrogen source. However, as nitrate is the principal form of inorganic nitrogen in secondary treated wastewater, algal species that prefer nitrate tend to dominate the turf. Annual mean inorganic nitrogen levels in the Patterson influent and effluent were 9.2 $g\,m^{-3}$ and 6.1 $g\,m^{-3}$, respectively. The longer Fruitland ATS system reduced inorganic nitrogen levels from 20 $g\,m^{-3}$ to 4 $g\,m^{-3}$ and could probably be enhanced if additional carbon was added.

Phosphorus Removal

(see also ACTIVATED SLUDGE — MICROBIOLOGY OF NITROGEN REMOVAL.)

Mean annual total phosphorus concentrations in the influent and effluent of Patterson ATS systems were 3.1 $g\,m^{-3}$ and 1.5 $g\,m^{-3}$, respectively. Periphyton can remove phosphorus from wastewater by a combination of filtration, adsorption, assimilation (including luxury uptake), and precipitation (20). Most of the phosphorus removal in ATS wastewater treatment systems is by assimilation into algal biomass or by precipitation of soluble reactive phosphorus (SRP), which is the main form of phosphorus in secondary treated effluents. Precipitation of SRP with cations such as Ca^{2+}, Mg^{2+}, and Al^{3+} is known to occur at pHs between 8.9 and 9.5, depending on the buffering capacity of the water (21). SRP removal therefore is dependent on the wastewater pH reached while the wastewater is on the floway. The increase in the pH of the ATS effluent is a result of carbon limitation of the turf algae and their subsequent use of bicarbonate as a carbon source for photosynthesis (22). At Patterson, a threshold pH of approximately 9.0 was required before SRP removal occurred to any great degree.

Reducing the hydraulic loading velocity of the ATS system from 1.4 to 0.11 $m\,d^{-1}$ increases the residence time of the wastewater on the floway and the pH attained in the floway effluent, hence SRP removal by precipitation is improved. SRP precipitation on the algal turf scrubber floway is indicated by the reduction of alkalinity, hardness, and conductivity that occurs as the pH of the effluent increases. Maintenance of the pH of the ATS system effluent above the level at which phosphate precipitates may provide an effective means of controlling SRP removal by ATS systems. The threshold pH may be easily achieved by controlling the length of time the wastewater is in contact with the algal turf. This may be done either by altering the hydraulic loading rate of the floway or by

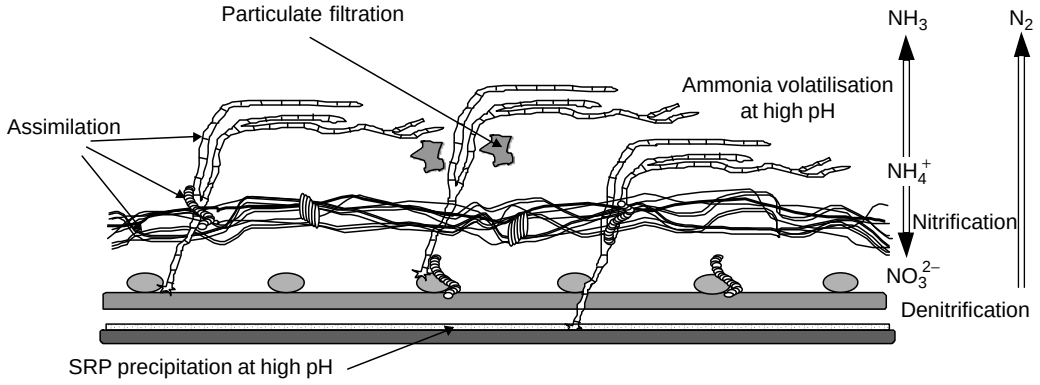

Figure 4. Schematic drawing of nutrient removal processes that occur on an ATS.

passing the wastewater down different lengths of the floway. However, other factors need to be considered in determining the residence time of the floway, such as the temperature attained in the ATS effluent, which may restrict algal growth (12).

Nighttime decline of the ATS system effluent pH to below the threshold pH results in the dissolution of some of this precipitate and the release of SRP back to the ATS effluent. Discharge of this released SRP can be prevented either by recirculating the ATS effluent at night or by greatly reducing the flow at night such that little or no water is discharged until the effluent pH has risen above the threshold again.

ATS systems could be designed to enhance phosphorus removal from wastewater by a two-stage process (11). The first floways would be only operated during the day and have low hydraulic loading to promote pH-mediated precipitation with cations. This would be followed by the second floways with high hydraulic loading and perhaps recirculation to promote rapid algal growth and assimilation of phosphorus into the algal biomass. The efficiency of treatment under both of these modes of operation is affected by the amount of biomass on the floway (11). Frequent harvesting would maintain an exponential growth of the biomass in the second floways, whereas a longer harvest interval would maintain a large standing crop to raise pH in the first floways.

Algal Turf Nutrient Content

The mean annual percentages of nitrogen and phosphorus in the accumulated solids of the ATS floway at Patterson were 3.96% and 1.83%, respectively (11). The values for nitrogen are typical of algal biomass. However, those for phosphorus are higher than that (<1%) normally associated with periphyton biomass (17,23–25). Adey and coworkers (10) found a phosphorus content of 0.4% in periphyton grown on agricultural runoff. The high phosphorus content of the algal turf of ATS wastewater treatment systems further indicates the role of pH-mediated SRP precipitation in phosphorus removal.

On the basis of percentages of nitrogen and phosphorus in the accumulated solids and the mean annual turf solids accumulation rate ($24\ g\,m^{-2}\,d^{-1}$), the mean removal of nitrogen was $0.95 \pm 0.48\ g\,m^{-2}\,d^{-1}$ and the mean removal of phosphorus was $0.44 \pm 0.22\ g\,m^{-2}\,d^{-1}$. The pilot ATS system treating agricultural runoff achieved phosphorus removal rates of $0.12\ g\,m^{-2}\,d^{-1}$ (10). Mass balance calculations of the wastewater treatment system show that more nitrogen is removed than is accumulated in the algal turf and indicate that denitrification does occur, perhaps in anoxic micro environments of the algal turf.

Algal Turf Biomass

The solid content of harvested turf biomass usually does not exceed 5%. However, the fibrous material may simply be dried using drying racks or sand beds and is otherwise suitable for dewatering by filter press or drum and spray dryers. Finding a use for the turf biomass remains unresolved, although there are several potential applications (11):

Fertilizer: Dried or composted algal turf biomass is very suitable for use as a high-quality soil amendment and slow-release fertilizer.

Energy: The turf biomass could also be used to produce energy through fermentation to alcohol or methane gas.

Feed: Turf algae have a high protein content and thus could be used as a feed additive for ruminants, poultry, and fish.

CONCLUSION

Algal turf scrubbers are capable of removing nitrogen and phosphorus from secondary wastewater without added chemicals and with minimum energy expenditure. When covered with filamentous algae, ATS systems are capable of filtering significant amounts of suspended solids and the BOD, TSS, nitrogen, and phosphorus associated with these suspended solids. Inorganic nitrogen removal is due to assimilation and some denitrification, whereas soluble reactive phosphorus removal is a result of assimilation and precipitation. Maintenance of the pH of the ATS system effluent above the threshold at which precipitation occurs could provide a simple means of controlling phosphorus removal by ATS. Control of phosphorus removal by ATS systems may be achieved by altering the length of time the wastewater is in contact with the algal turf, either by reducing the hydraulic loading velocity of the floway or by passing the wastewater down a longer floway. Stopping overnight flow until the threshold pH is regained the following day also prevents resolution of precipitated phosphorus at night. A comparison of the hydraulic loading velocities used for the Patterson ATS wastewater treatment system with those for pond and wetland treatment systems (26–28) indicates that a hydraulic loading velocity of as low as $0.25\ m^3\,m^{-2}\,d^{-1}$ would remain economical (Table 1).

ATS treatment systems have good potential for the removal of nutrients and other contaminants from wastewaters. The simplicity of ATS treatment systems and the ease with which configuration and operational parameters such as hydraulic loading, floway length, and harvest period can be changed should enable process

Table 1. Comparison of the Typical Hydraulic Loading Rate of ATS Floway Wastewater Treatment Systems to Those of Other Wastewater Treatment Methods

Treatment Method	Hydraulic Loading Rate ($m^3\,m^{-2}\,d^{-1}$)
Activated sludge	10–50

ALKALIPHILES: ALKALINE ENZYMES AND THEIR APPLICATIONS

KOKI HORIKOSHI
Kanagawa and Toyo University
Kawagoe, Japan

There are no precise definitions of what characterizes an alkaliphilic or an alkali-tolerant organism. Several microorganisms exhibit more than one pH optimum for growth, depending on the growth conditions, which are influenced by nutrients, metal ions, and temperature. Therefore, in this article, the term *alkaliphile* is used for microorganisms that grow optimally or very well at pH values above 9, often between 10 and 12, but cannot grow or grow only slowly at the near-neutral pH value of 6.5.

The discovery of alkaliphiles occurred fairly recently. Only 16 scientific papers on alkaliphiles could be found when the author started experiments on alkaliphilic bacteria in 1968 (1). Since then, the author and his colleagues have isolated a great number of alkaliphilic microorganisms using a variety of different media. Alkaliphiles are a diverse group, including representatives from the three major domains of life; many of these have been proposed as new taxa. They can be isolated from nominal environments, but viable counts of alkaliphiles are higher in alkaline environments. The particular adaptations of alkaliphiles to their environment are not completely understood, but it is thought that the cell surface plays a key role in maintaining the intracellular pH between 7 and 8.5.

The industrial use of alkaliphilic microorganisms has a long history in Japan. From ancient times, indigo

from indigo leaves has been reduced by the particular bacteria that grow under the highly alkaline conditions of the traditional process called "indigo fermentation." The most important factor in this process is the control of the pH value. Formerly, this could only be accomplished by the skill of the craftsmen. It was not until we rediscovered alkaliphiles that the process could be studied and understood from a microbiological point of view. Even then, alkaliphiles remained little more than interesting biological curiosities, and no further industrial application was attempted or even contemplated. The situation has changed since then. The first paper concerning an alkaline protease was published in 1971 (2). Now, biological detergents contain enzymes, notably proteases and cellulases derived from alkaline bacteria; 60% of the total world production of enzymes is destined for the laundry detergent market. The industrial production of cyclodextrin using cyclomaltodextrin glucanotransferase is another important application of alkaliphile-derived enzymes. This enzyme reduced the cost of production and paved the way for the use of cyclodextrin in large quantities in foodstuffs, chemicals, and pharmaceuticals. It has also been reported that alkali-treated woodpulp could be biologically bleached by xylanases produced by alkaliphiles. Other applications are also contemplated.

GENETIC MAPS OF CHROMOSOMAL DNAS OF ALKALIPHILIC *BACILLUS* STRAINS

How alkaliphiles have adapted to their alkaline environment is one of the most interesting and challenging topics facing microbiologists. In addition, the genes of alkaliphiles are potentially a valuable source of information waiting to be explored and exploited by biotechnologists. Physical maps of the chromosomes of two alkaliphilic *Bacillus* strains, *Bacillus pseudofirmus* OF4 (3) and *Bacillus halodurans* C-125 (4), have been published; the complete sequence of the genome of *B. halodurans* C-125 has also been determined (5). The physical map of the chromosome in *B. pseudofirmus* OF4 is consistent with a circular chromosome of approximately 4 Mb, with an extrachromosomal element of 110 kb (3,6). Although the analysis is still in progress, several open reading frames for Na^+/H^+ antiporters that may be involved with pH homeostasis have been detected. The physical map of the chromosome in *B. halodurans* C-125 is consistent with a circular chromosome of approximately 4.20 Mb. As can be seen in Figure 1, many open reading frames show significant similarities to those of other microorganisms, such as a fragment of an intracellular serine protease from *Thermoactinomyces* sp. HS682 or a G6-amylase from the

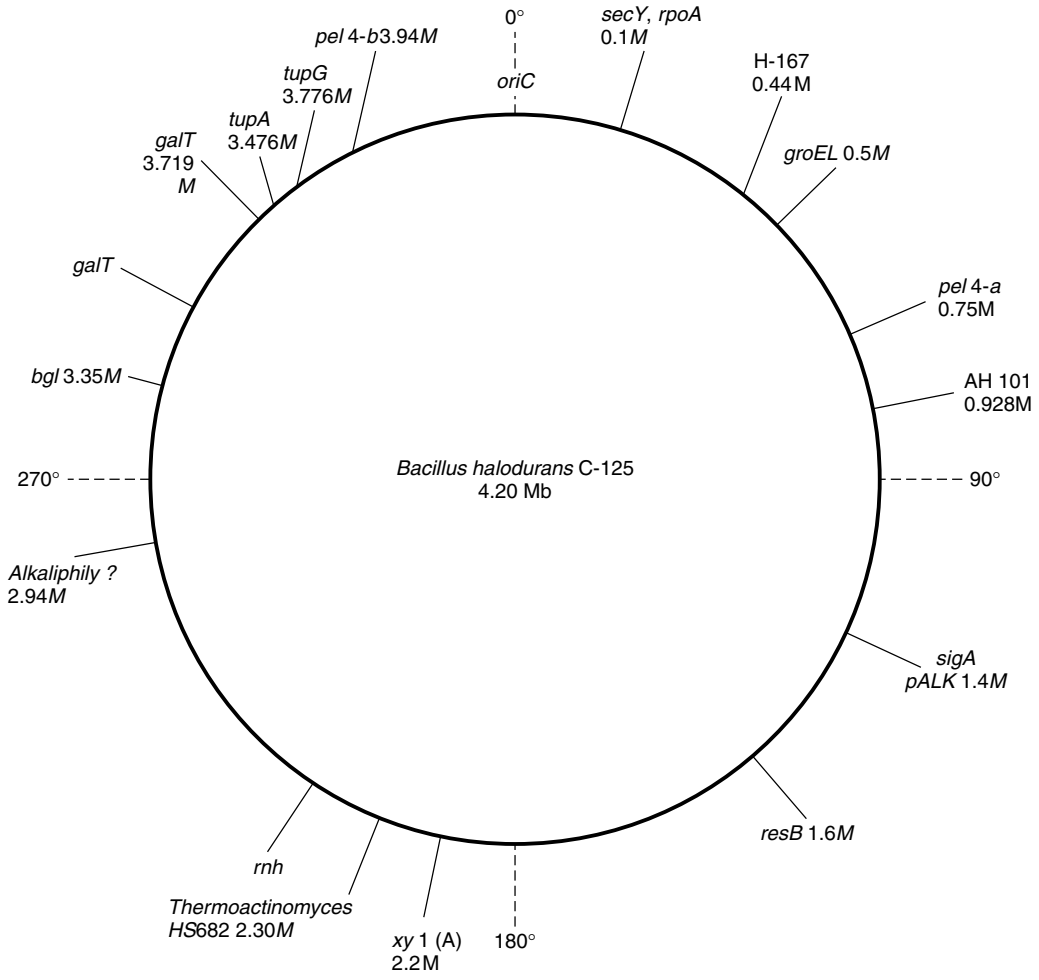

Figure 1. Genetic map of the chromosome of *B. halodurans* c-125.

alkaliphilic *Bacillus clausii* H-167. These DNA fragments do not code for functional enzymes because they are truncated, but they do suggest that there must be some degree of horizontal gene transfer between *B. halodurans* and other microorganisms (5,7–11).

MECHANISMS OF CYTOPLASMIC pH REGULATION

The cells of *B. halodurans* C-125 have two barriers to reduce pH values from 10.5 to 8.

The plasma membrane must be kept below pH 9 because it is very unstable at alkaline pH values much below the pH optimum for growth (12). It has been suggested that the cell wall may play a role in protecting the cell from alkaline environments. In addition to peptidoglycan, alkaliphilic *B. halodurans* C-125 contains certain acidic polymers, such as teichuronopeptide, composed of polyglucuronic acid and a polypeptide of acidic amino acids. The negative charges on the acidic non-peptidoglycan components may act as a barrier to sodium and hydronium ions and repulse hydroxide ions, and consequently, may assist cells to grow in alkaline environments (13,14). Aono and coworkers reported that teichuronopeptide (TUP) is one of the major structural components of the cell wall of *B. halodurans* C-125. A mutant defective in TUP synthesis grows slowly at alkaline pH. An upper limit of pH for growth of the mutant was 9.4, while that of the parental strain C-125 was 11.0. A gene *tupA*, directing synthesis of TUP, was cloned from the parental C-125 chromosomal DNA. Introduction of the *tupA* gene into the TUP-defective mutant complemented the mutation responsible for the pleiotropic phenotypes of the mutant, leading to simultaneous disappearance of the defect in TUP synthesis, the diminished ability for cytoplasmic pH homeostasis, and the low tolerance for alkaline conditions. These results demonstrate that the acidic polymer TUP in the cell wall plays a role in pH homeostasis in this alkaliphile (15).

Plasma membranes may also maintain pH homeostasis by using Na^+/H^+ antiporter system ($\Delta\Psi$-dependent and ΔpH-dependent), K^+/H^+ antiporter and ATPase-driven H^+ expulsion. Recent works in several laboratories on the critical antiporters have begun to clarify the number and characteristics of the porters that support active mechanisms of pH homeostasis (see AEROBIC ALKALIPHILES).

The author's group isolated a non-alkaliphilic mutant strain from *B. halodurans* C-125 as the host for cloning genes related to alkaliphily. A 3.7-kb parental DNA fragment (pALK fragment) from the parental strain restored the growth of an alkaline-sensitive mutant 38,154 at alkaline pH. The transformant was able to maintain an intracellular pH that was lower than the external pH and contained an electrogenic Na^+/H^+ antiporter driven only by $\Delta\Psi$ membrane potential, interior negative. Membrane vesicles prepared from the mutant 38,154 did not show membrane potential $\Delta\Psi$-driven Na^+/H^+antiporter activity. These results indicate that the mutant 38,154 affects, either directly or indirectly, electrogenic Na^+/H^+ antiporter activity. This was the first report of a DNA fragment responsible for a Na^+/H^+ antiporter system in the mechanism of alkaliphily (16–22).

Independently, Aono and coworkers isolated an alkali-hypersensitive mutant AS-350 from *B. halodurans* C-125 as a host for protoplast transformation. A gene that restored the alkaliphilic growth of the mutant was cloned from the parent strain (23). The mutation in the AS-350 was complemented with a 1.0-kb fragment expressed as "Alkaliphily" in Figure 1. However, role of this fragment is not yet clear.

Krulwich and her coworkers have focused their studies on the *B. pseudofirmus* OF4, which is routinely grown on malate-containing medium either at pH 7.5 or at pH 10.5. Current work is directed toward clarification of the characteristics and energetics of membrane-associated proteins that must catalyze inward proton movements (see the previous section by M. Ito).

ALKALINE ENZYMES

Studies of alkaliphiles have led to the discovery of many types of enzymes that exhibit interesting properties. The first report concerning an alkaline enzyme published in 1971 described an alkaline protease produced by *Bacillus* sp. 221 (2). More than 100 new enzymes have been isolated and purified in many laboratories (24). Some of these are summarized in Table 1.

Alkaline Proteases

In 1971, Horikoshi (2) reported the production of an extracellular alkaline serine protease from alkaliphilic *B. clausii* No. 221. This strain, isolated from soil, produced large amounts of alkaline protease that differed from the subtilisin group. The optimum pH of the purified enzyme was 11.5 with 75% of the activity maintained at pH 13.0. The enzyme was completely inhibited by diisopropylfluorophosphate or 6 M urea but not by ethylenediamine tetraacetic acid or *p*-chloromercuribenzoate. The addition of a 5 mM solution of calcium ions was reflected in a 70% increase in activity at the optimum temperature (60 °C). The gene encoding this enzyme was cloned in *E. coli* and expressed in *Bacillus subtilis*. An open reading frame of 1,140 bases, identified as the protease gene was preceded by a putative SD sequence (AGGAGG) with a spacing of 7 bases. The deduced amino acid sequence had a peptide of 111 residues followed by the mature protease comprising 269 residues (25). Subsequently, two *Bacillus* species, AB42 and PB12, which also produced an alkaline protease were reported (61). These strains exhibited a broad pH range of pH 9.0 to 12.0, with a temperature optimum of 60 °C for AB42 and 50 °C for PB12. Since these reports, many alkaline proteases have been isolated from alkaliphilic microorganisms (62–66). Fujiwara and coworkers (67) purified a thermostable alkaline protease from a thermophilic alkaliphilic *Bacillus* sp. B18. The optimum pH and temperature for the hydrolysis of casein were pH 12 to 13 and 85 °C, both of which are higher than those of alkaline proteases. Han and Damodaran (68) reported the purification and characterization of an extracellular endopeptidase from a strain of *B. pumilus* displaying high stability in 10% (w/v) sodium dodecyl sulfate and 8 M urea. Following these studies, many alkaline proteases for

laundry detergent additives were isolated from various alkaliphilic *Bacillus* strains, although their properties are almost the same as those reported previously (69–71).

Some of the enzymes are now commercially available as detergent additives.

Takami and coworkers (26) isolated a new alkaline protease from alkaliphilic *B. halodurans* No. AH-101. The enzyme was most active toward casein at pH 12 to 13 and stable under 10-minute incubation at 60 °C and pH 5 to 13. The optimum temperature was about 80 °C in the presence of 5 mM calcium ion. The alkaline protease showed a higher hydrolyzing activity against insoluble fibrous natural proteins such as elastin and keratin in comparison with subtilisins and proteinase K (72–76). Cheng and coworkers (77) reported a keratinase of a feather-degrading *Bacillus licheniformis* PWD-1. This enzyme was stable from pH 5 to 12. The optimum reaction pHs for feather powder and casein were 8.5 and 10.5 to 11.5, respectively. Zaghloul and coworkers also reported isolation, identification, and keratinolytic activity of several feather-degrading bacteria isolated from an Egyptian soil. These isolates could degrade chicken feathers (78).

Other Proteases

Several alkaline proteases produced by alkaliphilic actinomycetes have been reported. Tsuchiya and coworkers (11,79,80) isolated thermostable alkaline protease from alkaliphilic *Thermoactinomyces* sp. HS682. The strain grew in alkaline media between pH 7.5 to 11.5. Maltose gave the highest productivity of protease at a concentration of 10 g/L. The protease had the maximum proteolytic activity around pH 11.0 and at 70 °C. In the

presence of Ca^{2+} ions, maximum activity was observed at 80 °C. An intracellular alkaline serine protease gene of alkaliphilic *Thermoactinomyces* sp. HS682 was cloned and expressed in *Escherichia coli*. Yum and coworkers (81) purified an extracellular alkaline serine protease produced by *Streptomyces* sp. YSA-130. The optimum temperature and pH for the enzyme activity were 60 °C and 11.5, respectively. The enzyme was stable at 50 °C, and between pH 4 and 12. A keratin-degrading serine protease of *Streptomyces pactum* DSM 40,530 was purified by casein agarose affinity chromatography by Bockle and coworkers (82). The proteinase was optimally active in the pH range from 7 to 10 and at temperatures from 40 to 75 °C. After incubation with the purified proteinase, a rapid disintegration of whole feathers was observed. Extracellular proteolytic activity was also detected in the haloalkaliphilic archaeon *Natronococcus occultus* as the culture reached the stationary growth phase (83). Proteolytic activity was precipitated with ethanol and subjected to a preliminary characterization. Optimum conditions for activity were attained at 60 °C and 1 to 2 M NaCl or KCl. Gelatin zymography in the presence of 4 M betaine revealed a complex pattern of active species with apparent molecular masses ranging from 50 to 120 kDa. Subsequently, several haloalkaliphilic proteases have been isolated from haloalkaliphilic archaea. These enzymes were dependent on high NaCl concentrations in order to express protease activity and stability (84,85).

Industrial Applications of Alkaline Proteases

1. Detergent Additives.

   The main industrial application of alkaliphilic enzymes is in the detergent industry, and detergent enzymes account for approximately 30% of the total worldwide enzyme production. Not all of these are produced by alkaliphilic bacteria. However, almost all alkaline proteases have been produced by alkaliphilic *Bacillus* strains and are commercially available.
2. Dehairing.

   Alkaline enzymes have been used in the hide-dehairing process, in which dehairing is carried out at pH values between 8 and 10. These enzymes are commercially available from several companies.
3. Others.

   An interesting application of alkaline protease was developed by Fujiwara and coworkers (66,67,86,87). They reported that an alkaline protease was used to decompose the gelatinous coating of X-ray films, from which silver was recovered. Protease B18′ had a higher optimum pH and temperature, around 13.0 and 85 °C, respectively. The enzyme was most active toward gelatin on film at pH 10.

STARCH-DEGRADING ENZYMES

The first alkaline amylase was produced in Horikoshi-II medium by cultivating alkaliphilic *Bacillus* sp. No. A-40-2 (28). Several types of alkaline starch-degrading enzymes were observed. No alkaline amylases produced by neutrophilic microorganisms have so far been reported. Recent studies revealed that the starch-degrading enzymes α-amylase and cyclodextrin glycosyltransferase (CGTase) are functionally and structurally closely related.

α-Amylases of Alkaliphilic Bacillus Strains

The production of the alkaline amylase was first achieved in an alkaliphilic *Bacillus* species strain No. A-40-2 (ATCC21592) that was selected from about 300 colonies of bacteria grown in Horikoshi-II medium (28). The enzyme is most active at pH 10.0 to 10.5 and retains 50% of its activity between pH 9.0 and 11.5. The enzyme is not inhibited by 10 mM EDTA at 30 °C and is completely inactivated by 8 M urea. The enzyme can hydrolyze 70% of starch to yield glucose, maltose, and maltotriose and is a type of saccharifying α-amylase. Boyer and Ingle (88,89) reported an alkaline amylase in the strain NRRL B-3881, which was the second report of an alkaline amylase. The B-3881 amylase had its optimum pH at 9.2. The enzyme yields maltose, maltotriose, and a small amount of glucose and maltotetraose, all of which have a β-configuration. Considerable diversity of α-amylases has been reported. Kim and coworkers (90) reported that an alkaliphilic *Bacillus* sp. Strain GM8901 produced five alkaline amylases in a culture broth. McTigue and coworkers studied the alkaline amylases of three alkaliphilic *Bacillus* strains (91,92). *Bacillus halodurans* A-59 (ATCC 21591), *Bacillus* sp. NCIB 11203, and *Bacillus* sp. IMD370 produce alkaline α-amylases with maxima for activity at pH 10.0. One of the strains isolated, *Bacillus* sp. No. H-167, produced α-amylases that yielded maltohexaose and the main product from starch. The nucleotide sequence of the G6-amylase gene from alkaliphilic *Bacillus* sp. H-167 was determined. The open reading frame of the gene consisted of 2,865 bp encoding 955 amino acids. The DNA sequence and the deduced amino acid sequence of the G6-amylase gene showed no homology with those of other bacterial α-amylases, although the consensus amino acid sequences of the active center were well conserved (10,29–31). It is of interest that this nucleotide sequence, which is fragmented, was well conserved in the DNA of *B. halodurans* C-125, although no enzymatic activity was expressed.

Kelly and coworkers (93) found that the alkaline amylase of *Bacillus* sp. IMD 370 could hydrolyze raw starch. The enzyme digested raw cornstarch to glucose, maltose, maltotriose, and maltotetraose. The maximum pH for raw starch hydrolysis was pH 8.0 compared with pH 10.0 for soluble starch hydrolysis. It is of interest that degradation of raw starch was stimulated sixfold in the presence of β-cyclodextrin. Lin and coworkers (94) have recently reported the production and properties of a raw-starch-degrading amylase from the thermophilic and alkaliphilic *Bacillus* sp. TS-23. Activity staining revealed that two amylases with molecular masses of 150 and 42 kDa were produced. The 42-kDa amylase only hydrolyzed raw starch. Igarashi and coworkers isolated a novel liquefying α-amylase (LAMY) from cultures of an alkaliphilic *Bacillus* isolate, KSM-1378 (95). The enzyme had a pH optimum of 8.0 to 8.5 and displayed maximum

activity at 55 °C. The structural gene for the amylase contained a single open reading frame 1,548 bp in length, corresponding to 516 amino acids that included a signal peptide of 31 amino acids. The four conserved regions were found in the deduced amino acid sequence. Essentially, the sequence of LAMY was consistent with the tertiary structures of reported amylolytic enzymes, which are composed of domains A, B, and C. Furthermore, Igarashi and coworkers (96) improved the thermostability of the amylase by deleting an arginine-glycine residue in that molecule. Then they reported that thermostability of the enzyme was also improved by proline substitution (Arg124 to Pro124) (97).

Another modification to improve stabilization was reported by Villalonga, and coworkers (98). Carboxymethylcellulose activated by periodate oxidation was covalently linked to α-amylase. The thermostability and pH stability were improved for α-amylase by this modification. The conjugate was also more resistant to the action of denaturant agents such as urea and sodium dodecylsulfate. They concluded that modification of enzymes by the anionic polysaccharide carboxymethylcellulose might be a useful method for improving enzyme stability under various denaturing conditions.

Other α-Amylases

Kimura and Horikoshi (39,40,99–102) isolated a number of starch-degrading alkaliphilic psychrophilic microorganisms from the environments. Recently, a gene coding for a new amylolytic enzyme from *Pseudomonas* sp. KFCC 10818 was cloned, and its nucleotide sequence was determined (103). A deduced amino acid sequence contained four highly conserved regions of α-amylases. A haloalkaliphilic *Natronococcus* sp. strain Ah-36 produced an extracellular maltotriose-forming amylase (104). The amylase exhibited maximal activity at pH 8.7 and 55 °C in the presence of 2.5 M NaCl. Kobayashi and coworkers (104) have cloned this α-amylase and expressed it in *Haloferax volcanii*.

Cyclomaltodextrin Glucanotransferases (CGTase)

Nakamura and Horikoshi discovered several alkaliphilic *Bacillus* strains producing CGTases. A crude enzyme of *Bacillus* sp. No. 38-2 was a mixture of three enzymes: acid CGTase having optimum pH for enzyme action at 4.6, neutral CGTase at 7.0, and alkaline CGTase at 8.5 (32–35). In 1975, Matsuzawa and coworkers established the industrial production of cyclodextrin by using the crude CGTase of *Bacillus* sp. 38-2 (105). Since then, several alkaliphilic microorganisms producing CGTases have been reported (35,105). Georganta and coworkers (106) isolated CGTase producing alkaliphilic psychrophilic bacteria from samples of deep-sea bottom mud. The isolate No. 3-22 grew at 4 °C and showed activity in both broad temperature and pH 5 to 9 ranges. The CGTase produced predominantly β-cyclodextrin (β-CD), with minor amounts of α- and γ-CDs. The formation of various cyclodextrins was observed after accumulation of maltooligosaccharides with degrees of polymerization more than seven (107). Salva and coworkers isolated sixty-eight CGTases from alkaliphilic bacteria from among 400 soil bacteria (108). An enzyme of isolate No. 76 was partially purified by starch adsorption and some of its properties were investigated. The enzyme properties seem to be quite similar to those of *Bacillus* sp. 38-2 enzyme (33). Chung and coworkers isolated a thermostable CGTase from alkaliphilic *Bacillus stearothermophilus* ET1 (109). The optimum pH for the enzyme-catalyzed reaction was pH 6.0, and the optimum temperature was observed at 80 °C. A 13% (w/v) cornstarch solution was liquefied and converted to CDs solely using this enzyme. The cornstarch conversion was 44%, and α-, β-, and γ-CDs were produced in the ratio of 4.2 : 5.9 : 1. Terada and coworkers studied the initial reaction of CGTase from an alkaliphilic *Bacillus* sp. A2-5a on amylose (110). Cyclic α-1,4-glucans with a degree of polymerization ranging from 9 to more than 60, in addition to α-, β-, and γ-cyclodextrin, were detected at an early stage of enzymatic reactions. Subsequently, large cyclic α-1,4 glucans were converted into smaller cyclic α-1,4-glucans. The final major product was β-CD. From the industrial point of view, γ-CD is of practical interest because it is rare and can encapsulate larger compound molecules. Recently, Parsiegla and coworkers reported that mutation of *Bacillus circulans* Strain No. 8 was effective in increasing the γ-cyclodextrin production (111).

Yamane's group has extensively investigated molecular structure of the CGTase of alkaliphilic *Bacillus* sp. 1,011. Kimura and coworkers isolated the enzyme, purified, and cloned its gene (112,113). The enzyme, consisting of 686 amino acid residues, was crystallized and subjected to X-ray analysis. The molecule consists of five domains, designated A to E, and its backbone structure was similar to the structure of other bacterial CGTases. The molecule had two calcium binding sites where calcium ions were coordinated by seven ligands, forming a distorted pentagonal bipyramid. Three histidine residues in the active center of CGTase participate in the stabilization of the transition state. His-327 is especially important for catalysis over the alkaline pH range (114). Three-dimensional structures of cyclodextrin glucanotransferases (CGTases) revealed four aromatic residues, which are highly conserved among CGTases but not in α-amylases, are located in the active center (115). Ishii and coworkers analyzed the crystal structure of asparagine-233-replaced enzyme. The enzyme that was a site-directed mutation of histidine-233 to asparagine changed the nature of the enzyme such that it no longer produced α-cyclodextrin. The neighborhood of asparagine-233, maintaining the architecture of the active site cleft, seems to be responsible for the change in molecular recognition of both substrate and product of the mutant CGTase (116,117).

Industrial Production of Cyclodextrins

In 1969, Corn Products International Co. in the United States began producing β-CD using *B. macerans* CGTase. Teijin Ltd. in Japan also produced β-CD using the *macerans* enzyme in a pilot plant. However, there were several serious problems in both the production processes: (*1*) The yield of CD from starch was not high, and (*2*) toxic organic solvents such as trichloroethylene, bromobenzene,

and toluene were used to precipitate CD because of the low conversion rate.

The use of CGTase of alkaliphilic *Bacillus* sp. No. 38-2 overcame all these weak points and led to the mass production of crystalline α-, β-, γ-CD at low cost without using any organic solvents. The yield of CD was 85 to 90% from amylose and 70 to 80% from potato starch on a laboratory scale. Owing to the high conversion rate, CDs could be directly crystallized from the hydrolyzate of starch without the addition of organic solvents (105). These simple methods reduced the cost of β-CD from 200,000 yen to 1,000 yen/kg, and that of α-CD to within 3,000 yen/kg. This has paved the way for its use in large quantities in foodstuffs, chemicals, and pharmaceuticals. Several other processes to produce CDs have been reported after Matsuzawa's original paper (105). Kim and coworkers reported an enzymatic production of cyclodextrins from milled cornstarch in an ultrafiltration membrane bioreactor to reduce product inhibition (118). As compared with an operation without ultrafiltration, the conversion yield was increased by 57% in a batch operation with ultrafiltration. Okada and coworkers also developed a bioreactor system with the enzyme immobilized on a capillary membrane (119). The percentage of CDs to total sugar obtained was slightly more than 60% under most operating conditions. Abraham (120) immobilized CGTase for the continuous production of cyclodextrins. The immobilized enzyme had a pH optimum shifted to the alkaline side (from 6.5 to 7.5) and had a reduced temperature optimum (from 60 °C to 50–55 °C). Lima and coworkers developed a unique cyclodextrin production process (121). A 10% (w/v) solution of cassava starch liquefied with α-amylase was incubated with CGTase using only the enzyme, added ethanol (from 1 to 5%) followed by the addition of yeast, *Saccharomyces cerevisiae* (12% w/v), plus nutrients. However, production costs were not reported.

Pullulanases

In 1975, Nakamura and coworkers discovered an alkaline pullulanase of *Bacillus* sp. No. 202-1 (38). The enzyme had an optimum pH for enzyme action at 8.5 to 9.0 and was stable for 24 hours at pH 6.5 to 11.0 at 4 °C. The enzyme was most active at 55 °C and was stable up to 50 °C for 15 minutes in the absence of a substrate. Kelly and coworkers (122) found that alkaliphilic *B. halodurans* No. A-59 (ATCC21591) produced three enzymes, namely, α-amylase, pullulanase, and α-glucosidase, in culture broth. These three enzymes were separately produced, and the levels of α-glucosidase and pullulanase reached maxima after 24-hour cultivation at the initial pH 9.7. Although this pullulanase was not purified, the indicated pH optimum was at 7.0.

Two highly alkaliphilic pullulanase-producing bacteria were isolated from Korean soils (123,124). The two isolates were extremely alkaliphilic since bacterial growth and enzyme production occurred at pH values ranging from pH 6.0 to 12.0 for *Micrococcus* sp. Y-1 and pH 6.0 to 10.0 for *Bacillus* sp. S-1. The enzyme displayed a temperature optimum of around 60 °C and a pH optimum of around pH 9.0. The extracellular enzymes of both bacteria were alkaliphilic and moderately thermoactive; optimum activity was detected at pH 8.0 to 10.0 and between 50 °C and 60 °C.

In screening alkaline cellulases for detergent additives, Ito's group isolated a novel alkaline pullulanase from alkaliphilic *Bacillus* sp. KSM-1876, which was identified as a relative of *B. circulans* (125,126). The enzyme had an optimum pH for enzyme action of around 10.0 to 10.5. This enzyme is a good candidate for use as an additive to dishwashing detergents. Furthermore, another alkaline amylopullulanase from alkaliphilic *Bacillus* sp KSM-1378 was also found. This enzyme efficiently hydrolyzed α-1,4 and the α-1,6 linkages of amylose, amylopectin, and glycogen at alkaline pH values. The kinetic studies revealed two independent active sites for the α-1,4 and α-1,6 hydrolytic reactions. Incubation of the enzyme at 40 °C and pH 9.0 caused complete inactivation of the amylase activity within 4 days, but the pullulanase activity remained at the original level under the same conditions (126). This alkaline amylopullulanase can therefore be considered to be a "two-headed" enzyme molecule. Limited proteolysis with papain also revealed that the α-1,6 and α-1,4 hydrolytic activities were associated with two different active sites (127). Furthermore, amino acid sequence and molecular structure analysis of the enzyme showed two different active sites (128). The enzyme was observed by transmission electron microscopy; it appeared to be a bent dumbbell-like molecule with a diameter of approximately 25 nm.

Takagi and coworkers reported diversity in size and alkaliphily of thermostable α-amylase pullulanases produced by recombinant *E. coli*, *B. subtilis*, and the wild-type *Bacillus* sp. XAL601 (129). It was revealed that the noncatalytic C-terminal region may be responsible for the high optimum pH of the enzyme activity. These observations were also reported in CGTase (130,131) and alkaline CMCase (132).

Lin and coworkers purified a thermostable pullulanase from thermophilic alkaliphilic *Bacillus* sp. strain TS-23. This purified enzyme had both pullulanase and amylase activities. The temperature and pH optima for both pullulanase and amylase activities were 70 °C and pH 8 to 9, respectively. The enzyme remained more than 96% active at temperatures below 65 °C, and both activities were retained at temperatures up to 90 °C in the presence of 5% SDS (133).

In some food industries, enzymes showing activity at lower temperatures have been requested for food processing. Psychrophilic bacteria are thought to be potential producers of these enzymes. Kimura and Horikoshi (39,40) reported that an alkalipsychrophilic strain, *Micrococcus* sp. 207, produced amylase and pullulanase extracellularly. The pullulanase of *Micrococcus* sp. 207 was purified to an electrophoretically homogeneous state by conventional ways. The purified enzyme was free of α-amylase activity. The enzyme had a pH optimum at 7.5 to 8.0 and was relatively thermostable (stable up to 45 °C). The enzyme could hydrolyze the α-1,6-linkages of amylopectins, glycogens, and pullulan. Although many alkaline pullulanases

have been reported as described earlier, no industrial application has been developed yet.

CELLULASES

Alkaline Cellulases of Alkaliphilic Bacillus Strains

Commercially available cellulases display optimum activity over a pH range from 4 to 6. No enzyme with an alkaline optimum pH for activity (pH 10 or higher) had been reported before the rediscovery of alkaliphiles. Horikoshi and coworkers found bacterial isolates (*Bacillus* sp. No. N4 and No. 1,139) producing extracellular alkaline carboxymethylcellulases (CMCases) (41,43). One of these alkaliphilic *Bacillus* sp. No. N-4 (ATCC21833) produced multiple CMCases that were active over a broad pH range (pH 5 to 10). Sashihara and coworkers cloned the cellulase genes of *Bacillus* sp. No. N-4 in *E. coli* HB101 (42). Another bacterium, *Bacillus* sp. No. 1,139, produced one CMCase, which was purified and shown to have optimum pH for activity at pH 9.0. The enzyme was stable over the range of pH 6 to 11 (24 hours at 4 °C and up to 40 °C for 10 minutes). The CMCase gene of *Bacillus* sp. No. 1,139 was also cloned in *E. coli* (43–47). Nakamura and coworkers (132) and Park and coworkers (134) constructed many chimeric cellulases from *B. subtilis* and *Bacillus* sp. N-4 enzyme genes in order to understand the alkaliphily of N-4 enzymes. Despite the genes having high homology, the pH activity profiles of the two enzymes are quite different; *B. subtilis* (BSC) has its optimum pH at 6 to 6.5, whereas *Bacillus* sp. N-4 enzyme (NK1) is active over a broad pH range from 6 to 10.5. The chimeric cellulases showed various chromatographic behaviors, reflecting the origins of their C-terminal regions. The pH activity profiles of the chimeric enzymes in the alkaline range could be classified into either the BSC or the NK1 type, mainly depending on the origins of the fifth C-terminal regions.

Alkaline Cellulases from Other Alkaliphiles

Park and coworkers and Damude and coworkers (135,136) studied a semi-alkaline cellulase produced by alkaliphilic *Streptomyces* strain KSM-9. Dasilva and coworkers (137) reported two alkaliphilic microorganisms, *Bacillus* sp. B38-2 and *Streptomyces* sp. S36-2. The optimum pH and temperature of the crude enzyme activities ranged from 6.0 to 7.0 at 55 °C for the *Streptomyces* and 7.0 to 8.0 at 60 °C for the *Bacillus* sp. B38-2. However, their results indicated that the properties of these enzymes were not sufficient for industrial purposes.

Cellulases as Laundry Detergent Additives

The discovery of alkaline cellulases created a new industrial application of cellulase as a laundry detergent additive. Ito (personal communication) mixed alkaline cellulases with laundry detergents and studied the washing effect on cotton underwear. The best results were obtained by one of the alkaline cellulases produced by an alkaliphilic *Bacillus* strain. However, the yield of enzyme was not sufficient for industrial purposes. Consequently, Yoshimatsu and coworkers (138) isolated an alkaliphilic *Bacillus* sp. No. KSM-635 from a soil and succeeded in producing an alkaline cellulase as a laundry detergent additive on an industrial scale.

Besides the KSM-635 enzyme, Shikata and coworkers isolated three strains, alkaliphilic *Bacillus* KSM-19, KSM-64, and KSM-520, producing alkaline cellulases for laundry detergents (139). Their activities (pH optima: 8.5 to 9.5) were not inhibited at all by metal ions or various components of laundry products, such as surfactants, chelating agents, and proteinases. With a view to increasing industrial production, Sumitomo and coworkers (140,141) overexpressed alkaline cellulase of alkaliphilic *Bacillus* sp. KSM-64 by using *B. subtilis* harboring their vector pHSP64. By this process, they produced 30 g of alkaline cellulase in one liter. After the discovery of the industrial application of alkaline cellulase as a detergent additive, many microbiologists have extensively studied alkaline cellulases (142–147). Further details are reviewed by Ito (148).

Alkaline Lipases

Although the initial motivation for studying alkaline lipases was its application to detergents, many alkaline lipases were significantly inhibited in the presence of either alkylbenzene sulfate or dodecyl benzene sulfonate.

Watanabe and coworkers (48) conducted an extensive screening for alkaline lipase-producing microorganisms from soil and water samples. Two bacterial strains were selected as potent producers of alkaline lipases. These were identified as *Pseudomonas nitroreducens* var. *thermotolerans* and *Ps. fragi*. The optimum pH of the two lipases was 9.5. Both enzymes were inhibited by bile salts such as sodium cholate, sodium deoxycholate, and sodium taurocholate at a concentration of 0.25 %.

A thermophilic lipase-producing bacterium was isolated from a hot spring area of Yellowstone National Park (49). The organism characterized as *Bacillus* sp. grew optimally at 60 to 65 °C and in the pH range of 6 to 9. The partially purified lipase preparation had an optimum temperature of 60 °C, at an optimum pH of 9.5. It retained 100% of the original activity after being heated at 75 °C for half an hour. The enzyme was active on triglycerides containing fatty acids with a carbon chain length of 16 to 22 as well as on natural fats and oils. Bhushan (149,150) found a lipase produced from an alkaliphilic *Candida* species in a solid-state fermentation. The lipase from this microorganism had temperature and pH optima of 40 °C and 8.5, respectively, and was stable at 45 °C for 4 hours. Enzyme activity was stimulated by Ni^{2+} and Ca^{2+} ions whereas Fe^{2+} and Fe^{3+} ions inhibited the activity.

Large-scale industrial application such as laundry detergent additives has not been reported yet.

XYLANASES

Xylanases of Alkaliphilic Bacillus Strains

The first paper describing a xylanase from alkaliphilic bacteria was published in 1973 by Horikoshi and Atsukawa (50). The purified enzyme of *Bacillus* sp. No. C-59-2 exhibited a broad optimum pH ranging from 6.0

to 8.0. In the culture broth of *B. halodurans* No. C-125, two xylanases were found (51). Xylanase A had molecular weight of 43,000 and xylanase N had a molecular weight of 16,000. Xylanase N was most active at pH 6 to 7 and xylanase A was most active at a pH range of 6 to 10 and had some activity at pH 12. The xylanase A gene was cloned, sequenced, and expressed in *E. coli* (151–155). Four thermophilic alkaliphilic *Bacillus* strains (W1 (JCM2888), W2 (JCM2889), W3 and W4) produced xylanases (156,157). The pH optima for enzyme action of strains W1 and W3 was 6.0 and that for strains W2 and W4 was between 6 to 7. The enzymes were stable between pH 4.5 and 10.5 at 45 °C for 1 hour. The optimum temperatures of xylanases of W1 and W3 were 65 °C and those of W2 and W4 were 70 °C. The degree of hydrolysis of xylan was about 70 % after 24-hour incubation.

After the demonstration that alkali-treated woodpulp could be biologically bleached by xylanases instead of the usual environmentally damaging chemical process using chlorine, the search for thermostable alkaline xylanases has been extensive. Dey (158) isolated an alkaliphilic thermophilic *Bacillus* sp. (NCIM 59) that produced two types of cellulase-free xylanase at pH 10 and 50 °C. Khasin and coworkers reported that alkaliphilic *B. stearothermophilus* T-6 produced an extracellular xylanase that was shown to optimally bleach pulp at pH 9 and 65 °C (159). Nakamura and coworkers also reported that an alkaliphilic *Bacillus* sp. strain, 41M-1, isolated from soil produced multiple xylanases extracellularly (160–162). One of the enzymes, xylanase J, was most active at pH 9.0. The optimum temperature for the activity at pH 9.0 was around 50 °C. Then, another alkaliphilic thermophilic *Bacillus* sp. strain TAR-1 was isolated from soil (52). The xylanase of *Bacillus* sp. strain TAR-1 was most active over a pH range of 5.0 to 9.5 at 50 °C. Optimum temperatures of the crude xylanase preparation were 75 °C at pH 7.0 and 70 °C at pH 9.0. Many thermostable alkaline xylanases have been also produced from various alkaliphiles isolated from geothermal areas (163–165).

Recently, biobleaching by xylanases of *Streptomyces thermoviolaceus* and *Staphylococcus* sp. SG-13 have been reported besides *Bacillus* sp. Xylanase (166–170). These xylanases did not act on cellulose, indicating a possible application of the enzyme in biological debleaching processes.

PECTINASES

The first study on alkaline *endo*-polygalacturonate lyase produced by alkaliphilic *Bacillus* sp. No. P-4-N was published in 1972 (36). The optimum pH for enzyme action was 10.0 for pectic acid. Recently, the gene for this alkaline pectate lyase, Pel-4A of *Bacillus* sp. No. P-4-N was cloned, sequenced, and overexpressed in *B. subtilis* cells (37). The deduced amino acid sequence of the mature enzyme (318 amino acids, 34,805 Da) showed moderate homology to those of known pectate lyase in the polysaccharide lyase family 1. The purified recombinant enzyme had an isoelectric point of pH 9.7 and a molecular mass of 34 kDa and exhibited very high specific activity compared with known pectate lyases reported so far. The enzyme activity and stability were stimulated by the addition of NaCl at an optimum of 100 mM. Fogarty and Kelly (171,172) then reported that *Bacillus* sp. No. RK9 produced *endo*-polygalacturonate lyase. The optimum pH for the enzyme activity toward acid-soluble pectic acid was 10.0. Ito and his colleagues isolated two excellent pectate lyase producers, *Bacillus* sp. strains KSM-P7, KSM-P15 (173–175). This high-alkaline pectate lyase, Pel-7 from strain KSM-P7 was purified to homogeneity and its molecular weight was about 33,000. The isoelectric point was close to or higher than pH 10.5. It exhibited optimum activity at pH 10.5 and around 60 to 65 °C in glycine-NaOH buffer. The gene was cloned and sequenced, and the deduced amino acid sequence of mature Pel-7 (302 amino acids) was obtained. The Pel-7 is basically grouped into the Pel super family, although the enzymatic and molecular properties are different. Another high molecular weight enzyme, Pel-15W from strain KSM-P15, had a molecular weight of 70,000, the pI was around pH 4.6. Pel-15 HHrandomly trans-eliminated polygalacturonate in the presence of $Ca2^{+}$ ions, and the maximum activity was observed at pH 11.5 and at 55 °C in glycine-NaOH buffer. The gene for Pel-15 HHwas cloned and sequenced, and the structural gene contained a 2,031-bp open reading frame that encoded 677 amino acids including a possible 28-amino acid signal sequence.

Several papers on potential applications of alkaline pectinase have been published. The first application of alkaline pectinase-producing bacteria in the retting of Mitsumata bast (*Edgeworthia papyrifera*, plant for Japanese paper making) was reported by Yoshihara and Kobayashi (176). The pectic lyase (pH optimum 9.5) produced by an alkaliphilic *Bacillus* sp. No. GIR 277 has been used in improving the production of a type of Japanese paper. A new retting process produced a high-quality, nonwoody paper that was stronger than the paper produced by the conventional method. Tanabe and coworkers (177,178) tried to develop a new waste treatment by using an alkaliphilic *Bacillus* sp. No. GIR 621-7. Cao and coworkers (179) isolated four alkaliphilic bacteria, NT-2, NT-6, NT-33, and NT-82, producing polygalacturonase and xylanase. They selected high-producers of polygalacturonase from mutants resistant to rifampin in alkaliphilic *Bacillus* sp NT-33. One strain, NT-33, had an excellent capacity for degumming ramie fibers.

CHITINASES

Tsujibo and coworkers (53) isolated chitinases from an alkaliphilic *Nocardiopsis albus* subsp. *prasina* OPC-131. The isolate produced two types of chitinases. The optimum pH of chi-A was pH 5.0 and that of chi-B was pH 7.0. Suresh and Chandrasekaran (180) isolated a chitinolytic fungus, *Beauveria bassiana*, from a marine sediment. The organism was strongly alkaliphilic and produced maximum chitinase at pH 9.20. The NaCl and colloidal chitin requirements varied with the type of moistening medium used. The addition of phosphate and yeast extract resulted in the enhancement of chitinase yield. This is the

first report of the production of chitinase from a marine fungus.

Recently, Bhushan and colleagues isolated an alkaliphilic, chitinase-producing *Bacillus* sp. BG-11 (54,55). The purified chitinase exhibited a broad pH and temperature optima of 7.5 to 9.0 and 45 °C to 55 °C, respectively. It was stable between pH 6.0 to 9.0 and 50 °C for more than 2 hours. The pH and thermostability of immobilized chitinase were enhanced significantly. The chitinase immobilized on chitosan was stable between pH 5.0 and 10.0, and the half-life of chitosan-immobilized enzyme at 70, 80, and 90 °C was 90, 70, and 60 minutes, respectively. No industrial application has been investigated.

METABOLITES PRODUCED BY ALKALIPHILES

Antibiotics

The first report was published in 1980 by Sato and coworkers (181), in which they recorded the isolation of *Paecilomyces lilacinus* No. 1,907 from soil using an alkaline medium with a pH of 10.5. New antibiotics were produced only under alkaline conditions (pH 9 to 10.5). *Paecilomyces lilacinus* No. 1,907 produced one major product, 1907-II, and a minor product, 1907-VIII, which had antibacterial and antifungal activities. Subsequently, an alkaliphilic *Nocardiopsis dassonvillei* that produced phenazine antibiotics under alkaline culture conditions was isolated (182). Bahn and coworkers isolated a novel aldose reductase inhibitor from alkaliphilic *Corynebacterium* sp. YUA25-1. Compound YUA001 was purified from the supernatant of culture broth by successive silica gel column chromatography. The compound had no antimicrobial activity against some gram-positive and gram-negative bacteria, fungi, and yeasts (183).

Since alkaliphiles have been rediscovered, many Japanese pharmaceutical companies have tried using alkaline media to discover new microorganisms producing new antibiotics. Although several have been found and reported, none are as yet commercially available.

2-Phenylamine

Hamasaki and coworkers found that a large amount of 2-phenylethylamine was synthesized by cells of alkaliphilic *Bacillus* sp. strain YN-2000. This amine was secreted in the medium during the cell growth (184).

Carotenoid of Alkaliphilic Bacillus Strains

Aono and Horikoshi reported that alkaliphilic *Bacillus* sp. No. A-40-2, No. 2B-2, No. 8-1, and No. 57-1 produce yellow pigments in the cells (185). These are triterpenoid carotenoids. However, A-59, M-29, and Y-25 white strains when grown in Horikoshi-II medium did not produce carotenoids. The physiological role of the yellow pigments was not reported.

Siderophores

Gascoyne and coworkers isolated a siderophore-producing alkaliphilic bacterium that accumulated iron, gallium, and aluminum (186,187). Enrichment cultures initiated with samples from a number of alkaline environmental sources yielded 10 isolates. From this group, selections were made on the basis of growth at high pH and the gallium-binding capacity of the siderophores. It was found that some isolates grew well and high concentrations of siderophore were detected, whereas others grew well in the presence of much lower concentrations of siderophore. The effect of iron, gallium, and aluminum on growth and siderophore production batch culture was investigated for six isolates. The presence of iron greatly decreased the siderophore concentration in these cultures, whereas the response to added gallium or aluminum was dependent on the isolate.

Cholic Acid Derivatives

Kimura and coworkers isolated an alkaliphilic *Bacillus* strain from soil that grew well in media containing cholic acid (CA) at 5% (w/v) or higher concentrations (188). The 7- and 12-hydroxyl groups of CA were efficiently converted into keto groups, with the conversion rate for both hydroxyl groups reaching 100% after 72 hours of cultivation. The strain also converted a 3α-hydroxyl group to a keto group, but the conversion rate was about 5% after 72 hours. The strain neither affected any other part of the CA molecule nor oxidized 7β-or 12β-hydroxyl groups. By nitrosoguanidine (NTG) mutagenesis, Kimura and coworkers isolated five mutants that selectively produced the following compounds from CA at high yield (closed 100%): Strains M-4 and M-5 produced 7,12-diketolithocholic acid; strain No. 250 produced 7-ketodeoxycholic acid; strains No. 124 and 336 yielded ketochenodeoxycholic acid from CA. Furthermore, strains M-4, M-5, and No. 250 produced only 7-ketolithocholic acid from chenodeoxycholic acid.

Organic Acids

During the cultivation of alkaliphiles, pH values of the culture media often decrease sharply owing to the production of organic acids, which are produced by growth on carbohydrates. Paavilainen and coworkers (189) reported comparative studies of organic acids produced by alkaliphilic bacilli. Four bacilli, *Bacillus* sp. 38-2 (ATCC21783), *B. alkalophilus* subsp.*halodurans* (ATCC27557), *Bacillus alcalophilus* (ATCC27648) and *Bacillus* sp. 17-1 (ATCC31007) were cultured in the presence of various 1% (w/v) sugars and related compounds such as sugar alcohols. All these alkaliphiles produced acetic acid (4.5–5 g/L at the maximum) while formic acid was produced by only one of the strains. In contrast to neutrophilic bacilli, acetoin, butanediol, or ethanol were not detected. Moderate amounts of isobutyric, isovaleric, α-oxoisovaleric, α-oxo-β-methylvaleric, α-oxoisocaproic, and phenylacetic acids were generated with three of the alkaliphiles.

CONCLUSION

Since the rediscovery of alkaliphilic bacteria, more than 1,200 studies have been published on many aspects of alkaliphiles and alkaliphily. The alkaliphiles are unique microorganisms with great potential for microbiology

and biotechnological exploitation. The aspects that have received the most attention in recent years include (*1*) extracellular enzymes and their genetic analysis; (*2*) mechanisms of membrane transport and pH regulation; and (*3*) the taxonomy of alkaliphilic microorganisms. It is unclear what the next development will be, but it may be the wider application of enzymes. Alkaline enzymes should find additional uses in various fields of industry, such as chiral synthesis, biological wood pulping, and more sophisticated enzyme detergents. Furthermore, alkaliphiles may be very good general genetic resources for such applications as signal peptides for secretion and promoters for hyperproduction of enzymes.

In the 1970s, Lettinga and his coworkers developed the upflow anaerobic sludge blanket (UASB) reactor to allow anaerobic treatment of a variety of high-strength wastewaters at relative high loading rates (1). An important feature of the UASB system is the ability to retain a high biomass concentration, which makes it possible to operate at high loading rates. Since the first development of the UASB system, a variety of modifications of this process have been developed, but all consist of an upflow-type reactor. Examples of modified UASB systems include the expanded granular sludge blanket (EGSB) reactor (2), compartmentalized UASB reactors (3), and upflow sludge bed filters (USBF) (4). The biomass in UASB and related reactors typically develops into separate spherical entities of a few millimeters in diameter, which are called anaerobic granules. Therefore, the biomass as a whole is referred to as granular sludge. Although the formation of granules is not necessary for the operation of a UASB reactor (5), granulation is desirable to allow operation at high loading rates. Recently, the formation of granular sludge has also been observed in a few other types of reactors, in particular in the anaerobic migrating bed reactor (AMBR) (6) and the anaerobic sequencing bed reactor (ASBR) (7).

Various aspects of granular sludge characteristics and granulation processes are reviewed in this article. We start with a review of studies that determined the abundance of various microbial populations in anaerobic granules. The research reviewed in this first section used techniques that did not allow preservation of granular structure. In the second part, we summarize the results of studies on techniques that preserved granular structure. In a third section, we review research that studied granulation processes with the general objective to minimize the start-up period for granule formation. Finally, the recommended start-up procedures for UASB reactors are summarized.

MICROBIAL COMPOSITION OF ANAEROBIC GRANULES

Various anaerobic microorganisms exhibit wide-ranging abilities to utilize different substrates and have variable affinities for similar substrates. Furthermore, growth and death rates, and requirements for nutrients and microenvironments vary greatly for different anaerobes. Therefore, it can be expected that wastewater characteristics, reactor configuration, and reactor operating conditions determine the microbial composition of anaerobic granules. However, as discussed later, the microbial composition of granules obtained from widely varying systems is often quite similar, suggesting key roles for certain populations present in granules.

Wu and coworkers (8) used enrichment methods and microscopy to identify microorganisms in granules from a UASB reactor treating brewery wastewater (with 0.6 to 1.2 mM sulfate present). It was found that *Methanobacterium*-like cells were the prevalent H_2-CO_2 and formate utilizers, whereas *Methanospirillum*-like cells were occasionally found. *Methanosaeta*-like cells were the most abundant aceticlastic methanogens. In addition, *Desulfovibrio*-like and *Desulfobulbus*-like cells were found in enrichments prepared with ethanol and propionate (with or without sulfate), respectively. In a subsequent study, enrichments were obtained from granules fed a medium containing acetate, propionate, and butyrate (with 0.15 mM sulfate) (9). Using most probable number (MPN) estimates combined with microscopy, the authors found that fermentative *Clostridium*-like spore-forming rods were present at 10^9 cells/g suspended solids (SS), that syntrophic propionate-degrading bacteria were detected at 10^{10} to 10^{11} cells/g SS, and that syntrophic butyrate-degrading bacteria were found to be present at 10^{11} cells/g SS. The observed hydrogenotrophic methanogens included *Methanobacterium formicicum*-like cells (10^{12} cells/g SS) and *Methanospirillum*-like cells (10^9 cells/g SS). The aceticlastic methanogens *Methanosarcina mazei*-like and *Methanosaeta*-like cells were observed at levels of 10^8 cells/g SS and 10^{12} cells/g SS, respectively.

These two studies demonstrated that the most abundant aceticlastic and hydrogenotrophic methanogens were similar in granules from UASB reactors fed different

wastewaters. *Methanosaeta* spp. and *Methanobacterium* spp. dominated granules from both systems. It was also observed that *Methanobacterium formicicum*-like cells were dominant in the MPN test using acetate (9). This might indicate that a significant amount of acetate was first converted to CO_2 and H_2 by acetogens, which was then converted to methane by *M. formicicum*-like cells. So far, only two strains have been isolated that can convert acetate to CO_2 and H_2, the thermophilic strain AOR (acetate oxidizing rod) and *Clostridium ultunense* (10). Other researchers also found that the indirect conversion of acetate to methane by acetogens and hydrogenotrophic methanogens can be significant in granular sludge (11–13).

Several methods were used to reveal the microbial composition of granules obtained from a UASB reactor treating sugar refinery wastewater (original granules) and after they were adapted to ethanol and propionate for 6 and 36 months, respectively (14). Direct counting based on morphology and autofluorescence showed that 20% of the total cells in the original granules were *Methanosaeta*-like organisms, 10% were *Methanosarcina*-like, and 15% were hydrogenotrophic methanogens. After six months of adaptation to ethanol, *Methanosaeta*-like cells made up less than 1% of the community, *Methanosarcina*-like cells increased to 20%, and hydrogenotrophic methanogens decreased to around 10%. On the other hand, granules adapted to propionate for 36 months contained 30% of *Methanosaeta*-like cells, less than 1% *Methanosarcina*-like cells, and 40% hydrogenotrophic methanogens. MPN methods were used to estimate the abundance of populations in these three sets of granules using various enrichment media and antibodies were used to identify the cells present in the positive highest dilution tubes of the MPN test. Both *Methanosarcina barkeri* and *Methanosaeta concilii* were detected in the original granules, but only *M. barkeri* was present in the ethanol-adapted granules and *M. concilii* in the propionate-adapted granules. Similarly, both *Methanospirillum hungatei* JF1 and *Methanobrevibacter arboriphilus* AZ were found in the original granules, but only *M. hungatei* JF1 was present in the ethanol-adapted granules and *M. arboriphilus* AZ in the propionate-adapted granules.

Visser and coworkers (15) used monoclonal antibodies to show changes in the microbial composition of granules, which were obtained from a mesophilic UASB reactor treating a potato-processing wastewater and were exposed for 20 days to a medium containing acetate, propionate, and butyrate. The authors found no changes in population patterns (in terms of the degree of antigenic relatedness to different methanogens) after 20 days of adaptation to the VFA-based medium. However, the total number of methanogens detected dropped from 12% in the original granules to 5%. The authors documented changes in the population profiles for different groups of immunologically related methanogens after the reactor was operated at thermophilic conditions for four months. The abundance of *Methanobrevibacter smithii* PS, *M. smithii* ALI, *M. hungatei* JF1, *Methanogenium cariaci* JR1, and *Methanosarcina thermophila* TM1 related cells increased immediately after the rise in temperature, and gradually decreased to lower levels, which persisted throughout the observed period. The populations of methanogens related to *M. concilii* Opfikon and *M. arboriphilus* AZ increased, and reached a stable level after 21 and 76 days, respectively. The population of *Methanobacterium thermoautotrophicum* ΔH related organisms continued to increase over the observed period.

Several research groups have used oligonucleotide hybridization probes targeting ribosomal RNA (rRNA) to determine the microbial composition of anaerobic granules. Zheng (16) applied 16S rRNA targeted oligonucleotide probes to analyze the microbial composition of granules sampled at different heights from a UASB reactor treating wastewater from a corn processing plant, which produced ethanol as its major product. The levels of archaeal (methanogenic) rRNA ranged from 18.4 to 30.6%, with 4 to 5.9% of *Methanosaeta* spp., 3.4 to 4.3% *Methanomicrobiales*, and 10.5 to 13.6% *Methanobacteriaceae*. The predominant sulfate-reducing bacteria (SRB) were *Desulfovibrionaceae* (28.6 to 53.3%), but *Desulfobulbus* spp. (2.7 to 6.2%), and *Desulfobacter* spp. (1.3 to 2.6%) were also present.

The same method was used to show the population changes after granules formed in potato-processing industry wastewater adapted to different substrates (17). The inoculum had very low levels of *Desulfobulbus* spp. (around 2% of total 16S rRNA) and of the syntrophic propionate degrader, strain SYN7 (less than 1% of total 16S rRNA). After adaptation, the *Desulfobulbus* spp. increased significantly (up to 35%) in the granules fed propionate and sulfate, whereas SYN7 increased to around 10% in the granules fed propionate only.

Granules from two laboratory-scale UASB reactors also were characterized using 16S rRNA targeted oligonucleotide probes (18,19). The feed for one of the UASB reactors contained glucose (Reactor NP), whereas the second reactor was fed glucose and propionate (Reactor P). Despite these differences in feed composition, the methanogenic composition of granules from the two reactors were very similar. Granules from both reactors contained around 40% archaeal (methanogenic) rRNA. *Methanosaeta concilii* was the predominant methanogen in both reactors. Species within the family *Methanobacteriaceae* were the dominant hydrogenotrophic methanogens in Reactor NP, whereas species belonging to the *Methanobacteriaceae* and *Methanomicrobiales* were equally abundant in Reactor P.

Sekiguchi and coworkers (20) evaluated the diversity of mesophilic and thermophilic granular sludge that had been maintained in UASB reactors treating a sucrose/propionate/acetate-based artificial wastewater by constructing 16S ribosomal DNA (rDNA) clone libraries using prokaryotic primers. Partial sequencing of the clones showed that about 20% of the clones were *Archaea*, all of which were close relatives of known methanogens and most of them were affiliated with *M. concilii* and *M. thermophila* for the mesophilic and thermophilic granules, respectively. An important difference between the two clone libraries was that a major group in the mesophilic clone library (27% of clones) belonged to the delta subclass of the *Proteobacteria* and contained close relatives of SRB (*Desulfovibrio* spp. and *Desulfobulbus* spp.)

and syntrophic bacteria (strain SYN7 and *Syntrophobacter fumaroxidans* [strain MPOB]). In contrast, none of the clones in the thermophilic clone library was affiliated with the *Proteobacteria*, but clones that were closely related to gram-positive syntrophic bacteria (*Thermosyntropha lipolytica* and propionate-oxidizing spore formers A and B) were identified. Using fluorescence in situ hybridizations (FISH), they further determined that approximately 40% and 45% of total cells (as determined using the intercalating dye 4',6-diamidino-2-phenylindole [DAPI]) were labeled with archaeal and bacterial oligonucleotide probes, respectively. This discrepancy between FISH and cloning results lead Sekiguchi and coworkers (20) to believe that their DNA extraction method did not result in sufficient lysis of all cells, which may have limited their estimate of diversity.

In summary, the studies reviewed earlier have shown that the microbial composition of granules depends on the type of substrate, and can change substantially when substrates or environmental conditions are changed. However, there are similarities, especially with regard to methanogen representation. This suggests that the presence of certain methanogens is critical for the anaerobic degradation of organic compounds in general and for systems depending on granulation in particular. Because different microbial characterization techniques were used in the various studies, results need to be interpreted with care. For example, cultivation-based methods, such as MPN estimates, may underestimate the abundance of *Methanosaeta* spp. and syntrophic bacteria as pointed out by Grotenhuis and coworkers (14). When using oligonucleotide probes for population quantification, only those organisms that are targeted by the probes are included in the quantification. Furthermore, rRNA targeted oligonucleotide probe hybridizations provide estimates for rRNA levels, and not for biomass levels or cell numbers. Techniques based on cloning have the potential to reveal microbial diversity, but can be biased when DNA is not uniformly retrieved.

STRUCTURE OF GRANULAR SLUDGE

Layered Structure

To study the structure of granules, MacLeod and coworkers (21) used mesophilic granular sludge that had been fed a sucrose-based wastewater for one month (after transfer from a UASB reactor treating cheese whey wastewater). Transmission electron microscopy (TEM) and scanning electron microscopy (SEM) determined that the granules consisted of three layers:

- Organisms in the external layer were of diverse morphology: chain-forming coccoids, long thin filaments (*Methanospirillum*-like), small rods and cocci, clustering coccoids (*Methanococcales*-like), and chain-forming rods (*Methanosaeta*-like). Some of the large coccoids were surrounded by extracellular polymers (ECP).
- The middle layer was tightly packed with ECP and rod-shaped bacteria similar to *Methanobrevibacter* spp. and *Syntrophobacter* spp.
- *Methanosaeta*-like organisms were dominant in the center. In addition, the center contained many cavities, which might help to release produced biogas.

On the basis of these observations Guiot and coworkers (22) proposed a model for anaerobic granules formed on carbohydrate-based substrates (Fig. 1), consisting of:

- an external layer, in which fermenters are predominant, but which also contains some hydrogenotrophic microorganisms;
- a middle layer that contains syntrophic consortia;
- a core that contains mainly aceticlastic methanogens, usually *Methanosaeta* spp.

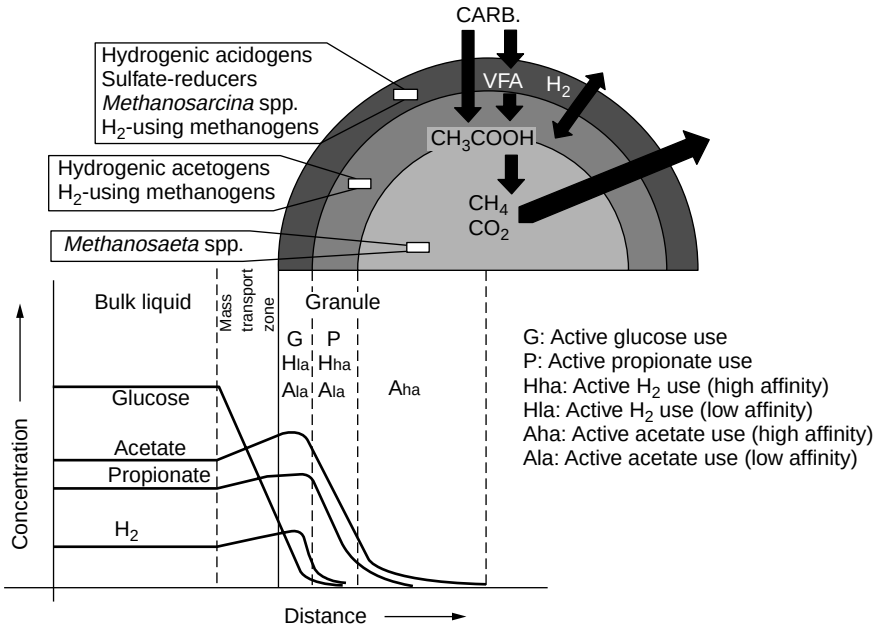

Figure 1. Proposed structure of arrangement of populations in glucose-fed granules. Reproduced with permission from. S. R. Guiot et al., *Water Sci. Technol.* **25**, 1–10 (1992).

As discussed by Guiot and coworkers (22), the layered structure develops because of diffusion limitations. Because the substrates in the wastewater can only diffuse for a certain distance into the granules, fermenters stay in the external layer. Volatile fatty acids (VFAs) produced by the fermenters diffuse further into the granules and are utilized by syntrophs. Acetate produced here diffuses into the core and is used by aceticlastic methanogens. Because H_2 is produced in the external layer and the middle layer, hydrogenotrophic microorganisms are present in both layers.

The model was supported also by results from metabolic activity tests for granules formed on carbohydrate-based substrates (22). First, the metabolic activity on formate, acetate, and propionate was greater for larger granules. This observation was explained by the low surface-to-volume ratio of larger granules and by assuming that glucose can only diffuse for a certain distance into the granules. Second, metabolic activity tests were performed on the three fractions that resulted from abrasions of anaerobic granules. The external layer had the highest specific activity on glucose, but the lowest specific activity on propionate, whereas the core exhibited the opposite effect. However, the specific activity on glucose was relatively high for all three fractions and the specific activity on acetate was similar for all three fractions. Thus, each layer was not exclusive of other trophic groups.

Similar layered granular structures with *Methanosaeta* spp. dominant in the center were also reported for mesophilic granules treating sucrose (23), paper factory wastewater (24), paper-mill wastewater (25), and sugar refinery wastewater (25). These observations were made using SEM, TEM, phase contrast microscopy, or epifluorescence microscopy on sectioned granules.

Using FISH with rRNA targeted oligonucleotide probes, Harmsen and coworkers (17,26) were able to show the microbial structure of granules in more detail. They observed three layers in granules that were originally obtained from a system treating sugar beet wastewater and were adapted to sucrose for six months (Fig. 2; 26):

- The external layer contained mainly bacterial cells.
- The middle layer consisted of syntrophic microcolonies that contained propionate degraders and *Methanobrevibacter* spp. (as suggested by positive hybridization signals with a probe for the family *Methanobacteriaceae* and morphological similarity to *Methanobrevibacter* spp.). This layer also contained

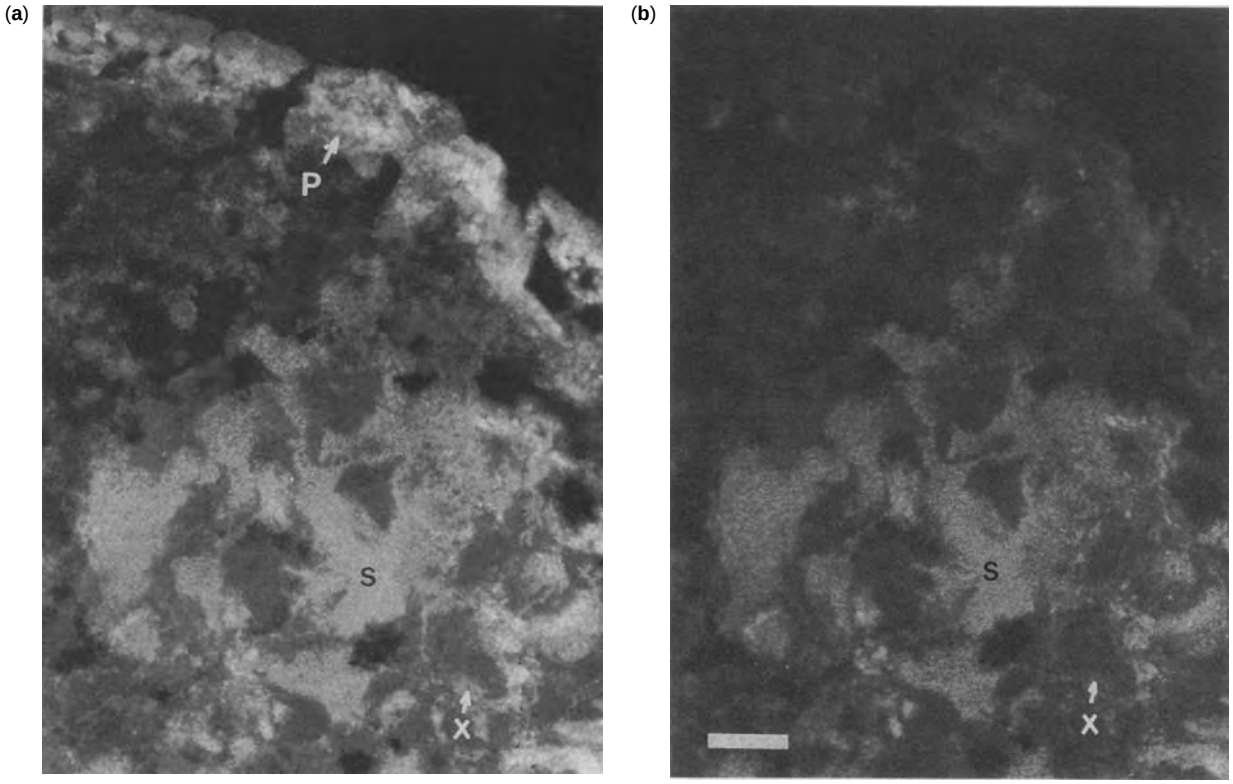

Figure 2. FISH of a sucrose-fed granule viewed by epifluorescence microscopy at a 200-fold magnification. (**a**) A fluorescein-labeled bacterial probe detects bacterial cells mainly located in the outer layer of the granule (P, peripheric location) and the syntrophic microcolonies more toward the inside of the granule (S, syntrophic microcolony). (**b**) A rhodamine-labeled probe specific for a syntrophic population detects only the microcolonies inward of the granule. X, autofluorescence. Bar, 50 μm. Reproduced with permission from H. J. M. Harmsen et al., *Appl. Environ. Microbiol.* **62**, 1,656–1,663 (1996). See color insert.

microcolonies of *Methanosaeta* spp. (as revealed by both TEM and FISH), which were usually located close to the syntrophic microcolonies.

- The core contained inorganic material with large cavities and some methanogens (positive hybridization signal with an *Archaea*-specific probe, but not with a *Methanosaeta*-specific probe).

Thus, in contrast with the observation made by MacLeod and coworkers (21), Harmsen and coworkers (26) found that the core did not contain large numbers of *Methanosaeta* spp., but that *Methanosaeta* spp. formed microcolonies near the syntrophic microcolonies in the middle layer. Granules that were originally obtained from a system treating sugar beet wastewater and adapted for six months to a mixture of butyrate, propionate, and acetate, had an additional thick layer rich in microcolonies of *Methanosaeta* spp. and *Methanosarcina* spp. between the external layer and the middle layer (as detected by FISH and based on the morphology of *Methanosarcina* spp.) (26). The authors explained the presence of this extra layer by the high acetate concentration in the feed. High concentrations of acetate are inhibitory to syntrophic propionate degradation caused by the unfavorable thermodynamics of propionate conversion. *Methanosaeta* spp. and *Methanosarcina* spp., present in the thick layer, removed the acetate before it reached the syntrophic microcolonies. Because the feed contained only butyrate, propionate, and acetate, the authors suggested that the *Bacteria* in the external layer were mainly butyrate degraders.

A similar structure was observed also in granules from a thermophilic UASB reactor treating alcohol distillery wastewater using SEM (27). This reactor was inoculated with mesophilic granules treating fruit-juice wastewater. The surface of the granules was covered with filamentous bacteria, presumably fermenters. The second layer was dominated by *Methanosaeta* spp., whereas the core contained *Methanobacterium*-like cells.

The same mesophilic and thermophilic granules that were characterized in terms of diversity by constructing clone libraries by Sekiguchi and coworkers (20) (see previous discussion) were recently analyzed using FISH (28). Granules from both reactors consisted of outer and inner layers dominated by *Bacteria* and *Archaea*, respectively (Fig. 3). The center did not show hybridization signals with

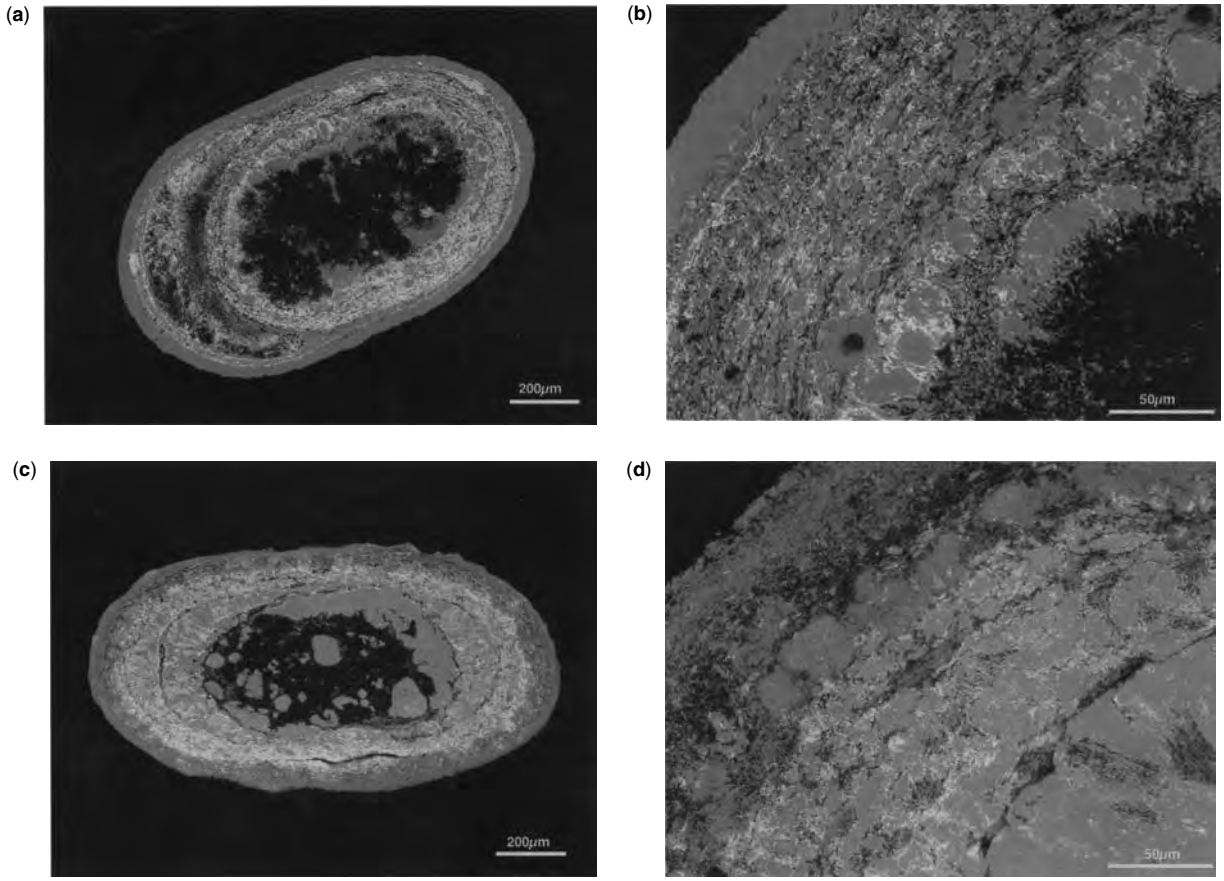

Figure 3. FISH of sections from mesophilic (**a** and **b**) and thermophilic (**c** and **d**) granules viewed by confocal laser scanning microscopy. The sections were simultaneously hybridized with a Cy-5-labeled bacterial probe (green) and a rhodamine-labeled archaeal probe (red). Reproduced with permission from Y. Sekiguchi et al., *Appl. Environ. Microbiol.* **65**, 1,280–1,288 (1999). See color insert.

a bacterial probe or with an archaeal probe. *Methanosaeta* spp. were the predominant *Archaea* in both types of granules. In the mesophilic granules, *Methanobacteriaceae* cells juxtaposed with *Bacteria* and some *Methanomicrobiales* cells were distributed in the granules. In the thermophilic granules, *Methanobacteriaceae* and *Methanosarcina* cells were detected. The authors also tried to locate the microorganisms that were found to be significant in their earlier study using clone libraries (20,28). For mesophilic granules, *Desulfobulbus* cells were found in the outer layer of the granules. Cells that were closely related to *Syntrophobacter* were shown to form microcolonies together with *Methanobacteriaceae* cells in the mesophilic granules. FISH with a probe that targets clones associated with green nonsulfur bacteria revealed filamentous cells on the surface of the thermophilic granules.

In another recent study, FISH revealed a layered structure for granules used to treat a methanol-containing wastewater (29). *Methanosarcina barkeri* were found in the outer layer, and *M. concilii* cells were located in the inner layer and core. Layered structures were also observed using FISH for granules from two lab-scale UASB reactors treating glucose- and glucose/propionate-containing wastewaters (18,19). In both reactors, granules contained large cores that consisted almost exclusively of *M. concilii*. Granules from both reactors exhibited a thin outer layer of *Bacteria*, most of which had a filamentous morphology. For granules treating glucose/propionate-containing wastewater, a layer surrounding the core consisted of both *Bacteria* and*Archaea*. Finally, Santegoeds and coworkers (29) used molecular techniques (denaturing gradient gel electrophoresis and FISH) and microsensors for hydrogen sulfide and methane to study anaerobic granules originally obtained from three full-scale UASB reactors. They observed a layered structure and found that the localization of sulfidogenic, methanogenic, and syntrophic populations determined by FISH and microsensor data corresponded well.

Nonlayered Structure

Nonlayered granules were observed under a number of conditions. A random distribution of an ethanol-degrader (strain EE121), *M. hungatei* JF1, and *M. mazei*-related organisms were found in granules adapted to ethanol (14). The same study also demonstrated a nonlayered structure for granules fed propionate. These granules were dominated by *M. arboriphilus* and *M. concilii* together with a bacterium, presumably a propionate oxidizer. Recently, Rocheleau and coworkers (29) found that granules treating protein-rich wastewater also exhibited nonlayered structures in which *M. concilii* were randomly distributed.

On the basis of observations that granules fed propionate, peptone, or glutamate exhibited nonlayered structures, Fang (30) proposed that the initial degradation rate of the substrate determines the granular structure. If the initial step for degradation of a substrate is the rate-limiting step, some of the substrate can diffuse into the granules before it is degraded by the microorganisms at the surface, resulting in nonlayered granules.

Temperature can also play a role. A layered structure was only observed for granules treating low-fat milk at 5 °C, but not at 15 °C and 25 °C (7). As discussed by the authors, the nonlayered structure at 15 °C and 25 °C was probably related to the low hydrolysis rate of the substrate. At 5 °C, the diffusion rate was also low, possibly allowing the fermenting bacteria to degrade the substrate before it diffused into the granules.

A nonlayered structure also can develop when the substrate can be fully degraded by a single population. For example, granules obtained from a methanol-fed UASB reactor were dominated by *Methanosarcina* with small numbers of rods and filaments in the center (31).

Microcolonies

Microcolonies often have been observed in granules. Wu and coworkers (8) observed microcolonies in mesophilic granules from a full-scale UASB reactor treating brewery wastewater. The wastewater contained mainly ethanol, some propionate and acetate, sulfate, and trace amounts of glucose, butyrate, lactate, and succinate. Three types of microcolonies were found:

- type 1: *Methanosaeta*-like cells mixed with small amount of *Methanobacterium*-like cells;
- type 2: *Methanobacterium*-like cells juxtaposed with *Desulfobulbus*-like cells;
- type 3: *Methanobacterium*-like cells combined with *Desulfovibrio*-like cells.

Type 2 and type 3 were believed to be syntrophic microcolonies, which were responsible for syntrophic degradation of propionate and ethanol, respectively.

Two types of microcolonies were found in propionate-fed granules (14). One was solely made up by *M. concilii*-related organisms, and the other one contained *Methanobrevibacter arboriphilicus* AZ and a possible propionate degrader, which was not closely related to *Syntrophobacter wolinii*.

Similarly, Harmsen and coworkers (17) found two types of microcolonies in propionate-fed granules using FISH. One microcolony was dominated by *Methanosaeta* spp.; the other one was a syntrophic microcolony that contained the syntrophic propionate degrader, strain SYN7, and a methanogen from the order *Methanomicrobiales*, morphologically similar to *Methanospirillum* spp. Harmsen and coworkers (26) also found two types of microcolonies in both sucrose-fed granules and VFA-fed granules (discussed earlier), that is, *Methanosaeta* dominated microcolonies and syntrophic microcolonies containing syntrophic propionate degraders and *Methanobrevibacter* spp.

Three types of syntrophic microcolonies were found in granules treating carbohydrate-containing wastewater (32). Two types consisted of acetogen cells juxtaposed with hydrogenotrophic methanogens (*Methanobrevibacter*-like), whereas the other type consisted of clusters of acetogens in close proximity to clusters of *Methanobrevibacter*-like cells.

Using wax-embedded sections and histogram stains, Morgan and coworkers (25) observed that the diameters of microcolonies increased from the outer layer to the center. To explain this observation, they suggested that inner microcolonies were older than those at the outside.

In summary, studies on granular structure generally have found two types of microcolonies. One type consists of syntrophic consortia, and the other type contains mainly *Methanosaeta* spp. The mechanism of microcolony formation seems to be obvious. Once a microorganism colonizes, it starts to grow and its offspring stays in the same area. This results in the formation of a single-species microcolony. The juxtaposition of syntrophic partners is probably the result of internal mixing of the offspring (10).

Other Studies Related to Granular Structure

Distribution Patterns of Methanogens. Macario and coworkers (33) observed that thermophilic VFA-fed granules consisted of a two-layered structure with an outer layer and a core. Both the outer layer and the core had a thin, dense outer layer. In some granules, this dense layer separated the core into several parts. Using antibody probes, the authors showed the distribution pattern of different groups of methanogens (methanogens immunologically related to *M. thermoautotrophicum* ΔH, *M. thermophila* TM1, *M. concilii* Opfikon, *M. arboriphilus* AZ, and *M. smithii* ALI) located in a spongy matrix formed by other organisms or by intercellular material.

The immobilization patterns of *Methanosarcina* and *Methanosaeta* cells in autoclaved granules were studied using polyclonal antibodies (34). *Methanosaeta* was immobilized on the surface and in the center of the granules, and all immobilized *Methanosaeta* cells were single short rod-shaped. *Methanosarcina*, on the other hand, stayed on the surface or in the cavities. They grew as single cells, small clusters, or large clusters (especially when the acetate concentration was high).

Metabolic Activity Zones. Lens and coworkers (35) observed metabolic activity zones in granules using pH and glucose microelectrodes. For example, in granules (diameter 0.5 to 2.0 mm) from a full-scale UASB reactor treating potato starch wastewater that were acclimated to glucose or diluted molasses for about 10 days, they identified an outer, glucose-converting zone of 200 to 300 μm and an inner methanogenic activity zone. The authors were not able to correlate these two activity zones to the granular structure. *Methaonsaeta*-like cells were found throughout the granules, even in the surface layer. In addition, coenzyme F_{420} was found to be distributed homogeneously in the granules.

Hydrophobicity. Three layers of different hydrophobicities were observed in gray colored granules fed sucrose (36). The outer layer was hydrophilic, the second layer was very hydrophobic, and the core was moderately hydrophobic. In general, fermenting bacteria are hydrophilic, whereas acetogens and methanogens are hydrophobic. This finding again supported the structured model proposed by Guiot and coworkers (22).

Extracellular Polymers (ECP). ECP were found around some clusters of microorganisms in the surface layers of granules from two full-scale UASB reactors treating paper mill and sugar refinery wastewater (25). There was very little ECP in the area where *Methanosaeta* was dominant. In addition, lots of empty sheaths of *Methanosaeta*, which are rich in proteins, were observed. This might explain why other researchers have found proteins to be dominant in the center of granules (see following section).

Quarmby and Forster (37) used gram staining, as well as staining for carbohydrates, proteins, and lipids to show the structure of granules taken from UASB reactors treating different industrial wastewaters. The surface contained mainly gram-positive cells with some colonies of gram-negative cells, whereas the center mainly consisted of gram-negative cells. Carbohydrates were dominant in the outer layer and decreased inwards, whereas proteins were present at relatively low levels in the outer layer and increased inwards. Lipids were evenly distributed throughout the granules. The structures of granules treating the same types of wastewater were observed to be different, demonstrating that other factors such as organic loading rate, pH, and the strength of the wastewater may also affect the structures.

In summary, the structure of anaerobic granules can be either layered or nonlayered, depending on substrate characteristics. In addition, diffusion factors and degradation rates play important roles in determining the structure. Microcolonies are observed in both layered and nonlayered granules. They fall into two groups, one group consists of juxtaposed syntrophs and hydrogenotrophic methanogens; the other one contains mainly *Methanosaeta* spp. *Methanobrevibacter* spp. also are observed frequently in syntrophic microcolonies.

GRANULATION PROCESSES

Because it is generally accepted that granules are merely spherical biofilms, Schmidt and Ahring (38) used a modification of biofilm formation theory to explain that the granulation process consists of four steps: (*1*) transport of cells to the surface of uncolonized inert material or other cells (nucleus), (*2*) initial reversible adsorption to the nucleus by physicochemical forces, (*3*) irreversible adhesion of the cells to the nucleus by microbial appendages and/or polymers attaching the cells to the substratum, and (*4*) cell growth and development of granules. Thus, the granulation process starts with the colonization of cells onto a nucleus (inert material or other cells). The cells then grow into granules of visible size.

Importance of Nuclei

Nuclei can be particles consisting of inert material and/or cells present in the original inoculum, or they can be particles added to a reactor together with inoculum to enhance the granulation process. Precipitates, such as iron sulfide can also act as nuclei (39).

Hulshoff Pol (40) demonstrated that particles with dimensions between 40 and 100 μm are important for granulation. He showed that granulation still happened after particles larger than 100 μm had been removed by sieving of the inoculum. However, when the inoculum was sieved using a 40-μm sieve, no granulation was observed.

Several studies demonstrated that the addition of particles resulted in a higher rate of granulation.

Addition of 100-μm hydroanthracite particles (with good adhesion properties) reduced start-up time and increased granulation rate (40). Using a water-absorbing polymer (WAP, made mainly of an acrylic compound with particles between 100 and 200 μm), Imai and coworkers (41) were able to enhance the start-up process of UASB reactors using anaerobic digester sludge as the inoculum. Laboratory-scale reactors fed with glucose showed that the granulation time reduced from 60 days to 40 days when WAP was added. For a laboratory-scale reactor fed with acetate, propionate, and butyrate, granulation was observed after 70 days when WAP was added, and no granulation had taken place in the control reactor after four months of operation. In pilot-scale studies with acetate, propionate, and butyrate as substrates, however, granulation enhancement was less significant (65 days with WAP addition versus 75 days without). SEM showed that WAP particles appeared in the center of the granules and were gradually decomposed.

Not all inert particles can enhance granulation. Four different carriers, powdered activated carbon (PAC), granular activated carbon (GAC), gamet sand, and silica sand were tested for the enhancement of granulation in ASBRs treating synthetic wastewater containing mainly sucrose (42). All average particle diameters were 0.5 mm. Only the addition of GAC and PAC showed significant enhancement of the granulation process, suggesting that GAC and PAC provided sites to which microorganisms could adhere and thus be retained.

The addition of 30- to 100-μm gravel particles to digested sewage sludge did not show significant enhancement of granulation for a thermophilic UASB reactor fed acetate as the major substrate (43). *Methanosaeta* was believed to be more important as a nucleus than the inert material. Attachment of *Methanosaeta* filaments to the inert particles was considered a requirement for granulation and the lack of significant enhancement of granulation in this case was believed to be caused by the low numbers of *Methanosaeta* in the inoculum.

These results are consistent with observation reported by Yoda and coworkers (44). Powdered zeolite (50 to 100 μm) was used in an anaerobic expanded microcarrier bed reactor. A thin biofilm developed on the zeolite powder, which was later transformed into granules. *Methanosaeta* spp. were the predominant organisms in the thin film.

Beeftink and Staugaard (45) demonstrated that sand grains were important during the start-up of an anaerobic gas-lift reactor. Later, granules were found to have no sand center and the sand was gradually lost in the system. This indicates that once granules have been formed, there is no need for further addition of inert particles to maintain the granules.

The nucleus can also consist of small aggregates of microorganisms. For example, by recycling small microbial aggregates back to a UASB reactor, Thiele and coworkers (46) found that granule bed growth was stimulated. Microorganisms or groups of microorganisms believed to play important roles in the granulation process are discussed below.

Fermenting Bacteria. On the basis of observations that granulation was promoted by wastewater containing carbohydrates but not by preacidified wastewater, Vanderhaegen and coworkers (47) suggested that fermenting bacteria that produce ECP act as "nucleation centers" and that other microorganisms subsequently associate with this nucleus. Filamentous fermenters also were believed to be responsible for promoting granulation in UASB and anaerobic fixed film reactors treating partially acidified wastewater (48).

Methanosaeta. Wiegant (49) proposed the "spaghetti theory" by analyzing available data from other researchers. This theory states that as a result of the upflow velocity in a UASB reactor, *Methanosaeta* cells are forced to grow as filaments and/or attached to inert material in order to be retained in the system. These filaments serve as precursors of granulation for "healthy" UASB reactors. Because granulation usually is much faster than the maximum growth rate of *Methanosaeta* spp., Wiegant suggested that aggregation of *Methanosaeta* with or without inert material is very important during the initial stage of start-up. Once the nuclei are formed, they grow out to granules by individual growth of trapped microorganisms and entrapment of nonattached microorganisms.

On the basis of their observation of layered, sucrose-fed granules, MacLeod and coworkers (21) proposed that the granulation process started with *Methanosaeta* aggregation. Then, acetogens (syntrophs) and hydrogenotrophic methanogens colonized outside the *Methanosaeta* aggregates. Finally, fermenting bacteria and hydrogenotrophic methanogens colonized the surface. A similar process was also proposed by Morgan and coworkers (21) after they observed layered granules treating paper mill and sugar refinery wastewater. They proposed that the granulation process started with a nucleus consisting of aggregates of *Methanosaeta* spp. and other microorganisms. As *Methanosaeta* filaments grow, they form bundles. The bundle sizes increase and eventually grow into each other and exclude other microorganisms from the center.

Methanosarcina. During a granulation experiment with defined species (including a butyrate-degrading strain BH, a propionate-degrading strain PT, *Methanosaeta* sp. strain M7, *M. formicicum* T1N, and *M. mazei* T18), *M. mazei* T18 was found to be in the center of the granules (50). Obviously, the aggregation of *M. mazei* T18 served as the nucleus for the granulation. However, the authors were not convinced that *Methanosarcina* was essential for granulation and suggested that inert particles may be able to function in a similar manner.

Some *Methanosarcina* spp. (usually isolated from nonmarine environments) can form aggregates up to several millimeters during their life cycle (51). A pure culture of *M. barkeri* formed granules in a UASB reactor with recycling (52). It is possible that small aggregates of *Methanosarcina* form and serve as nuclei for granulation because the acetate concentration can be sufficiently high (>200 mg/liter) to favor the growth of *Methanosarcina* during start-up (10). Later, when

the acetate concentration decreases, the growth of *Methanosarcina* aggregates will stop.

Although it is possible to use *Methanosarcina* aggregates as nuclei, *Methanosarcina* dominated granules are usually of less practical significance because this type of granules are easily washed out of UASB reactors (43,49).

Unidentified Filaments. A UASB reactor fed with methanol was inoculated with sludge (fine floc) from another UASB reactor treating methanolic waste (31). Electron micrographs showed that granules contained rod-type and long filaments in the core and *Methanosarcina* at the surface. The rod and filament cells likely served as nuclei for the granulation. Thin filaments (possibly SRB) also may have served as nuclei for granulation during start-up of a UASB reactor treating wastewater high in sulfate (5 g/L) (53).

Syntrophic Consortia. In a study by Grotenhuis and coworkers (52), granulation of a coculture consisting of a propionate degrader and *Methanosaeta* proceeded very fast (11 days) in a UASB reactor with recycling. A few other studies also compared the effectiveness of syntrophic consortia as nuclei with other possible nuclei. For example, El-Mamouni and coworkers (54–56) compared the influence on granulation of nuclei that contained mainly *Methanosaeta* spp., *Methanosarcina* spp., syntrophic consortia, or fermenters. The characteristics of four types of nuclei enriched in four different USBF reactors are summarized in Table 1. The fermenter nuclei had the smallest size, lowest settling velocity, and lowest ash content, whereas they had the highest ECP content and were rich in carbohydrates. The *Methanosaeta* nuclei had the highest ash content, which might be due to the precipitation of calcium carbonate, magnesium carbonate, and iron sulfide. Together with suspensions of municipal anaerobic sludge, the four types of nuclei were used to inoculate four USBF reactors treating sucrose (54). The mass ratios of municipal anaerobic sludge to nuclei were 1 : 4 g VSS/g VSS. At the end of the experiment (on day 120), the granules in the reactor seeded with syntrophic nuclei reached their plateau of stabilization and had the largest size (mean diameter of 3.1 mm). The granules in reactors seeded with *Methanosarcina* or *Methanosaeta* nuclei were still in the exponential phase at this point, and the mean sizes were 2.4 and 2.7 mm, respectively. In the reactors seeded with fermenter nuclei, granules were still in the lag phase and had a mean diameter of 1.1 mm. The authors suggested that the following two factors led to the fast start-up of the reactors seeded with the syntrophic, *Methanosarcina*, and *Methanosaeta* nuclei. First, syntrophic bacteria and methanogens have relatively low growth rates. The presence of these organisms in the nuclei secured a fast start-up. Second, the nuclei with syntrophs and aceticlastic methanogens effectively promoted the attachment of fermenters and prevented flocculant growth.

In another study, the potential for *M. concilii* and propionate-degrading syntrophic consortia to serve as nuclei for granulation was tested by monitoring granulation in two laboratory-scale UASB reactors inoculated with nongranular sludge and treating synthetic wastewaters containing glucose (Reactor NP) and glucose and propionate (Reactor P) (19). The effluent acetate concentrations were controlled to be below 200 mg/L. Quantitative membrane hybridizations and FISH with oligonucleotide probes targeting 16S rRNA were used to monitor changes in microbial communities and to study cell aggregate structures during granulation. *Methanosaeta concilii* cells were present at high levels and demonstrated good settling ability. Increases in their abundance were associated with significant increases in cell aggregate sizes at the early stage of granulation. *Methanosaeta concilii* cells were found to serve as backbones in small cell aggregates with other archaeal cells and bacterial cells attached to them, and they remained dominant in large cell aggregates and mature granules. These observations support the hypothesis that *Methanosaeta* cells serve as nuclei for granulation. On the other hand, syntrophic propionate-oxidizing bacteria, namely *Syntrophobacter* spp., exhibited poor settling ability and were easily washed out from the system. Their contribution to granulation was probably minimal.

In summary, studies have shown that nuclei can be inert particles or aggregates of microorganisms. Particles with diameters ranging from 40 to 100 μm are important for granulation and the addition of certain types of inert particles can increase the granulation rate. Also, several studies pointed to the importance of *Methanosaeta*, which is believed to attach to inert particles first after which granulation is started. Filamentous microorganisms (e.g.,

Table 1. Characteristics of Four Types of Microbial Nuclei for Granulation (55)

Nucleus Type	Syntrophic Consortia	*Methanosaeta* spp.	*Methanosarcina* spp.	Fermenters
Enrichment medium	Ethanol/Acetate	Acetate[a]	Methanol	Sucrose[b]
Settling velocity (m/h)	10.5	11.3	8.7	3.2
Size (mm)	up to 1.2	up to 1.2	up to 1.2	<0.6
Ash content (%)	30	60	40	16
Extracellular polymers (mg/g VSS)	35.2	42.2	26.6	216.5
Carbohydrates: ECP (%)[c]	12	19	21	84
Proteins: ECP (%)[d]	41	43	64	7

[a] Effluent acetate concentrations were controlled to be below 150 mg/Liter;
[b] Reactor was overloaded (3 to 5 g COD/g VSS·day) and pH was 5;
[c] Percentage of carbohydrates in ECP.
[d] Percentage of proteins in ECP.

Methanosaeta, fermentings filaments) or small aggregates (e.g., syntrophic consortia and *Methanosarcina*) can serve also as nuclei. Finally, syntrophic consortia, at least in some studies (54,55,56), appear to be better nuclei than *Methanosaeta*, *Methanosarcina*, and fermenters.

Colonization

Once the nuclei are formed, microorganisms need to attach to them in order to be retained in the system, which results in the formation of granules. The following factors can affect the adhesion process.

Divalent Cations and Cation Polymers. Divalent cations such as Ca^{2+} and Mg^{2+} can promote granulation in two ways. First, they condense the diffusive double-layers resulting in a stronger effect of van der Waals attractive forces. Second, they may directly neutralize the negatively charged cell surface. Mahoney and coworkers. (57) confirmed this experimentally. They shortened the start-up time of a process treating a synthetic wastewater consisting of acetate, propionate, and butyrate through the addition of 2.5 mM Ca^{2+}. Compared to a system without Ca^{2+} addition, the granules formed in the system with Ca^{2+} addition were larger and exhibited a settling ability three to four times higher. Similarly, addition of 0.2 mM Mg^{2+}, 0.34 mM Ca^{2+}, and trace elements enhanced the granulation in a mesophilic UASB treating sucrose (58). However, too much Ca^{2+} can deteriorate the granulation process. For example, Thiele and coworkers (46) demonstrated that the addition of 25 mM Ca^{2+} caused washout of the biomass.

Schmidt and Ahring (59) studied the importance of Mg^{2+} concentration (0 to 100 mM) for the formation of stable granules (using acetate as the substrate at 55 °C). At very low Mg^{2+} concentrations (0 and 0.5 mM), the biomass was washed out at high rates (50% and 20%, respectively). On the other hand, high Mg^{2+} concentrations (100 mM) resulted in breakage of *Methanosarcina* cell aggregates and adversely affected the granulation process. In addition, the presence of high Mg^{2+} concentrations (30 and 100 mM) resulted in biofilm formation on the reactor wall rather than enhancement of granulation. The authors recommended that the Mg^{2+} concentration should be higher than 0.5 mM but lower than 30 mM to promote granulation.

Analyses of ECP indicated that Co^{2+} and Fe^{2+} were found in extracted ECP (60), in which they might bind to polymers and play important roles in linking ECP, which is usually negatively charged. Furthermore, calcium and phosphorus were found to be the dominant elements in ashed ECP (39). They might also contribute to the stability of granules.

Adding cationic polymers during the start-up of an ASBR reduced the granulation time from four months to one month (42). The cationic polymers were believed to enhance granulation through bridging negatively charged bacterial cells and through the formation of large biomass aggregates via sweep-floc mechanisms.

Hydrophobicity. From the point of view of surface thermodynamics, the free energy change during adhesion of two identical bacteria is determined by liquid surface tension (γ_{LV}) and the surface tension of the bacteria (γ_{BV}) (61). Calculations demonstrated that the adhesion of hydrophilic cells was favored for γ_{LV} less than 50 mN/m, and adhesion of hydrophobic cells was favored for γ_{LV} greater than 55 mN/m. When γ_{LV} was between 50 and 55 mN/m, neither process was favored. Contact angle measurement of pure cultures showed that, in general, fermenters are more hydrophilic than acetogens and methanogens (62). Granules treating sucrose wastewater consisted of three layers, an outer hydrophilic layer, a middle hydrophobic layer, and a core with an intermediate level of hydrophobicity. When the surfactant linear alkylbenzenesulfonate was added to a UASB reactor fed with sucrose to lower the γ_{LV}, the outer layer became more hydrophilic and the middle layer more hydrophobic (62). These granules had the advantage that biogas bubbles did not adhere strongly to their more hydrophilic outer layers and thus were less susceptible to washout than granules with less hydrophilic outer layers, resulting in higher reactor stability when the volumetric loading rate was high (36,61). It appeared that microorganisms in the granules were able to change their position according to the γ_{LV}. When the feed contained higher levels of VFAs, the surface of the granules became more hydrophobic because of the presence of fewer fermenters.

In addition, protein degraders are very hydrophilic compared to other fermenters (62). Their high γ_{BV} might explain why it is difficult to form granules in protein-rich wastewater. Daffonchio and coworkers (62) demonstrated that the addition of a polycation, which reduces the γ_{BV} of the cells, to a wastewater consisting of 20% molasses and 80% peptone with an intermediate liquid surface tension ($\gamma_{LV} = 55$ mN/m) increased the yield of granules significantly (60 to 75%).

Modification of hydrophobicity can help in certain reaction systems, but does not promote granulation per se because granules should contain both hydrophilic fermenters and hydrophobic acetogens and methanogens. Changing the level of surface tension will only favor one type of cell. Two lab-scale UASB reactors were started with sludge from a full-scale anaerobic digester in a yeast production plant (63). Linear alkylbenzenesulfonate was added to one of the reactors to reduce the liquid surface tension to 48 mN/m. No granulation was observed in either of the reactors 50 days after start-up. When the sugar level in the wastewater increased from 7% to 27%, granules formed in both reactors at the same time.

Species-Specific Interactions. Some species prefer to form aggregates with certain species rather than with others. This type of aggregation may be determined by the production and consumption of intermediates, for example, in the case of syntrophic interactions.

In batch experiments with pure cultures, butyrate-degrading bacteria (strain BH) formed strong aggregates with *M. formicicum*, but not with *M. hungatei* (50). In addition, propionate-degrading bacteria (strain PT) only formed strong aggregates with *M. formicicum* when a

Methanosaeta sp. was present. Wu and coworkers (50) demonstrated that *M. formicicum* played a very important role during granulation when a number of defined species (strain BH, strain PT, *Methanosaeta* sp. strain M7, *M. formicicum* T1N, and *M. mazei* T18) were used. *Methanobacterium formicicum* covered the surface of *Methanosarcina* aggregates and served as a link between the nuclei and the other cells. This study also demonstrated the importance of a *Methanosaeta* sp., which encouraged the aggregation between *M. formicicum* and strain PT and thus helped with syntrophic degradation.

Extracellular Polymers (ECP). ECP is an alternative name for glycocalyx, which is defined as the polysaccharide-containing structures from bacterial (or archaeal) origin located outside the cell wall (64). It contains polymers of saccharides, proteins, lipids, phenols, and nucleic acids (38). ECP can be present in forms of slime layers or capsules and appears outside of almost all types of prokaryote cells (64). ECP is sometimes also referred to as extracellular polymeric substances (EPS). However, EPS also stands for extracellular polysaccharides. Here, we use ECP to represent extracellular polymers, and EPS to designate extracellular polysaccharides.

As discussed previously, ECP play an important role in granulation. They help to form strong bonds between nuclei and cells. Also, they help to trap the offspring of attached cells to form microcolonies. This theory was supported by MacLeod and coworkers (21) who found ECP in all three layers of sucrose-fed granules.

The ECP content in granules ranges from 0.6 to 20% of VSS (38), and is much lower than in activated sludge (39). The main components of the ECP extracted from granules are proteins and polysaccharides, and a typical ratio between these two components is 2 : 1 to 6 : 1 (w:w). The lipid contents are usually very low, only 0.02 to 0.05% of VSS.

The production of ECP depends on the growth conditions and characteristics of wastewater. At high substrate concentrations and thus, high growth rates, the ECP content of anaerobic sludge is high, and vice versa (65). Excessive production of ECP can have a negative effect on granulation because the negative surface charge increases with increasing ECP yields (39) in a linear relationship (65). When the substrate is propionate or butyrate, the increase of negative surface charge is linearly correlated with the increase of protein content of ECP. However, when the substrate is glucose, the negative surface charge increases with both protein and carbohydrate content (65).

Schmidt and Ahring (66) determined the ECP content of six types of granules treating different wastewaters at different temperatures. It was found that granules treating complex substrates have higher total ECP and higher polysaccharide and protein contents, but lower lipid contents than those fed acetogenic and methanogenic substrates. Methanogens and acetogens seemed to have a limited ability to produce ECP, particularly polysaccharides, possibly because the production and excretion of ECP require too much energy. On the other hand, fermenters were believed to be the major organisms, which produce polysaccharides (38). For granules grown on acetogenic or methanogenic substrates, proteins may play an important role in granulation, and lipids might be compensating for the lower amounts of polysaccharides and proteins. The authors also pointed out that high ECP levels are not necessary for the production of active granules.

Thermophilic granules were found to have a lower total ECP yield as well as a lower content of polysaccharides and proteins, but higher lipid levels (66). Similar observations for thermophilic granules were reported by other researchers (67,68). This indicates that the production of polysaccharides and proteins may be limited, or that they are degraded faster under thermophilic conditions. It was also found that thermophilic granules were not as strong as mesophilic ones (68), which might be due to the lower total ECP in thermophilic granules.

In general, fermenters are believed to play an important role in producing ECP and enhance the granulation process. Using vinasse as the feed for a UASB reactor, Vanderhaegen and coworkers (47) demonstrated that preacidification of the feed resulted in a growth yield of granules ten times lower than that fed with fresh vinasse. The authors believed that the presence of high-energy carbohydrates favors granulation by enhancing the growth of populations of fermenters, which produce ECP. First, VFAs produced through the degradation of high-energy carbohydrates provide selective conditions for fermenters, which are insensitive to VFAs. The insensitiveness is acquired by secreting ECP. Second, because of the production of hydrogen, fermenters that do not produce hydrogen are favored, such as *Propionibacterium*, which can effectively produce ECP. In another study (discussed earlier), granulation only happened when the sugar content in the feed increased to 27% (in terms of COD) (63). Yoda and coworkers (44) found that when a reactor was fed VFAs (acetate, propionate, and butyrate), only 10 to 40% of the biomass changed to granular sludge, whereas in the reactor fed with glucose or molasses, all the sludge became granular. The authors believed that the presence of fast-growing fermenters produced large amounts of ECP, which was beneficial for granulation.

However, the addition of fermenters to a UASB reactor resulted in flotation of granules (69), suggesting the need of the right types of fermenters (i.e., fermenters with suitable surface characteristics). In another study by Brito and coworkers (70), granulation only started in a UASB reactor inoculated with digested activated sludge when the VFA content of a low strength wastewater (1,000 to 1,500 mg/L COD) changed from 15% to 85%. The authors found that only fluffy flocs were formed when the feed contained 15% VFA and 85% glucose. The polysaccharide ECP was very high in the fluffy flocs as a result of the predominance of fermenters, and it decreased after granules formed. The same changes were observed for protein ECP. The electrophoretic mobility of the biomass was less negative after granulation. This could relate to the predominance of *Methanosaeta*, which has a less negative surface in comparison with other anaerobic microorganisms isolated from granular sludge (71).

Beside fermenters, some other microorganisms are also found to be important in producing ECP for granulation. For example, *M. arboriphilicus* can synthesize all amino acids but cysteine. When hydrogen and nitrogen supply is high and cysteine is limiting, *M. arboriphilicus* cells secrete extra amino acids as peptide polymers. These polymers are believed to be important for granulation (72). TEM observation of granules fed VFAs showed that cells in the granules were surrounded by ECP and attached to each other by fibrous polymers (73). Chemical analysis of the components of EPS of the granules demonstrated that they were the same as EPS of *M. mazei* and *M. formicicum*. The authors concluded that these two microorganisms, especially *M. formicicum*, contributed significantly to the production of the ECP of anaerobic granules, and facilitated granulation.

The importance of the effect of polymers on granulation was also demonstrated by El-Mamouni and coworkers (74). UBF reactors were started up with syntrophic consortia as inoculum, or disintegrated biomass with natural or synthetic polymers. The granulation rate of the reactor with natural polymer was the highest, whereas the one with syntrophic consortia was the lowest. Metabolic activity tests on the three types of granules showed that polymer enhanced granules had higher substrate activities on acetate and ethanol, but demonstrated lower substrate activity on glucose compared to granules developed from syntrophic consortia.

In summary, ECP contributes to granulation by allowing microorganisms to stick together. The proper amount of ECP can make granules stronger. In addition, it can make the granules more hydrophilic and prevent flotation (75). Fermenters can produce large amounts of ECP with high-carbohydrate content. Their presence could enhance granulation. However, excessive ECP (as in the flocs) causes repulsion between cells and prohibits granulation (38). Moreover, *Methanobrevibacter* spp., *Methanobacter* spp., and *Methanosarcina* spp. also can be important in secreting ECP for granulation.

Colonization involves the attachment of different organisms to the nuclei as a mechanism to be retained in the reactor. In addition to interactions between different organisms, cell surface characteristics play an important role at this stage. Granulation can be enhanced by stimulating the production of ECP by selecting for populations that produce significant amounts of ECP and by the addition of chemicals such as surfactants, cations, or synthetic polymers.

START-UP PROCEDURES FOR REACTORS THAT UTILIZE GRANULAR SLUDGE

The ultimate goal when studying granular sludge and granulation processes is to change reactor designs and operational strategies to improve the start-up and performance of anaerobic wastewater treatment systems. There are two types of start-up procedures for UASB reactors, namely, primary start-up and secondary start-up. A primary start-up indicates that the inoculum consists of nongranular sludge (e.g., anaerobic digester sludge and crushed granular sludge). Some general guidelines for primary start-up of UASB reactors were summarized by Lettinga (5). These guidelines reflect the current understanding of the mechanisms involved in granulation. For instance, given the importance of nuclei, it is recommended to use inert carrier particles or crushed granules to promote start-up (40). Similarly, based on the fact that *Methanosaeta* spp. usually are present at high levels in various granules and play an important role in granulation, it is generally recommended to maintain the acetate level below 200 mg/L to promote the growth of *Methanosaeta*. Furthermore, given that *M. arboriphilicus* secretes ECP and can enhance granulation, Wentzel and coworkers (72) suggested that a UASB should be operated in plug-flow or semi plug-flow pattern with high hydrogen partial pressure (P_{H2}) in the lower zone of the reactor. This should enhance the growth of *M. arboriphilicus* and promote secretion of ECP, thus enhancing granulation. In addition, because fermenters can produce large amounts of ECP, wastewaters containing high-energy substrates (e.g., sugars) should be ideal for granulation. However, because of the high growth rate of fermenters, it may be necessary to control the levels of fermenting bacteria (40). For example, an excessive abundance of fermenters can result in fluffy granules as observed in a UASB reactor fed with 85% glucose and 15% VFAs (acetate and propionate) at low COD concentrations (1,000 and 1,500 mg/L) (70). The mixing level and/or the upflow velocity can be adjusted to selectively remove some of the fermenters from fluffy granules (19).

As an alternative to primary start-up, a reactor can be started up with (nonadapted) granular sludge (76). This is called secondary start-up. With more and more full-scale UASB reactors in operation, excess granular sludge is becoming available. As a result, secondary start-up is becoming more popular.

As discussed in the previous sections of this article, the microbial composition and granular structure change when feed composition and operating condition change. These changes are likely to cause problems when nonadapted granular sludge is inoculated into a new reactor. Problems often associated with secondary start-up have been summarized by Lettinga in several reviews (2,5,76):

- Dispersed fermenters present in wastewater can act as carrier material for methanogens, or can attach to granules. Both phenomena result in flotation.
- Flotation can also be caused by the formation of hollow spaces inside granules and/or the formation of poorly gas-permeable scales of organic (e.g., lipids) or inorganic (e.g., $CaCO_3$) scales, which retard or completely obstruct the escape of biogas bubbles.
- Granules may disintegrate, which can result in a serious drop in the amount of granular sludge biomass. Disintegration can be caused by changes in loading rate, substrate types, or level of acidification of the substrate.
- Granules can become too big, which may lead to serious substrate transport limitations.

- It may also be difficult for organisms with low growth rates to develop to high levels in nonadapted granular seed sludge. For example, it may take a long time to increase the levels of organisms required for the degradation of specific compounds present in a new wastewater or of thermophilic organisms when starting up a thermophilic reactor using mesophilic granules.

Because of these problems, in particular problems associated with granular structure, crushed granules may be a better inoculum than intact granules (76). Crushed granules can provide nuclei and the specific microbial populations necessary for granulation.

CONCLUSION

Three decades have passed since the development of the UASB reactor and the use of granular sludge to treat wastewater were first reported. During this time period, the UASB reactor and its derivatives have demonstrated their potential as high-rate anaerobic wastewater treatment systems, and our understanding of granules and granulation processes has improved significantly. This article reviews achievements in understanding the microbial composition and the architecture of anaerobic granules, the mechanisms of granulation, and the role of different microorganisms in granulation processes. These achievements in turn have contributed to the improvement of start-up and operating strategies for reactors, which utilize granular sludge.

Some of the recent findings can be attributed to the development and application of new technologies for investigating complex microbial communities. In particular, nucleic acid based techniques (e.g., rRNA targeted probe hybridizations, PCR, and cloning) and techniques based on immunology (e.g., antibody techniques) have made it possible to study microbial community composition and structure without the limitations and biases of cultivation. However, our current understanding of granules and granulation processes is far from complete. For example, we still need to answer questions such as what are the metabolic activity levels within granules, how are substrates transferred into granules, and how do the characteristics of microorganisms influence the granulation process and the properties of granules. The ability to answer these questions largely depends on the availability of suitable techniques, such as in situ metabolic activity assays, in situ measurement of concentration profiles, and in situ microbial identification and determination of microbial characteristics.

During the last twenty years, our understanding of the phylogeny of living things has undergone significant change. The once commonly held notion that there were two basic cell types, the complex eukaryotes and the more simple, ancestral prokaryotes, was tested when molecular biochemical techniques became available to study an integral part of the protein synthesis machinery, Ribosomal RNA (rRNA) (1). Because rRNA is ubiquitous in nature and the product of highly conserved genes, comparing the sequence of nucleotides in rRNA of different organisms provided an excellent means for assessing the relatedness of two organisms. The relative length of time since the two organisms diverged from a common ancestor could also be estimated once the molecular clock is adequately calibrated against evolutionary events. Early studies showed that prokaryotes and eukaryotes had evolved from a common ancestor by separate pathways (2).

Closer examination of prokaryotes revealed a group as distinctly different, biochemically and structurally, from other bacteria as it was from eukaryotes (2,3). These microorganisms formed the third phylogenetic Kingdom and were named *Archaeabacteria* (1) to reflect their primitive evolutionary status; they are at least as old as the other major bacterial groups. The term *Archaeabacteria* was changed subsequently to the archaeal domain (4). The domain is divided into two Kingdoms (5). The first, *Euryarchaeaota*, contains members that are physiologically diverse and includes the methanogens that produce methane from hydrogen and carbon dioxide or other simple carbon compounds in a strictly anaerobic environment (6), extreme *halophiles* that grow aerobically in highly saline environments and maintain an extremely high internal salt concentration (7), and *thermophiles* found in close proximity to terrestrial and shallow water–hot springs and deep-sea hydrothermal vents. The second kingdom, *Crenarchaeaota*, includes members of the extremely thermophilic sulfur-metabolizing phenotype. Originally known as *thermoacidophiles*, these bacteria have also been well studied (8).

In addition to their ability to inhabit specific "extreme" environments and the presence of identifying 16S rRNA sequences, there are several other characteristics held in common by the Archaea studied thus far. Archaeal cell walls are complex structures but do not contain muramic acid common to bacteria (9). Cell membranes of the Archaea are made of lipids containing ether linkages and phytanyl chains (10). Transfer RNA lacks ribothymidine in one very specific loop in the secondary structure of the molecule (11). The subunit structure of RNA polymerase is unique (12), and several unique coenzymes have been found among the methanogenic Archaea (11). Many of these characteristic molecular or biochemical traits can be exploited to detect Archaea, and methods to do so are described in this chapter.

CULTURING METHODS

Classical microbiological techniques have been applied extensively to the culturing of Archaea. Isolation media for Archaea are selective in themselves, and growth is a direct method of detection as few other bacteria share the growth optima common among the Archaea. However, there is some overlap, and selective culturing methods have been used to detect Archaea in mixed communities. Many Archaea are enriched in media containing antibiotics such as kanamycin, penicillin, or vancomycin, which inhibit the cell walls of bacteria.

Bile Salts and Antibiotics

Halophilic Archaea grow at salt concentrations between 1 M and 4.5 M (7). Halophilic bacteria can also exist at the lower end of this range, although some, such as members of the family *Halomonadaceae*, do live in saturated brines. Low concentrations of bile salts such as sodium deoxycholate or sodium taurocholate have been shown to lyse *Halobacterium* and related Archaea, whereas both halophilic bacteria and *halococci* remain intact. Antibiotics such as anisomycin behave in a similar fashion (13). In this way, halophilic Archaea can be detected indirectly and population sizes can be estimated among mixed communities (14,15).

Most Probable Number (MPN)

Methanogens produce methane by metabolizing carbon substrates and hydrogen within reduced environments (Eh below −330 mV). Although most methanogens are *mesophiles*, marine species include *psychrophiles, thermophiles*, and *hyperthermophiles* and they are ubiquitous despite their special growth requirements (16).

The concentration of viable cells from these various environments can be roughly calculated using MPN techniques. This involves the mathematical estimation of the viable count from the fraction of multiple cultures that fail to show growth in a series of dilution tubes containing a suitable medium (17). The procedure involves preparing several replicate dilutions in a growth medium selective to the particular methanogen under study and noting the fraction of tubes showing bacterial growth. Tubes with no growth are assumed to not have received even a single cell capable of growth. Accuracy in detecting and estimating methanogenic biomass using the MPN technique increases with the use of increasing numbers of culture tubes. This, combined with the use of anaerobic media, can result in

this approach being a cumbersome technique when applied to methanogenic Archaea.

Despite these drawbacks, the MPN method has been applied to many anaerobic environments, such as rice fields (18), where selective media enabled the enumeration of the populations from four major methanogenic trophic groups. In another study, MPN counts showed that viable methanogens coexisted with homoacetogens at depths of 45 m to 446 m below sea level in a deep-granite aquifer (19). In a third study, MPN of methanogens from a rumen were used to elucidate the relationship between Archaea and ciliate protozoans in the gut (20).

MOLECULAR TECHNIQUES

Despite the search for new strains, all Archaea isolated using classical microbiological culturing techniques fall into one of the three basic phenotypes. Traditional laboratory enrichment and culturing methods identify microorganisms based on metabolism, morphology, and physiology (16). The current opinion is that this method of detection uncovers less than 0.1% of microbes in the environment (21–23). Molecular techniques have provided a means by which to determine the presence of Archaea and to characterize them while circumventing the need for culturing (16,24). However, the physiology and ecological role of many of the "uncultivatable" Archaea still requires elucidation.

Molecular Cloning

The advent of nucleic acid sequencing techniques have opened up the potential to study archaeal members of microbial communities from environments in which they were never before known to exist (25,26). Short segments of deoxynucleotides have been used as probes to bind very specifically to targeted sequences of 16S rRNA. This allows the total chromosomal DNA of a specific group to be detected in a complex microbial population. Sections of archaeal 16S rRNA genes bound by Archaea-specific primers are amplified by PCR (see RIBOTYPING METHODS FOR ASSESSMENT OF IN SITU MICROBIAL COMMUNITY STRUCTURE, this Encyclopedia). Individual fragments are then cloned and sequenced, and the sequences are then compared to known Archaeal rDNA sequences. In this way, the phylogeny of Archaeal members of a population can be determined quickly and without the need for classical culturing techniques (16).

These molecular techniques were applied to marine plankton (25). Sequences that were speculated to be from a previously undescribed Archaeal group were found. These microorganisms may have diverged from ancestors of other previously characterized microorganisms very early in evolution. More recently, these techniques have been used to detect Archaea in cold Antarctic marine surface waters, where they were estimated to comprise 34% of the prokaryotic biomass (26). Archaea were found to be widespread in the deep sea when this method was applied to samples taken at great depth (1,000–3,000 m) from both the Atlantic and Pacific Oceans (27). These researchers concluded that previously unknown and uncultured Archaea may be among the most abundant microorganisms on earth. The microbial community of Deep Lake in Vestfold Hill, Antarctica, was found to be made up almost entirely of halophilic Archaea, including several novel lineages (28). In the past, conventional culturing methods had resulted in the isolation of one halophilic Archaeon from Deep Lake (29).

Denaturing Gradient Gel Electrophoresis (DGGE)

Another technique that avoids the need for cloning has been developed. It involves the fractionation of PCR-amplified 16S rDNA fragments on polyacrylimide gels containing a denaturing reagent consisting of formamide and urea. The level of denaturation of individual sequences is used to resolve mixtures of DNA fragments. Gel patterns generated can be used to compare different environmental samples and individual bands can be directly analyzed by sequencing. This method has been applied to study microbial communities in deep-sea sediments (30) in which archaeal 16S rRNA represents 2.5–8.0% of the total prokaryotic DNA.

Fluorescent In Situ Hybridization (FISH)

Chemical staining has been used in the past to detect cells in culture and in environmental samples. These methods tend to be nonspecific (31,32). Fluorescent antibodies used as stains can be highly specific (33–35), but the strain specificity is dependent on the use of well-studied microbes (24). A staining method that involves hybridization of oligodeoxynucleotide probes (24) has been described. The probes binding to complementary regions of 16S rRNA sequences (17–34 nucleotides in length) are chosen because they are specific to a particular phylogenetic group (e.g., Archaea). This molecular probe–staining method is highly specific, but requires no previous knowledge of the organisms under study, and has successfully been applied to archaeal cells (see FLUORESCENT PROBES FOR IN SITU ANALYSES OF MICROBIAL COMMUNITIES). The probes are tagged with a fluorescent label for microscopic examination. Cells are harvested from a culture or environmental samples, resuspended in buffer, and fixed with formaldehyde. Cells are then smeared on a slide coated with gelatin, dried and fixed again (36). Smeared slides are treated with buffered fluoro-labeled probes, incubated in hybridization mixture, and then viewed.

Optical Tweezers

An extremely sensitive microscopic technique has been used to complement the accuracy of these molecular detection methods. A highly focused infrared laser is coupled to a computer-controlled inverse microscope and this system, called "*optical tweezers*" is used to micromanipulate single Archaeal cells from a mixed microbial population for culturing. Using this method, it can be demonstrated that cultures obtained subsequently from this single cell correspond to the one detected in situ (16,37). In the past, such detection and description of Archaea would have been possible only by in situ phylogenetic analyses. This new method was used to isolate anaerobic Archaea, which, at 83 °C, produce

grapelike aggregates of coccoid cells that were previously overgrown during enrichment by filamentous cells.

CELL ENVELOPE — CHEMICAL TECHNIQUES

The cell envelope includes the cell wall and cell membrane constituents. The latter includes lipid in the membrane bilayer and quinones. With reference to Archaea, these specific constituents and methods to detect them are described in the following section.

Cell Wall

Methods to detect Archaea by measurement of cell wall components are neither direct nor as conclusive as either molecular (previous section) or signature lipid techniques (following section). Nevertheless, a range of protocols exist for measuring cell wall constituents and methods to detect them are described in the following paragraphs.

In bacterial cell walls, a polymer of peptidoglycan (or murein) provides strength and rigidity to the cell. Although it differs slightly from one bacterial species to the next, three main components form the basic structure: (*1*) *N*-acetylmuramic acid (NAM), (*2*) *N*-acetylglucosamine (NAG), and (*3*) a tetrapeptide containing D-amino acids (38).

Archaea possess cell walls that are markedly different from those of bacteria (39–41). Changes in chemical composition of the constituents are reflected in structural differences. Cell walls of the Archaea, when they are present, do not contain peptidoglycan as muramic acid, and D-amino acids are absent. Instead, glycoproteins or polysaccharides and proteins give rigidity to the cell wall. The composition of the cell walls of the various members of the Archaeal group reflects the heterogeneity of the group. No common cell wall component, such as muramic acid found in bacteria, is present in the Archaea (42). In Archaea such as *Thermoplasma*, the cell wall is completely absent (43). The gram reaction is highly variable among the Archaea, and is dependent on the combination of cell wall components involved in this structure (44).

Pseudomurein

The cell wall components of Archaea have not been as thoroughly studied as those of bacteria, but there is enough evidence to support their use as taxonomic markers (44). Archaea of the genus *Methanopyrus* and those of the order *Methanobacteriales* have cell walls composed of pseudomurein (45). This polymer consists of peptide subunits (Lys, Glu, Ala or Thr) that cross-link glycan strands composed of an N-acetylated amino sugar (glucosamine or galactosamine) that is common to bacteria and an *N*-acetyl-L-talosaminuronic acid that is unique to Archaea (42,44).

Although there are many different variations in the peptide subunit of murein in bacteria, only one structure for pseudomurein has been found so far in Archaea. However, substitution in the peptide subunit can occur. For taxonomic purposes, elucidation of the chemical composition of pseudomurein is sufficient (45). Initially, the cells are mechanically disintegrated and then digested with trypsin (40,46,47). Purified cell walls can be further degraded into constituent amino acid and amino sugar residues by acid hydrolysis. Identification and quantification of amino acids and sugars are carried out with an amino acid analyzer. Talosaminuronic acids may be qualitatively determined after short-term hydrolysis (4 M HCl, 30 minutes, 100 °C) (40,45). After isolation by thin-layer chromatography, the acid and lactone forms of the acid are determined by an amino acid analyzer (41). Neutral sugars are converted to their alditol derivatives, which are then identified by gas chromatography (GC) (48).

S-Layers (Surface Layers)

Protein S-Layer. Methanogens of the order *Methanococcales* have a cell envelope consisting of the cell membrane and a layer of nonglycosylated protein subunits arranged hexagonally. This outer layer is referred to as an S-layer, and differences in the molecular weights of S-layer proteins are useful taxonomic markers (49). Methods for the isolation of S-layers and S-layer proteins of methanococci have been described (44). After mechanical disruption, cells are treated with DNAase and then a surfactant. The S-layer is extracted by a modified Bligh-Dyer (50) extraction. Dialysis is followed by gel electrophoresis to obtain the S-layer protein. Protein is determined by measuring absorbance at 750 nm (51).

Glycoprotein S-Layers. The surface layer of *Halobacterium halobium* is made up of glycoprotein subunits that maintain the shape of the cell (52). This S-layer dissolves in salt concentrations below 12% in contrast to S-layers of other cells, which tend to aggregate in water.

In *Methanothermus* spp., S-layer glycoproteins and glycoprotein sugars are characteristic. Extraction with trichloroacetic acid followed by reversed-phase chromatography yields the purified glycoprotein (53). Molecular weights obtained through SDS–polyacrylamide gel electrophoresis together with other features can be useful taxonomically (44,54).

The glycoprotein of the S-layer in *Sulfolobus acidocaldarius* contains predominantly the polar amino acids serine and threonine. To isolate and quantify these components the acidic culture is neutralized, and after centrifugation the buffered pellet is digested with DNAase. Cell envelopes are disintegrated with heat (60 °C) at pH 9, and the resultant glycoprotein is purified by molecular-sieve chromatography (55). After acid hydrolysis, amino acid residues are identified and quantified using an amino acid analyzer (44).

Methanochondroitin

Methanochondroitin is a cell wall component unique to *Methanosarcina*, with a few exceptions (*M. acetovorans* and *M. frisia*) that have only a single S-layer. A polymer of uronic acid and *N*-acetylgalactosamine residues present in a 2 to 1 molar ratio gives cell aggregates their cuboid appearance (56). Methanochondroitin is isolated according to methods used for the isolation of pseudomurein. Cells are mechanically disintegrated and then digested

with trypsin (40,46,47). Uronic acids are subjected to methanolysis and then derivatization before identification by capillary GC (48).

Heteropolysaccharide

Methods have been described for the isolation and identification of heteropolysaccharide and constituent components (41,57). To date they have not been demonstrated to be taxonomically useful and their use for detecting Archaea may therefore be limited. Of interest is the observation that *Haloccocus morrhuae* has a rigid cell wall of a complex heteropolysaccharide that prevents cell lysis at low-salt concentration.

Microscopy

Electron micrographs of thin sections of Archaeal cells reveal a variety of profiles, which give rise to two basic gram reactions. Gram-positive Archaea are most similar to gram-positive non-Archaea cells. The cells have a pseudomurein layer surrounding the cytoplasmic membrane and in some cases a heteropolysaccharide or a single layer (S-layer) of protein or glycoprotein as well. Most Archaea are gram-negative and contain an S-layer surrounding the cytoplasmic membrane. Cells containing mitochondroitin and an underlying S-layer may gram stain positive or negative.

Thin sections of Archaea are prepared after cells are fixed in gluteraldehyde, washed, dehydrated, and embedded. After cutting, thin sections are contrasted with lead citrate, washed, dehydrated, and then contrasted again. Cells may also be subjected to platinum shadowing or negative staining before electron microscopy (58).

Membrane Lipids

General Considerations. Along with the cell wall, the cell membrane is a major component of the cell envelope. A number of terms have been used to describe molecules used for the measurement of lipid components in cultured Archaea and environmental samples. These include molecular marker, biomarker, lipid biomarker, signature lipid, signature lipid biomarker, and chemical fossil. In this chapter, the term signature lipid is used as it is more often the term preferred by microbial ecologists. The main criteria for an ideal signature lipid are: (*1*) source specificity and (*2*) conservative behavior.

Source specificity refers to the link between a signature lipid and its source. Under ideal conditions, this link should be direct and unique (59). In showing conservative behavior, a signature lipid should be stable over timescales relevant to the processes under study. Most signature lipids will be subject to microbially-mediated transformations and/or breakdown in the environment. To assess the potential use of a signature lipid as a quantitative tool, we need to understand all aspects of its behavior in the environment.

The recognition that Archaea contain unique lipid profiles comprising ether-linked isoprenoid alkyl side chains relative to bacteria and eukaryotes has encouraged the assay of ether lipid distribution in pure isolates and field samples. Specific structures of selected archaeal signature lipids are shown in Figure 1. The isoprenoid side-chains are usually of C_{20} and C_{40} chain length. When two C_{20} isoprenoid side chains are linked to a single glycerol moiety, the structure is termed a diether (DE) lipid (diphytanylglycerol, archaeol). When two C_{40} side chains are linked to two glycerol units, the structures are termed tetraether (TE) lipids (bidiphytanyldiglycerol, caldarchaeol). The diether and tetraether "lipid cores" refer to the hydrophobic or lipid portion of the membrane lipids.

C_{15} and C_{25} side-chains may be present in the diether lipids from selected Archaea, as may be a hydroxy group at the C_3 position of the isoprenoid side chains. A variation to the DE core lipid occurs with the macrocyclic DE present in deep-sea methanogens (60); a single C_{40} side chain is linked at both ends to one glycerol molecule. Variations to the tetraether lipid structure include the presence of between zero and eight cyclopentane rings.

Other variations to the tetraether structure include the presence of a cyclic $C_6H_{11}O_5$ unit at the second glycerol, calditoglyceroarchaeol (61,62). In Archaea, the diether and tetraether lipids are generally present in phospholipid and glycolipid structures.

Within the Archaea, the compositions of the lipid cores, phospholipids, and glycolipids can be used to distinguish between the three subgroups, extreme *halophiles*, methanogens, and extreme *thermophiles* or *thermoacidophiles*, and to some extent between members of the different genera within each subgroup (63). The analysis of pure cultures provides taxonomic information as the distribution of specific ether lipids may be restricted to certain subgroups of Archaea (Table 1). Application of the signature lipid assays to field samples then allows the detection of Archaea by microbial ecologists, organic geochemists, and other scientists interested in understanding the role of Archaea in the environment.

In their use of signature lipids, microbial ecologists are often more interested than organic geochemists in the viable component of the community. As all living cells are surrounded by a membrane containing polar lipids, the component fatty acid and ether lipid side

Table 1. Listing of Main Archaeal Groups and a Summary of Their Ether Lipid Composition (adapted from reference 63). See Table 2 for explanation of abbreviations.

Group/Genus	Ether Lipids Present DE, Diether; TE, Tetraether
Halophiles *Halobacterium, Haloferax, Haloarcula, Halococci*	DE (diphytanylglycerol, archaeol)
Haloalkaliphiles	DE
Methanogens *Methanococcus, Methanosarcina, Methanobacterium, Methanothermus*	DE and TE (bidiphytanyldiglycerol, caldarchaeol). 3-OH group may be present in the isopranyl side chains.
Thermophiles *Desulfurococcus, Thermoplasma, Sulfolobus, Thermoproteus*	DE and TE. TE may contain cyclopentane rings in the isopranyl side chains.

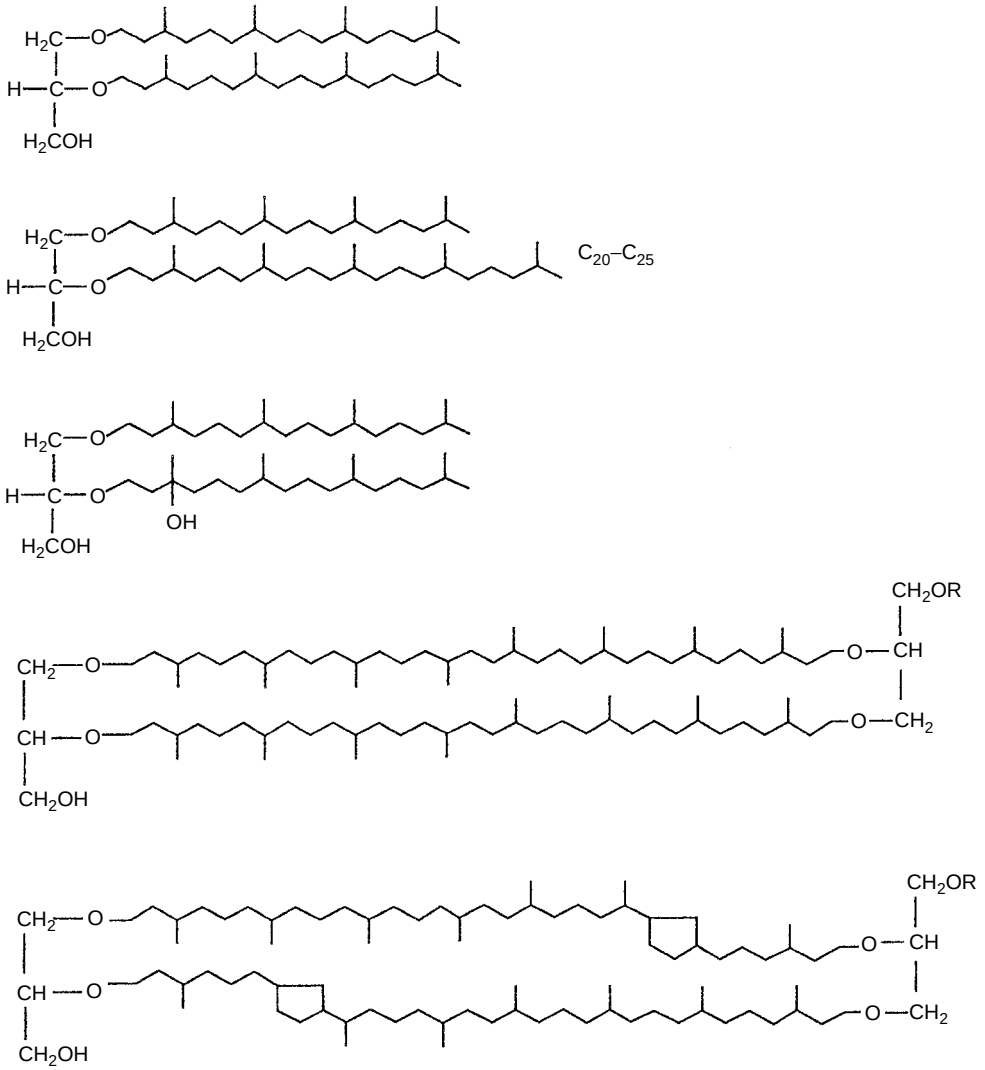

Figure 1. Structures of ether lipid cores. Upper three diether (DE) core lipid structures: 2,3-O-diphytanylglycerol, archaeol; 2-O-sesterterpanyl-3-O-phytanylglycerol; 3-hydroxy-2-O-phytanyl-3-O-phytanylglycerol. Lower two tetraether (TE) core lipid structures: bidiphytanyldiglycerol, caldarchaeol; an example representative of a cyclopentanyl-containing caldarchaeol.

chains are considered to be several of the more important signature lipid classes (64). Unlike many other lipids, phospholipids are rapidly degraded within hours of cell death. Therefore, the examination of phospholipid-derived fatty acids of eubacteria and eukaryotes and phospholipid ether lipids of Archaea allows the viable community to be investigated (65,66). The concept and use of signature lipids is discussed more fully in the entry LIPID BIOMARKERS AND IMMUNOLOGICAL METHODS IN ENVIRONMENTAL MICROBIOLOGY.

Lipid Extraction and Fractionation

Total lipids are extracted quantitatively from most Archaea using a modified Bligh-Dyer one-phase (chloroform-methanol-water, 1/2/0.8, v/v/v) extraction procedure (50,63). *Halophiles* with rigid cell walls (e.g., *Halococcus* spp.) are subjected to sonication before extraction, and acidic conditions may be needed with certain methanogens (see following section). The lipid-containing chloroform layer is obtained by addition of chloroform and water to the Bligh-Dyer extraction (final solvent ratio, chloroform-methanol-water, 1/1/0.9, v/v/v). A representative scheme for the preparation of ether lipids is shown in Figure 2.

A combined lipid and DNA extraction method for environmental samples has been recently reported (67). At the phase separation stage of the Bligh and Dyer procedure, lipids partitioned into the organic phase and DNA partitioned into the aqueous phase. The DNA was not degraded during the lipid extraction procedure, although DNA recovery was 40 to 50% compared to samples treated by conventional DNA extraction techniques alone. An advantage of the Bligh and Dyer procedure was that it also resulted in DNA extracts from field samples containing lower amounts of humic material, compared to conventional DNA extraction. The method shows utility for the co-recovery of both signature lipids and DNA from a single sample; this is particularly useful when only

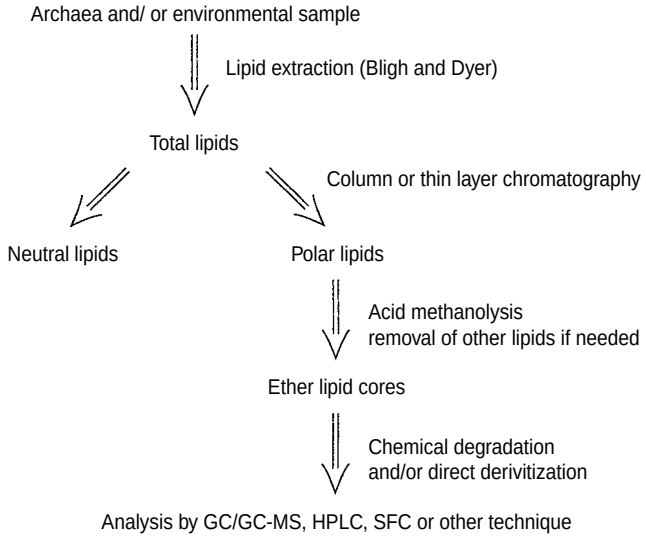

Figure 2. Flow diagram for the preparation and separation of total lipids from bacteria, Archaea, and environmental samples.

Table 2. Listing of Selected Abbreviations Used with Archaeal Components and Detection Methods

Abbreviation	Description
	Chemical Structures
DE	Diether
MDE	Macrocyclic diether
OH	Hydroxy-containing structure
PLEL	Phospholipid ether lipid
TE	Tetraether
	Instrumental and Other Methods Used to Separate Archaeal components
DGGE	Denaturing gradient gel electrophoresis
FISH	Fluorescent in situ hybridization
FTIR	Fourier transform infrared spectroscopy
GC	Gas chromatography
GC–MS	Gas chromatography — mass spectrometry
HPLC	High performance liquid chromatography
MPN	Most probable number
PCR	Polymerase chain reaction
rRNA	Ribosomal ribonucleic acid
SFC	Supercritical fluid chromatography
TLC-FID	Thin layer chromatography

small samples are available. This procedure was used with samples containing bacterial lipid (i.e., phospholipid fatty acids, PLFA), and is yet to be applied to archaeal-containing samples.

Total lipids are separated into lipid classes (neutral lipid, glycolipid, and phospholipid) by silicic acid column chromatography (68), acetone precipitation, or other procedures. TLC can also be used to separate individual components (see following section).

Degradative Procedures

Following extraction and column chromatographic fractionation of total lipid material, chemical breakdown of the complex lipids is undertaken to produce the diether and tetraether lipid cores. A standard strong acid methanolysis treatment of the complex lipids with 0.6–2 N methanolic HCl at 80–100 °C for 1–3 hours has been often used to produce the diether and tetraether side-chains.

Identification of the hydrocarbon type and chain length of diether and tetraether lipid cores is performed by cleavage of the ether linkages with $BCll_3$, BBr_3, or HI. The ether lipid is made to react with the reagent for 4 to 12 hours, typically at 100 °C (69). The alkyl halides or derived acetates produced by treatment with glacial acetic acid in an excess of silver nitrate or hydrocarbons produced by treatment with $LiAlH_4$, are then analyzed by GC. The analyses of ether lipids by these cleavage techniques are essential for their structural elucidation. However, such analyses involve many steps and generally result in low recoveries and therefore have been deemed as not appropriate for routine or quantitative analysis of environmental samples (70).

Thin Layer Chromatography (TLC)

Preparative TLC has been used to fractionate both polar lipids (e.g., individual phospholipids) and ether lipid cores (diether and tetraether). For separation of the polar lipids, the chromatography is generally by silica gel, and mixtures of chloroform/methanol/acetic acid/water (e.g., 85/30/15/5, v/v) (71) are used as the solvent system. In two-dimensional developments, ammonia replaces the acetic acid in the first development (71). Following preparation of the ether lipid cores by acid methanolysis, TLC has also been widely used to separate the ether lipid cores. Again, silica gel is the standard plate used with solvent systems composed of light petrol or hexane/ethyl ether/acetic acid mixtures (e.g., 50/50/1, v/v; 70/30/1, v/v) (71).

A simple TLC procedure has been used to resolve mixtures of tetraether lipid cores containing up to eight cyclopentane rings (72). Silica gel F254 was used with hexane/ethyl acetate (7/3, v/v) as the solvent system. For most TLC systems, components are qualitatively observed by using iodine vapor or dichlorofluoroscein spray (all lipids), or more selective sprays (e.g., ninhydrin, amino groups; acid molybdate, phospholipids; α-naphthol, glycolipids).

A TLC–flame ionization detector (TLC–FID) analyzer has been used to quantitatively analyze lipid mixtures from a range of sample matrices (73). The analyzer uses silica-gel coated glass rods with conventional development of the rods in solvent tanks for component separation. Detection of the separated lipid classes is by the sensitive FID; sensitivity is within the submicrogram to the 10-mcg range. The TLC-FID analyzer has not, to our knowledge, been used for the separation of ether lipid cores. This technique may be useful for both qualitative screening and quantitative analysis of both archaeal isolates and environmental samples, including determination of the concentrations of diether and tetraether.

Issues with Extraction and Other Processing Procedures

A few studies have reported the occurrence of unsaturated diethers in Archaea. The halophilic *Halobacterium lacusprofundi* isolated from an Antarctic lake was first reported to contain unsaturated diether lipid (74). Based on this finding, *Methanococcoides burtonii* was subsequently noted to also contain unsaturated diethers (75). Subsequently, it was also reported that novel 3-OH hydroxydiether lipids (hydroxyarchaeol) were present in a number of methanogens (76,77), and that the standard strong acid methanolysis treatment (0.6–2 N methanolic HCl) of these lipids produced various products including a methoxy derivative, 3-mono-O-phytanyl-sn-glycerol (78), and an unsaturated diether lipid (79). This finding was confirmed in further studies examining the ether lipid composition of *M. burtonii* in which it was noted that the unsaturated ether lipids were most likely produced during sample preparation (80,81). Based on these findings, we believe that the identification of the unsaturated diether in *H. lacusprofundi* may also be doubtful.

Production of the artifacts from the 3-OH hydroxyether lipids can be avoided by use of milder acid methanolysis conditions. The core ether lipids may be obtained without degradation, and in good yield, by mild acid methanolysis in 0.18% HCl (0.05 N) in methanol (71,79) or in 5% methanolic HCL/chloroform (1 : 27, v/v) at 50 °C for 24 hours (82).

Low recovery of ether lipids using the Bligh and Dyer procedure has been noted for *Methanobacterium thermoautotrophicum* and other methanogenic species containing highly polar and acidic lipids (82,83). These studies demonstrated that recovery of the ether lipids was increased by first extracting with the standard Bligh and Dyer procedure and then rapidly with a mildly acidic Bligh-Dyer one-phase solvent, chloroform/methanol/5% aqueous trichloroacetic acid (1/2/0.8, v/v/v). This method was also applied to environmental samples containing methanogens. The total lipid in the chloroform layer is washed using methanol and water to remove any traces of acid.

Compared with the considerable literature available on PLFA abundance in bacteria, only limited data are available for phospholipid ether lipid (PLEL) concentrations in Archaea. Conversion factors are routinely used to translate PLFA concentration results into either number of cells/g or number of cells/L; the average Bacterium is generally assumed to contain 100 μmoles of PLFA/g cells (dry weight) (64,84). However, the as-yet-limited quantitative data available for Archaea has shown large variations between species. Therefore, care may now be needed in the use of PLEL concentration data and conversion factors as is routinely performed with PLFA data. Notwithstanding this qualification, PLEL analysis will still prove to be a reliable tool for determining and comparing viable archaeal populations in environmental samples.

High Performance Liquid Chromatography (HPLC)

Several research groups have used HPLC procedures to separate the diether and tetraether core lipids. HPLC was first used to separate the diether core lipid derived from methanogens (85). The diether core lipids were initially obtained by acid methanolysis. The *p*-nitrobenzoyl ester of the diether core lipid was separated using a silica column and gradient elution (hexane to hexane-diethyl ether, 80/20, v/v) with detection at 254 nm. The tetraether core lipids were not separated using this system.

A further HPLC separation of the diether core lipids was obtained using 9-anthroyl derivatives (82,86). The derivatives were formed using 9-anthroyl nitrile with purification needed. Separation was then obtained using a C_8-bonded silica column employing a spectrofluorometric detector. The solvent was an isocratic acetonitrile/isopropanol mixture (80/20 v/v). The technique was also capable of separating the 3-OH diether core lipids.

The HPLC systems noted above only separate the diether core lipids. Several other procedures have been developed that enable simultaneous separation of both the diether and tetraether core lipids. The first HPLC system developed to separate both ether lipids used an amino silica column, with an isocratic solvent, hexane/n-propanol (87). Unlike the HPLC systems that separate the diether core lipids alone with detection of derivatized components, this system employed refractive index (RI) detection of underivatized diether and tetraether core lipids. An advantage of this system was an absence of impurities derived from the derivatization procedure. However, the RI detector is prone to baseline drift restricting the analysis to use of an isocratic solvent. The sensitivity of RI detection is also lower than for other common HPLC detectors. This system was shown to also separate the macrocyclic diether derived from *Methanococcus jannaschii*, a thermophilic deep-sea methanogen. Separation of the diether, tetraether, and macrocyclic diether obtained using this system is illustrated in Figure 3. Component identification was further confirmed by FT–IR (DRIFT mode) analysis of HPLC fractions. The various ether lipid cores were differentiated by Fourier self-deconvolution of infrared spectra. This HPLC technique has been applied in environmental studies to measure methanogenic biomass in an Antarctic lake and in digestors (87–89).

A second HPLC system capable of separating the diether and tetraether core lipids has been reported (90). The system comprised an Inertsil ODS-2 column and UV detection at 254 nm of dinitrobenzoyl (DNB) derivatives of the core ether lipids following gradient elution (acetonitrile/2-propanol, 40/60–20/80, v/v). The technique claimed to have greater sensitivity than the first HPLC system developed (87). However, based on the chromatograms presented, the diether was not adequately resolved from the internal standard (1,2-di-O-hexadecyl-rac-glycerol), and impurities introduced by the derivatization procedure tailed into both the internal standard and diether core lipid peaks. Furthermore, the preparation of DNB derivatives involved three additional steps, and verification by TLC of derivatization was also required. Several of the advantages claimed for this HLPC procedure have to be weighed against possible disadvantages.

Considerable advances have occurred in recent years with evaporative light-scattering detectors (ELSD), including application with a range of lipid classes (91). To

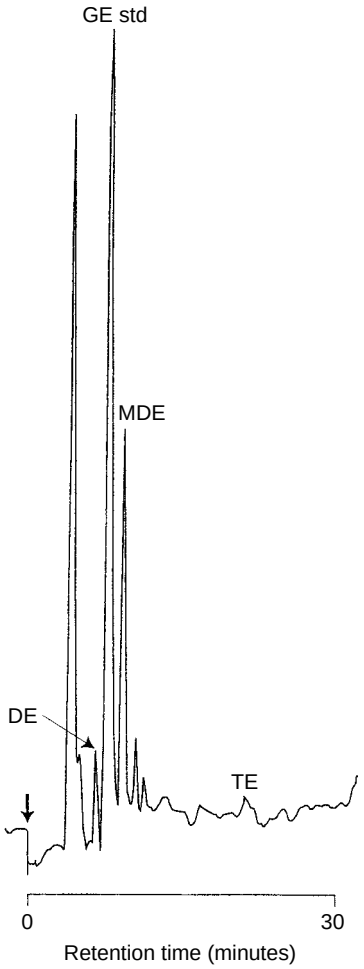

Figure 3. HPLC chromatogram showing separation of the ether lipid cores derived from the glycolipids of *Methanococcus jannaschii*. Solvent, hexane/isopropanol, 99/1 v/v. Abbreviations: Std, internal standard; DE, diether; MDE, macrocyclic ether; TE, tetraether.

our knowledge, the use of HPLC with ELSD has not been applied to ether lipid analysis. Such an application has potential for routine analysis of ether lipids and is worthy of investigation. Similarly, it would be particularly useful if HPLC procedures capable of resolving both diether and tetra ether core lipids could be routinely interfaced to mass spectrometers to further facilitate the identification of the tetra ether core lipids in particular. With recent developments in HPLC-MS, it is foreseen that such analyses will be increasingly used by researchers.

Gas Chromatography (GC)

GC is the most widely used instrument employed by lipid researchers for the analysis of fatty acids and other lipid classes, including hydrocarbons and sterols. Many studies on ether lipids have used GC analysis to measure the C_{20} and C_{40} hydrocarbon or other products derived from the ether lipid alkyl chains obtained using chemical degradation procedures. Typical operating conditions for analysis of the C_{20} and C_{40} hydrocarbon and other products, such as alcohols or alkyl chlorides, include use of a nonpolar column (e.g., SE30, OV17, HP1) with the GC oven initially run isothermally, followed by temperature programming to between 300 and 340 °C (92–94). Detection is usually by flame ionization detection (FID) or GC–mass spectrometry (GC–MS).

A number of researchers have analyzed diether core lipids, derived from cultured Archaea and environmental samples, by GC. In the environmental samples, measurement of the concentration of diether core lipids has been used to estimate the biomass of methanogens (69,95) and other Archaea (96). The protocol usually involves solvent extraction of the total lipid, chemical breakdown of the complex lipids to produce the diether lipid core, derivatization, purification by TLC (this step may be excluded), and analysis by capillary GC. Measurement of diether core lipids is related to cell numbers, methane production and turbidity (69), and to production of organic matter (95).

Conditions for the GC analysis of the diether core lipids are similar to those noted earlier for the C_{40} hydrocarbon. In particular, a high final oven temperature is required (e.g., 300–340 °C) to ensure that the diether core lipids elute from the column. A number of internal standards have been employed in diether core lipid analysis. These are generally phytanyl acetate prepared from phytol (69) and 1,2-di-O-hexadecyl-rac-glycerol (as the O-trimethylsilyl ether), following treatment with N,O-bis(trimethylsilyl)trifluoroacetamide(BSTFA) (96). An issue with the analysis of the 3-OH ether core lipids is their incomplete derivatization when using silylating reagents such as BSTFA. Complete derivatization of hydroxyarchaeol to the di-TMSi derivative occurs on using BSTFA in pyridine/dichloromethane (1/2 v/v) (97).

For cases in which GC has been used to determine diether core lipid composition and content, the diethers have been usually purified first. This removes the fatty acids that, in environmental samples, are derived from bacteria, eukaryotes, and other sources. A capillary GC procedure capable of simultaneous estimation of microbial phospholipid-derived fatty acids and diethers was recently reported (98) and applied to the microbial consortia of wetland sediments. See Figure 4 (99). The fatty acids (as methyl esters) and diethers were not separated before analysis. In particular, a slow oven temperature-heating rate (from 110–220 °C at 1 °C/minute) was employed to gain separation of the novel signature lipids, C_{16} and C_{18} monounsaturated fatty acids derived from methanotrophs (e.g., 16 : 1ω6c, 16 : 1ω8c, 16 : 1ω5c & t, 18 : 1ω8c), in the same chromatogram as the more conventional C_{16} and C_{18} monounsaturated fatty acids and the diether lipid core. The slower oven-heating rate was used to achieve separation of novel fatty acids that are generally not resolved when using more standard oven-heating programs (e.g., from 150 °C to 250 °C at 2 or 3 °C/minutes).

Archaeal diether and tetraether lipid cores were analyzed simultaneously by high-temperature capillary

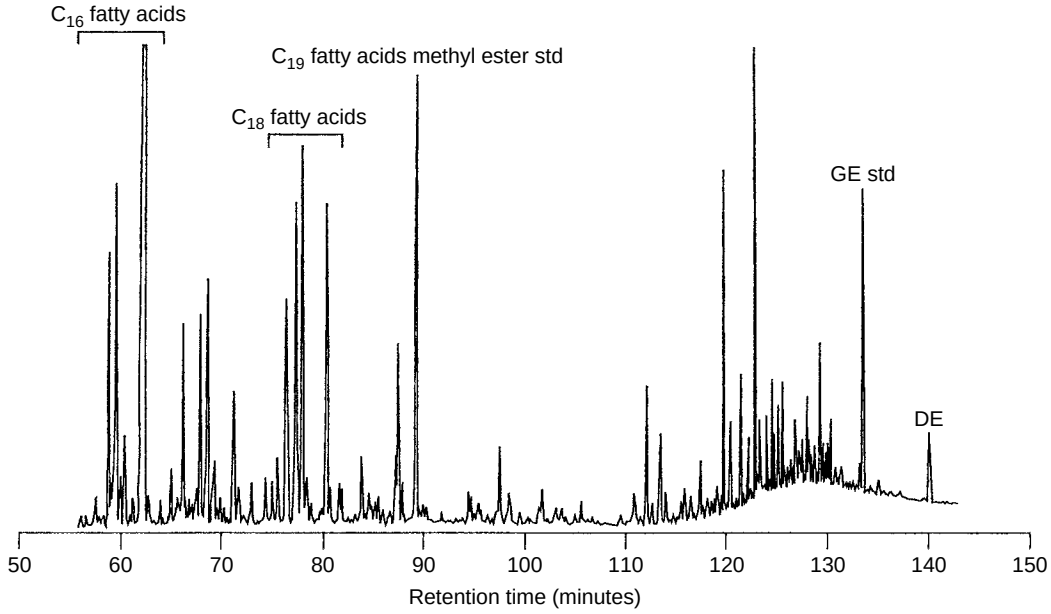

Figure 4. Partial gas chromatogram (HP1) showing phospholipid fatty acids (as methyl ester) and diether lipid (as OTMSi ether) from Billabong sediments. Abbreviations: GE std, glyceryl ether internal standard; DE, diether. Adapted from P. Virtue, P. D. Nichols and P. I. Boon, *J.Microbial. Methods* **25**, 177–185 (1996).

GC (80). The high-temperature GC achieved separation of diether, tetraethers, and cyclopentane-containing tetraethers. A short BPX5-fused silica capillary column (3 m × 0.25 mm) and on-column injector were used for the analyses. Initial research on high-temperature GC separation of diether and tetraether core lipids used novel Aluminum-clad capillary columns. Separation was obtained, but the columns were brittle and their use was not pursued. With other columns tested, loss of tetraether was observed; this was most probably due to the breakdown of this component by active sites on the column. The use of the BPX5 phase on a short capillary column overcame these problems and the tetraether recovery remained stable for continual running of the column over a period of several months. The GC oven was temperature-programed from 90 °C to 190 °C at 30°/minutes and then to 380 °C at 10 °C/minutes. The final temperature was maintained for 15 minutes. Using FID, the instrumental limit of detection for individual ether lipids was approximately 1–2 ng. Representative GC traces illustrating the separation of ether lipids obtained using the high-temperature capillary column are shown in Figures 5 and 6.

It was recommended for high-temperature GC analysis of samples containing both di- and tetraether core lipids that appropriate standard mixtures containing known proportions of the two ether lipid cores be run routinely. Alternately, internal standards that elute close to the di- and tetraether core lipids can be used to assess recoveries.

GC is widely used in many research laboratories. Therefore, the use of high-temperature capillary GC for measurement of Archaeal diether and tetraether lipids provides considerable potential for routine analysis of these microbial lipids in taxonomic, microbial, ecological, and organic geochemical studies. It was reported that the high-temperature GC procedure was at least comparable to and generally better than other techniques in use, and that these features provide new possibilities for measuring Archaea in industrial projects (80). It would be particularly useful if the high-temperature GC procedure could be interfaced to a mass spectrometer to further facilitate the identification of tetra ether core lipids.

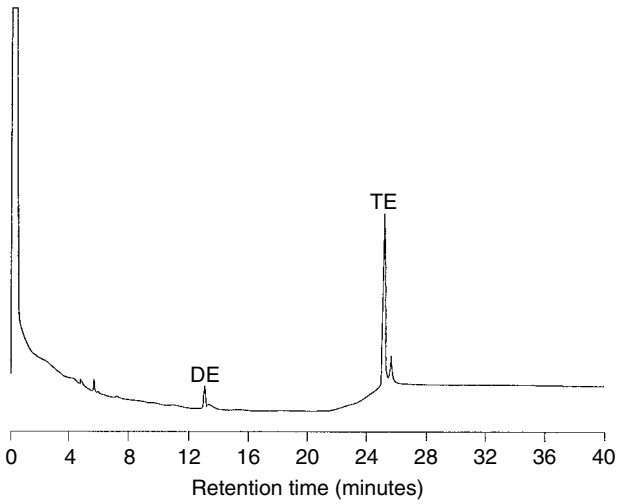

Figure 5. Capillary gas chromatogram (BPX5) showing phospholipid-derived ether lipid distribution of *Methanobacterium thermoautotrophicum* strain Hverigerdi. Abbreviations: DE, diether; TE, tetraether. Components eluting between four and six minutes are fatty acid methyl esters. Adapted from P. D. Nichols, P. M. Shaw, C. A. Mancuso and P. D. Franzmann, *J. Microbiol. Methods* **18**, 1–9 (1993).

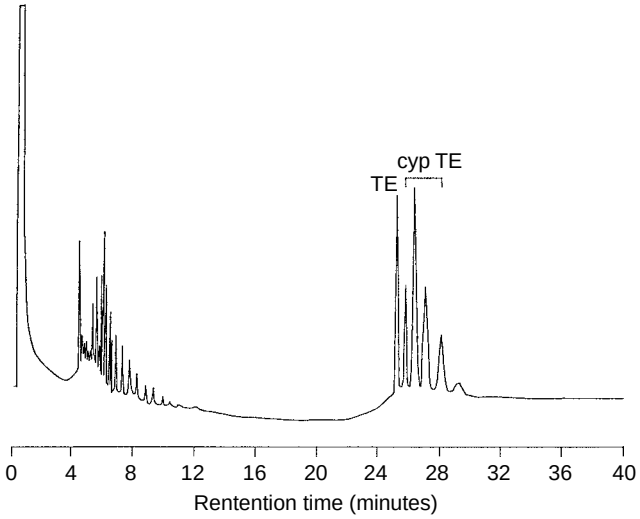

Figure 6. Capillary gas chromatogram (BPX5) showing ether lipid distribution of *Thermoplasma acidophilum*. Abbreviations: TE, tetraether; cypTE, cyclopentane-containing tetraethers. Components eluting between 4 and 10 minutes include phytadienes and monophytanyl glyceryl diols. Adapted from P. D. Nichols, P. M. Shaw, C. A. Mancuso and P. D. Franzmann, *J. Microbiol. Methods* **18**, 1–9 (1993).

In a specific application, highly sensitive gas chromatography combined with negative chemical ionization mass spectrometry (with selected ion-monitoring) enabled the detection, for the first time, of C_{15} and C_{25} homologs of the normal C_{20} isopranyl side chain in several strains of methanogens (100). These methods would be applicable to field samples for determining archaeal community structure.

Mass spectral data is often not reported for studies that examine the distribution of core ether lipids in Archaea and environmental samples. The mass spectra of the diether lipid core (as the trimethyl silyl ether) derived from the methanogen, *Methanoccoides burtonii*, is shown in Figure 7. Further details on formation of the major mass fragments observed have been reported (96).

Recent developments with GC analysis include multidimensional GC and cryo-focusing. Both procedures can be used to enhance component resolution. Should these and other techniques become more widely used, they could be readily applied to obtain increased resolution of the various ether lipid components when analyzed by GC.

Supercritical Fluid Chromatography

Several researchers have used supercritical fluid chromatography (SFC) to analyze archaeal lipids. SFC is a separation technique similar to GC and HPLC. GC and HPLC employ a gas and liquid phase respectively as the mobile phase, but a compressed gas is used in SFC; carbon dioxide is the gas employed in most SFC separations. It has been stated that the versatility of SFC and its range of applications is directly related to the unique physicochemical properties of the supercritical fluid.

The first report of SFC applied to ether lipids demonstrated separation of a range of tetraethers from *Thermoplasma* and also tetraether-derived isopranyl hydrocarbons (101). Complete separation of the tetraether core lipids that differed only by the number of cyclopentane rings present in the isopranyl side chains was achieved. With the phased used, the tetraether core lipids eluted in order of increasing cyclopentane content. The method was suitable for qualitative- and quantitative-screening for ether lipids in living organisms and sedimentary organic matter.

A strategy was developed for use of SFC to separately analyze the polar lipid, glycolipid, and lipid-extracted residue fractions, and the approach was applied to seven strains of Archaea (70). The methodology was suitable for integration with a protocol for the analysis of bacterial lipids. Currently, the SFC methodology does not have sufficient resolution for the analysis of the more complex fatty acid mixtures. The limited literature results available to date for SFC assay of individual strains of Archaea show that separation of individual ether lipid structures is comparable to other chromatography (GC

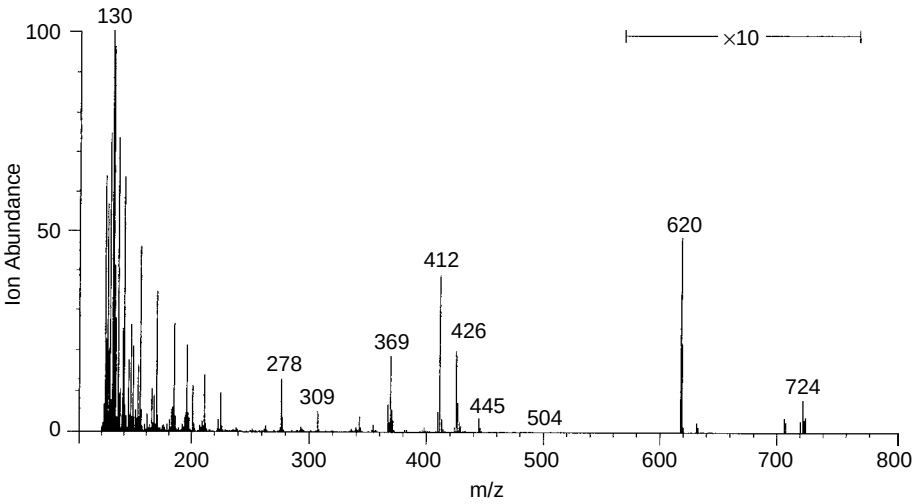

Figure 7. Mass spectrum of the diether lipid (as the trimethyl silyl ether) derived from the methanogen *Methanoccoides burtonii*. Instrument: VG Autospec Ultima mass spectrometer. Mass spectrum kindly provided by Dr. Noel Davies and Ms. Jenny Skerratt, University of Tasmania, Hobart, Tasmania, Australia.

and HPLC) procedures. However, the use of SFC has generally not been widespread and, to our knowledge, the technique is not used in many laboratories performing microbial lipid assays.

Other Signature Lipid Procedures

Carbon isotopic fractionation has been used to determine carbon sources, including the contribution from methanogens, in environmental samples. It is generally considered that methanogens produce biomarkers, including ether lipids and pentamethyleicosane (PME) that are ^{13}C-depleted compared to their carbon source. The advent of GC–isotope ratio mass spectrometry (GC–IRMS) as a research tool now permits more routine examination of the isotopic composition and fractionation for cultured microorganisms and environmental samples. In a recent study, the finding of highly ^{13}C-depleted ether lipid and polyisoprenoid moieties, compared to the ^{13}C-content of biomass of cultured methanogens suggests that there is significant isotopic fractionation inherent in the lipid biosynthetic pathways of some Archaea (81).

Other instrumental procedures have been used in the structural elucidation of ether lipids. These include NMR (both ^{13}C and ^{1}H), probe MS, and fast-atom bombardment MS (FAB MS). These procedures have been invaluable for the determination of precise structural details (102). For example, in a report on the extremely halophilic Archaea *Halobacterium cutirubrum*, FAB (tandem) mass spectrometry was used to analyze intact polar ether lipids (103). Simple positive and negative ion mass spectra of the three major polar lipids extracted from *H. cutirubrum* were obtained that contained ions with masses corresponding to cationized or deprotonated lipid molecules. Structural information was then obtained on individual components of the polar lipid mixtures by discrete selection of ion masses when the instrument was operated in tandem mass spectrometric mode.

These procedures are generally not routinely used to detect Archaea in environmental studies. However, their use is noted here, although they are not covered further in this section. Further information on many of these methods is available (102).

Quinones

The structure and distribution of the various types of isoprenoid quinones in Archaea has been reviewed (102). Isoprenoid quinones are recovered from the neutral lipid fraction of total lipid extracts obtained from aerobic Archaea (Fig. 2) and their structures are based on naphthoquinone or benzothiophenquinone chromophores. Separation of components has been performed by TLC and HPLC procedures, with structural elucidation by NMR, MS, UV, and visible spectroscopy. Studies of archaeal quinones have mainly focused on thermophilic and halophilic strains; detailed studies of the quinone composition of methanogens are yet to be performed (102).

Thermophilic Archaea are divided into two groups with respect to their quinone composition. Members of the genera *Acidianus, Desulfurolobus, Metallosphaera, Stygiolobus and Sulfolobus* are, with few exceptions, based on the benzothiophene nucleus, whereas members of the genera *Archaeoglobus*, *Thermoplasma*, and *Thermoproteus* contain only unsaturated or fully saturated isoprenoid naphthoquinones. The application of quinone methodology to environmental samples for measuring Archaea remains to be explored.

OTHER PROCEDURES

Methane Production

Several studies that have used ether lipids or other techniques to estimate methanogenic biomass have also measured methane. In marine sediments (86), a direct correlation was found between methane concentration measured by a headspace procedure (104) and diether core lipid measured by HPLC.

In water samples, methane is measured by purge and trap procedures. Such techniques have been applied to ocean waters (105). The increased recognition of the presence of methanogens in oxygenated surface oceanic waters has occurred over the past decade. This observation was even termed *the ocean methane paradox* (106). Methane measurements in northern Pacific Ocean waters showed that methane was supersaturated with respect to its equilibration with atmospheric methane (107). To gain further insight into this interesting phenomenon, application of the signature lipid approach in combination with methane measurements and molecular probes would be extremely fruitful.

The direct measurement of methane production rates can be used to detect archaeal activity. This is achieved by measurement of $^{14}CH_4$ formed from $NaH^{14}CO_3$, [^{14}C] — formate and [^{14}C-2] — acetate in time-course experiments using the gas chromatography–gas proportional counting (GC–GPC) procedure (108). In an application of this method in a unique Antarctic lake (109), the sensitivity of the method was demonstrated and a maximal methane production of 2.5 $\mu mol\,kg^{-1}\,day^{-1}$ was estimated.

A signature lipid and radiotracer analysis approach has been used to determine anaerobic conversion of biomass to methane (110). Methane was measured by GC — GPC, and both PLFA and PLEL (the latter by SFC) were measured to determine the bacterial and archaeal biomass, respectively, as well as the community structure. In addition, radiolabel incorporation into PLFA and PLEL fractions was also determined.

CoEnzymes

Methanogens — Coenzyme F_{420}. Coenzyme F_{420} is the N-(NL-lactyl-γ-L-glutamyl)-L-glutamic acid phosphodiester of 7,8-didemethyl-8-hydroxy-5-deazariboflavin 5′-phosphate (111). The enzyme functions as an electron carrier in methanogens for anaerobic respiration and cell carbon synthesis (112). On exposure to UV light, fluorescence emitted by this molecule allows for tentative ID as either coenzyme F_{420} or its analog has been found in all methanogens analyzed to date (113). After purification

by HPLC (114), quantification of the coenzyme has been used to measure methanogenic biomass in mixed systems (115). However, recent studies have shown that the levels of this cofactor and others varied significantly among methanogens as well as within individual methanogens, according to growth substrate (113).

Fourier Transform–Infrared (FT–IR) Spectroscopy

FT–IR spectroscopy has been used by microbial ecologists to examine microbial biomass and nutritional status, including exopolymer production (116,117). Use of the FT–IR technique offers the potential for rapid and nondestructive analysis of bacteria and bacteria-polymer mixtures. The protein-derived amide I band at 1,680 cm^{-1} defines biomass, and bands at 1,740 cm^{-1} — derived from the storage product polyhydroxybutyrate — and 1,150 cm^{-1} are indicative of exopolymer-containing carbohydrate.

The ratio of the various IR bands provides a comparative tool for use in environmental studies. Differences in IR spectra for a range of bacteria have also been reported, suggesting that the FT–IR technique may be capable of providing information on community structure. This possible application of the technique is certainly less developed than its use in examining biofilms of the key constituents just noted.

To our knowledge, FT–IR has not been used to directly examine members of the Archaea. Given the promising findings to date for bacterial communities and noting the distinctive biochemical properties of Archaea with respect to their lipid and cell envelope composition, use of this instrumental approach may offer potential for examining this unique kingdom.

CONCLUSION

The routine measurement of Archaea in taxonomic and environmental studies is now possible, based on developments in the past two decades. In environmental samples, in particular, the use of modern molecular and signature lipid techniques enables the detection and quantification of these important microorganisms. The choice of equipment available to the researcher will influence the selection of a suitable protocol with the signature lipid approach. Further research on molecular techniques is necessary before such methods can become routine and quantitative. It is expected that further developments will undoubtedly occur with these procedures and will increase their resolving power and widen their application. For example, it should be possible to detect methanogens during climate change and in other research programs in which modeling studies of the role of this key group will increasingly need validation via field measurements.

Acknowledgments

We are indebted to Prof. D. C. White for his long-standing encouragement and support in our pursuit of the development and application of methods for the measurement of Archaea in environmental samples. Drs. Peter Franzmann, John Bowman, Peter Rothlisberg, and an anonymous referee provided helpful comments on the draft manuscript. We sincerely thank CSIRO and Antarctic CRC colleagues, including Prof. Tom McMeekin, Mark Rayner, and Jenny Skerratt, for their assistance and support.

ARCHAEA IN BIOTECHNOLOGY

D. A. COWAN

Cape Town, South Africa

S. G. BURTON
Department of Biochemistry
and Microbiology
Grahamstown, South Africa

The Archaea represent one of the three fundamental domains of life. Genotypically, they are as distinct from Bacteria because they are from higher organisms (the Eukarya). The domain Archaea is composed of at least three phenotypically distinct groups, each dominated by members inhabiting extreme environments (high temperature/low pH, anoxia, hypersalinity). The unique biochemistry of some members of the Archaea (such as the methanogens), coupled with the molecular and physiological adaptations of others to physical and chemical extremes, has endowed this group of microorganisms with significant biotechnological potential. The use of enzymes in diagnostics and biocatalysis, fermentations in methane production and metal ion recovery, and cellular bioproducts as food additives and separation membranes are all examples of the enormous capacity for biotechnological exploitation of this diverse group of organisms.

ARCHAEAL PHYLOGENETICS

The Archaea comprise one of the three fundamental groups (domains or superkingdoms) of living organisms (Fig. 1). This fundamental tripartite topology is derived from small subunit rRNA sequence comparisons (1) and is rooted by the inclusion of pairs of paralogous genes (related genes that duplicated and diverged before the three domains separated) as out-groups (2,3). The rooting of the phylogenetic tree places the Archaea as a very deep branch on the Eukaryotic lineage, linking these two more closely in evolutionary terms than the Bacteria and the Archaea. Notwithstanding the importance of genetic transfer between members of the three domains, the close evolutionary relationship between the Archaea and the Eukaryotes has considerable significance in terms of Biotechnology, for example, in the potential use of Archaea as primitive models for eukaryotic cells.

Until relatively recently the Archaeal domain has been clearly separated, on the basis of the genotypic relatedness of cultured organisms, into two kingdoms, the Crenarchaeotes and Euryarchaeotes (Fig. 1). The crenarchaeote kingdom was thought to be phenotypically homogenous and composed largely of the so-called sulfur-dependent thermoacidophiles (Table 1). The euryarchaeote kingdom was more phenotypically diverse and included the methanogens, the extreme halophiles, and various thermophiles, including the fermentative sulfate reducers. For in-depth discussions of the phylogeny of the Archaea, the reader is directed to some excellent reviews (4,5).

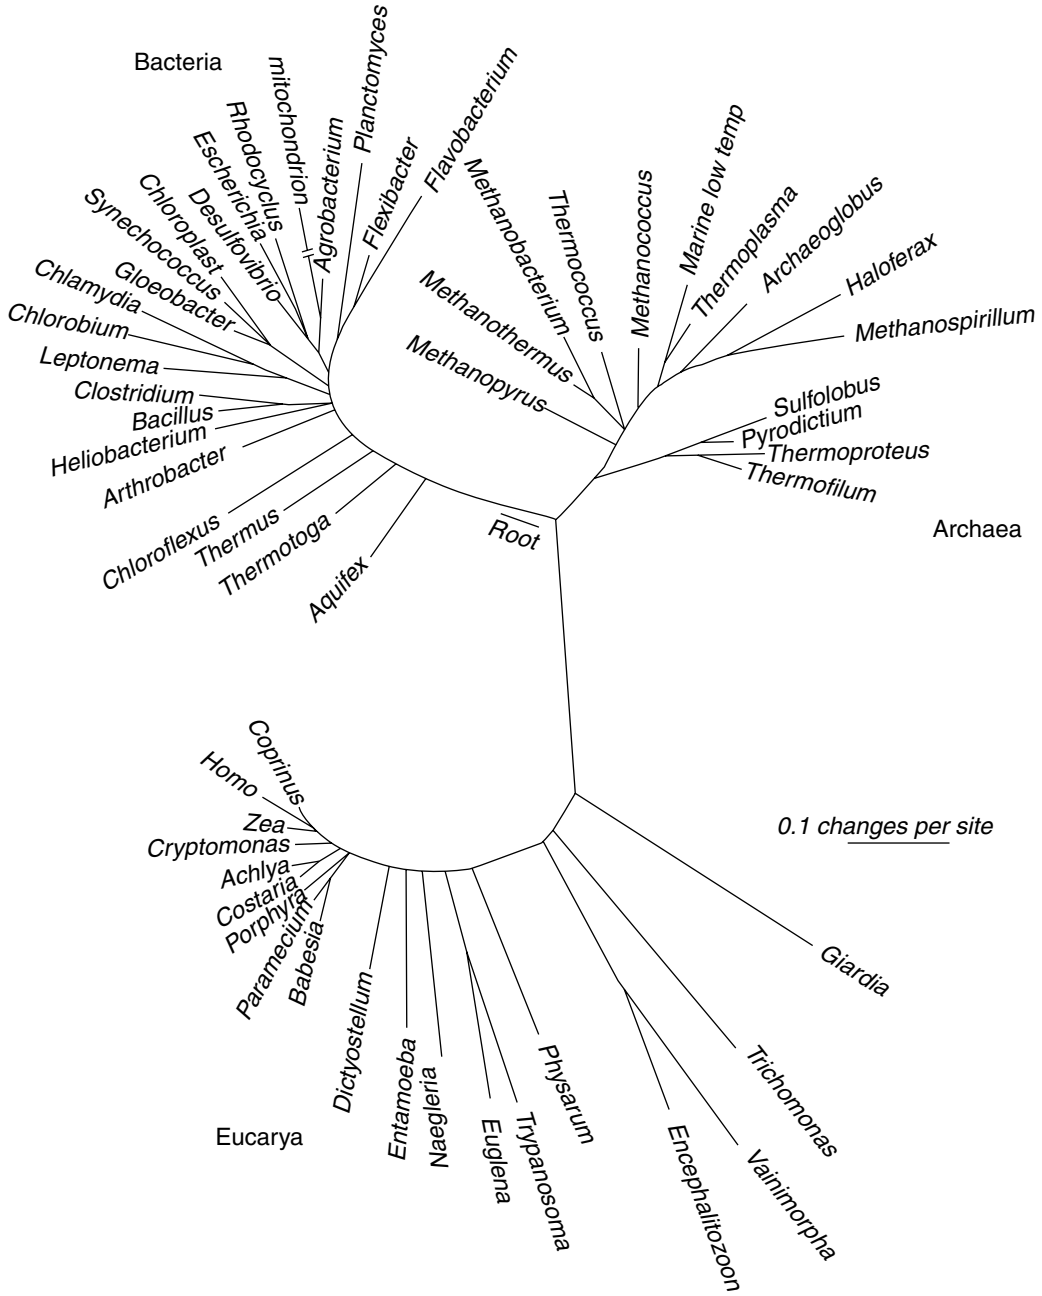

Figure 1. The universal phylogenetic tree. (Reproduced with permission from pace [18]).

The clear-cut twin kingdom structure of the domain Archaea has been substantially blurred, over the last decade of the twentieth century, by the application of molecular phylogenetics to microbial population analysis. The direct extraction of microbial community DNA, coupled with PCR amplification of 16S rRNA genes using universal and Archaea-specific primers (14), has led to a multitude of phylotypes positioned between the two kingdoms (15,16), generating a more homogeneous single domain. Molecular phylogenetic analysis of community DNA has also added apparently new phenotypic and genotypic groups to the domain. One of the startling revelations of this method has been the appearance of numerous low temperature marine and terrestrial derived phylotypes (17,18) in the hitherto exclusively thermophilic crenarchaeota. The discovery of several sequences that branch very deeply in the crenarchaeote lineage has led some to propose a third archaeal kingdom [the "Korarchaeota" (19,20)] and others to speculate on the generation of treeing artifacts.

ARCHAEAL DIVERSITY

The intense interest in all aspects of the Archaea has led to the isolation and characterization of hundreds of different genera and species. Tables 1 to 3 summarize the current

status of archaeal species diversity, divided as the three primary phenotypic groupings, the Thermoacidophiles, the Halophiles, and the Methanogens. The reader should be aware that this list represents only cultured archaea, that it will be out of date before publication as a result of taxonomic revisions and new isolations, and that the true archaeal diversity includes the hundreds or thousands of new species and higher orders so far seen only as 16S rRNA sequences or not yet observed. Given that some of the uncultured phylotypes represent major phenotypic groups (such as the low-temperature crenarchaeotes), the "mining" of the genomic resources of the Archaea has barely started.

The Archaea show a wide metabolic diversity, with a number of unique pathways. For example, the methanogenesis pathway of all methanogens (Fig. 2), reviewed in detail by Daniels (21), contains completely novel sets of enzymes and cofactors. Many of the cofactors are structural analogs of coenzymes in either bacteria or Eukarya, but some are unique to the methanogens. Among the thermoacidophiles and halophiles, a variety of chemolithoautotrophic, fermentative, and chemo-organotrophic modes of metabolism have been identified, for example, see Reference 6. Most are not unique to the Archaea, although certain central catabolic pathways such as the modified Entner-Doudoroff pathway (in halophiles) and the nonphosphorylated Entner-Doudoroff pathway (in thermoacidophiles) seem to be common in the Archaea but very rare outside this domain (22). Other key enzymes, such as the thermostable hydrogenases of the chemolithoautotrophic thermoacidophiles, have unique properties of considerable potential application (shown later). For more comprehensive reviews of the evolution, ecology, physiology, and biochemistry of the Archaea, the reader is directed to more specialized articles (6–13).

UNCULTURED ARCHAEA

The number of known and cultured Archaea is now far exceeded by the number of "new" species and higher taxa known only through their 16S rRNA sequences (phylotypes). Phylotypic analyses of microbial community DNA from established "archaeal" habitats such as thermal pools (19) and hypersaline lakes (23) inevitably show numerous novel phylotypes, in which each represents a new species, genus, or higher order of thermoacidophile or halophile. Even more significantly, phylotypic analyses of many other terrestrial, freshwater, marine, and other habitats have shown that entire groups of Archaea await isolation. Table 4 shows a selection of the "uncultured" phylotypes that have been revealed in recent years. Some of these phylotypes appear to be virtually ubiquitous and in many, such as the low-temperature crenarchaeotes (Table 4), not a single example organism has been isolated. It is perhaps ironic that one such organism, a psychrophilic symbiont of a marine sponge (24), is presently a target for genome sequencing (Table 5) despite never having been cultured.

ACCESSING UNCULTURED GENOMES

There is obviously a great need for new technologies to isolate and culture novel microorganisms. However, in

recent years, methods have been developed that partially circumvent the current limitations of microbial isolation. On the basis of direct extraction of total "community" DNA and the generation of multigenomic libraries (43,44), this technology (Fig. 3) accesses a much higher proportion of the prokaryotic genomes present in any environmental sample than can be obtained from classical microbial isolation. A second advantage is that any number of gene products may be targeted, limited only by the ingenuity and design of the assay method.

Current limitations in these methods, including uncertainties in extraction efficiency, biases introduced during cloning and transformation, and low expression efficiencies due to the presence or absence of upstream and downstream control sequences, will clearly be reduced by further developments in recombinant technology. Although still relatively new, multigenomic cloning will undoubtedly be adapted and optimized for eukaryote genomes (e.g., via cDNA technologies), for expression screening of libraries, and for the targeting of components of the "metabolome" (the complement of metabolites generated by an organism) via specialized vectors accepting large DNA inserts and capable of expressing the components of partial or entire synthetic pathways.

ARCHAEAL GENOME SEQUENCES

The complete sequencing of an organism's genome provides a comprehensive blueprint of the metabolic and functional characteristics of the organism. A genome sequence is also a valuable biotechnological resource for the rapid acquisition, via PCR cloning, of known genes and for the identification of novel or hitherto unidentified genes. The latter requires powerful computational tools, but must always be confirmed by traditional biochemical methodologies.

Given the relatively small number of known Archaeal species compared with known bacteria, the number of Archaeal genomes being sequenced (Table 5) is disproportionately high. This preoccupation with the Archaea, particularly the hyperthermophiles, reflects the biochemical and physiological novelty of the domain and the widespread belief that hyperthermophile genes and gene products will yield substantial rewards for basic science (such as new molecular mechanisms of protein stabilization) and for biotechnology.

The novelty of the Archaea is evident in the proportion of their genomes constituted by unassigned open reading frames (ORFs) (Table 5). These hypothetical protein sequences (identified computationally by the presence of putative start and stop signals) are categorized either as *conserved hypothetical* proteins (observed in another genome, but function unknown) or *hypothetical* (not seen elsewhere, function unknown) proteins. Although the proportion of the latter decreases with each new genome sequence, functional annotation of the former is slow because it is primarily dependent on more detailed biochemical or computational characterization.

The mining of information from new genomes is clearly hampered by the limitations in assigning structure and/or function to hypothetical protein sequences. New computational tools, such as more sophisticated and

reliable methods for searching for structural or functional motifs, are required. Rapid methods for identifying the functional properties of expressed ORFs are also essential. The development of automated microarray technologies for monitoring binding or catalytic functions (45) would be a significant advance.

FERMENTATION AND PRODUCTION

The successful and economically feasible exploitation of Archaeal products, such as enzymes, structural proteins, lipids, pigments, compatible solutes, and so on, will, in many cases, be dependent on the ability to generate high biomass yields in fermentation. Alternatively, for primary gene products, the ability to express Archaeal genes in heterologous hosts at high levels is equally important. Table 6 outlines some of the current limitations associated with Archaeal fermentations and production of recombinant Archaeal products (47).

One major problem associated with generation of high biomass yields of two of the three groups of Archaea, the hyperthermophiles and the methanogens, is that many of these organisms are autotrophs. Chemoautotrophic metabolism is generally energy inefficient, and typically results in low cellular doubling times and culture growth rates and poor biomass yields. In addition, many of these organisms grow optimally at temperatures above 85 °C. Apart from the practical and physical disadvantages of high temperature growth (Table 6), it is probable that high temperatures impose a significantly greater metabolic burden on cellular constituents than low temperatures. The higher requirement for molecular repair and regeneration in hyperthermophiles is probably a significant factor in low biomass space-time yields. Thermal degradation of key nutrients, such as vitamins, may also be a limiting factor.

In consequence, biomass yields for Archaeal fermentation are generally very much lower than for many other microorganisms, as indicated by consensus figures from various batch fermentations (Table 7; 48). These figures are only broadly representative, because the degree of fermentation development varies between organisms, and the mode of fermentation (e.g., batch vs. fed-batch vs. continuous) has a marked effect on space-time yields (49). Recent developments in fermentor technology, including the use of gas-lift and membrane-dialysis fermentors, have resulted in substantially increased biomass yields (48).

For production of primary gene products (enzymes, proteins), the obvious answer to problems of low native biomass yields is the cloning and expression of the relevant gene in a suitable heterologous host. Yields of recombinant gene product are then dependent on expression levels and biomass yields of the host organism.

Despite predictions that hyperthermophilic proteins might not fold correctly in mesophilic hosts, there is ample evidence that this is not the case. Many thermophilic and hyperthermophilic protein genes have now been expressed in a variety of mesophilic hosts, including *E. coli*, *Pichia pastoris*, Saccharomyces cerevisiae and insect cells, and, in most cases, the recombinant enzymes are functionally identical to the native protein. There is some evidence, largely anecdotal that some recombinant hyperthermophilic proteins are significantly less thermostable than the purified native proteins, but no structural or mechanistic basis has yet been established.

The production of recombinant extreme halophile proteins in heterologous hosts is severely limited. Many proteins from the haloarchaea have an obligate requirement for 1 to 2 M intracellular salt concentrations for correct folding and stability and are normally expressed as insoluble, inactive inclusion bodies in nonhalophilic hosts. Halophilic host-vector systems for expression of salt-dependent proteins are currently under development (50).

PRODUCTS OF ARCHAEA

Enzymes

The Archaea present a unique source of novel enzymes because growth in extreme environments requires unique enzyme properties with respect to both activity and stability. The metabolic rates, and hence biochemical reaction rates, in extremophilic cells are not significantly different from those in mesophilic cells, yet the extreme environmental conditions impose unusual constraints on the protein structure-function relationships of extremophilic enzymes. Various studies, using techniques such as genome sequencing and protein crystallography, and comparisons with mesophilic enzymes, have demonstrated that archaeal enzymes have certain structural properties that allow them to maintain their catalytic activity under conditions of extreme temperature, pH, salinity, or chemical environment. These properties make archaeal enzymes particularly attractive as candidates for industrial bioconversion processes, in which stringent reaction conditions frequently prevail. Enzymes possessing enhanced stability and selectivity, unusual or novel reactions and/or substrate specificities, are well-established goals in the field of biotransformations. Furthermore, the technologies of molecular biology now allow us to manipulate genes and

Table 6. Limitations in the Production of Archaeal Biomass and Gene Products

	Hyperthermophiles	Methanogens	Extreme Halophiles
Archaeal fermentations	High temperatures increase wear and tear on steel vessels, bearings, lines, and detectors	Methanogenic metabolism is inefficient	Very high chloride concentrations are detrimental to steel vessels
	Operating costs are high	Methane end-product may pose safety issues	Native enzymes are unstable in low-salt buffers
	Large-scale culturing of chemoautotrophs is difficult	Many low-temperature methanogens have very low doubling times	Some halophilic archaea are genetically unstable
Expression of Archaeal genes in heterologous hosts	No high-level *extremophilic* host-vector expression systems are yet available.		
	Hyperthermophilic genes expressed in mesophilic hosts are not always as stable as the wild-type gene products	No known major problems for mesophilic methanogenic genes	Most mesophilic hosts are incompatible with correct folding of extremely halophilic proteins, which typically require molar intracellular salt concentrations

Table 7. "Laboratory" Biomass Yield Ranges for Various Organisms

Organism	Growth Temperature (°C)	Metabolism	Maximum Batch Fermentation Biomass Yields (g/L w.w.)
Streptomyces	25	Heterotrophic, aerobic	20–100
Bacillus	30	Heterotrophic, aerobic	20–50
Escherichia coli	37	Heterotrophic, aerobic	20–100
Natronobacterium	37	Heterotrophic, aerobic	5–15
Bacillus stearothermophilus	60	Heterotrophic, aerobic	5–10
Thermus	70	Heterotrophic, aerobic	2–5
Methanothermus	85	Autotrophic, anaerobic	1–5
Sulfolobus	85	Heterotrophic, aerobic	2–10
Methanococcus	95	Autotrophic, anaerobic	0.1–1
Pyrococcus	98	Heterotrophic, anaerobic	2–10
Pyrodictium	98	Autotrophic, anaerobic	0.1–0.5

gene products to the extent that enzymes with desirable extremophilic properties may be fine-tuned for specific biotechnological applications.

Enzyme Properties

Thermostability. The remarkable activity and stability of thermophilic enzymes at high temperature suggests numerous advantages with regard to their biotechnological application. Many industrial processes are ideally run at elevated temperatures, in which, for instance, increased reactant solubilities or equilibrium ratios may be favored. Higher enzyme stability and resistance to inactivation reduces the need for replacement or regeneration of the biocatalyst. Structural thermostability also confers resistance to inactivation by chemical denaturants (detergents, chaotropic agents), oxidizing agents, proteases, and organic solvents, and hence to the harsh conditions that may prevail in many industrial process situations (51,52). Conversely, of course, the high temperature-optima of thermophilic enzymes constrains reaction conditions to the extent that the process proceeds less efficiently at lower temperatures.

Thermophilic enzymes have evolved to control cellular metabolic activity optimally at the elevated temperatures of their environment, generally by means of mechanisms causing the proteins to have less conformational flexibility than homologous mesophilic enzymes, and more resistance to the unfolding processes that initiate denaturation (53). Recent research has indicated that a number of relatively minor modifications to the higher order structures of the proteins are responsible for these differences (Table 8), and protein sequences do not appear to vary significantly between functionally homologous thermophilic and mesophilic enzymes (54,55). In particular, the presence of extended networks of ionic interactions on the surfaces of the proteins, increased hydrogen bonding, reduced sections of random loop structure, and structural mechanisms resulting in compact protein packing, such as hydrophobic interactions and subunit association, have all been observed in thermophilic enzyme structures. In addition, low proportions of thermolabile amino acids enhance

Table 8. Structural Modifications Leading to Increased Thermostability in Archaeal Proteins

Structural Property	Modification	Example	Reference
Primary structure	Reduced number of thermolabile amino acids, e.g., Met, Cys, Asn, Gln	*Pyrococcus furiosus* citrate synthase	11
	N- and C-terminal amino acid residues immobilized into protein structure	*Methanothermus fervidus* histone	56
Polar and ionic interactions	Extended ion-pair networks acting over extensive portions of protein	Glutamate dehydrogenases from a range of thermophiles including *P. furiosus*	57,58
	High concentration of hydrogen bonds	Glutamate dehydrogenase from *P. furiosus*	59
	Binding of calcium ions	Extracellular protease Archaelysin from *Desulfurcoccus* strain $Tok_{12}S1$	51
Protein folding structure	Increased hydrophobic interactions giving close packing and excluding solvent	*Staphylothermus marinus* surface protein	58
	Increased inter-subunit interactions and oligomer formation	—	—
	Extended secondary structure	—	—
	Few and /or short random loops	Citrate synthase from *P. furiosus*	11
	Solvent-filled hydrophilic cavities	*S. solfataricus*	—

stability in the primary structure and the absence of many glycine residues reduces peptide chain flexibility. Extrinsic factors such as binding of calcium ions also contribute to thermostabilization in some proteins (51).

Wherever thermophilic enzyme genes are expressed in mesophilic hosts, the thermostability of the recombinant enzyme confers the advantage of facile purification, in which contaminating mesophilic proteins can be removed by heat shock.

Halotolerance. The defining feature of the enzymes of halophilic microorganisms is resistance to inactivation in high ionic strength (low water activity) solutions with salt concentrations of 2 to 5 M. Conversely, the presence of a high ionic strength environment is mandatory for the correct folding and biological activity of many extreme halophile proteins. One strategy for the survival of halophiles is the intracellular accumulation of inorganic ions, such as K^+ and Cl^-, which means that intracellular proteins must be halotolerant to the same extent as extracellular enzymes. Significant adaptations of the protein structures are required to give the proteins the unusual resistance to the unfolding and aggregation processes that typify mesophilic proteins exposed to high ionic strength conditions. The halophilic proteins are commonly characterized by a high proportion of acidic amino acids (glutamate and aspartate), which contribute a high concentration of negative charge on the protein surface. This facilitates the binding of hydrated counterions from solution (halophilicity), maintaining the protein surface hydration and decreasing the surface hydrophobicity that would otherwise lead to aggregation (54).

A high salt environment is an absolute requirement for many extreme halophiles, and their enzymes are frequently observed to be unstable in the absence of high ionic strength media. This can be a serious disadvantage in the successful expression of extreme halophile protein genes in common hosts, in purification procedures, and in the development of biotechnological applications.

Organic Solvent-Tolerant Enzymes. The advantages in biocatalysis of using organic or aqueous-organic media for enzyme catalyzed reactions (e.g., increased substrate solubility and/or stability, reduced water-mediated side reactions, reduced microbial contamination) have provided the incentive for seeking and characterizing solvent-tolerant enzymes. The stability of halotolerant enzymes originates at least partly from the ability to withstand very low water activity; such adaptations can also confer solvent tolerance. The solvent tolerance of several enzymes from halophilic Archaea has been reported (Table 9). Similarly, the mechanisms leading to enzyme thermostability, particularly reduced conformational flexibility, also confer resistance to solvent-mediated denaturation (53,60).

Cold-Tolerant Enzymes. Numerous potential applications of cold-tolerant enzymes, particularly in the food, detergent, and textile industries, have stimulated interest in psychrophiles (64,65). Advantages in the use of cold-tolerant enzymes include the facility to inactivate them by moderate increases in temperature, increased reaction yields with unstable substrates, and energy cost savings. Among the very few archaeal cold-tolerant enzymes that have been reported is a psychrophilic DNA polymerase from *C. symbiosum*, isolated by direct genomic DNA cloning (60). The structural features that apparently facilitate activity at low temperature included extended charged surface loops, reduced numbers of hydrogen bonds and disulfide bridges, and increased ion-pair content, all of which would lead to increased protein flexibility (66). This increased flexibility has potential value in biocatalysis applications in which low water activity is used, but broad substrate selectivity must be maintained.

Table 9. Examples of Solvent-Tolerant Enzymes from the Archaea

Archaeal Group	Enzyme	Potential Application	Reference
Halophiles	*Halobacterium cutirubrum* catalase	Removal of H_2O_2 from reaction mixtures	61
	Haloferax mediterranei protease	Peptide synthesis	60
	Halobacterium halobium extracellular protease	Peptide synthesis with advantage of broad substrate specificity and very high activity	59
Thermophiles	*Sulfolobus solfataricus* malate dehydrogenase	Biocatalytic redox reactions	60
	Sulfolobus solfataricus alcohol dehydrogenase	Biocatalytic redox reactions	62
	Thermococcus stetteri proteinase	Stereospecific peptide or amide synthesis	63

Pressure-Tolerant Enzymes. High pressure is generally regarded as a denaturing condition for proteins. However, in the case of thermostable archaeal proteins, high pressure has been shown to increase the stability and even reaction rate, as demonstrated for a protease from *M. jannaschii* (11). Pressure-stabilization is thought to be due to increased packing of hydrophobic core regions. The DNA polymerase of *Pyrococcus* strain ES4 was used as an example of a barophilic enzyme with high thermostability in a study that indicated that pressure-tolerance is related to restricted volume changes during protein unfolding (67).

Applications — Low Specificity Enzymes

Glycosyl Hydrolases. Thermostable glycosyl hydrolases derived from Archaea act on intracellular and extracellular polysaccharides, facilitating the utilization of external energy sources and maintaining a dynamic equilibrium in the formation and break down of carbohydrate osmolytes (68). Heterotrophic hyperthermophiles that can grow on starch or β-linked carbohydrates are common and have been well documented (Table 10; 69,70). The functions of the glycosyl hydrolases are not always clear, as in the case of the autotrophs such as *M. jannaschii* (71). Hyperthermophiles produce numerous glycosyl hydrolases with varying activities and exhibit both α- and β-hydrolyzing specificities. Typically, extracellular hydrolases are more stable than the intracellular enzymes (53).

Enzymes that are stable and active at the high temperatures required to gelatinize starch form one of the largest-scale industrial applications of biocatalysis. The glycosyl hydrolases of importance in the starch industry include amylases exhibiting both α-1, 4- and β-1, 4 specificity, β-glucosidases that hydrolyze nonreducing terminal 1,4-linkages, and pullulanases (debranching enzymes) required to release glucose monomers from 1,6-linked branches in the polymers (Fig. 4). Biotechnological applications of bacterial thermostable glycosyl hydrolases are well established, and as the availability of bulk, low-cost archaeal enzymes improves, their potential should be realized (Table 11). For example, the halotolerant amylases produced by the halophilic Archaea *H. halobium* and *Natronococcus* could provide useful alternatives to the commercial enzymes currently in use (72). In addition, more specialized reactions may be developed, such as transglycosylations catalyzed by *P. furiosus* β-glycosidase for the production of modified chiral sugars used in pharmaceuticals (53).

Proteases. Thermostable proteases have particular application in protein hydrolysis because the elevated temperatures accelerate the unfolding of a protein polymer and increase accessibility of the peptide to protease activity. Conversely, proteases that are resistant to denaturation by organic solvents find application in peptide synthesis carried out in low water activity media. Thermostable proteases have been isolated

Table 10. Thermostable Glycosylases Produced by Archaea (66,67)

Enzymes			Properties
α-specific	Amylase	*Pyrococcus furiosus*	T_{opt} 100 °C Recombinant enzyme cloned into mesophilic host, expressed extracellularly
	Glucosidase		T_{opt} 115 °C
	Amylopullulanase		T_{opt} 100 °C Extracellular recombinant enzyme
	Glucosidase	*Sulfolobus solfataricus*	T_{opt} 105 °C
	Amylase		T_{opt} 115 °C
	Pullulanase	*Pyrococcus woesei*	T_{opt} 120 °C Recombinant enzyme
β-specific	Glucosidase	*Pyrococcus furiosus*	T_{opt} 105 °C Recombinant, expressed in *E. coli*
	Glucosidase	*Sulfolobus solfataricus*	T_{opt} 105 °C

and/or cloned from a number of thermophilic Archaea (Table 12).

Halotolerant proteases, produced by the halophilic species, are utilized for proteolysis reactions in the high-salt (up to 25% w/v salt) fermentations used to convert certain foods (commonly fish or vegetables) into strongly flavored sauces such as *nuoc mam* and soy sauce. Members of the Archaeal *Halococcus* and *Halobacterium* genera have been isolated from such fermentations, having originated, putatively, from the salt added to the fermentation (72). Halotolerant exoproteases are also produced by *H. salinarum* and other *Halobacteriaceae* strains.

Applications — High Specificity Enzymes

DNA Polymerases. DNA polymerases catalyze intracellular reactions involved with the replication and repair of DNA. The biotechnological applications of DNA polymerases, particularly in thermal cycling reactions for amplification of DNA (the polymerase chain reaction), have led to very significant developments in molecular biology. Although the first used and perhaps best known DNA polymerase, Taq (from *Thermus aquaticus*), is not a product of an archaeal microorganism, thermostable DNA polymerases from archaeal thermophiles represent an important potential source of variety. The heat-stable "Vent" and "Deep Vent" polymerases from *Thermococcus litoralis* (73) and Pfu polymerase from *P. furiosus* have been characterized, cloned, and successfully expressed, and are widely used in molecular biology.

Table 11. Potential Biotechnological Applications of Glycosyl Hydrolases

Enzymes	Sources	Potential Application
Xylanases	*Thermococcus zilligii*	Xylans associated with lignin in wood pulping effluent treatment (74)
Hemicellulases	*Thermatoga neopolitana*	Decreasing viscosity of mannan solutions, e.g., guar gum (70)
Cellulases		Cellulose degradation to release glucose Laundry detergent additives (68) Stonewashing cloth
Amylase	*Natronococcus* sp.	Conversion of starch to maltotriose (75)
Amylase + pullulanases + glucosidase	*Pyrococcus furiosus*	One-step starch-to-glucose process (70)
Pullulanases	*Pyrococcus furiosus*, *P. woesei*	Glucose polymer 1,6-linkage debranching in starch hydrolysis
Amylase	*Halobacterium halobium*	Complete starch conversion to glucose
β-glycosidase	*Pyrococcus furiosus*	Transglycosylation of chiral sugars (70)

Table 12. Thermostable Proteases from Archaea

Archaeal Source/Protease	Properties	Ref
Aeropyrum pernix 'Pernilase'	Intracellular;T_{opt} 90 °C; $t_{1/2}$ 12 minutes at 110 °C	74
Aeropyrum pernix "Aeropyrolysin"	Extracellular;T_{opt} 100 °C; $t_{1/2}$1.2 hours at 125 °C	75
Sulfolobus acidocaldarius "Thermopsin"	—	76
Sulfolobus solfataricus neutral protease	T_{opt} 87 °C	77
D. mucosus "Archaelysin"	T_{opt} 100 °C; purified protease active up to 125 °C	78
Pyrococcus furiosus protease "Pyrolysin"	T_{opt} 115 °C; protease in cell-free extracts still active after 24 hours boiling with 1% SDS	79
Pyrococcus furiosus protease Pfp1	T_{opt} 95 °C; $t_{1/2}$19 minutes, 95 °C	80
Pyrobaculum aerophilum "Aerolysin"	—	81
Methanococcus jannaschii proteosome	700 kDa complex;T_{opt} 100 °C	82

These enzymes have functional advantages over Taq polymerase, with higher thermostability and proofreading (3′-5′ exonuclease) activity. More recently, other DNA polymerases from *T. acidophilum*, *M. thermoautotrophicum*, *S. acidocaldarius*, and *S. solfataricus*, have been reported (53). Although none of the aforementioned show these properties, any thermostable polymerase with particularly high fidelity DNA amplification or extended (e.g., megabase) read-through will almost certainly be commercializable.

Restriction Endonucleases. Restriction nucleases with unusual site specificity are of particular value in molecular biology, for use in the cloning and/or the restriction analyses of DNA. Such a nuclease, produced by *Halococcus acetoinfaciens*, was reported by Obayashi and coworkers (76). Although many Archaea possess Type 2 endonuclease activities, few have unique (and therefore particularly valuable) recognition- and/or cut-site specificities. In addition, there are currently no significant applications in which high thermostability in restriction endonucleases is perceived to be an advantage. In most instances, the simple and effective removal of activity after a restriction digest is paramount.

Inteins. Inteins (protein introns) are internal portions of protein sequences that are post-translationally excised although the flanking: regions are spliced together, making an additional protein product. Inteins have been found in a number of homologous genes in yeast, mycobacteria, and hyperthermophilic Archaea such as *P. furiosus* and *M. jannaschii* (86). Inteins are probably multifunctional, autocatalyzing their own splicing and, in some cases, exhibiting endonuclease activity.

Yeast intein genes have been used in the development of an innovative expression-purification system. The IMPACT™ system, developed by New England Biolabs, Inc. U.S.A., used a chimeric *E. coli* expression vector incorporating fused genes encoding the yeast intein and a *Bacillus* chitin-binding protein. The heterologous protein gene is inserted into a multiple cloning site at the N-terminal autocleavage site of the intein. After capture of the expressed fusion protein (using a chitin affinity column), the heterologous protein can be released autocatalytically after addition of a reducing agent.

This novel expression-purification system has many possible applications. The potential use of a thermophilic archaeal intein gene rather than the mesophilic yeast gene may provide an alternative approach to the rapid purification of heterologous thermophilic proteins

DNA Ligases. The DNA ligase reaction system (ligase chain reaction) allows defects in DNA to be detected through mismatching during hybridization of DNA samples with specifically selected primers. The reaction depends on thermostable ligase activity catalyzing the annealing of previously heat-denatured oligonucleotides. Such a reaction has potential application in detection of genetic defects (87) or specific pathogens (88). Although a thermostable DNA ligase from the bacterial *Thermus thermophilus* has been cloned and made available, there is potential value in the search for additional, more thermostable, ligase enzymes from the Archaea.

Specialist Enzymes for Biocatalysis. With the rapid expansion of biotransformation technology, the need for biocatalysts with very specific characteristics now drives the search for novelty in enzyme function. The exquisite stereospecificity of many enzymes is not readily matched in conventional synthetic chemistry, and enzymes possessing both high selectivity and stability under extreme conditions potentially have a high-value market. For example, the alcohol dehydrogenases of *S. solfataricus* and *H. butylicus*, which have thermal stability and solvent tolerance, have good stereoselectivity in the catalysis of secondary alcohol oxidations or carbonyl compound reductions (53). Similarly, esterases with solvent tolerance have application in stereochemical resolution and in transesterifications and ester hydrolyses. Thermostable and halotolerant archaeal enzymes may well provide new sources of these activities. Biocatalytic redox reactions may also impose unusual constraints, such as specific redox potential or cofactor recycling. Enzymes with high stability and activity and able to function in organic solvent media, would be especially valuable in cofactor regeneration. For example, pyruvate dehydrogenase from *P. furiosus* (T_{opt}>95 °C), glutamate dehydrogenase from *P. furiosus* (T_{opt}95 °C), glutaraldehyde-3-phosphate dehydrogenase from *P. woesei*, and formaldehyde oxidoreductase from *T. litoralis* (T_{opt}95 °C) (50) may all be candidates for developing such applications.

Lipids

The "core" lipids of the Archaea are largely based on saturated isoprenoid chains linked to a glycerol backbone by ether bonds. Common structures include the monomeric diphytanylglycerol ethers and the dimeric dibiphytanyldiglycerol tetraethers and dibiphytanyl glycerol nonitol tetraethers (a generic structure is shown in Fig. 5). The former, termed archaeols, are found in all Archaea, whereas the latter, termed caldarchaeols and nonitolcaldarchaeols, are found only in the thermophilic Archaea. The caldarchaeols and nonitolcaldarchaeols exhibit further modification by containing up to four cyclopentane rings in each of the C_{40} biphytanyl chains. The addition of cyclic structures in the transmembrane portion of the lipid appears to be a thermoadaptive response, resulting in enhanced membrane packing and reduced membrane fluidity (89).

Although few, if any, studies have been carried out on the chemical stability of purified ether lipids, the stability of artificial ether-lipid membranes (liposomes) has attracted considerable attention. Membranes composed of

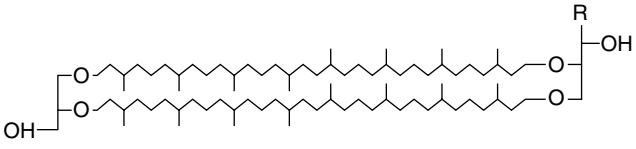

Figure 5. Biphytanyl tetraether core lipid structure (where R = H, calditol, etc).

C_{40} membrane spanning (boliform amphiphilic) tetraether lipids maintain a constant thickness of 25 to 30Å (89), somewhat thinner than typical C_{18} phosphodiester bilayer membranes. Nevertheless, these archaeal membranes are much more physically stable than those formed from phosphodiesters. For example, large (600 nm) vesicles generated from *T. acidophilum* ether lipids were found to be more resistant to physical disruption by high temperature and surface-active agents such as phenol, alcohols, and detergents than dipalmitoyl phosphatidylcholine vesicles (90). In a more extensive study of liposome stability, Sprott and coworkers (91) compared liposomes prepared from the ether lipid extracts of a number of archaea with egg phosphatidylcholine and dipalmitoyl phosphatidylcholine liposomes. In virtually all instances, the archaeal ether lipid liposomes showed higher levels of stability to temperature, pH, serum proteins, and long-term oxidative effects than the ester lipid vesicles. Not surprisingly, the former were also highly resistant to the addition of phospholipases. The use of fluorescent probe techniques to measure the thermal stability of *S. acidocaldarius* lipid liposomes over a temperature range of 25 to 85 °C showed little variation in proton permeability across the temperature range (92).

The remarkable physical and chemical stability of archaeal ether lipid liposomes, attributed to the presence of the ether linkage, to the intimate packing of the phytanyl chains, and to the reduced degree of molecular translational freedom in a boliform structure, has provided a significant incentive to the practical utilization of such liposomes. A number of applications, including drug delivery systems (91) and bioelectronics components (93), have been proposed.

The recent demonstration that Archaeal lipid fractions could be formed into stable liposomes (termed archaeosomes) has led to a resurgence of interest in these structures as vaccine and drug delivery systems (94). The uptake of archaeosomes by phagocytic cells can be up to 50-fold greater than normal liposomes (95), and toxicity trials have not shown any adverse reactions. Mice treated with archaeosome preparations containing antigenic peptides have been shown to give immune responses of the same order as when using conventional adjuvants (96). In addition, tissue distribution data following administration of archaeosomes by different routes suggests that some degree of organ targeting may be possible (97).

S-Layers

The cell walls of most Archaea are characterized by the presence of a regular arrangement of paracrystalline, homogenous protein, or glycoprotein subunits, the Surface-layer (S-layer), as the outermost surface barrier of the cell. The protein subunits are usually of high molecular weight (40–200 kDa) and are arranged in lattices with characteristic patterns of symmetry and complexity, conferring varying degrees of porosity (98). In some archaeal species, such as *H. salinarum*, *H. halobium*, and *S. acidocaldaricus* (99), the cell wall is composed only of an S-layer, a simple protein layer outside the plasma membrane. However, the composition and complexity of the S-layer varies considerably, with some species possessing multiple layers with higher order structures, and/or layers incorporating unusual glycoprotein polymers.

The S-layer proteins of Archaea have a high proportion of hydrophobic amino acids and are often highly glycosylated, sulfated, and/or acidic. The glycosyl components involved frequently have complex composition, with unusual methylation or acetylation of amino groups on the polysaccharide backbone. For example, in *H. halobium*, 50 sulfate groups are present per molecule, on acetylated glucuronic acid and acetylated *N*-aminogalactosyl residues (100). In some methanogens, the S-layer peptidoglycan subunits also contain the unusual polymer pseudomurein, which contains the amino acids L-lysine, L-glutamic acid, L-alanine, and sometimes ornithine, in addition to certain unusual N-acetylated amino sugars. The cell walls of *Methanosarcina* spp. contain methanochondroitin, another specialized glycopeptide, in which the carbohydrate residues are N-acetylated glucosamine and galactosamine (101). Such glycosylation and chemical diversity patterns are far less common in the bacteria.

The functions of S-layers are believed to include maintenance of shape, protection, cell adhesion, molecular surface recognition, and molecular binding to the cell surface (102). The well-defined pore-size, 30 to 40 kDa (103), is likely to confer a molecular exclusion function, protecting the cell against attack by lytic enzymes, immunogens, and biocides. Pseudomurein, for instance, is resistant to cell-wall antibiotics, lysozyme, and proteases and methanochondroitin is resistant to cellulolytic activity. Whatever the structure or function of the S-layer, continuous recrystallization occurs, allowing the dynamic processes of protein turnover and cell expansion and division (98). The highly active expression systems required for continuous in vivo S-layer production are of considerable interest in the development of vectors for high-level expression of heterologous proteins.

Biotechnological Applications of S-Layers. The capability of S-layer proteins to self-assemble and recrystallize correctly and consistently is also observed in vitro, even after disruption due to chemical treatment, which suggests a number of potential biotechnological applications for S-layers. The cloning and overexpression of bacterial S-layer proteins has facilitated their production for reassembly on foreign (non cell-surface) surfaces, in amounts sufficient for industrial applications.

Porous monolayers can be obtained by allowing S-layer proteins to self-assemble on a variety of different type surfaces, including inorganic (e.g., silicon) and metallic (e.g., gold). The orientation of the protein subunits is such that there is asymmetry in the monolayer, with respect to hydrophobicity of the component molecules, so that the layers assemble with a more hydrophobic face presented to the more hydrophobic portion of any biphasic environment such as an air-water or water-solvent interface or on solid or liquid supporting surfaces (104). Thus, selection of the medium permits some control over the nature of the monolayer that forms and hence its function.

The exploitation of archaeal S-layers has been less commonly reported, possibly because of difficulties in the

large-scale fermentation or expression of archaeal proteins. Nevertheless, the progress of production technology is sufficiently rapid to justify the assumption that archaeal S-layer proteins will soon be accessible in quantities that allow the industrial exploitation of these more complex monolayers. The discussion in the following text therefore reports largely on results achieved with bacterial S-layer proteins, but may be extrapolated to the application of archaeal S-layers.

Ultrafiltration Membranes from S-Layer Proteins. Self-assembled monolayers obtained from S-layers have regular and well-defined dimensions (5–15 nm thick, with pores of 2–8 nm), making them particularly suitable for use as ultrafiltration membranes for high-selectivity molecular exclusion, with molecular cutoff of 30 to 40 kDa (103). The consistency of their chemical composition and charge distribution, as well as physical structure, give S-layer membranes more uniform characteristics than conventional synthetic ultrafiltration membranes. The proteins are allowed to assemble on synthetic microfiltration membranes, and may be cross-linked chemically to provide physical resilience. Further chemical modification of the protein monolayers can be used to produce customized membranes with specific functions such as antifouling properties (105).

Immobilization of Biomolecules on S-Layers. The functional groups of S-layer proteins and their associated carbohydrate moieties provide a variety of potential reaction sites for immobilization of other biomolecules, such as enzymes, antibodies, or lipids (106). Such immobilized systems can be formulated on a micro- and nanoscale, as in the case of immobilization of enzymes for use as microscale biosensors in the detection of sucrose (98,107). Coimmobilizing multiple biomolecules allows application of the technology to biochemical reactions of considerable complexity, for example, in immunoassays (106). More sophisticated surfaces, formed by combining S-layers with bimolecular lipid membranes and incorporating various biochemical systems such as proton pumps, provide much potential for new applications (107).

Nanotechnology. In more advanced applications, recrystallized monolayers can be laid down in predesigned patterns on a silicon surface and etched by use of ultraviolet radiation, resulting in practical nanoscale semiconductor components. Coatings of S-layer proteins can also be used to mask areas of silicon surfaces before etching. Alternatively, nanometer scale metallic particles (3–5 nm) and lattices can be formed with preselected symmetry, by using S-layer assemblies as templates (104).

Compatible Solutes

An important characteristic of halophilic and hyperthermophilic microorganisms is the accumulation of a range of low molecular weight compounds in cells, serving as osmoprotectants of cellular components, including proteins (68,108). The chemical nature of these "compatible solutes" varies between species, but all are hydrophilic, water-compatible molecules. Although significantly more information is known regarding the bacterial solutes, hyperthermophilic members of the archaeal group are known to accumulate di-myo-inositol-1, 1′-3, 3′-phosphate, cyclic 2, 3-bisphosphogycerate, or trehalose (109). In thermophilic Archaea, these compatible solutes are considered to have a role in protein thermostabilization, and in halophiles, in osmoregulation and stabilization against high ionic strength denaturation. In certain halobacteria, production of compatible solutes such as biodegradable polyalkanoates and ectoines has been developed for commercial applications, but no such applications have yet been developed for archaeal sources. Nevertheless, an understanding of the role of these solutes in protein stabilization is likely to provide mechanisms whereby biotechnological and pharmaceutical products can be stabilized.

ARCHAEAL PROCESSES

Methane Production

The generation of methane through the mesophilic (and sometimes thermophilic) anaerobic metabolism of methanogenic Archaea is a naturally-occurring and widespread process and is particularly evident in swamps, rice paddies, landfill sites, and in ruminant and mammalian digestive processes. Many of the consequences of this process may be considered to be detrimental, particularly where unwanted methane production generates an explosion hazard (as in landfill sites) or through the supposedly deleterious effects on the ozone layer. However, under "controlled" conditions, Archaeal methanogenesis (biogas) has been exploited as an inexpensive and effective source of energy for many centuries. The first biogas production plant was constructed in India in 1859 and some 10 million small-scale digestion plants are now in use worldwide for local heating and lighting. Large-scale energy production employing methanogenesis is now commonplace in Denmark.

Biogas production is based on the digestion of inexpensive renewable organic material, including animal manure, organic industrial waste, and municipal solid waste. On a larger scale, the biogas production process is frequently integrated into the treatment of industrial, commercial, and municipal wastewaters and effluent streams. For additional information, the reader is directed to the following reviews (110,111).

H_2 Production

An innovative application of hyperthermophilic archaeal enzymes to molecular hydrogen production has recently been proposed. Because of its high energy content, hydrogen is a particularly favored fuel, although biological production methods have received relatively little attention. The discovery (112) of an NADPH-dependent hydrogenase in the hyperthermophilic Archaeon *P. furiosus* has provided an in vitro mechanism for H_2 production. By coupling NADPH production to an enzymic generation system, such as a thermophilic glucose dehydrogenase, a process that uses an inexpensive feedstock (glucose) and generates

two high-value products (glucuronic acid and H_2) can be developed. Preliminary results that show high conversion efficiencies are promising (113).

Biomining: Biological Extraction of Metals

The ability of iron- and sulfur-oxidizing acidophilic microorganisms to enhance the extraction of metals such as copper, gold, and uranium (known as biomining or bioleaching) has been employed commercially for some years. Piles or dumps of low-grade mineral ores are typically acidified by addition of mineral acid, stimulating the natural populations of Fe^{II}- and S-oxidizing organisms (primarily the mesophilic bacteria *Thiobacillus ferrooxidans*, *Thiobacillus caldus*, and *Leptospirillum ferrooxidans*; 114). Where natural heating occurs, populations of the moderately thermophilic bacterium *Sulfobacillus* and archaeon *Thermoplasma* may become significant. At higher temperatures (e.g., >60 °C), the extremely thermophilic Archaea, *Sulfolobus, Acidianus*, and *Metallosphaera*, dominate. The process of metal recovery is dependent on oxidative solubilization of copper and iron sulfides (chalcopyrite and iron pyrite), releasing soluble metals (e.g., copper) and insoluble metal particles (e.g., gold and uranium).

For recovery of high-value metals, it is economically feasible to leach mineral sulfide concentrates rather than low-grade ores and to employ bioreactor technology (typically simple but large stirred tank reactors) rather than ore piles. A number of pilot plants and large-scale demonstration plants are currently operating in Brazil, South Africa, Ghana, and Australia (115,116), with throughputs of a few tens to more than a thousand tonnes of ore per day (Table 13).

The interest in thermophilic bioleaching is derived from advantages in process economics, mineral solubility, and reaction rates from operating at elevated temperatures (117). Norris and coworkers (118) have demonstrated that efficiency of extraction increases proportionally with temperature up to around 80 °C. Furthermore, when operating an exothermic batch reaction in a hot climate, the use of thermophilic organisms precludes the requirement for costly cooling technology. Possible disadvantages lie in the sensitivity of archaeal cells to physical damage in stirred reactors (116) and in the sensitivity of some archaeal strains to high concentrations of soluble metal ions (118). However, the recent identification of *Sulfolobus* strains capable of tolerating concentrations of copper ions up to 40g/L (Fig. 6) suggests that these organisms may be well suited to large-scale metal ion recovery.

Table 13. Operating Mineral Processing Bioreactors (100,116)

Location	Throughput (tonnes ore/day)	Reactor Capacity (m^3)
Fairview, South Africa	40	900
São Bento, Brazil	110	1,160
Wiluna, W. Australia	152	4,240
Obuasi, Ghana	1,152	21,360

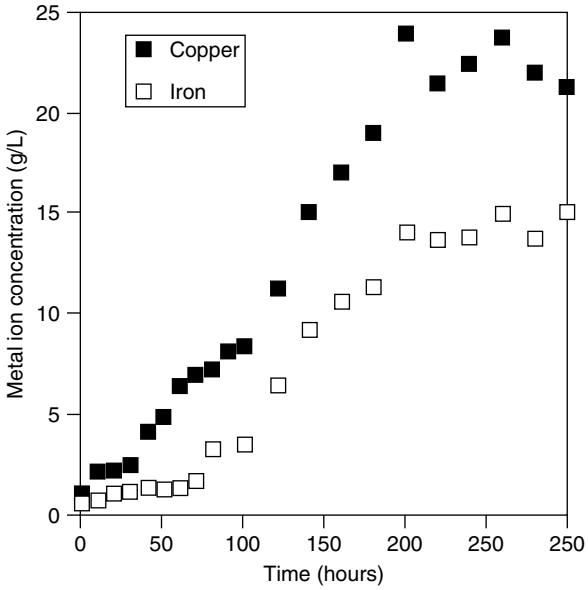

Figure 6. Solubilization of chalcopyrite ore at 78 °C using thermophilic archaea (redrawn with permission).

CONCLUSION

The reader will note that one of the most used terms in the entry with regard to the value of Archaea in biotechnology is the term *potential*, reflecting the reality that while much information is available and more is being generated very rapidly, the number of real commercial applications is limited. This situation is strangely at odds with the level of interest in both academic and industrial sectors with respect to extremophiles in general and Archaea in particular. One factor contributing to this is limited success in developing efficient expression systems for the purposes of enzyme production in recombinant hosts.

Additionally, the operating conditions required for fermentation processes for generating Archaeal bioproducts are substantially different from those of conventional industrial processes and require novel approaches in terms of reactor development, process engineering, and economy. Both of these problem areas are currently being addressed by modern technology developments. The section of the entry describing Archaeal products, whether potential or real at this stage, provides justification for the attention the field is receiving.

ARCHAEA IN MARINE ENVIRONMENTS

ALISON E. MURRAY
Desert Research Institute
Reno, Nevada

Archaea were originally thought to exist solely in extreme anoxic, hot, or hypersaline environments. However, technological advances in the past 20 years have led to a significant revision of this view. Archaea are now recognized to be abundant in the largest habitable regions on earth, the ocean, and in underlying sediments, at times rivaling the abundance of the bacteria (1–3). Marine Archaea have been detected as free-living plankton associated with suspended particles in oxic and anoxic zones of marine sediments, in the guts of fish and holothurians, and as symbionts of marine sponges. Phylogenetic diversity of the marine Archaea is somewhat limited in comparison to the diversity of marine organisms in the bacterial domain, although it is evident that we do not currently know the extent of archaeal diversity, as new groups are continually being discovered (4–6). Although most of these newly described Archaea remain to be cultivated, promising results from environmental genomic, stable isotopic, and microautoradiographic analyses suggest that at least some phenotypic characterization of these important organisms is possible. Evidence suggests that the Archaea are probably important to present day biogeochemical cycles and to past conditions on earth.

NEWLY RECOGNIZED ARCHAEAL DIVERSITY

Recent developments in the study of molecular evolution have led to a unified view of life on earth in which all life falls into three evolutionarily distinct forms, Bacteria, Archaea, and Eucarya (Fig. 1; 7,8) as opposed to five kingdoms (Monera, Protista, Fungi, Plantae, and Animalia) or two forms (Eucaryotic and Prokaryotic) as suggested by other theories based on morphology. Biochemical, genetic, phenotypic, and now genomic data collectively suggest that there are two kinds of prokaryotes, the bacteria and the Archaea, and that the Archaea are as distinct from the bacteria as they are from the Eukaryotes. Archaea were formally recognized to be distinct from bacteria in the late 1970s following the work of Carl Woese (7). There are a number of distinctions on which these divisions have been based, supporting

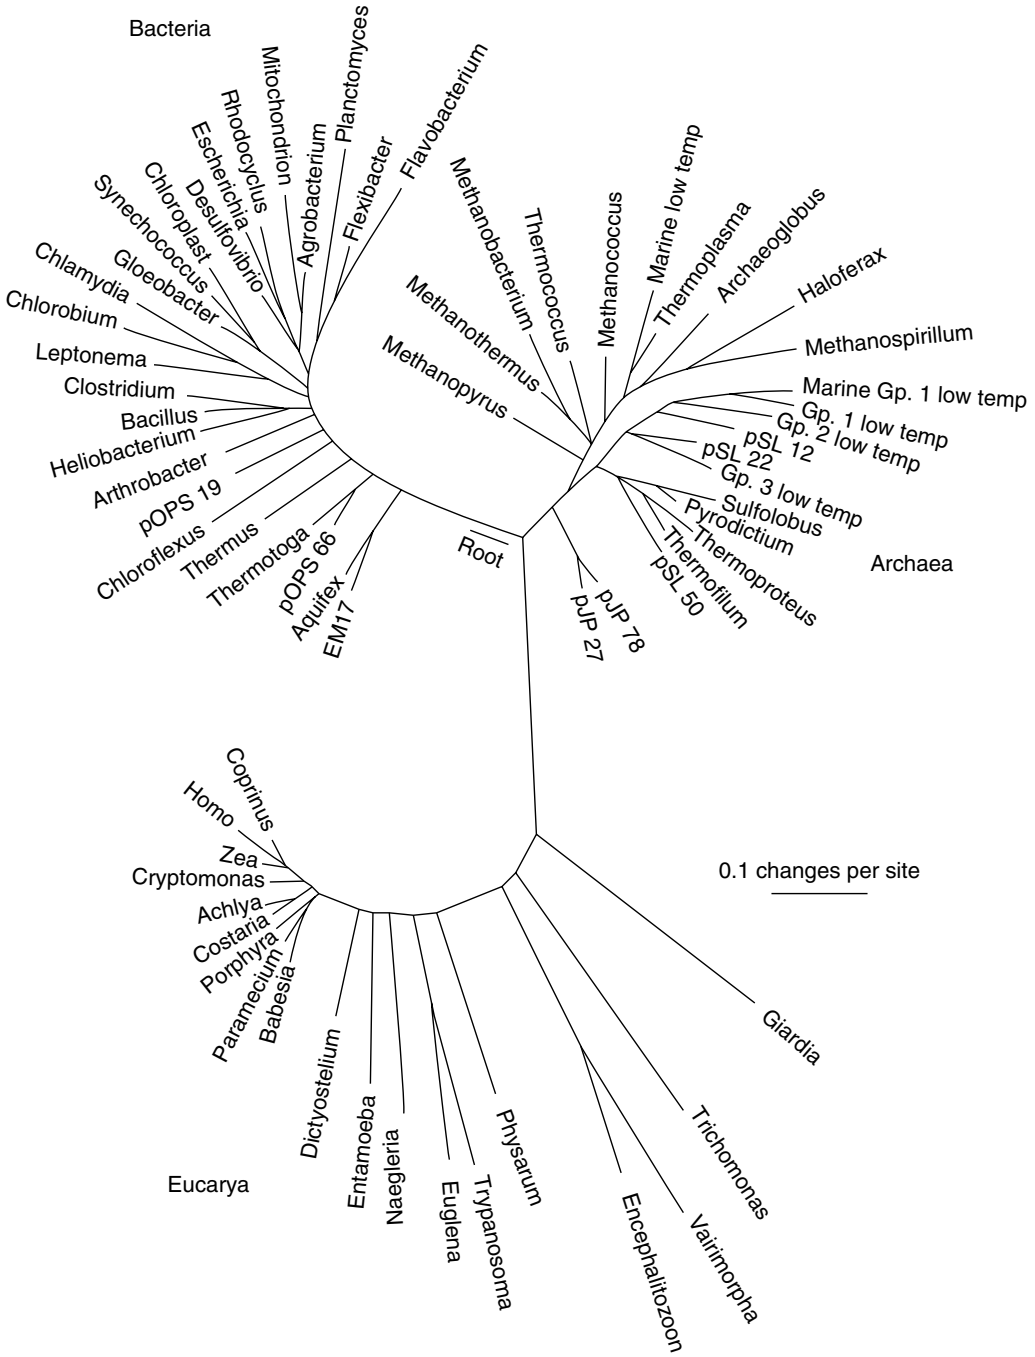

Figure 1. Universal phylogenetic tree based on small subunit rRNA sequences for the three domains of life. (Reprinted (abstracted/excerpted) with permission from N. R. Pace, A molecular view of microbial diversity and the biosphere, *Science*, copyright, 1997, American Association for the Advancement of Science.)

their unique properties. For example, the Archaea harbor the replication machinery of eukaryotes, and the basic metabolic attributes of the bacteria. Initially only thought to occur in extreme (hot, saline, or anaerobic) environments representing ancient forms of life, representatives of the Archaea have been found globally in both terrestrial and marine environments, in oxygenated and anoxic habitats. The phylogeny of the archaeal division strongly supports the existence of two deep branching lineages, the Crenarchaeota (traditionally thought of as the sulfur-dependent hyperthermophiles), and the Euryarchaeota (thought to comprise the methanogens, some thermophiles, and halophiles, which require salt at concentrations greater than 1M).

From the perspective that scientists have been studying marine bacteria for more than 200 years and the deep sea for 120 years, scientists may have unknowingly been studying marine Archaea since the establishment of

marine microbiology. This is a result of the fact that under the microscope most prokaryotes basically look the same and Archaea cannot be readily distinguished by direct cell counts. The history about the existence of Archaea (as they are now formally recognized) in marine environments dates back to at least 1951 with the isolation of a marine methanogen, *Methanococcus vannielii* from San Francisco Bay sediments (9). Marine methanogens, thermophiles, and hyperthermophiles have been isolated subsequently from extreme environments such as deep-sea hydrothermal vents, firmly establishing that Archaea occupy marine ecosystems (10,11). Since then, a number of significant revelations about the extent of marine archaeal diversity, distribution, and abundance have irreversibly transformed the perception of the importance of these organisms in marine environments, with the most revolutionary discoveries following introduction of modern molecular biology to the study of marine environments. Before 1992, all Archaea were thought to exist solely in extreme environments, in which they harbored unique metabolisms and performed specialized biogeochemical transformations for survival. On the whole, Archaea were not considered to be important in marine environments because the habitats in which they flourished were relatively scarce and geographically isolated. However, after molecular tools enabled the discovery that there are mesophilic and psychrophilic Archaea affiliated with both the Crenarchaeota and Euryarchaeota in seawater and marine sediments (12–15), this view has changed dramatically.

In recent years, molecular surveys have repeatedly indicated that cultivated microorganisms represent only a minority of the naturally occurring microbial diversity (16 and references therein); the planktonic Archaea are exemplary of this observation. Today Archaea are often found in molecular surveys of marine environments. Cultivation of the mesophilic and psychrophilic Archaea remains to be accomplished, although many experts have extended efforts to do so. Although the closest relatives of the uncultivated marine crenarchaeotal psychrophiles are the cultivated hyperthermophiles, there are a number of lines of evidence suggesting that these organisms belong to a phylogenetically distinct lineage. The marine crenarchaeotes appear to have a common ancestor with the hyperthermophiles and may have adapted to the colder habitats in which they have been detected. The approach for sampling organisms directly from the environment is tremendously valuable for detecting organisms and establishing relationships in an evolutionary framework, yet the molecular signatures do not provide much in the way of physiological potential, role, or capability.

This chapter addresses the topic of Archaea in marine environments from a global biological diversity and ecological perspective that has risen largely as a result of technological advances made with modern biology. Because the salinity of seawater does not approach the levels required by the extreme halophiles, they are rarely recovered from marine samples (although they are common in ancient hypersaline seas), and thus will not be covered in this article. A key finding from these studies is that the cultivated Archaea numerically represent a minority of the naturally occurring Archaea.

DETECTION OF MARINE ARCHAEA

Microorganisms are inherently difficult to recognize and study because of their small size and limited morphological characteristics. In fact, it is thought that microbiologists are able to cultivate less than 1% of the microbial diversity on this planet (17). At times, sophisticated equipment and media are required for microbial cultivation. Methanogenic members of the Euryarchaeota were the first marine Archaea to be isolated. They are widely distributed in marine environments (mostly sediments), and are thought to be the most commonly cultivated archaeal groups in marine environments (18). They are typically associated with low-temperature anoxic sediments in which they carry out the final step in carbon oxidation to methane. Isolation of marine methanogenic archaea was followed by characterization of hyperthermophilic methanogens; these discoveries precipitated a number of cultivation-based efforts at hydrothermal vents (see HYDROTHERMAL VENTS: BIODIVERSITY IN DEEP-SEA HYDROTHERMAL VENTS and HYDROTHERMAL VENTS: PROKARYOTES IN DEEP-SEA HYDROTHERMAL VENTS, this Encyclopedia).

Cultivation approaches by necessity limit the diversity sampled because the organisms are taken out of their environment. Thus, a major trend in the study of microorganisms living in the environment in the past 15 years has turned to approaches that directly sample the diversity of organisms in natural ecosystems. Significant advances in recognizing archaeal diversity can be attributed to recognition that small subunit ribosomal rRNA (SSU rRNA) sequences can be used to study microbial diversity in natural environments (19). Thus far, it is thought that Archaea in the Crenarchaeota division harbor single ribosomal operons, whereas Euryarchaeota can have as many as four. There is no single genomic organization of these genes, because a variety of patterns (tandemly linked and randomly distributed) have been identified (20).

A number of SSU rRNA-based approaches have been adapted for studying marine Archaea. (*1*) SSU rRNA amplification and clone library generation and DNA sequence analysis was performed in initial studies of marine Archaea (i.e., 12,13). SSU rRNA sequences provide robust data for biological diversity and phylogenetic studies. (*2*) Denaturing gradient gel electrophoresis (DGGE) analysis has been useful for assaying diversity in a comparative framework. This approach was recently used to describe archaeal diversity in deep marine sediments (4). (*3*) Terminal fragment length polymorphism (T-RFLP) analysis of SSU rRNA gene fragments is not as sensitive as DGGE, although it is useful for discriminating between marine crenarchaeotal and euryarchaeotal sequences (21). A recent study demonstrated the utility of this approach for detecting marine Archaea only after a 10-cycle amplification (22) in which the different phylogenetic clusters could be resolved easily, and more closely related

archaea could be resolved following multiple digestions. Amplification-based approaches are typically not very useful for quantifying specific prokaryotic groups, although recent work in this area shows promising results for estimating the abundance of groups of organisms in natural populations using highly sensitive nucleic acid detection techniques such as the 5′ nuclease assay (Taqman assay, 23,24).

For quantification, quantitative membrane hybridizations and fluorescently labeled in situ hybridization (FISH, 25,26) that was modified to increase sensitivity (1,2,27), have proven to be quite effective for estimating natural abundances of marine Archaea. The first quantitative marine Archaea data was determined using oligonucleotide probes designed to be complementary to archaeal SSU rRNA sequences (12). Application of oligonucleotide hybridizations has enabled the detection of Archaea in numerous samples because it is amenable to multiple sample analysis and is relatively quick to perform. Membrane-based oligonucleotide hybridizations to marine community rRNA has proven to be quite accurate in comparison to direct counts of whole cells that are fluorescently labeled (1), and to gene copy numbers estimated by quantitative PCR methodologies (23), although owing to intricacies with probe design, secondary structure conformation, and sequence biases, overestimation, and underestimation are known to occur.

Another recent technological advance has enabled phylogenetic identification of microbial cells (FISH) to be combined with metabolic activity (microautoradiography, 28,29). The cells then are triple stained with 16S rRNA probe, DAPI (binds DNA), and the radiolabeled substrate (incorporated into proteins, DNA, or membranes), which can be visualized under phase contrast following emulsification and developer treatment. This approach has enabled researchers for the first time to show incorporation of a substrate into planktonic marine archaeal cells (30).

One of the unique and unifying characteristics of all Archaea is that archaeal membranes are derived from ether linked isoprenoid-based alkyl chains, as opposed to acyl-ester membrane lipids of all Bacteria and Eukaryotes. The major membrane lipid present in methanogens and halophiles is diphytanylglycerol (archaeol), whereas hyperthermophiles and a few methanogens contain caldarchaeol, a dibiphytanyl-diglycerol tetraether (31). Detection of archaeal lipids in marine waters and sediments (32–34) has confirmed that (*1*) the Archaea are present in abundance in planktonic marine environments, (*2*) their lipids are similar to membranes of other archaea, and (*3*) because of the recalcitrant nature of the ether-linked compounds, marine planktonic Archaea probably contribute significantly to lipids in marine sediments, and hence, are present in the geologic record. Four major lipid compounds found exclusively in Archaea possessing a C_{40} biphytane carbon skeleton containing zero to three cyclopentane rings have been detected from seawater and sediment samples collected from diverse locations (Fig. 2).

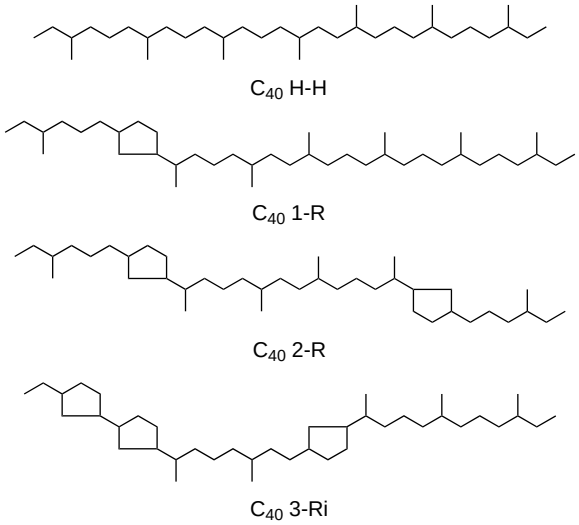

Figure 2. Caldarchaeol-derived acyclic and cyclic biphytane structures derived from Antarctic picoplankton lipid extracts. Symbols: R, pentacyclic ring; i, isomer.

MARINE ARCHAEAL HABITATS, ECOLOGY, AND DIVERSITY

Archaea have been isolated from or detected in a growing number of marine environments. The extremophiles (methanogens, thermophiles, or hyperthermophiles) are not considered to be numerically dominant in earth's ocean systems as they are typically associated with hydrothermal vents, anoxic marine sediments, or associations with guts of marine organisms. They are covered to some degree later in the text and in other articles in this Encyclopedia. Refer to Table 1 for a synthesis of the various studies that have been completed in recent years reporting diversity of marine Archaea using small subunit ribosomal RNA sequences.

Marine Plankton

Biological Diversity and Environmental Distribution. Planktonic Archaea have been detected in both coastal and open ocean ecosystems worldwide in which only four divergent groups (Marine GI-IV) have thus far been identified. All four groups remain uncultivated to date and are distantly related to known thermophiles and methanogens. Cumulative evidence from studies of planktonic archaeal diversity indicate that the most commonly recovered sequences are phylogenetically closely related in a cluster known as the marine group I (Marine GI, 12), in fact, these organisms might be one of the most abundant microbial species on the planet (3).

The marine GI Archaea were originally detected by phylogenetic analysis of environmentally-derived sequences in 100 mm and 500 mm waters off the coast of California (13). At the same time marine GI and GII sequences and archaeal rRNA (using small subunit rRNA-targeted oligonucleotide hybridization) were detected in coastal waters of the Santa Barbara Channel and at Cape Cod (12). Interestingly, at that time, no archaeal sequences were recovered from surface

waters of the central Pacific or Atlantic Ocean gyres. The GI sequences were distantly related to known sulfate-reducing hyperthermophiles grouping with the Crenarchaeota, whereas the GII sequences were most closely related to the *Methanomicrobiales*, a diverse group of methanogens (12). Since then numerous studies have most commonly detected close relatives of marine GI Archaea in midwater to deep ocean depths (Table 1).

Investigations of the extent of diversity of the marine planktonic Crenarchaeota, in particular the marine GI cluster, have indicated that the diversity of this group is fairly restricted, perhaps only being represented by a few closely related species (52). Comparisons of 16S rDNA (Fig. 3a) and ribosomal spacer (internal transcribed spacer, ITS) region suggest that there is a population level structure (ecotypes) in this group that defines two surface-associated clades, an Antarctic clade, and a deep-ocean clade, which harbors the greatest diversity. Diversity of the marine planktonic Archaea supports the view that prokaryotes can have global distribution. It remains to be shown how different the genomes and physiologies of such closely related ecotypes will be.

Although it was initially thought that the planktonic archaeal diversity was restricted to the marine GI and GII, this view has also changed. A cluster of euryarchaeaotal sequences classified as the marine GIII was reported from sequences recovered from deep-sea samples collected in the Pacific and Atlantic Oceans (36). Representatives from this apparently deep-sea-adapted cluster have since been detected in the Aegean Sea (22), and at 3,000 m in the Antarctic Polar Frontal region (Fig. 3b). Similarly, another marine archaeal lineage, referred to as marine GIV, was detected in deep waters (3,000 m) in the Antarctic polar front region. These deeply branching Euryarchaeota are affiliated with the haloarchaea clade (Fig. 3b). Surveys of various regions across the Drake passage, in the Mediterranean, and North Atlantic confirmed the presence of these organisms using primers specific to the marine GIV cluster in samples collected at depth (occasionally at 100 m, and more commonly below 500 m), and never in the upper water column [<100 m (6)]. Recent detection of the marine GIV cluster is probably due to the divergence of this group, which would not have been discovered with several commonly used primer sets. Also, detailed phylogenetic investigations of the deep sea are scarce, and it appears that although the marine GIV organisms are commonly present in deep-sea samples, they might not be very abundant (6).

Several studies have indicated that planktonic archaeal populations are vertically distributed in the water column and that this distribution has phylogenetic coherence. Studies in the Santa Barbara Channel (36,53) and Monterey Bay (1,23) have established the ecological distribution of the two groups of the marine Archaea. The marine GI affiliated sequences appear to be more frequently isolated from deeper in the water column, whereas marine GII Archaea have been typically detected intermittently in the surface waters (Table 1). Planktonic archaeal ecotypes have been shown to be associated with specific environments, such as a biogeographical region studied in the Columbia River Estuary (CRE, 39) or in the anoxic zone of the Cariaco Basin (42). Most reports of marine Archaea suggest that they are free-living, although studies from the Pacific coast, Mediterranean coast of Spain, and North Sea have found archaeal 16S rRNA sequences to be associated with particles (12,21,39,51,54).

An important confirmation that the planktonic archaea were indeed significant residents of the plankton resulted from the gas chromatographic (GC) and GC-mass spectroscopy (GC-MS) lipid analyses. Archaeal lipids containing a biphytane carbon (C40) skeleton, with zero to three cyclopentane rings have been detected in seawater from Arthur Harbor, Antarctica, the Santa Monica Basin, Cariaco Trench, and the Black sea, (Fig. 4), and the Cariaco Trench (34). Acyclic and cyclic biphytanes were the most dominant lipids found in the Arabian Sea at water depths between 450 and 1,500 m (34). The marine picoplankton and *Cenarchaeum symbiosum* were found to contain caldarchaeol and derived acyclic and cyclic dibiphytanes, in which the acyclic head to head biphytane was the most abundant isoprenoid identified (Fig. 4). The value of these lipids as biogeochemical tracers is just beginning to be realized, indicating that these organisms contribute significantly to carbon deposition in the sea (33).

Marine Archaeal Abundance. Several studies have reported direct counts of Archaea in marine coastal and open ocean environments from surface waters to the deep sea where values ranged from 1×10^3 to nearly 2×10^5Archaea $\times$ mL^{-1} seawater, representing 1 to 60% of the DAPI-stained cells (Table 2). There is substantial variability in archaeal abundance (as well as community diversity) with depth (Table 2). In the coastal and continental shelf studies, it appears that the GI Archaea dominate below 60 m, whereas the GII cells are mostly restricted to the upper 40 mm with seasonal peaks in surface waters (1,53). In the open ocean, the GI Archaea peak between 150 and 500 mm and persist in high relative abundance throughout the mesopelagic and bathypelagic zones to the ocean bottom (5,000 mm Fig. 5). In a study at Station Aloha in the north pacific, the abundance of marine GI Crenarchaeota below 1,000 mm equaled the numbers of bacteria and approached up to 40% of the DAPI-stained cells (Fig. 5). The marine GII cells at Station Aloha represented at most a few percentage of the DAPI-stained cells, although sporadic peaks in abundance were detected in the upper water column. Abundance of marine GII declined throughout the mesopelagic zone then increased again in deeper samples. The abundance of marine GI and GII planktonic Archaea have also been estimated using a Q-PCR Taqman assay, in which the marine GI and GII sequences could be detected at the level of 2.5×10^3 to 2.5×10^7 gene copies per reaction (sensitive enough to detect archaeal in one milliliter of seawater, in many locations, 23).

Seasonal Variation. Most molecular-based studies have described archaeal abundance by single point surveys or described distributions of the Archaea down the water column, leaving far less known about the seasonal dynamics of the Archaea. Four temporal studies exist, which

Microbiol.*, copyright, (2001), Blackwell Publishers.

paint partially divergent stories about the persistence of these organisms in marine waters. Antarctic archaeal vertical distribution differs from the patterns described earlier, because the planktonic Crenarchaeota dominate the surface waters of the coastal Antarctic Peninsula. The pattern of seasonal abundance is striking in these waters, where the surface archaeal signal (approaching 25% of the total rRNA signal), which is high in the austral winter to early spring, drops significantly with the onset of spring, and stays low, (1 to 2%) until fall (Fig. 6). A similar observation was made during the late winter to spring transition (October to November) at a station in coastal waters of the Gerlache Strait, Antarctica where relative proportions of the Archaea diminishing from 5 to 1% in surface waters, and 20 to 10% in deep (500 m) waters (56). The GI Archaea were dominant in

Microbiol.*, copyright, 1998, American society for microbiology.

the Gerlache Strait waters (69% of the archaeal signal), although a surface-associated GII rRNA hybridization signal was also detected. In the Antarctic studies, negative correlations were apparent between chlorophyll (and Eukaryal hybridization signal) and the planktonic archaeal hybridization signal (56,57,60). Hypotheses to explain the difference in Antarctic archaeal vertical distributions include increased biological competition in the

Antarctic summer, reaction to increased light irradiance with the onset of summer, or other responses to the onset of summer, because Antarctic surface winter water is analogous to temperate and tropical deep water.

In comparison with the dramatic seasonal variation seen in Antarctic archaeal rRNA abundance, studies in temperate waters off the coast of Santa Barbara and at Station Aloha in the North Pacific reported little correlation between archaeal rRNA abundance and season (3,53).

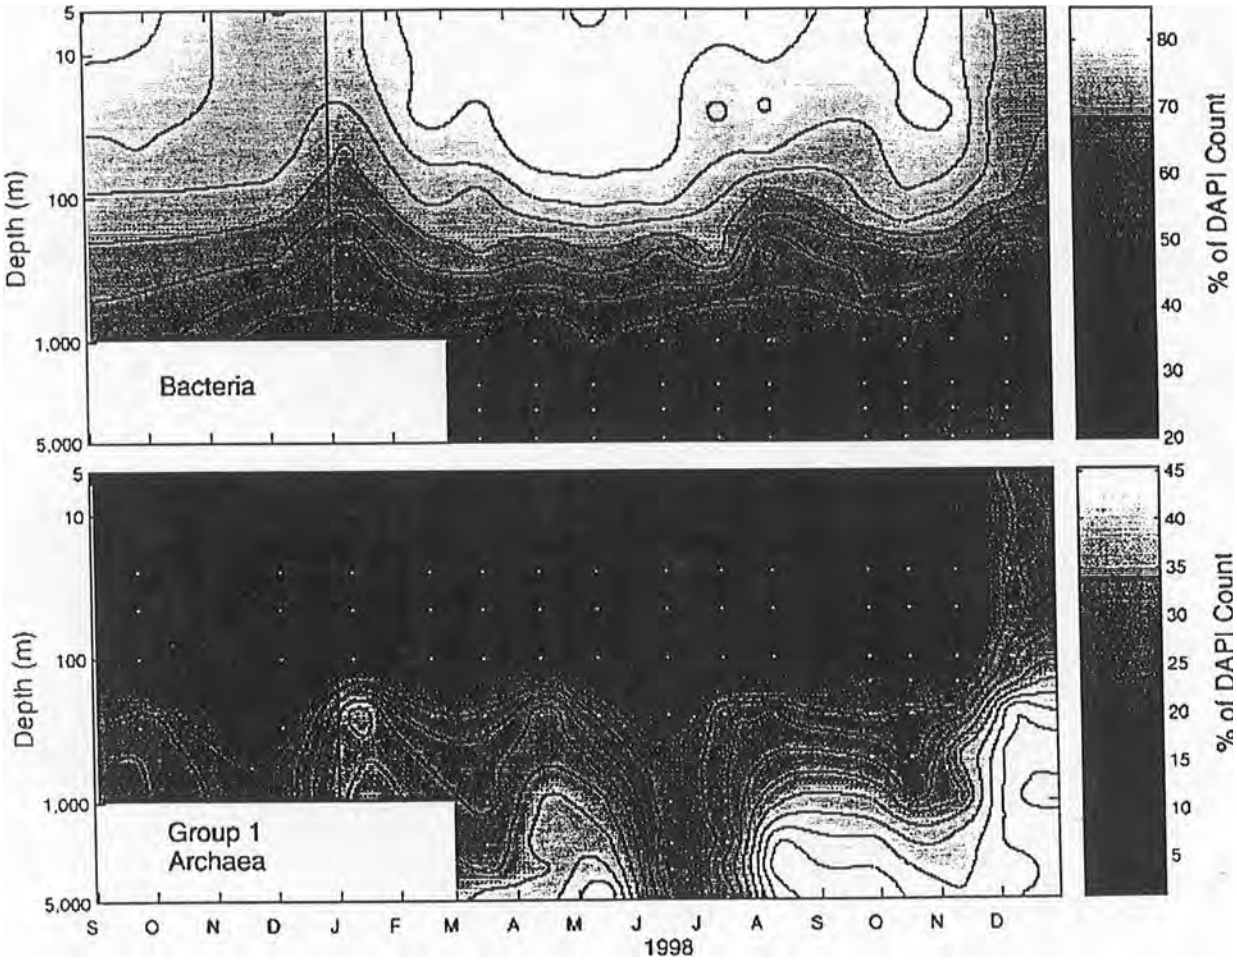

Figure 5. Temporal distribution of bacterial and crenarchaeotal cells indicated by contour plots at the Hawaii Ocean Time-series station, ALOHA, in the North Pacific subtropical gyre. White dots indicate sample depths. Contours represent percentages of the bacterial or crenarchaeotal cells hybridizing with fluorescently labeled polynucleotide probes, in comparison to the numbers of cells stained with the DAPI nucleic acid stain. Reprinted (abstracted/excerpted) with permission from Karner et al. "Archaeal dominance in the mesopelagic zone of the Pacific Ocean," *Nature*, copyright, 2001, Macmillan publishers Ltd.

The differences in the latitude between the polar and more subtropical-temperate environments may partially explain this discrepancy. In polar environments, the influence of strong periodicity in season has immeasurable impact on biological organisms and processes. In the Santa Barbara Channel (SBC) and the North Pacific, mesoscale processes might play a more important role in influencing planktonic archaeal distribution and abundance. The marine GI Archaea appear to consistently inhabit the waters 75 mm or below, although during upwelling periods in the SBC when deep, nutrient-rich water is brought to the surface, GI archaea were detected in surface waters. The marine GII were detected on occasion, typically in SBC surface waters (<20 m). Peaks in the marine GII rRNA signal succeeded phytoplankton blooms four out of nine times, suggesting a potential biological connection to their distribution. One trend seen with studies in the Antarctic and in the SBC is that the GI Archaea are rarely dominant in conditions of high biological activity or prokaryotic abundance (53,60).

Marine Sediments

Originally, methanogens were thought to exist only in anaerobic marine sediments. However, following the isolation of *Methanococcus jannaschi* at a marine hydrothermal vent and other thermophilic methanogens in subsequent studies, it is apparent that the marine methanogens are widely distributed in anoxic marine habitats, where they have since been isolated from psychrophilic, thermophilic, and hyperthermophilic marine environments. It is now thought that methanogens are the most cosmopolitan of the presently cultured Archaea (61). Methanogens have been isolated from seawater particles (62,63), suggesting the existence of anoxic microzones within the particles.

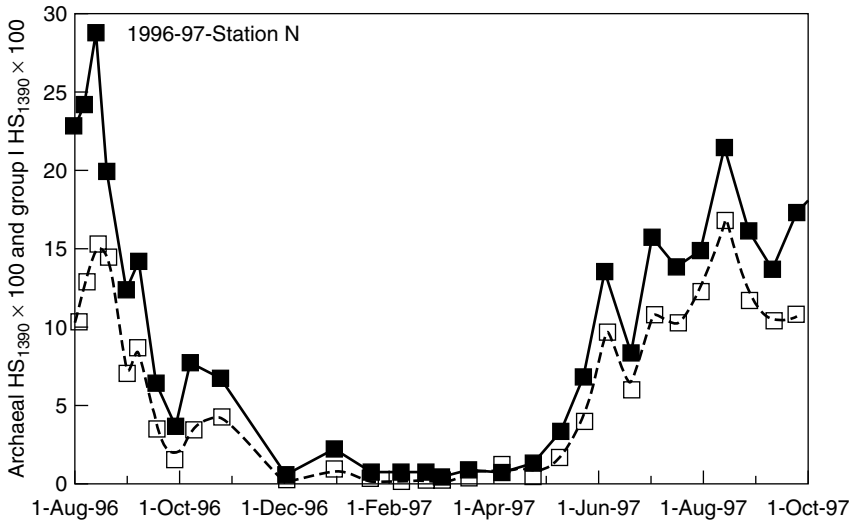

Figure 6. Temporal variation in the planktonic archaeal rRNA hybridization signal (black boxes) and marine Group I hybridization signal (open boxes) in the near-shore waters of Arthur Harbor, Antarctica. Reprinted (abstracted/excerpted) with permission from Murray et al. "Seasonal and spatial variability of bacterial and archaeal assemblages in the coastal waters near Anvers Island, Antarctica," *Appl. Environ. Microbiol.*, copyright, 1998, American Society for Microbiology.

Archaea have been detected in marine sediments around the world in a number of molecular surveys in the past six years. Sediment-associated Archaea consist of a ubiquitous diverse consortium in which several previously unknown lineages have been repeatedly found. Similar to early findings in the plankton, molecular detection suggests that the cultivated groups of methanogens probably do not represent the abundance or diversity of the benthic archaeal microbiota, although several studies have detected some methanogen-related sequences. One of the first such studies conducted in salt marsh sediments detected a diverse assortment of Euryarchaeal sequences including some that clustered with different methanogenic groups (*Methanococcoides* and *Methanolobus*) that either reduce carbon dioxide, or a suite of noncompetitive substrates (14). Sequences affiliated with a halophilic clade, which is surprising because halophiles that require at least five times the amount of salt that is found in the ocean, were detected along with sequences clustering with the marine GII sequences found in the plankton.

Kato and coworkers (43) sampled perhaps the deepest marine sediments on the planet in the Marianas Trench (11,000 m), and reported finding sequences that grouped with the Marine GI cluster. Because the marine GIs are thought to be planktonic in origin, the investigators presume that the Archaea arrived from the middle ocean with settling planktonic particles. Marine GI affiliated sequences were also the most common phylotype found in cold-seep sediments sampled in the Japan Trench [6,400 m (64)]. Diversity of Archaea in deep-sea sediments sampled in the NW Atlantic appears to have higher complexity, including four Crenarchaeota and two Euryarchaeota-affiliated sequences that are distantly related to each other (with 70 to 80% sequence divergence, 4). Both RFLP analysis of clone libraries and DGGE analysis indicated that community diversity increased with sediment depth.

Using 16S rRNA-targeted oligonucleotide probes, reports of archaeal abundances in Arctic sediments of Svalbard showed a trend of increasing archaeal rRNA with depth (Table 2, 65). In the same region, abundance of marine benthic Archaea was determined by FISH (58). Although generally a small fraction of the community, the Archaea were detectable mostly in the surface sediments (up to 6.4% of DAPI-stained cells), and decreased rapidly in abundance, although they represented about 1% of the DAPI-stained cells even at 15 cm; however, difficulties with detection of cells decreased substantially below 10 cm, probably because of low activities and rRNA amounts in those cells.

The same archaeal lipids detected in the plankton have also been found in abundance in marine sediments in the Cariaco Trench, Indian Ocean, Black Sea, Arabian Sea, and other geologic formations (32–34,65). Arabian sea sediments had significant concentrations of acyclic and cyclic biphytanes at depths between 0 to 141 cm (34). In comparison to lipids detected in the plankton, marine sediments off California and Antarctica contained higher lipid concentrations, probably indicating their stability and recalcitrant nature rather than the abundance of organisms in sediment environments, although this has yet to be quantitatively determined (33). It may also be possible to estimate the abundance of Archaea in marine sediments from lipid concentrations, as was suggested by a study conducted in Tokyo Bay in which high concentrations of archaeol, and caldarchaeol were detected in bay sediments (66). The Tokyo Bay study that focused on quantifying archaeol, (to relate concentrations to methanogens) also noted that dibiphytanyl glycerol and cyclophytanyl glycerol were detected in appreciable concentrations in relation to the archaeol.

Methane Hydrates. Methane hydrates consist of a frozen combination of methane and water that can be found in continental margin subduction zones, the deep sea, and in the Polar Regions. Studies have found that active areas of microbial activity are associated with methane hydrates, although the rates of carbon remineralization are thought to be slow. These habitats have been known to harbor dense assemblages of chemoautotrophic sulfide-oxidizing communities composed of *Beggiatoa* mats, tubeworms, and clam fields (*Calyptogena*). The sulfide

source supporting the chemoautotrophic community has often been puzzling because sulfate-dependent carbon mineralization was not occurring in these sediments at appreciable rates. A relatively new, and very interesting story has unfolded in recent years regarding the diversity and metabolic capabilities of the microbial consortia associated with this habitat. Biogeochemical evidence has suggested that methane is being consumed in anaerobic habitats before contacting the aerobic water column or atmosphere. However, no organisms have been isolated that perform this process (67). To get a cultivation-free assessment of the microbial assemblage, Hinrichs and coworkers (5) characterized the small subunit rRNA phylogenetic diversity and stable isotopic signatures of lipids found in methane hydrate deposits off California in the Eel River Basin. This study indicated the existence of a microbial community containing sequences from known anaerobes including methanogens (*Methanosarcinales*), sulfate-reducing bacteria, gram-positive bacteria, and a novel lineage distantly related to the *Methanosarcinales* and *Methanomicrobiales* (5). The stable isotopic signatures of methanogenic archaeal lipid biomarkers (archaeol and hydroxyarchaeol) were strongly depleted in ^{13}C, indicating that they were derived from methane, which has less ^{13}C than any other biologically produced compound. Currently, effort is being extended to cultivate these organisms because they may be a key link in the global methane cycle and past climates.

Rapid progress has led to a much better view of the microbial processes occurring at methane hydrates and in other anoxic marine sediments in general. Results from several studies have detected *Methanosarcinales*-related sequences in methane-enriched environments (5,68–71) suggesting that these organisms, which were thought only to perform methanogenesis (using acetate as a carbon source), may be operating methanogenesis in reverse. A key piece of evidence supporting the existence of a methane-oxidizing sulfate-reducing microbial consortia was demonstrated using FISH in several independent studies, in which cells hybridizing to a *Methanosarcinales*-targeted archaeal probe (ANME-probe) were aggregated in a cluster (1–11 mm in diameter) that was surrounded by cells hybridizing to probes for sulfate-reducing bacteria (70–73). These studies and others have also suggested that there are probably more archaeal species involved in the system because not all archaeal cells hybridize to the ANME-probe (72), the diversity of lipid structures and/or rRNA sequence diversity found indicate the presence of other archaeal groups (70,74), and recently, a study combining FISH with the ANME-probe and secondary ion mass spectrometry presented striking evidence that the non-ANME archaeal cells had significantly higher d13 CCratios than the *Methanosarcinales*-hybridizing clusters (71).

Hydrothermal Vents

Archaeal diversity has been studied in both deep (>4,000 m) and shallow (<100 m) hydrothermal vents using a combination of isolation, enrichment, and cultivation-independent approaches. There are 18 marine archaeal hyperthermophilic genera, 16 of which have exclusively marine origins (75). These groups all are salt requiring, and do not appear to have a pressure requirement. The predominant metabolism thus far known involves the use of elemental sulfur as an electron acceptor, and organic carbon (amino acids/peptides, carbohydrates) as electron donor, and thus is heterotrophic. However, autotrophic Archaea such as the methanogens (growing at temperatures from 2 to 100 °C), and a couple of crenarchaeotal genera including *Pyrolobus* and *Ferroglobus* have also been isolated (75).

Molecular surveys have also turned up new microbial diversity in hydrothermal environments (Table 1). One study at a shallow hydrothermal vent in Tachibana Bay, Japan (45) recovered organisms related to commonly cultivated hyperthermophiles in vent water samples, as well as members of the *Korarchaeota*, a newly recognized third division of the Archaea, described by Barns and coworkers (76). Korarchaeotal sequences were also recovered from a study at a deeper vent site (18). Marine GI archaeal sequences have been detected in the sediments associated with a hydrothermal vent (45), in microbial mats associated with a venting sea mount (46), in black smoker vent water, and a nearby chimney (18). The explanation for this is either that the members of this group actually can reside, and perhaps thrive, in mesophilic-thermophilic sediments, or that because the marine group I have been thought to dominate the archaea found in the plankton, the sediment-derived sequences are from planktonic origin. At many hydrothermal vents, the bacterial diversity exceeds that of the archaeal diversity, although within the Archaea, diverse sequences have been reported (18,45,48). Between 3 to 26.5% of universally primed clone libraries were represented by archaeal sequences in a survey of several deep hydrothermal vent environments (Table 2), and archaeal rRNA abundances from 0.7 to 22.2% were detected from shallow vent sites in sediments sampled in Milos, Greece (48). In situ hybridization analyses confirmed cloning and sequencing results that the black smoker chimney and hot sediments had high cell numbers, and relatively high levels of archaeal diversity (Table 2).

Although it is logistically challenging to do experimental research at the hydrothermal vents, Reysenbach and coworkers (49) succeeded in conducting short-term growth experiments in an in situ growth chamber at a vent site on the Mid-Atlantic Ridge. This study reported substantial archaeal diversity in which representatives from the *Thermococcales* dominated the community (71% of the clones), followed by a significant representation from the *Archaeglobales* group (22%). *Thermococcales* are known to be widespread at deep-sea hydrothermal vents. A couple sequences affiliated with the *Thermoplasmales* (thermoacidophiles) were detected, which were not previously known to exist in hydrothermal vent ecosystems, and a sequence that was in the marine GII lineage that appears to group with other deep-sea sediment Archaea (4).

One of the questions stemming from hydrothermal vent research has been the origin and source of the hyperthermophilic microorganisms. In one case, Summit and Baross (47) sampled a recently venting plume and were able to isolate thermophiles from 8 of 9 samples

at one plume, and 9 of 13 samples in a second plume, in contrast to background samples from the same area where they were unable to cultivate any thermophiles. Their conclusion was that there is a subsurface reservoir of thermophilic organisms, and suggested that these subsurface microbes likely thrive in the vicinity of mid-ocean ridges because of circulation and chemical energy sources.

ECOPHYSIOLOGICAL ATTRIBUTES OF MARINE ARCHAEA

Planktonic Archaeal Metabolism

Determining the metabolic role of the planktonic Archaea has been the subject of many investigations, although few if any have made headway in accurately measuring growth rates, or even determining definitively their basic metabolism. It is likely that the planktonic Archaea do influence oceanic biogeochemistry and elemental cycling because of their shear abundance (20% of the global picoplankton population). Regardless of their metabolism, it is agreed that they contribute significantly to planetary carbon biomass. It was suggested by Karner and coworkers (3) that the GI Archaea are better adapted to the oceanic environment than most pelagic prokaryotes, such that they have probably adopted a common adaptive strategy that has enabled their expansive radiation. It is also the default assumption that, because of the environmental conditions in which the marine GI Archaea prevail, they have aerobic heterotrophic lifestyles, although the evidence for this is scant (27,36). Scientific clues are mounting in a couple of directions, although until these organisms have been cultivated, or enough of their genome sequence is determined, this may remain largely guesswork. Stable isotopic analyses of membrane lipids suggest that the archaeal lipids have ^{13}C ^{12}C ratios ranging between 19.7 to 23 parts per mil (32,34). Hoefs and coworkers (32) proposed two alternative hypotheses to explain the results; (*1*) that the Archaea use dissolved inorganic carbon as their carbon source, and do not discriminate against ^{13}C as other primary producers do, or (*2*) the Archaea carbon and energy source are acquired from low-molecular weight organics such as acetate and methylated amines derived from algal carbohydrates and proteins. The archaeal lipid signatures in the Arabian Sea were typically enriched in ^{13}C compared to algal sterols (34).

One of the facets of Archaea is that they are resistant to many antibiotics that inhibit bacterial activity. On the basis of this premise, experiments conducted on Antarctic planktonic microbiota set out to measure the activity remaining following erythromycin treatment of concentrated plankton in which the Archaea represented between 1 to 9% of the assemblage (<1.6 μm fraction, (56), Massana and coworkers 1998). Although these investigators failed to detect any activity signal higher than background in those experiments, they suggested that the marine Archaea could be sensitive to erythromycin, perhaps do not incorporate leucine at appreciable rates, were damaged in the concentration procedure, or simply were not as active as their biomass indicated.

Probably the most promising evidence that the planktonic GI Archaea are active came from a study in which FISH was used in tandem with microautoradiography. The results of this study suggest that 60% of the planktonic Archaea were active, and that they incorporated dissolved amino acids (30). This finding led the researchers to conclude that the archaeal cells were heterotrophic, and perhaps as active as the heterotrophic bacteria in the same sample (by comparisons of the staining intensities). However, more work in this arena will be necessary to determine whether the amino acids are being used in assimilatory or dissimilatory pathways.

It is possible that the marine GII, GIII, and GIV have different metabolic properties than the GI, given the differences in their phylogenetic groupings as well as their close relationship to the methanogens and halophiles. Fuhrman and Davis (36) postulated that the marine GII and GIII could be methanogens — because oceanographers have reported on midwater methane signals (77,78), but little proof exists to support this hypothesis and some reports have found the marine GIIs to bloom in surface waters, although these occurrences have been shown to occur following periods of upwelling (53). The potential that GIV phylotypes are halophilic is possible on the basis of their close relationship to cultivated halophiles (6).

Methanogenesis in Marine Environments

Methanogenesis has been thought to occur in marine sediments either where there are low concentrations of sulfate, so that they are not in competition for substrates with sulfate reducers, or when the methanogens can use non-competitive substrates such as methanol, methylamines, or methionine. Both physiological and molecular data support both conditions. Methanogen-related sequences have been isolated from surface sediments. The topic of methanogenesis will be covered elsewhere in this Encyclopedia and will not be covered in more detail here.

Sulfur-Dependent Anaerobic Methane Oxidation

Anaerobic oxidation of methane (AOM) not only occurs at methane hydrate sites, it is also suspected to occur in areas with substantial methane production and sulfate availability, including marine sediments, anoxic waters, deep continental margin sediments, and soda lakes (79). Theoretical and field-based lines of evidence indicate that AOM occurs in the presence of sulfate reduction by a consortium of organisms. Thermodynamics suggests that AOM would only be favorable if there was a removal process for hydrogen, which could occur if sulfate reducers were consuming the hydrogen. Lipid analyses from a well-known methane-enriched mud volcano in the Eastern Mediterranean, methane hydrates in the Eel River basin and Santa Barbara Channel, and seeps in the Black Sea have indicated that *archaeol* and *hydroxyarchaeol* are present along with a number of other archaeal and sulfate-reducing bacteria derived lipids (68,70,74,80). These studies showed that not only were the archaeal lipids strongly depleted in ^{13}C, but glycerol ethers and fatty acid products from Bacteria were abundant, and showed similarly depleted ^{13}C values in comparison to

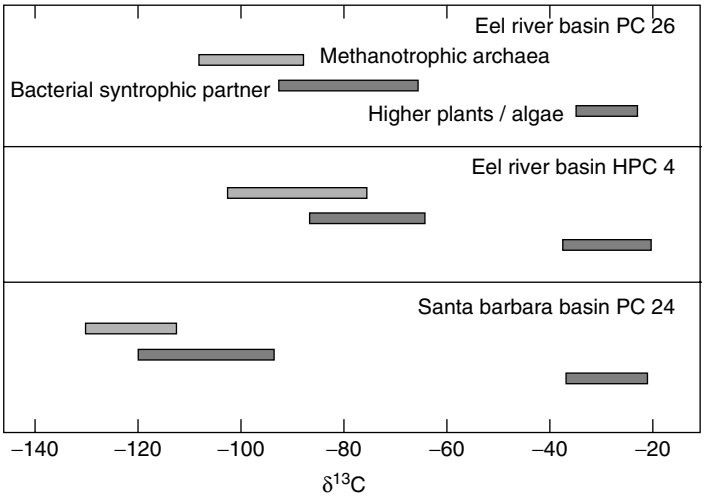

Figure 7. Carbon isotopic concentrations of sedimentary lipids assigned to methanotrophic archaeal, bacterial syntroph, and plant/algal sources from three different methane seeps. Note the similarities in ^{13}C depletion for the methanotroph and bacterial syntrophy in comparion to the relatively ^{13}C enriched algal lipids, indicating that the carbon source for the methanotroph and syntrophy was methane, and not algae or terrestrially-derived carbon. Reprinted (abstracted/excerpted) with permission from Hinrichs et al. "Molecular and isotopic analysis of anaerobic methane-oxidizing communities in marine sediments", *Org. Geochem.*, copyright, 1999, Elsevier science.

control sites (Fig. 7). In addition, algae and plant lipids from the nearby sites was significantly enriched in ^{13}C in comparison to either the methanotrophs or bacterial syntrophs, indicating different carbon sources (CO_2 versus CH_3, Fig. 7). Control sites with similar carbon input as the hydrate sites consistently had less recalcitrant carbon in the sediments in comparison with methane seep sites that had significant levels of residual carbon in the sediments, suggesting that sulfate removal processes, rather than remineralization, are occurring at methane seeps (68). A recent review proposed a mechanism for the sulfur-dependent methane oxidation process, in which the following reaction provided the highest energy yield of the different reactions examined (79), and produces twice the amount of energy predicted from a reverse methanogenesis reaction.

$$\text{Methane Oxidation: } 2CH_4 + 2H_2O \rightarrow CH_3COOH + 4H_2 \quad (1)$$

$$\text{Sulfate reduction: } 4H_2 + SO_4^{-2} + H^+ \rightarrow HS^- + 4H_2O \quad (2)$$

$$\text{Sulfate reduction: } CH_3COOH + SO_4^{-2} \rightarrow 2HCO_3^- + HS^- + H^+ \quad (3)$$

$$\text{Net reaction: } 2CH_4 + 2SO_4^{-2} \rightarrow 2HCO_3^- + 2HS^- + 2H_2O \quad (4)$$

Whether this reaction or something similar is actually occurring as a result of an archaeal-sulfate-reducing bacterium syntrophy remains to be seen.

Archaeal Metabolism at Hydrothermal Vents

Hyperthermophilic microbes contribute significantly to geochemical cycling in hot environments in present day environments and in early earth conditions. There are three major metabolic processes currently thought to dominate hydrothermal vent habitats, reduction of sulfur compounds, methanogenesis, and iron reduction. Sulfate reduction rates measured in hydrothermal sediment samples collected in the Guaymas Basin had optimum of 70 °C and 82 °C in different cores, with an upper limit determined to be 102 °C, where Archaea such as *Archaeglobus profundus* have been previously isolated (81). Dissimilatory reduction of iron is a relatively new discovery (82), and was recently shown to occur in the tandem with humic substance reduction (83). In this case, the extracellular quinones in the humics are reduced and the electrons are abiotically transferred to neighboring iron oxides, thus regenerating the humics.

ARCHAEAL ASSOCIATIONS WITH MARINE ORGANISMS

Endosymbiosis has been a common feature of methanogenic euryarchaeotes (*Methanomicrobiales* and *Methanobacteriales*) including associations with ciliates, insects, and a large number of vertebrates including humans. The discovery that psychrophilic Crenarchaeota were found in associations with marine organisms was initially quite surprising. Marine GI archaeal sequences were first found to be associated with the midgut of a deep-sea deposit feeding holothurian (50). Perhaps not as surprising in light of recent molecular surveys of marine sediment habitats in which the Archaea appear to be common constituents (although the GII-affiliated sequences and other euryarchaeotal benthic Archaea appear to be more common), this was an important finding because this was the first nonmethanogenic archaeal group to be characterized in association with another organism. Since then a true symbiosis has been described for the marine sponge *A. mexicana*, which hosts the marine GI symbiont *C. symbiosum* in its tissues (27). The rationale for determining that the association was symbiotic was based on the high archaeal cell numbers, active cell division, and persistence of the association. *Cenarchaeum symbiosum* appears as a rod, with a specific nuclear region, which can be discriminated when using DNA and rRNA stains. Archaea have been detected in other marine sponges off the California coast, in the Antarctica, and in the Great Barrier Reef (84,85), although the associations have not been described in detail. The exact nature of nutrient exchange, secondary metabolite production, or

other benefits from the archaeal-sponge interaction have not been elucidated as of yet.

Marine GII archaeal sequences have also been found in the guts of marine fishes, flounder, and grey mullet, as well as flounder fecal pellets (21). Marine GI clones (86) were also recovered from the flounder digestive tract, although marine GII sequences were more frequently represented (22 of 29 clones). In a later study, *Methanococcoides*-related archaeal sequences were detected in the flounder digestive tract using a nested-PCR approach (51). The sequences from the fish digestive tracts were quite similar to those detected on suspended particles in the surrounding water column, suggesting that a potential habitat for the anoxic methanogens lies in marine fish or other animal digestive tracts. Fecal pellets appear to be the marine particulate source of the methanogens detected, although the alternative that the fish acquire the Archaea via seawater ingestion cannot be discounted (51).

ARCHAEAL GENOMICS AND BIOTECHNOLOGICAL APPLICATIONS

A promising future for discovery in archaeal biology lies in genomics. The hopes entail developing an understanding of the basic biology of extremophiles in which comparisons to mesophilic and psychrophilic genomes will help determine how these organisms cope with the extreme conditions they inhabit. Similarly, for the uncultivated Archaea, environmental genomics may be one of the best ways to advance knowledge concerning the basic metabolic properties of these widespread yet poorly understood groups of organisms.

Approximately ten archaeal genome sequences are present in public databases, in which six are from organisms isolated from marine environments (Table 3). Genome organization is not well conserved among those archaeal genomes sequenced. However, comparative genomics studies of these genomes are presently taking place (87). The genome sizes of all archaeal autotrophs are reduced (approximately 1.6 Mbp), in comparison with bacterial heterotrophs (approximately 2.5 to 6 Mbp). The first archaeal genome to be sequenced was *M. jannaschi*, a methanogenic hyperthermophile, isolated from a hydrothermal vent at a depth of 2,600 mm. The novelty of finally having a whole genome sequence validated suspicions that archaea are composed of bacterial and Eukaryal genes. Although 56% of the *M. jannaschi* genome coded for hypothetical proteins, not matching any sequences in sequence databases, the genes associated with central metabolism and cell division matched sequences of bacterial origin, whereas genes coding for information processing, such as DNA replication, transcription, and translation were more eukaryotic like (88).

One of the key features of an environmental genomics approach is that it provides access to the genomes of uncultivated organisms. Several large archaeal DNA fragments have now been sequenced from environmentally derived samples (92–95). The first environmental contig was assembled from a 40 Kbp sequence prepared from a library assembled with DNA collected from a depth of 200 m off the coast of Oregon. The results of this study confirmed that the genome fragment containing an archaeal ribosomal operon contained several genes that had the highest similarity to archaeal sequences in the database, to the exclusion of the Bacteria or Eucarya (92).

Evidence for the thermal sensitivity of enzymes from the psychrophilic marine GI archaeon, *C. symbiosum*, resulted from a study in which the DNA polymerase gene discovered by sequence analysis of a 42.4-kbp fosmid was expressed in *E. coli* (93). The results indicated that the DNA polymerase from *C. symbiosum* was inactivated at 40 °C, which lent support to the nonthermophilic phenotype of this symbiont. Further screening of the *C. symbiosum*-sponge genomic library indicated the presence of two highly related, but nonidentical rRNA sequence variants with 28 kbp of overlapping sequence (94). Results

Table 3. Archaeal Genomes Sequences from Completed Genomes and Environmentally Derived Large DNA Fragments. Some Were Not Published (n.p.) at the Time of Printing. The *Pyrococcus Furiosus* Genome is being Sequenced by the Center of Marine Biotechnology/University of Utah, and the *Pyrococcus abyssi* Genome is being Sequenced by Genoscope

Species/Clone Name	Environmental Origin of Organism/Sample	Reference
Complete Genomes		
M. jannaschii	Submarine hydrothermal vent; East Pacific Rise, Pacific Ocean	88
Archaeoglobus fulgidus	Marine hydrothermal sediment; Vulcano island, Italy	89
Pyrococcus horikoshii	Marine hydrothermal vent; Okinawa Trough vents, Pacific Ocean	90
Aeropyrum pernix, K1	Marine solfataric vent, Japan	91
Pyrococcus furiosus	Marine sand surrounding sulfurous volcanoes	n.p.
Pyrococcus abyssi	Deep-sea hydrothermal vent, South-east Pacific	n.p.
Environmental Genome Fragments		
Fosmid 4B7	Marine plankton, crenarchaeotal marine group I	92
Cenarchaeum symbiosum (Fosmids 60A5, 101G10)	Marine sponge *A. mexicana*, symbiont	92,93
Fosmid 37F11	Marine plankton, euryarchaeotal marine group II	94

indicate that there is microheterogeneity in the GI archaeal symbiont population within the sponge host and suggest that heterogeneity will be a complicating factor in genomic studies of natural populations.

A 60-kbp marine GII archaeal insert was detected from a BAC library prepared from surface water picoplankton of the Monterey Bay (95). Sequence analysis of this large insert resulted in identification of 38 genes, with the majority of characterized genes having archaeal homologs, although eight genes appeared to have bacterial homologs, suggesting the potential for lateral gene transfer. Structural analysis of protein domains of unknown genes suggests the potential for a membrane-associated proteolytic system to be encoded by a couple of the open reading frames, thus demonstrating the potential for gene discovery in uncultivated organisms and the potential for predicting phenotypes from gene sequences.

The marine Archaea are a valuable resource for applications in the biotechnology field, providing enzymes active from -2 to $+130\,^{\circ}C$, biopolymers, and the ability as whole cells to perform chemical manipulations that currently require application of a number of toxic chemicals. Hyperthermophilic archaeal enzymes are being developed and used for their properties of high-temperature activity and tolerance for activity in organic solvents (96). Recent studies indicate that marine hyperthermophilic diversity is still untapped, and the potential for these organisms as a biotechnological resource, for example, in producing enzymes for research applications (polymerases, restriction enzymes, etc.), for the food industry, and in "green chemistry" is just being realized (97,98). Through the study of homologs in genomic fragments of the psychrophilic Archaea, important clues to enzymatic temperature adaptation are likely to unfold (16,94). One of the areas of future research, in particular regards to extremophilic genomics and developing an understanding of molecular adaptations to high temperatures will be predictive modeling and structural biology. Using signature 3-D structural themes in microbial proteins, modelers will be primed to apply this approach to the understanding of enzyme structure for hyperthermophiles and other extremeophiles.

ORIGINS AND EVOLUTION OF THE MARINE ARCHAEA

The "source" of the Archaea in marine planktonic environments has been debated since their discovery nine years ago. Theories that they arise from hydrothermal vent plumes, from anaerobic gut environments in marine fish or invertebrates (copepod guts) have mostly been put to rest because their widespread distribution, abundance, and occurrence in aerobic cold habitats is commonplace (16). However, hyperthermophilic archaea can survive in low-temperature oxic seawater (99), and have been found in hydrothermal vent plumes, which could potentially lead to the dispersal of these organisms far from the vent habitats (100,101). Similarly, methanogens could be resuspended from anoxic sediments, and have been isolated from oxic seawater (62,63). Evidence including the *C. symbiosum* symbiosis and other sponge-archaeal associations, thermolability of the *C. symbiosum* DNA polymerase, G + C content of the GI crenarchaeotal rRNA operon, detection of terrestrial GI Archaea, and so on indicated that the newly described, nonextremophilic Archaea belonging to the Crenarchaeota and Euryarchaeota branches of the Archaea are likely adapted to their cold, aerobic environments.

The cold-adapted Archaea have probably been long-term residents of marine planktonic and sediment environments, and have potentially played key roles in these present day and potentially ancient ecosystems. Archaeal lipids have been detected in sediments from the Eocene Era [50 million years ago, (32)], suggesting their long-term existence in marine environments. Furthermore, new studies investigating deep cores samples in the North Atlantic provide compelling support for dominance of non-thermophilic Archaea in sediment horizons correlating with oceanic anoxia (approximately 112 mya). Stable isotopic analysis of the archaeal lipids indicated that they had chemoautotrophic lifestyles (102). In addition, the recognition that anaerobic methane oxidation is a significant archaeal-mediated biogeochemical process also suggests that the same process could have occurred on early earth when the atmosphere may have consisted primarily of methane in which the anaerobic methane oxidizers could have played an important role in earth's climate (79).

Theories regarding the origins of life and early earth environmental conditions that led to the formation of life have been an active area of research in the past decade. One popular theory postulates that the earliest forms of microbial life existed in hot anaerobic environments. It is likely that the origin and evolution of many metabolic reactions and pathways occurred in the thermophiles and hyperthermophiles. For example, work by Lovley and coworkers (83) demonstrating the ability of hyperthermophiles to reduce quinones in extracellular humics may suggest a significant impact on early life on earth because extracellular quinones and iron oxides may have both been present in early earth conditions. The origins of the cold dwelling Crenarchaeota remain a mystery as to the history of life on earth, since the discovery of these organisms opened up the potential for psychrophilic origins from what was once argued to be the hot origin of life for the Archaea. However, a recent study conducted in Yellowstone appears to have recovered sequences that have a common ancestor (pSL12) with the cold Crenarchaeota (76).

CONCLUSION

Marine Archaea have been isolated or detected from environments with temperatures ranging the spectrum found on this planet, from more than $100\,^{\circ}C$ to less than $0\,^{\circ}C$ representing hyperthermophilic (>80 to $110\,^{\circ}C$), thermophilic (45 to $80\,^{\circ}C$), mesophilic (15 to $45\,^{\circ}C$), and psychrophilic ($<15\,^{\circ}C$) lifestyles. Archaea have been found to exist as free-living organisms, attached to particles, and associated with other marine organisms in a variety of habitats. Planktonic Archaea can be found throughout the water column from surface regions in coastal areas, to the deep abyss, and appear to be globally distributed among the world's oceans, including

the Southern Ocean, Atlantic, Pacific, North Sea, and the Mediterranean. The planktonic Crenarchaeota may be one of the most abundant bacteria on the planet (3). Archaea associated with marine sediments comprise a diverse consortium in which the diversity is largely defined by the geochemistry of the sediments. In contrast to the plankton, several members of sediment-associated archaeal communities have been cultivated, although molecular methods have revealed new diversity in nearly all phylogenetic archaeal lineages. Diversity recognized thus far includes methanogens, relatives of halophiles, anaerobic methane oxidizers, hyperthermophiles, and psychrophilic Crenarchaeota and Euryarchaeota.

The future holds promise for revealing detailed information about the presently uncultivated GI and GII planktonic lineages through applications of genomic technologies, which could eventually uncover mysteries of their physiological lifestyles, and the adaptations that these organisms have undergone for survival in cold environments. These organisms may hold the clues to understanding differences between thermophily and psychrophily because the nearest cultivated relatives of the GI Crenarchaeotea are hyperthermophiles. Along similar lines of discovery, the interdisciplinary approaches being applied to the anaerobic methane oxidizer consortia (69) through combining stable isotopic signature analysis with molecular identifications promises to be a highly valuable approach that will likely be applied to increasingly more microbial-biogeochemical investigations.

ARCHAEA IN SOIL HABITATS

HOLLY M. SIMON
ROBERT M. GOODMAN
University of
Wisconsin–Madison
Madison, Wisconsin

Archaea comprise a heterogeneous group of microorganisms, many of which contribute substantially to terrestrial biosphere processes through their unique metabolisms. Their "extremophile" image in popular literature as well as in scientific circles, derives from the fact that archaea, traditionally, have been isolated from "extreme" habitats, that is, high sulfide, hypersaline, anoxic, or hyperthermal. Today, molecular evidence shows that soils and aquatic environments of a "nonextreme" nature are also habitats of novel archaea with as yet unknown metabolic properties.

Here, we present an overview of soil as a habitat and a review of what is known about archaea in

soils. We describe what is known or deduced about the ecological properties of archaea found in both extreme and nonextreme soil habitats. Research on ecological roles of archaea in soils is scarce except with regard to methanogenesis, which is a globally important process carried out exclusively by members of the Archaea. We give an overview of the ecology of methanogenic archaea; however, this topic is more thoroughly discussed by R. Conrad (Flooded Soils) in another article in this Encyclopedia on the microbiology of flooded soil habitats.

SOIL AND THE BIOSPHERE

Soil is a major reservoir of microbial biomass, comprising from 10 to 50% of the Earth's terrestrial, prokaryotic carbon, with an estimated 26 Pg (1 Pg = 10^{15} gram) of organic C in 2.6×10^{29} cells (1). The global impact of prokaryotic metabolism in soil habitats is significant. For example, symbiotic N_2 fixation provides approximately 80% of the biologically fixed reduced nitrogen on land (2). Microorganisms in both water-saturated, anoxic, and drier, well-aerated soils are also important influences on atmospheric chemistry; they make a net contribution of about 60% of the CH_4 present (3) and contribute significantly to the cycling of carbon monoxide (CO), carbonyl sulfide (OCS), nitrous oxide (N_2O), and nitric oxide (NO) [(4) and refs. within]. A complete account of the contribution of archaea to the biomass and metabolism of soil prokaryotes awaits results and future studies on the prevalence, metabolic repertoire, and microhabitats of soil archaea.

Complexity of Soil

Although familiar and seemingly simple, soil is so complex as a microbial habitat that many of its secrets remain well guarded as the twentyfirst century dawns. Soil is a heterogeneous mixture of living organisms, decomposing organic materials, and inorganic substances (Fig. 1). Differences in particle composition, size, shape, density, and charge, combined with climatic variation, form the basis for diversity in colonization of soil by different life-forms. Plants, animals, and fungi, the latter two mainly microscopic, inhabit soil. Billions of prokaryotes also live in each gram of soil. Physical, chemical, and biological heterogeneity in soil creates a network of microenvironments; these are strongly influenced by temperature and can vary widely in ionic strength and composition, pH, and water and redox potential. The diverse prokaryotes that adapt to and exploit these microniches match this diversity in habitat with equally diverse metabolic capacities.

Soil Microorganisms and Biosphere Functioning

Potential productivity in both natural and cultivated systems is directly related to soil organic matter concentration and turnover, which in turn supplies most macronutrients required for plant growth. Through their roles in the decomposition of soil organic matter, soil microorganisms are largely responsible for terrestrial ecosystem development and functioning. Both prokaryotic and eukaryotic metabolisms influence the temperature regulation of the Earth through CO_2 turnover, whereas CH_4 cycling (3) and the recycling of crucial minerals such as N, S, and P are largely dependent on prokaryotic activities (4).

Figure 1. Electron micrograph of soil (scale bar 5 μm). Bacteria (B) are usually associated with organic matter that still contains carbohydrate (e.g., cell walls, W). Other highly lignified and convoluted organic matter (O) does not support bacteria, but there are numerous microorganisms (0.3 μm diameter) scattered throughout the clay (*). *P* is a pore, approximately 1 μm in diameter. Reproduced from R. C. Foster, *Quaestiones Entomologicae* **21**, 609–633 (1985).

Diversity of Soil Microorganisms

Soil is an immense reservoir of microbial diversity. The rich diversity of soil microorganisms can be glimpsed through use of the agar plating technique; a broad

array of different colony morphologies can be recovered upon plating a soil sample. Knowledge of the microbial composition of natural environments was, for a long time, based mainly on those organisms that were amenable to growth in vitro using such standard approaches. However, it was also known that a large discrepancy existed between culturable and total microscopic cell counts in natural habitats, and soil habitats in particular (5,6). This observation suggested many unknown and not easily cultured microorganisms were present. Torsvik and coworkers elegantly demonstrated this concept using DNA-DNA reassociation kinetics, showing that thousands of prokaryotic genomes are present in a gram of soil, compared with a relatively less complex genome mixture derived from the culturable subset (7,8). A staggering diversity of microorganisms is also inferred from the results of culture-independent methods that exploit direct recovery of genomic DNA and analysis to derive phylogenetic types (phylotypes) from sequences of ribosomal RNA; such analysis reveals that the majority of phylotypes recovered from soil are novel (9–14).

The Archaea serve as an example to illustrate the discrepancy between culture-based and nonculture-based knowledge derived from studies of microorganisms in the environment. Most archaea have not been cultured from habitats considered to be nonextreme, such as mesophilic soil or oxygenated marine surface waters. On the basis of culture-independent studies, it now appears that archaea are not only present in such habitats, but are reasonably (and in some cases very) abundant members of the microbial assemblages there (Table 1).

AN OVERVIEW OF ARCHAEA IN SOIL

Archaea: The Third Domain

The discovery of *Archaea* as a third domain of life revolutionized evolutionary thinking by establishing that prokaryotes are not monophyletic (23). Although archaea are prokaryotes and resemble bacteria in morphology (single cells lacking internal compartmentalization), in evolutionary lineage they are closer to the Eukarya than to bacteria. Archaea, in fact, share some characteristics with eukaryotes, for example, the homology of archaeal and eukaryotic RNA polymerases (24), but in other ways are similar to bacteria, for example, gene composition and order (24). Examples of characteristics exclusive to archaea include the sequence and structure of particular regions of ribosomal RNA (rRNA) (25) and the composition of membrane lipids and lipid linkages (26).

Table 1. Estimates of Abundance of Nonthermophilic Crenarchaeota

Habitat	Abundance	Ref.
Oxygenated coastal waters	2% total rRNA	15
Antarctic surface waters	34% prokaryotic biomass	16
Santa Barbara channel	20% total rRNA	17
Antarctic waters	1–24% total rRNA	18
Pacific mesopelagic zone	30–50% prokaryotic biomass	19
Axinella mexicana (marine sponge)	60% prokaryotic cells	20
Michigan soil	1.4% total rRNA	21
Tomato roots	3.3–16% prokaryotic cells	22

Taxonomy and Phylogeny of Archaea

There are two phylogenetic divisions of the domain *Archaea* represented by cultured isolates, *Crenarchaeota*, and *Euryarchaeota* (27), and a third proposed division, *Korarchaeota* (28), for which only rRNA sequences have been recovered (28–30). All cultured representatives of the Crenarchaeota are extremely thermophilic sulfur metabolizers. Examples include members of the genera *Sulfolobus* and *Thermoproteus*. The Euryarchaeota comprise cultured members with a more diverse metabolic repertoire, including methanogens, for example, *Methanothermus* and *Methanosarcina*, extreme halophiles ("salt-loving") such as *Halobacterium* and *Natronococcus*, and the thermophilic, wall-less acidophile *Thermoplasma*, in addition to sulfur-metabolizing hyperthermophilic archaea, for example, *Archaeoglobus* and *Thermococcus*.

Archaea in Soil

In this article, we describe the distribution of archaea in what are considered conventional soils, both extreme and nonextreme (see also METALS: MICROBIAL PROCESSES AFFECTING METALS). Archaea typically have been isolated from extreme (high sulfide or saline, elevated temperatures) and anoxic environments, resulting in the generally accepted idea that they represent a primitive group exiled from the (now) more common aerobic and nonextreme environments of contemporary earth. Until recently, this view extended to soil habitats as well. Archaea were previously and almost exclusively cultured from soils of an extreme nature, such as acidic hot soils heated by solfataric gases (a solfatara is defined as a volcanic fissure that gives off sulfurous vapors and steam) and evaporative saline soils. An exception to this observation is cultured isolates recovered from anoxic soils. Archaea isolated from these environments encompass diverse groups and physiologies. More recently, however, the known diversity among Archaea has been broadened considerably more by the inclusion of new members represented solely by small subunit (SSU) rRNA gene sequences recovered from temperate habitats, including mesophilic and low-temperature soils that have not previously yielded isolates of Archaea.

Distribution of Archaea in Soil

Archaea have been isolated by culturing from extreme and anaerobic soils located around the globe (Table 2). Examples include solfataric fields in Italy, the Azores, United States, Iceland, and New Zealand, and rice paddies in Japan and Italy. Even more novel SSU rRNA sequences of uncultured Archaea have now been recovered from soils all over the globe. Flooded soils and wetlands yield sequences representing members of both Euryarchaeota and Crenarchaeota (11,31), whereas only sequences representing the Crenarchaeota have been recovered thus far from dry soils (9,10,21,32,33). The phylogeny of archaeal sequences from the various

Table 2. Examples of Archaea Isolated from Soils

Division	Order	Family	Isolate Type	Soil Habitat	Reference
Euryarchaeota	Methanobacteriales	Methanobacteriacea	culture, SSU rRNA sequence.	Italian rice paddy soil, bog, pasture, and marsh	11,34–38
Euryarchaeota	Methanobacteriales	Methanothermaceae	culture,	solfataric mud, Iceland	36,115
Euryarchaeota	Methanococcales	Methanococcaceae	culture, SSU rRNA sequence	black shore mud, San Francisco Bay	37,39
Euryarchaeota	Methanomicrobiales	Methanomicrobiaceae	SSU rRNA sequence,	rice paddy soil, Italy	11,34,36
Euryarchaeota	Methanomicrobiales	Unknown	SSU rRNA sequence,	rice paddy soil, Italy	11,34,36
Euryarchaeota	"Methanosarcinales"	Methanosarcinaceae	culture, SSU rRNA sequence,	marshes, wetlands, Italian rice paddy, and garden soil	11,34,36–38,40
Euryarchaeota	"Methanosarcinales"	"Methanosaetaceae"	SSU rRNA sequence,	rice paddy soil, Italy	34,36
Euryarchaeota	"Methanosarcinales"	Unknown	SSU rRNA sequence,	rice paddy soil, Italy	11,34,36
Euryarchaeota	Unknown	Unknown	SSU rRNA sequence,	rice paddy soil, Italy	11,34,36
Euryarchaeota	"Thermoplasmatales"	Unclear	culture	solfataras, coal refuse piles	41,42
Euryarchaeota	Halobacteriales	Halobacteriaceae	culture	hypersaline soils in Spain & former USSR	43–45
Crenarchaeota	Sulfolobales	Sulfolobaceae	culture	acidic hot soils	46–48
Crenarchaeota	Thermoproteales	Thermoprotaceae	culture	Uzon caldera, Russia	41,49
Crenarchaeota	Thermoproteales	Desulfurococcaceae	culture	solfatars, Indonesia	41
Crenarchaeota	Unknown	Unknown	SSU rRNA sequence	agricultural, boreal forest, rice paddy soil	9,11,33,34,36,50

different soil habitats ranges from having close affiliation to members of known groups of Archaea, such as *Methanobacterium* and *Methanosaeta* (11), to being highly divergent from any cultured archaea (9).

GROUPS OF SOIL ARCHAEA

Methanogens

Methanogens are a phylogenetically congruent group of microorganisms that play critical roles in recycling elements through the biosphere. They provide the only significant biogenic source of the hydrocarbon methane (CH_4), the second most abundant carbon-containing gas in our atmosphere and a major greenhouse gas (3). Although very diverse, both morphologically and physiologically, methanogens have a limited substrate range and are all strictly anaerobic, obligate methane producers (51). Methanogenesis is important in anoxic environments with low redox potentials, in which the reduction of alternative oxidants such as nitrate, Mn(IV), Fe(III), and sulfate has occurred (52). Waterlogged soils are among the most common habitats from which methanogens are isolated, along with anaerobic sediments, sludge digesters, insect guts, and mammalian rumina and intestines. Soil-dwelling methanogens from wetlands, rice paddies, and landfills are major contributors to the global CH_4 cycle, contributing about 60% of atmospheric methane (3).

Members of four of the five methanogenic orders (Methanosarcinales, Methanococcales, Methanobacteriales, and Methanomicrobiales) have been isolated by culturing from soils. SSU rRNA gene sequences from members of the families Methanosarcinaceae, Methanococcaceae, and Methanobacteriaceae, as well as SSU rRNA gene sequences representing members of previously unknown groupings, have been recovered from soils (Table 2).

Morphology and Metabolism of Methanogenic Archaea

Methanogenic archaea exhibit diverse morphologies: rods, cocci, spirals, pseudosarcinae, and multicellular aggregates. They are either motile or nonmotile and they stain either gram-negative or gram-positive. Carbon and energy sources include $H_2 + CO_2$, formate, acetate, methyl compounds (methanol, methylamines, methsulfides, and possibly methylselenides), methanol + H_2, or alcohols + CO_2. A number of isolates are obligate or facultative autotrophs. Ammonia is the typical nitrogen source (although some isolates can use amino acids or fix nitrogen) and sulfur or sulfide is a source of sulfur (51).

Soil Habitats of Methanogenic Archaea

Soil macroenvironments can be divided into the zones above and below the water table (51). The zone below the water table is saturated with water, whereas the vadose zone above is not. O_2 diffuses rapidly through soil and thus anoxic vadose zones are extremely rare, although anoxic microenvironments can occur. Because O_2 diffuses more slowly through water than air, the water-saturated zone is often anoxic, and representative environments are waterlogged soils such as rice paddies, stagnant marshes, and bayous. Groundwater, which contains low amounts of O_2 even when air-saturated (less than 0.3 mM O_2 at 20 °C), can easily become anoxic and suitable for the growth of methanogens, particularly in polluted areas. Although methanogens are extremely sensitive to O_2 in culture, they are protected in oxic zones in nature by the activities of O_2-utilizing organisms (51).

Methanogens produce methane in three major ways, with acetate and H_2/CO_2 being the most important methanogenic substrates in soils (52). Some produce methane by the reduction of CO_2, using H_2, formate, or certain alcohols as an electron donor and CO_2 as the electron acceptor. This method is common among rumen methanogens. Methane production through the oxidation of C-1 compounds is another, less common, process. Some of the substrate molecules are typically oxidized to carbon dioxide and the remaining methyl groups are reduced to methane. Methanogenesis from C-1 compounds occurs in environments that are enriched for these substrates, such as marine sediments. A third manner of methane production occurs by an aceticlastic reaction, in which the methyl carbon of acetate is reduced to methane and the carboxyl carbon is oxidized to carbon dioxide. The ability to catabolize acetate among the known methanogens is limited to species of *Methanosarcina* and *Methanosaeta* ("*Methanothrix*"). Methane production from acetate is found in habitats such as freshwater sediments where other anaerobes are limited for acetate catabolism by the availability of alternate electron acceptors.

In nature, methanogens typically play a role in part of a degradative microbial consortium, performing the final anaerobic step in the decomposition of organic matter in soils (51). The major methanogenic precursors in the complete decomposition of organic matter to CO_2 and methane are acetate, formate, and $H_2 + CO_2$. Initially, bacterial fermentation converts organic matter into volatile organic acids. The longer-chain volatile organic acids (with three or more carbon atoms), such as propionate and butyrate, must be further metabolized to suitable methanogenic substrates. Interspecies electron transfer, an association involving methanogens with other, specialized groups of microorganisms, often helps accomplish this.

Anthropogenic Increases in Methane Production

A steady increase has occurred in the amount of atmospheric methane in conjunction with the rise in human populations (53–55). Both agricultural practices and landfilled waste are major sources of methane and contribute to erosion of the ozone layer. Over the last decade, the atmospheric content of methane has been measured at about 1.7 ppm, and is estimated to increase by 0.5 to 1% a year (see also TRACE GASES SOIL). Terrestrial environments, particularly forests, are the major sources of atmospheric methane. Although they are low-flux systems relative to waterlogged soils, their contribution of methane to the biosphere is significant because of their vast coverage area (56). Although methane production in terrestrial ecosystems has not been well studied, two major terrestrial habitats of methanogens are termite guts and the rotting heartwood of trees. Better studied are high-flux systems, including wetlands, rice paddy soils, and freshwater sediments, which account for between 15 and 45% of the total biogenic methane (54).

Thermoplasmales

Variable-shaped, wall-less members of the genus *Thermoplasma* have been isolated from solfataric fields in many geographic locations (Table 2). Originally found in smoldering coal refuse piles, solfataras appear to be the primary soil habitat of *Thermoplasma* species. Isolates have been cultured from these environments in wide geographic locations, including Italy, the Azores, United States, Iceland, and Indonesia; the two characterized species are *Thermoplasma acidophilum* and *T. volcanium* (42). In culture, these microorganisms grow heterotrophically as facultative anaerobes by sulfur respiration. They grow aerobically with yeast or other similar, complex extracts. Growth temperatures range from about 45 °C to 63 °C for *T. acidophilum* (42) and from about 33 °C to 67 °C for *T. volcanium* (41,42). Neither natural growth factors nor ecological roles are currently known for *Thermoplasma* spp. found in conventional soils.

Halobacteriales

General Characteristics. Cultured isolates of halophilic archaea are currently placed in a single family, Halobacteriaceae, in the order Halobacteriales (57). Halophiles comprise a variety of morphological types, including rods, pleomorphic forms, angular cells, and cocci. Isolates from saline soils, like other halophilic archaea, are red colored because of the presence of cellular pigments such as β-carotene and bacterioruberin (58). Some halophilic isolates are chemoorganotrophs and use only amino acids or organic acids as carbon sources, but many have the ability to grow on carbohydrates. Originally reported as obligate or facultative aerobes, there is a growing body of evidence suggesting that most species are facultative anaerobes (58). Certain species also synthesize ATP using bacteriorhodopsin as a light-driven proton pump.

Habitats and Ecophysiology. Halophilic archaea are found in hypersaline environments in which salt concentrations exceed 150 to 200 g/liter. Most exhibit optimum growth at NaCl concentrations of between 2 and 4 M, whereas extremely halophilic species can grow even at the saturation point for NaCl in water (5.5 M) (57). Halophiles fall into a number of ecophysiological groups on the basis of their response to salinity, magnesium concentration,

and pH (58,59). There is a reasonably clear division, for example, between alkiliphilic and neutrophilic members of Halobacteriaceae (no acidophiles have been reported). Halophilic archaea are most commonly found in aquatic environments, but representatives have also been isolated from saline soils (Table 2). Isolates have been recovered from saline soils of arid areas such as the Mediterranean coast of Spain (43) and in soils of various regions of the former Soviet Union (45). Examples include, among others, members of the genera *Halobacterium, Haloarcula*, and *Halococcus*. The ecology of halophilic soil archaea has not been studied, but by analogy to hypersaline aquatic environments, the concentration of divalent cations, especially magnesium and calcium, may be important (57,58).

Outward-directed sodium pumps in the cytoplasmic membrane of halophilic archaea are essential for regulating pH and for maintaining suitable intracellular ionic conditions. In addition, members of the Halobacteriaceae maintain osmotic balance in hypersaline habitats by the accumulation of inorganic ions to reduce internal concentrations of Na^+ (59). K^+ appears to be the main compatible ion used. Adaptations to highly ionic environments are also observed in the particular composition of halophilic membranes and proteins (58). (See also SALINITY EFFECTS ON THE PHYSIOLOGY OF SOIL MICROORGANISMS).

Thermoproteales

General Characteristics and Habitats. Members of Thermoproteales are strictly anaerobic gram-negative rods, discs, or spherical cells of varying sizes. These hyperthermophilic microorganisms, typically, have optimum growth temperatures between 85 °C and 105 °C. Members of Thermoproteales that can be found in soils include those from the genera *Thermoproteus*, *Pyrobaculum*, *Desulfurococcus*, and *Thermofilum*, all of which can be isolated from mud holes and soils of continental solfataras in Italy, the Azores, Iceland, United States, and New Zealand (Table 2). Many members of these and other genera are adapted for life in high saline, thermal submarine environments.

Physiology and Ecology of Thermoproteales. Unfortunately, there are no studies so far that describe the physiological ecology of members of Thermoproteales. In culture, all members are capable of sulfur respiration using various organic substrates and of producing CO_2 and H_2S (60). Sulfur can be replaced by various sulfur components under heterotrophic growth conditions. Some Thermoproteales are strict organotrophs, for example, *Pyrobaculum organotrophum* and members of the genus *Thermofilum*. Others, such as *Thermoproteus tenax, Thermoproteus neutrophilus, Pyrobaculum islandicum, Pyrodictium occultum*, and *Pyrodictium brockii*, are able to grow chemolithoautotrophically with CO_2 as the sole carbon source (61), reducing sulfur with molecular hydrogen and producing H_2S. In *T. neutrophilus*, an unusual reductive citric acid cycle for carbon assimilation was found with characteristics similar to those of pathways in eukaryotic microorganisms (62,64,114). Studies are needed to determine the relevance of the physiological characteristics of Thermoproteales members in culture to their ecology in situ.

Sulfolobales

Taxonomy and Habitats. The order Sulfolobales comprises a number of genera, including *Sulfolobus; Metallosphaera; Acidianus; Desulfurolobus*; "*Stygiolobus*" and, potentially, *Sulfurococcus*. Commonly isolated from continental solfataric water and mudholes of broad geographic distribution, members of the order Sulfolobales are all extremely thermoacidophilic aerobic organisms. The naturally geothermally heated terrestrial environments in which they have been isolated tend to be acidic (as low as pH 0.5) with low salinity (0.1 to 0.5% salt). *Sulfolobus and Acidianus* spp. occur in diverse locations such as the United States (46,65–67), Italy (68), the Azores (46), New Zealand (69), Japan (70), the West Indies (66), and Iceland (46,66,71). The typical irregular, lobed cells of members of the order can be present in quite high numbers (approximately 10^8 cells/ml) in these habitats, and are frequently recognized by the presence of an oily iridescent layer floating on the surface of muddy pools. *Sulfolobus* strains have been isolated as well from hot acid soils (72); such soils, in fact, being the dominant feature of solfataric fields (66).

In contrast to the cosmopolitan distribution of *Sulfolobus* and *Acidianus*, *Metallosphaera,* and *Stygiolobus* isolates have been recovered on a much more limited basis. *Metallosphaera* isolates have been found only within Neapolitan solfataras (73), and *Stygiolobus* exclusively from the Azores (74,75). It is presently unclear whether their limited detection is due to geographic isolation or selective cultivation.

Physiology of Sulfolobales. In culture, Sulfolobales possess diverse metabolic capabilities, spanning the biological spectrum from autotrophy (76,77) to heterotrophy (66–79) on a wide variety of complex organic substrates, sugars, and amino acids, to possibly even mixotrophy (77). All species are able to oxidize molecular sulfur to sulfuric acid (73,76,80), with the exception of *Stygiolobus*. MoO_4^{2-}(81) and Fe^{3+} (82) can both serve as alternative electron acceptors; S^{2-} (66), $S_4O_6^{2-}$, and Fe^{2+} (65,82) can all replace sulfur as an energy source. The ability to oxidize sulfur and ferrous iron results in the formation of soluble sulfates and subsequent mobilization of metals from sulfidic ores by some *Sulfolobus* species (65). This and other characteristics make these organisms important candidates for microbial leaching (83). See Brierley and Brierley (81) for a review of copper leaching studies performed with *Sulfolobus*.

Acidianus and *Desulfurolobus* can both oxidize and reduce molecular sulfur (74,84). Growth and sensitivity profiles suggest that strict and facultative aerobic species of Sulfolobales are microaerophiles. *Acidianus*, *Desulfurolobus,* and *Stygiolobus* species are capable of growth anaerobically by $S0/H_2$-autotrophy, with H_2S being produced (61).

Ecology of Sulfolobus. Although isolated from hot acid soils, *Sulfolobus* could not typically be observed directly in the soil or attached to soil particles (66). The organism was therefore quantified in such soils by microscopy, using most-probable-number dilutions in an

autotrophic medium containing elemental sulfur at pH 3.0 (72). *Sulfolobus* numbers measured across thermal gradients at two sites in Yellowstone National Park reached approximately 10^2 to 10^3 per gram of soil at temperatures ranging from about 50 °C to 70 °C (72). The uptake of $^{14}CO_2$ was measured in these soils, and a good relationship was found between cell counts and rate of CO_2 fixation for higher numbers of sulfur oxidizers. Two peaks were observed for $^{14}CO_2$ incorporation, one around 70 °C with a preliminary assignment to *Sulfolobus*, and another larger peak at around 30 °C, which was cautiously attributed to *Thiobacillus*. *Thiobacillus*, the only other organism detected by Fliermans and Brock (72) in these soils, demonstrated a growth peak at around 30 °C and overlapping growth with *Sulfolobus* at around 55 °C. There was not an exact correlation between CO_2 fixation and numbers of sulfur oxidizing microorganisms because no CO_2 fixation peak was observed corresponding to peaks of microbial growth at around 55 °C.

Distribution of Sulfolobales and Thermoproteales in Solfataras. The distribution of Sulfolobales and Thermoproteales differs within the solfataric habitat. Two niches have been identified in solfataric regions: (*1*) an upper, oxic zone that is approximately 30-cm thick, highly acidic (pH < 2) because of both biotic and abiotic oxidation, and rust-colored because of the presence of ferric iron (66,85), and (*2*) a deeper, highly anaerobic zone reduced by volcanic gases that is higher in pH (pH > or = 4) and blackish-gray in color because of the presence of heavy-metal sulfides (85). *Sulfolobus* are present in both niches, whereas members of Thermoproteales are found exclusively in the reduced zone. Unfortunately, there is no distribution data available for other archaeal members in solfataric habitats.

NONCULTURE-BASED APPROACHES TO MICROBIAL SAMPLING

The view that archaea are strictly extremophiles is now changing because of a "molecular revolution" (23) in microbial ecology that has led to the discovery of nucleic acid sequences and in situ evidence for previously unknown members of the Archaea (as well as for bacteria and Eukarya). The development and application of a variety of molecular techniques not reliant on culturing to detect and discriminate microorganisms has led to a restructuring of our view of microbial ecosystems. The most extensively used phylogenetic tools are those based on the exceptional conservation of SSU rRNA gene sequences among different organisms. Such approaches are powerful because they enable the recovery of sequences representing specific microbial phylotypes from natural environments, without cultivation of the corresponding microorganisms (5). Use of this approach has demonstrated the existence and abundance of novel archaea across a broad array of nonextreme terrestrial and aquatic habitats (9–11,15,16,19,21,22,31–33,86).

Because all techniques have biases, multiple approaches are often utilized when analyzing the microbial diversity of a particular habitat. Initial approaches leading to the discovery of microbial complexity in the environment involved DNA-DNA reassociation kinetics after strand dissociation of the DNA in a sample (7,8). Control experiments demonstrated that reassociation kinetics were affected by the diversity of genomic DNA in a sample. Subsequently, approaches taking advantage of phylogenetic conservation among the rRNA of various groups of microorganisms have involved the use of polymerase chain reaction (PCR). Typically, DNA is extracted from the environment of interest and SSU rRNA gene sequences are amplified from the sample by PCR and analyzed by various methods. The most informative approach for using rRNA information to study the microbial members of an ecosystem involves cloning and sequencing (87) and is also the most labor-intensive.

Less time-consuming, but also less informative, are methods such as amplified-ribosomal-DNA-restriction analysis (ARDRA, 112), denaturing-gradient gel electrophoresis (DGGE, 90), temperature-gradient gel electrophoresis (TGGE, 111), single-strand conformational polymorphism (SSCP, 63), and terminal-restriction fragment length polymorphism (T-RFLP, 113) analyses. These methods rely on size and/or nucleotide composition of the native or PCR-generated DNA fragments for discrimination, but do not reveal precise phylogenetic information without sequencing of specific bands or the use of quite specific primer sets.

Some methods, such as in situ hybridization (5,88), reverse-transcription PCR (89,90), TGGE or DGGE, and T-RFLP, are used to identify metabolically active or numerically dominant populations. However, all but the first method rely on PCR, which is known to demonstrate strong bias under certain circumstances (91–94). Attempts to avoid PCR bias have been made, for example, with a recent approach that takes advantage of the ability of the bacterial artificial chromosome (BAC) vector to accept large fragments of DNA (95,96) and act as an expression vector for environmental DNA in a surrogate host (97). Although molecular methods also have limitations, the evidence from their concerted use is uncontestable. Our knowledge of natural microbial populations was previously severely limited through use of culture-based techniques only.

UNCULTURED SOIL ARCHAEA

Research by Bintrim and coworkers serves as one example of a study examining the diversity of Archaea in a mesophilic soil environment (9). Phylogenetic analysis of sequences recovered from a Midwestern (fallow) agricultural soil placed all 35 of the archaeal clones recovered (designated SCA) in a clade that diverged deeply within the division *Crenarchaeota*. This and other such discoveries (10,21,32,33,98) were surprising because archaea had never before been suspected to be present in mesophilic dry soils.

Crenarchaeota SSU rRNA sequences have now been recovered worldwide from terrestrial and aquatic low- to moderate-temperature environments. The sequences belong to at least four distinct subgroups and appear

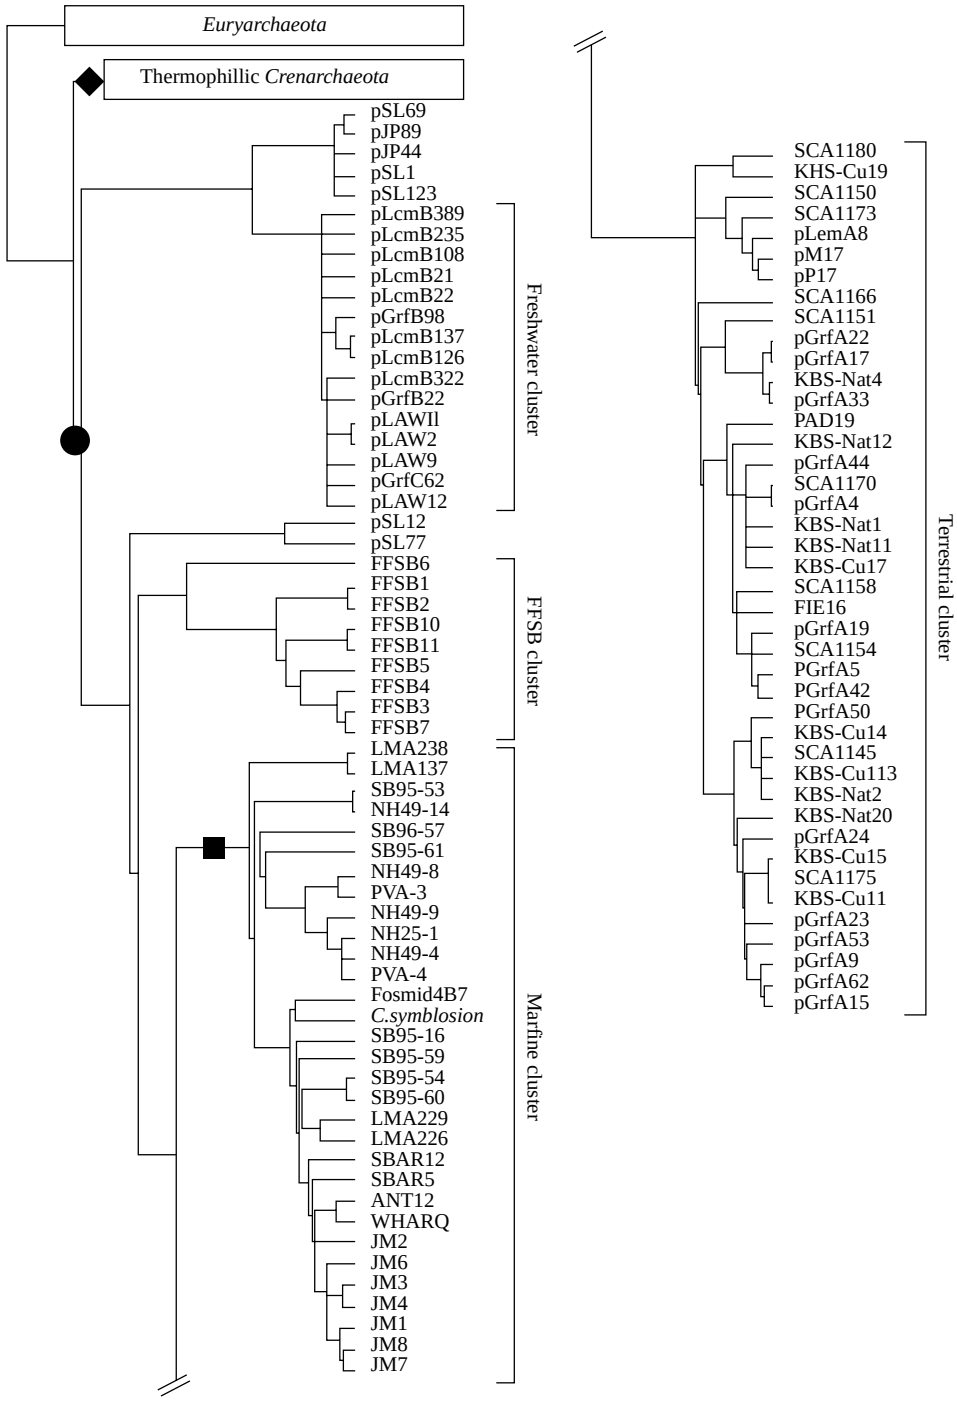

Figure 2. Phylogenetic tree showing the relationships of nonthermophilic Crenarchaeota 16S rDNA sequences. The symbols indicate the specificities of Crenarchaeota probe Cren499R (diamond), probes Cren667 and GI-554 (♦), and probe Cren745 (●). *Cenarchaeum symbiosum C. symbiosum*. Reproduced with permission from Buckley et al. (1998).

to have a common ancestry (Fig. 2; 21). The majority of archaeal sequences recovered from soil cluster together in one clade — with the exception of a group of sequences recovered from a single study of boreal soil from Finland (32) — which cluster in a separate group. Quantitative estimates of the total RNA of crenarchaeota in agricultural and undisturbed soils range from 0.37 to 1.4% relative to total community RNA (21) (Table 1). The closest affiliation of uncultured soil archaea is to a clade of marine, planktonic crenarchaeotes, designated as "Group 1 archaea" (15). Studies of the biomass contribution of planktonic archaea ranged from 2% (15) up to 34% (16) (Table 1). Thus, in both terrestrial and oceanic nonextreme habitats, archaeal members constitute a significant proportion of microbial assemblages. Similar trends of novelty, diversity, and abundance are also observed for SSU rRNA gene sequences representing uncultured members of the Euryarchaeota (15,16,18,99).

The Rhizosphere (See also RHIZOSPHERE MICROBIOLOGY)

Soil archaea thrive in another habitat previously thought to be the domain of bacteria and eukaryotes, plant

roots and the rhizosphere. The rhizosphere extends from the surface of the root (the rhizoplane) into the surrounding soil a few millimeters. It is a rich ecological niche abundantly exploited by soil microbes, in terms of both population numbers and activity. Roots and rhizosphere habitats are nutrient-rich relative to those of bulk soil. This is in part due to the fact that roots deposit from 5 to 30% of the total photosynthate of the plant into the surrounding soil in a process known as rhizodeposition (100), and in part due to sloughed, injured, or senescing plant cells that leak nutrients.

Although a far more nutrient-rich habitat than bulk soil, the rhizosphere consists of networks of microenvironments similar to those found in soils. Extreme niches exist in the rhizosphere as certainly as they do in soil, because the rhizosphere environment is subjected to dramatic climatic events resulting in fluctuations of water and osmotic potential, salt concentrations, pH, and soil particle structure (101–103). The question remains to be answered, however, as to whether archaea occupy extreme niches in soil and rhizosphere, or if, instead, the archaea there compete successfully against bacteria within nonextreme niches. Specialized metabolic activities such as methane production or nitrogen fixation may allow archaea, which typically grow more slowly than most bacteria, to overcome competition by making essential trophic contributions within the ecosystem.

Archaea in the Rhizosphere

Root-Associated Methanogens. The relative contribution of root-associated methane production to the atmosphere can be very important for flooded soil environments. For example, root-associated methane production in rice paddy soils varied between 4 and 52% in one study (104). In another study, removal of aboveground vegetation from natural wetlands resulted in more than an order of magnitude reduction in methane emissions, without a concurrent decrease of methane stored in soil (105).

Root Colonization by Archaea of Unknown Phenotypes. Additional evidence for archaeal associations with the rhizosphere comes from studies in both flooded (11) and dry (22) soils. SSU rRNA gene sequences were recovered from these environments using total rhizosphere and/or rhizoplane DNA and primers hybridizing to the SSU rRNA genes of archaea in PCR reactions. In keeping with the results from previous studies in soil, rhizosphere samples from rice plants grown in flooded soils harbored SSU rRNA sequences from both Euryarchaeota and Crenarchaeota (11), whereas rhizosphere samples from plants grown in dry soils, thus far, have yielded evidence for Crenarchaeota only (22). rDNA clones recovered from tomato rhizoplane (*Lycopersicon esculentum*) samples (designated TRC clones, with 91 to 99% sequence identity over 1,280 nucleotide positions) clustered with uncultured soil Crenarchaeota from dry, mesophilic environments. Phylogenetic analysis also indicated that TRC sequences were distinct from sequences representing uncultured Crenarchaeota clones from rice rhizospheres and rice paddy soil (designated ARR/ABS, 11). Direct sequence comparisons supported divergence of these two rhizosphere groups, yielding sequence similarity of 76 to 84% between the TRC and ARR/ABS sequences, compared with a range of 91 to 99% sequence similarity between the TRC and uncultured clones from West Madison (designated SCA, 9) and Michigan (designated KBS, 21) soils. These studies, like those on mesophilic soil archaea, indicate that rhizosphere Crenarchaeota comprise a phylogenetically coherent, but quite diverse, group of microorganisms.

Abundance of Crenarchaeota on Tomato Roots. In the first study to document colonization of plant surfaces by members of the Archaea, we showed that members of the nonthermophilic Crenarchaeota colonize the roots of tomato plants grown in soil (Fig. 3; 22). Our results demonstrated the recruitment of the crenarchaeotes from soil and their growth, and apparent persistence, on roots. The abundance of crenarchaeotes was documented on tomato roots by fluorescence in situ hybridization (FISH) assays, using probes designed to be specific for the SSU rRNA gene sequences of Crenarchaeota recovered from soil and tomato rhizospheres. We found Crenarchaeota broadly distributed on both young and senescent roots. Their abundance was determined to be about 3.3% relative to the number of total probe-positive cells (bacteria and crenarchaeotes) on young roots and about 16% on senescent roots of plants seven to eight weeks in age. Although they were present on all roots examined from plants spanning one to eight weeks of age, their abundance increased 10-fold on senescent roots compared with younger roots of about the same age, with a concurrent increase in the frequencies of cells in pairs (presumed to be dividing cells) and in colonies. By contrast, bacterial abundance increased only fewfold on senescent roots. Greater abundance of crenarchaeotes was also observed in the older regions of nonsenescent roots, whereas bacterial numbers decreased in these regions. These results suggest that rhizosphere Crenarchaeota may have roles in mediating later stages of root biology, a function previously unsuspected for members of the Archaea.

CONCLUSION

One of the great mysteries of the world lies beneath our feet in the guise of the mundane, a substance known simply as soil or dirt. Through time and considerable effort, humankind continues to push back the frontiers of science in the fields of chemistry, physics, and biology. We have yet to fully understand, however, the dynamics of these forces and how they interact to form that enduring interface between the organic and inorganic components of the terrestrial biosphere. Although scientific knowledge of the chemical and physical properties of soil is substantial, our understanding of microbial composition and contribution to soil ecosystem dynamics is incomplete. The recent discoveries regarding archaea in soil and other conventionally nonextreme habitats dramatically illustrate this point.

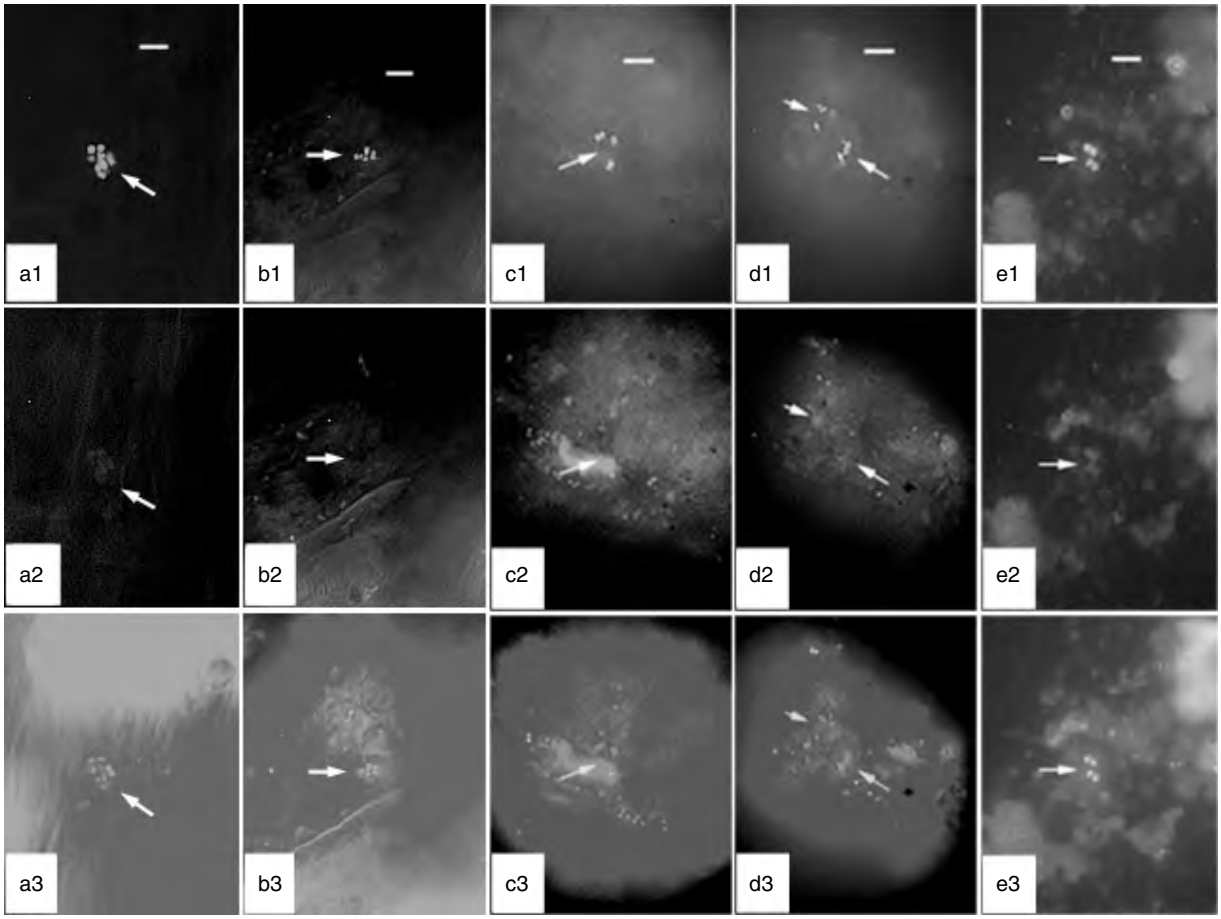

Figure 3. Fluorescence in situ hybridization of the tomato rhizosphere for Crenarchaeota. One-week-old (A) tap and (B) lateral rootlets, (C and D) senescent rootlets, and (E) rhizosphere soil. Oligonucleotide probes used were designed to be (1) specific for nonthermophilic Crenarchaeota and (2) Bacteria. Images in row (3) show results of DAPI staining of the same fields shown in rows (1) and (2). Scale bar represents 5 μm. Reproduced with permission from Simon et al. (2000). See color insert.

Extreme or Not Extreme — That Is the Question

The fact that isolation of archaea was initially successful in primarily extreme or uncommon environments implied the failure of archaea to compete with bacteria in more common habitats. Following this line of thought, archaea are successful because of their specialization. For example, adaptation to extreme environments, in which growth of bacteria and eukaryotes is limited, results in reduced competition. Thus, archaea may survive by avoiding direct competition with other microorganisms. On the other hand, the discovery of archaea in mesophilic habitats poses the question — do archaea thrive only in highly specialized niches, as dogma holds, or is our knowledge of the extent of their ecological range limited by our inability to culture them? Soil is an excellent case in point. It is well known that microscopic counts of microbial cells in soil far exceed, by as much as two orders of magnitude, the number of cells that can be cultured on typical agar medium (5,6). A hypothesis to explain this result states that a portion of cells in soil environments are in a starvation state and that makes them recalcitrant to growth in vitro. Such a "viable but nonculturable" state is known to exist for, at least, some culturable microorganisms under certain conditions (106). This leads to the prediction that we may have mislabeled mesophilic soil habitats as "nonextreme," and suggests that archaea thrive in soil precisely because it contains niches of an extreme nature. The recent discovery of archaea in other nonextreme habitats, such as low-to-medium temperature marine environments, can also be rationalized using this hypothesis. It can be argued that marine planktonic archaea are in relatively extreme environments as well, because the majority of the marine ecosystem is oligotrophic (contains 1–10 mg of carbon per liter), with microniches created, for example, by pockets of suspended detrital matter (107). The answers to the questions of what makes a habitat extreme (from a microbial point of view) lie, in part, within the physiological mysteries of the as-yet uncultured archaea found thriving, unexpectedly, in these so-called nonextreme environments. When we unlock the metabolic secrets of these archaea, we will gain a better understanding of the niches they inhabit.

The Future

Although molecular techniques have added substantially to our knowledge of the composition of microbial assemblages in soils and expanded our knowledge concerning the ecological range of archaea, there is more to learn in this regard as the list of habitats harboring these organisms lengthens. There are also a number of challenges involved in describing microbial dynamics in soil habitats that remain unsolved. For example, many questions remain relating to sampling; spatial heterogeneity and scale are both extremely complex problems that demand integrative and interdisciplinary approaches for their solution. Approaches monitoring chemical and physical parameters, in combination with microbial analyses at the micro- as well as macroscale level, are needed to address these issues and others.

Advances in the areas of genomics and high throughput monitoring of changes in microbial populations in response to ecosystem fluctuations will further illuminate microbial composition, metabolic potential, and dynamics in soil environments. Examples of such advances include obtaining genetic and functional information from soil microorganisms without culturing using metagenomics (97) and other direct access methods (50,108–110) and the use of oligonucleotide arrays to monitor detection, abundance, and gene expression of populations and assemblages of microorganisms.

Progress in defining ecological roles of archaea and other microorganisms will be realized best by using classical culturing and molecular approaches in concert. For example, sequences recovered from previously unknown and numerically abundant archaea in soil environments provide information for the design of specific oligonucleotide primers and probes hybridizing to the SSU rRNA gene sequences of those microorganisms. The oligonucleotides can then be used to monitor the growth of previously uncultured organisms in enrichment cultures. Growth of these archaea in pure culture will, in turn, potentially lead to an understanding of their metabolic capabilities and potential impact on ecosystem dynamics, predictions about which can be tested using phylogenetic and substrate-level probes in situ.

In conclusion, many questions remain regarding the ecological distribution and roles of archaea. We predict that archaea have far greater global impact on biosphere composition and function than previously thought. Archaea will be found to perform fundamental roles in conventionally nonextreme environments, as they do in typically extreme habitats. Their early evolution and history placed them in these environments as fundamental nodes in the microbial network; their unique physiological properties keep them there.

ASSESSING MICROBIAL PROTEOMES IN THE ENVIRONMENT

Oladele A. Ogunseitan
University of California
Irvine, California

Proteins are generally recognized as the molecular wheels of cellular machinery. Their functions include enzymatic catalysis, maintenance of the integrity of membrane receptors and general cellular architecture, and the mitigation of stressful environmental conditions. The profile of proteins synthesized by microorganisms under indigenous conditions offers a window through which investigators may glimpse complex environmental modulation of multilevel interactions between genetic endowment and natural selection. The term *proteome* was coined by Wilkins and Williams and their coworkers to describe a postgenomic field of research aimed at understanding the disposition of genetic potential in the strategic survival of organisms in variable environments (1–8). Microbial proteomics is an integrative approach toward the analysis of protein molecules in microbial communities, with particular emphasis on understanding how genetic potential is transformed into the observed array of diverse but compatible structures and functions in both natural and engineered environments (9–24). Proteomics research encompasses both the genetic and environmental underpinnings of microbial community integrity. Application of proteomics in environmental microbiology research is still evolving, but it is so far dominated by axenic culture studies. However, investigations of microbial community proteins are emerging in the literature (17,25–34). Early reports focused on methods of quantitative recovery of protein molecules from uncultivated but densely populated microbial communities (22,24), the radiolabeling of target proteins in heterogenous populations (21), and the direct assay for enzymatic proteins in situ (21). These research programs fulfill the need for methods to complement the remarkable progress that has been made toward the elucidation of phylogenetic diversity and microbial community structures, made possible by lipid-based and nucleic acid–based techniques for analyzing heterogenous microbial systems such as soils and groundwater (35–39). The methodological complementation is essential because knowledge of microbial community structure does not necessarily lead to useful information on microbial community functions such as metabolic capacity, control of population dynamics for native and invasive species, sensitivity to variable environmental conditions, and intrinsic niche diversity (40).

APPLICATIONS OF PROTEOME-BASED ASSESSMENTS IN ENVIRONMENTAL MICROBIOLOGY

The practical rationale for proteome analysis in aquatic microbiology is the desire to understand and harness the roles performed by protein molecules in a given sample of water for the improvement of environmental and public health. However, it is generally recognized that only about 10% of the microbial diversity in natural samples is extractable through traditional techniques involving laboratory cultivation. Additionally, methods developed for direct nucleic acid assessments such as DNA and rRNA fingerprints do not illuminate the response of the diverse microbial world to real-life environmental variations (Fig. 1). Similarly, assessment of bacterial mRNA is generally too temporary for its use in constructing a correlative map between environmental conditions and microbial response (41).

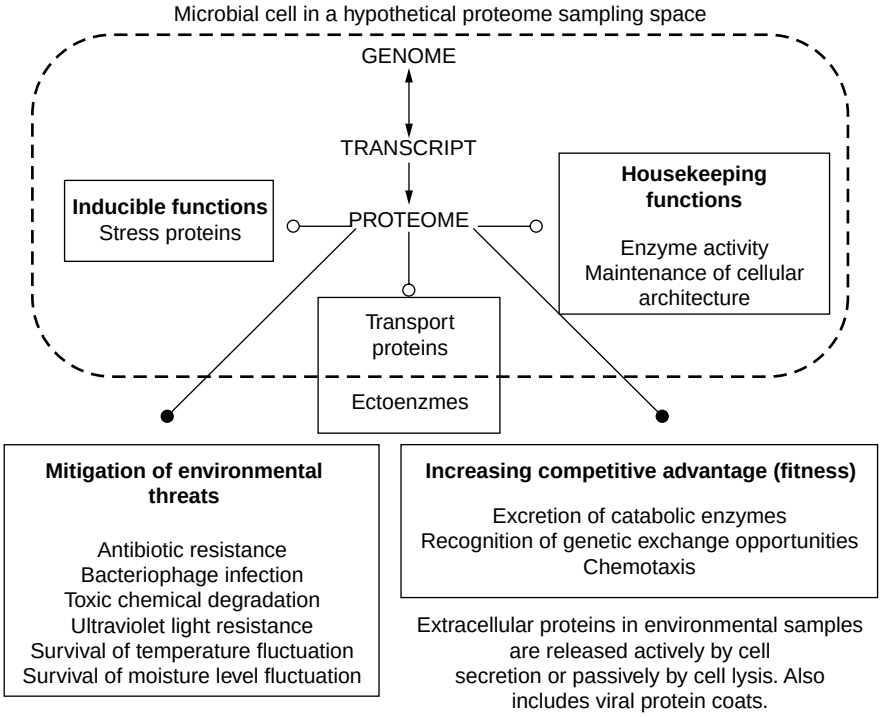

Figure 1. Conceptual diagram showing the transformation of genomic information into an array of proteins molecules that may be assessed within the framework of responses to influential environmental parameters. In theory, all species in a given environmental sample contribute to the collective proteome pool but responses by particular species present in large numbers may dominate the outcome of assessments limited by the stringency of molecular resolution.

Microbial community proteome analysis has been useful for understanding the ecotoxicological effects of chemical pollutants, the activity of catabolic enzymes in environmental bioremediation, the tracking of indicator species and pathogens in potable water distribution systems, and the tracking of genetically engineering microorganisms and their protein products following deliberate release into natural ecosystems.

Questions pursued by environmental microbiologists engaged in proteome assessments include the following:

1. Are specific pathogens present in a given environmental sample recognizable by defined protein profiles? For example, several waterborne pathogenic viruses are detected in polluted water samples through antigen–antibody reactions that are based on polypeptides in the structural backbone of the capsid protein. Similarly, pathogenic bacteria can be detected through screening for proteinaceous toxins (12,17).
2. When, and in what quantities, are certain enzymes capable of detoxifying chemical pollutants produced in contaminated environments? For example, direct assessment of mercuric reductase is possible in protein extracts from mercury-contaminated freshwater systems (18).
3. How do specific microorganisms respond to specific environmental stimuli through inducible gene expression? For example, the production of specific "head-shock" or stress proteins by bacteria cultivated under relatively uncomfortable environmental conditions has been a major application of proteome assessment in environmental microbiology (34). In some cases, microbial stress proteins have been designed to serve as biosensors of environmental change.
4. How does microbial community structure change in response to changes in biotic and abiotic modifications to their habitat? For example, protein-profile assessments have been used to monitor the status of the microbial community necessary for successful wastewater treatment in engineered processes and to diagnose microbial cellular states (42,43).
5. What is the evidence for evolutionary divergence and population disequilibrium in highly conserved niches that are inhabited by distinct phylogenetic groups of microorganisms? Investigators frequently find that different versions of an enzyme (allozymes or isozymes) have evolved over time despite the conservation of relevant catalytic function. For example, at least two versions of δ-aminolevulinate dehydratase, the key enzyme in porphyrin synthesis, are known to respond differently to toxic metal exposures (25,26). At least eight versions of β-glucosidase have been identified in marine microbial communities (33). The protocol of multilocus enzyme electrophoresis discussed later facilitates a rapid assessment of these physiological ecology questions through the analysis of protein molecules in their natural states.

EXTRACTION OF PROTEINS FROM AQUATIC ENVIRONMENTS

Several protocols have been developed to facilitate the recovery of proteins directly from environmental samples. The paramount consideration in selecting a method for recovery of proteins from environmental samples

is whether the study is a general survey of protein molecules or whether it focuses on a few targeted proteins assayed by function. In the former case, there may be no need to preserve the structure or catalytic function of recovered proteins and relatively harsh but thorough extraction techniques may be used. When emphasis is placed on preserving protein activity, conservative cell-lysis techniques are preferred. For the recovery of virus-associated or other cell-free proteins from aquatic samples, a combination of ultracentrifugation, adsorption, and/or precipitation is used (17) (Fig. 2).

Protein extraction methods have been developed for a variety of environmental sample materials including sediments, freshwater, seawater, and wastewater (20). In general, sonication is the preferred method for cell-lysis when the preservation of protein structure and function is essential. Chemical cell-lysis techniques including the use of detergents and alkali or boiling are used when the resolution of proteins requires denaturation (44–46). Because large numbers of polypeptides are expected in complex microbial communities, sample fractionation is usually required before the attempt to separate proteins on the basis of molecular mass, ionic charge, or both. Sample fractionation can be achieved by differential centrifugation, molecular sieves, and precipitation (7).

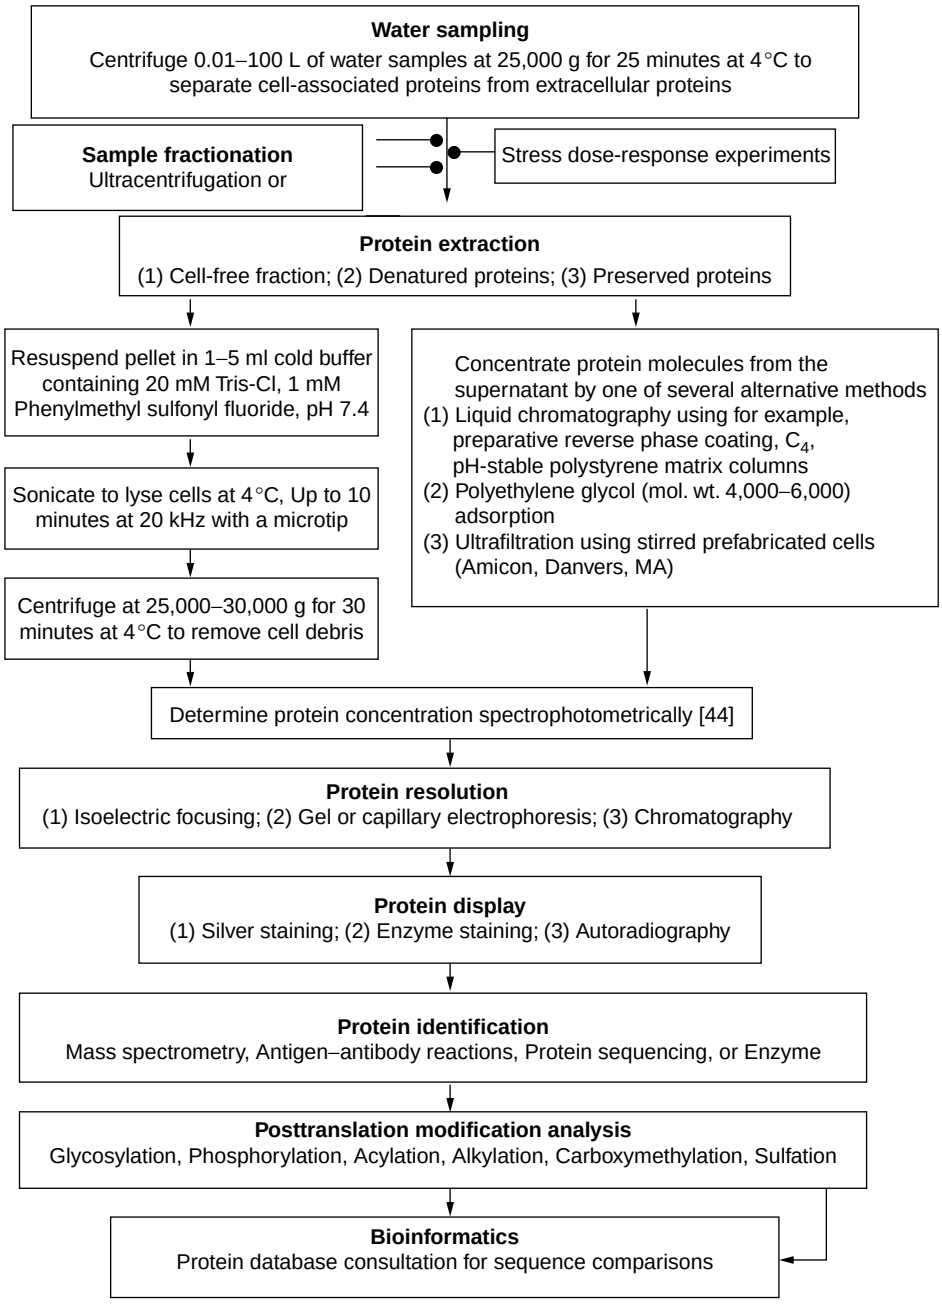

Figure 2. Flow diagram of procedures used in the construction of microbial protein profiles in environmental assessments. The initial volume of water sample is determined based on preliminary determinations of cell density and potential contaminating materials that may interfere with protein extraction and resolution.

RESOLUTION AND DISPLAY OF PROTEINS EXTRACTED FROM ENVIRONMENTAL SAMPLES

Gel Electrophoresis

Polyacrylamide gel electrophoresis is the most widely used method for protein resolution. The resolution power of one-dimensional electrophoresis is limited to less than 50 polypeptides, but it remains the most widely used method when highly specific methods are available to select from for the polypeptide(s) of interest. In theory, two-dimensional polyacrylamide gel electrophoresis (2D-PAGE) is capable of simultaneous separation of thousands of proteins and is uniquely suitable for resolving complex and highly diverse preparations (43,47). In practice, however, several factors can reduce the resolving capacity of 2D-PAGE, particularly with respect to sample preparation and solubilization. The configuration of the interface between the first dimension (isoelectric focusing (IEF) to resolve polypeptides according to ionic charge) and the second dimension (polypeptide resolution according to molecular size) is also important. It is now possible to analyze single spots from a 2D-PAGE gel partly because the availability of immobilized pH gradients have eliminated the problem of gradient instability during IEF. In addition, the reproducibility of electrophoretic conditions and the results have improved with the commercial availability of ready-made gels in a variety of prescriptions.

A few precautions enable a relatively trouble-free PAGE analysis. First, it is important that proteins remain soluble throughout the electrophoresis process. Therefore, chaotropes and surfactants such as thiourea and sulfobetaine are often used to enhance protein solubility (8,46). Secondly, nucleic acids must be removed from samples before electrophoresis to reduce the viscosity of samples. A combination of carrier ampholites and ultracentrifugation may be used to remove nucleic acids if the extraction is conducted at high pH. Alternatively, endonuclease digestion is recommended when sample preparation is performed at high pH (40 mM Tris). Thirdly, it is important to eliminate disulfide bonds that act to reduce protein solubility. Therefore, chemical-reducing agents such as β-mercaptoethanol, dithiothreitol, or tributyl phosphine are used before isoelectric focusing. Finally, when working with environmental samples, humic and fulvic substances are usually coextracted and must be removed. Several commercially available chromatographic matrix columns (for example, from Biorad, Hercules, Calif.) may be used to reduce the concentration of these compounds in samples in which they present a problem.

Capillary Electrophoresis

The use of capillary electrophoresis equipment to resolve complex preparations of biomolecules is increasing (48). Capillary electrophoresis of protein molecules is performed in very thin (internal diameter of 25–100 μm) fused silica tubes ranging in length from 25 to 100 cm. The dimensions of the capillary allow the use of high electric fields, leading to very fast separation of proteins with a protocol completion time of less than one hour compared with the typical four to ten hours required for slab gel electrophoresis. In general, capillary electrophoresis resolves polypeptides according to ionic charge, but the system is adaptable to the use of various detectors, including conductivity, ultraviolet and visible light absorbance, radioactivity, and fluorescence. It is also possible to couple capillary electrophoresis with mass spectrometry for measurement of the molecular mass of resolved polypeptides (49). Capillary electrophoresis has been used to study various aspects of proteome assessment in environmental microbiology, including the construction of protein profiles for phylogenetic differentiation (51), changes in bacterial outer membrane proteins in response to toxic chemicals (51), and enzyme polymorphism in marine bacterial communities (33).

Radioisotopes

Radioisotopes have been used extensively in proteome research involving single microbial species and their use is increasing in in situ investigations. The radioisotope tracer approach takes advantage of the fact that many microorganisms are able to incorporate externally supplied amino acids into polypeptide chains. For these organisms, ^{35}S-labeled amino acids, typically methionine, is added to the growth medium. For organisms that engage in de novo protein synthesis, radioisotope is supplied as $H_2{}^{35}SO_4$. When working with natural environmental water samples, it is better to use a combination of radiolabeled amino acids and sulfuric acid so as to cover the entire range of microbial protein synthesis preferences. The radioactive isotope tracer technique has been used to detect the synthesis of specific proteins in the immediate aftermath of exposure of freshwater microorganisms to toxic chemicals (22).

For most applications, cells pooled from aquatic samples are usually incubated for up to an hour with radioactive precursors of protein synthesis. During the incubation period, cells may be exposed to a variety of stressful environmental conditions (e.g., toxic pollutant exposure, temperature shift, high salt concentrations, or virus infection). Proteins are then extracted from the cells and resolved electrophoretically. The radiolabeled polypeptides are subsequently detected by exposing gels to an X-ray film for autoradiography, or if capillary electrophoresis is used, detection is achieved by direct measurement of radioactivity. Control experiments with cells incubated under relatively normal environmental conditions allow the detection of inducible proteins synthesized in response to specific environmental stress stimuli. Quantitative assessment of radioactivity incorporated into each polypeptide band is achieved with radioactive image analyzers. Such quantitative data provide valuable cross-scale information on the maintenance of homeostasis in microbial communities under variable environmental conditions. Intensely labeled polypeptides of interest can be isolated, sequenced, and compared with existing protein sequence databases for possible identification of function (5).

Immunofluorescence and Enzyme-Linked Immunosorbent Assay

Antigen–antibody reactions targeted against "signature proteins" are widely used for immunological detection of microorganisms in environmental samples (52). The increasing availability of genomic sequences is contributing to rapid revision and developments in the use of antisera for tracking and identifying microorganisms through immunofluorescence and enzyme-linked immunosorbent assays (ELISA) (52). Furthermore, because monoclonal antibodies recognize very specific protein targets, their use have virtually eliminated traditional limitations of immunologically based techniques involving polyclonal antibodies. Monoclonal antibody-based protocols are also amenable to quantitative assessment. Immunofluorescence and immunomagnetic extraction of proteins from aquatic sources are also undergoing rapid development, but are currently limited by the fact that microbial antigens exhibit different ranges of immunological specificity. In addition, the type-specific antigens may be shared by related microorganisms (52).

Enzyme Electrophoresis

Microbial enzymes are invariably of central importance to the major research issues in environmental microbiology. Hence, the influences of environmental conditions on enzyme activity in nature have implications for the understanding and controlling of desirable processes ranging from bioremediation of polluted local environments to the impact of global environmental change on ecosystem functions sustained by the microbial community. It is generally well understood that enzyme activities depend on assay conditions. Therefore, the forms and functions of specific enzymes in their natural habitat can be expected to vary somewhat from assays conducted under laboratory conditions. Therefore, it is important to develop methods useful for understanding enzyme diversity in microbial populations present in the environment. The fact that many enzymes depend on redox reactions for effective catalysis has been exploited to produce colorimetric assays amenable to rapid assessment of enzyme kinetics and enzyme polymorphism in environmental microorganisms. Such assays are linked to sensitive indicator dyes such as formazan that assume color simultaneously with the progression of enzyme-catalyzed reactions (19,30,45). The technique can be accomplished on the same gel or membrane used for protein resolution, thereby producing a documented zymogram.

Because small variations in protein properties can influence the course of microbial adaptation and evolutionary innovation, techniques such as multilocus enzyme electrophoresis (MLEE) have been developed to capture the occurrence and distribution of allozymes (multiple enzymes with similar functions encoded by different alleles at the same genetic locus) and isozymes (multiple enzymes with identical functions encoded by different genetic loci) in microbial populations (31). Hence, MLEE yields direct information on niche diversity and selective pressure at the molecular level in a given microbial community. MLEE has also been used extensively to investigate the determinants of population dynamics in single microbial species, but not much work has been done on the application of MLEE to whole microbial communities. In general, conservative extraction of total proteins present in cells pooled from 1 to 100 L of water samples is achieved by sonication and centrifugation. Protein extracts are then resolved on gels made with starch or very thin slabs of polyacrylamide under nondenaturing conditions. After electrophoresis, the location of enzymes that depend on the redox reactions can be ascertained by incubating the gel in solutions such that the enzymatic reaction is coupled to the electrochemical production of colorful dyes (45). A quantitative method has also been developed for routine screening of enzyme activity in natural microbial communities by immobilizing proteins on nitrocellulose membranes before the development of staining reactions (21). The membrane method is rapid, but precludes the detection of multiple bands that indicate molecular diversity MLEE.

Another approach toward assessing microbial enzyme profiles in aquatic environments involves the use of capillary electrophoresis coupled with the detection of fluorescent products of enzyme activity. For example, investigation of β-glucosidase isozymes in the microbial population present in 100 L of seawater revealed unsuspected isozyme polymorphism (9,33). Pooled protein extracts from aquatic microorganisms can be loaded onto capillary tubes filled with buffer containing fluorogenic substrates, for example, resorufin β-D-glucoside for glucosidase activity. During electrophoresis, isozymes separate according to electrophoretic mobility. The electrical current through the capillary is then interrupted for approximately 10 minutes to allow interaction between enzyme and substrate. Fluorescent products are then detected at the anodic end of the capillary.

Mass Spectrometry

The coupling of gel or capillary electrophoresis to mass spectrometry for the identification of polypeptides is a rapidly evolving protocol (5,6). Standardized protocols using this approach have generated reproducible maps of 2D gels that allow comparisons across multiple experiments. Consequently, the identification of polypeptides through mass spectrometry can be achieved by matching profiles across phylogenetic boundaries. Both matrix-assisted laser desorption-ionization mass spectrometry (MALDI-MS) and electrospray ionization mass spectrometry (ESI-MS) represent technological advancements in this category. Mass spectrometric analyses of peptides require enzymatic digestion of proteins. Therefore, not every routine gel-staining technique can be used for primary resolution of protein molecules. For example, traditional silver-staining methods are generally not compatible with enzymatic digestion unless they are modified to avoid the use of cross-linkers and strong oxidizing and reducing agents. A compilation of protein-staining methods that are compatible with mass spectrometry is available from Protana (Table 1). Mass spectrometric fingerprinting of protein molecules allows rapid collection of information on a large number of proteins in a given sample, but ultimately, several pieces of data derived by using different methods must be integrated to identify a given

protein unequivocally. A major follow-up aspect of polypeptide mass fingerprinting is the search for characteristic matches in established protein databases (Table 1).

The Proteinchip™ Array

The convergence of microchip electronics and high-fidelity biosensor technology continues to revolutionize environmental microbiological research. Microarray technology involves the immobilization of large numbers of biological molecules on tiny chip platforms for subsequent screening with molecular probes. This approach was initially developed to support large-scale genome sequencing efforts to facilitate the screening of large numbers of distinct DNA or mRNA molecules (for example, the GeneChip™ system developed by Affymetrix). Similarly, sophisticated technology is now available for proteome assessments. The surface enhanced laser desorption-ionization (SELDI) ProteinChip™ manufactured by Ciphergen (Palo Alto, CA) is designed to facilitate high throughput protein resolution and identification (49).

The ProteinChip™ array is typically made of metallic or plastic trays containing up to a thousand wells of 1 mm in diameter. The wells are chemically treated (e.g., with copper (II)) to capture trace quantities of unknown proteins (e.g., copper-binding proteins) in a given sample. Wells may also be coated with a known protein to be screened with biomolecules from unknown samples for the determination of protein function. Laser-based mass detection is then employed to measure the molecular mass of proteins. The stringency of molecular recognition in the array can be adjusted by washing and reading procedures to optimize signal-to-noise ratios. Potential applications of the protein microarray in environmental microbiology include the screening of proteins extracted from a natural microbial community for interaction with a given toxic metal. For such a task, metal ions are immobilized in the microarray wells and protein extracts will be added, followed by a stringent wash and read process. For example, molecular diversity in enzymes such as δ-aminolevulinate dehydratase and mercuric reductase that interact with lead and mercury, respectively, can be rapidly assessed (18,25,26). Other biomolecules that can be immobilized in microarray wells include membranes, receptor molecules, and antibodies.

Neural Networks and Cluster Analysis for Protein Profile Analysis

On the basis of the molecular size of microbial genomes, a prediction can be made about the expected number of independent proteins present in a cell at a given time. Although the one gene–one protein conjecture has proven to be inexact, it can be surmised that between 500 and

5,000 protein molecules are extractable, in theory, from each microbial component of environmental samples. The expected total number of proteins increases dramatically in environmental samples with highly diverse population of species. The development of highly sophisticated pattern recognition techniques is required for optimizing the information generated by protein profiles in natural microbial communities. Early attempts to identify microorganisms on the basis of protein profiles depended on statistical cluster analysis for recognizing matches between different protein profiles (42). More recent approaches to the interpretation of profiles from complex heterogenous microbial communities rely on strategies based on neural network computing (53,54). Artificial neural networks, also known as *parallel distributed processing*, have an aptitude for comparative assessment and retrieval of experiential information concerning large databases. Protein-profile management techniques should be commensurate with the molecular resolution capacity (Fig. 3). For example, profiles constructed using one-dimensional polyacrylamide gel electrophoresis can be managed with visual or linear image analysis programs, but two-dimensional electrophoresis requires more sophisticated pattern recognition techniques. A profiling database constructed with three-dimensional information, for example, on protein hydrophobicity, ionic charge, and molecular mass, on large numbers of organisms would be facilitated with neural network computing for pattern recognition.

INTERNET RESOURCES FOR ENVIRONMENTAL MICROBIAL PROTEOME ASSESSMENT

A comparative analysis of protein characteristics is central to proteomics research. Therefore, access to databases available on the World Wide Web for protein conformation, sequence, and function are becoming indispensible. In general, web sites for proteome researches specialize in one of six activities, namely, sequence depository and retrieval, comparative analysis of patterns and profiles, metabolic functions, posttranslational modification, two-dimensional maps, and three-dimensional structure databases. Table 1 shows selected web site addresses that are useful for consultation by both beginners and experienced proteomics researchers.

CONCLUSION

Accurate assessment of genetic expression is fundamental to all applications of biotechnology that involve the activities of viable cells. Furthermore, in biotechnological processes with an environmental dimension, the need for consistent analysis of gene expression is paramount because of the extensive range of environmental parameters that are known to influence the transformation of genetic potential to metabolic and ecological advantage. The goals of assessing microbial proteomes in the environment include (*1*) monitoring the expression and activity of specific enzymes or structural proteins in targeted populations that inhabit natural ecosystems, (*2*) identifying specific indicator organisms present in complex heterogenous microbial communities, (*3*) monitoring changes in the population structure of microbial communities as they respond to various environmental stimuli, and (*4*) tracking the tempo and mode of molecular evolution in microbial populations. With imminent technological advancements in protein extraction and analysis and in the robustness of protein characteristics databases, these already ambitious goals will undoubtedly be expanded dramatically to address the increasingly multifaceted research questions in environmental microbiology.

ASSIMILABLE ORGANIC CARBON (AOC) IN TREATED WATER: DETERMINATION AND SIGNIFICANCE

DICK VAN DER KOOIJ
Kiwa Water Research
Nieuwegein, The Netherlands

CONTROLLING MICROBIOLOGICAL WATER QUALITY

The quality of drinking water at the consumer's tap depends on a chain of processes, namely, the effects

of water treatment on the raw water, the effects of distribution on the composition of treated water, and the effects of the household plumbing system, respectively. Water quality criteria related to health are defined in national and international regulations and the water industry has the obligation to provide a safe drinking water. Microbiological safety is of major importance because ingestion of pathogens can have a direct impact on the health of the consumer. For this reason, multiple barrier approaches are used in water treatment in combination with frequent monitoring of indicator bacteria in treated water and pathogens (protozoa and viruses) in raw water, respectively. A multiple barrier approach is also used to ensure the safety of drinking water in the distribution system (1). Barriers against contamination of drinking water in the distribution system include (*1*) a constant high pressure in the mains, (*2*) cross-connection prevention measures, (*3*) safety procedures for activities in the distribution system, (*4*) reliable materials and construction techniques. Also, appropriate water quality monitoring is important to check the effectiveness of these preventive measures. Maintaining a disinfectant residual in drinking water during distribution is considered as an additional safety factor (2), but in a few European countries it is allowed to distribute drinking water without disinfectant residual (3–5). The main disadvantages of maintaining a disinfectant residual are the effect on taste and odor of the water, and/or the formation of disinfection by-products, including trihalomethanes with toxic properties (6–9).

A main function of the disinfectant residual is the prevention of multiplication of microorganisms in drinking water distribution ("regrowth"). Controlling regrowth is important to the water industry for the following main reasons (*1*) multiplication of coliform bacteria results in noncompliance with regulations (10), (*2*) the multiplication of opportunistic pathogenic bacteria, including species of *Legionella*, *Mycobacterium*, *Pseudomonas, Aeromonas*, and *Flavobacterium* poses a potential health threat to the consumer (11–15), (*3*) heterotrophic plate count values may exceed those defined in national legislation and may cause problems in the food industry, (*4*) microbial activity and biomass may affect turbidity, color, taste, and odor of the water (16), (*5*) microbiological processes may accelerate corrosion (Microbiologically Induced Corrosion, MIC) of pipe materials (17,18), (*6*) invertebrates multiplying on bacterial biomass may cause consumer complaints (19,20).

In the absence of a disinfectant residual regrowth is controlled by distributing biologically stable water, as obtained by a far-reaching removal of biodegradable compounds from water during treatment (21). Assessment of the degree of biological (in)stability requires a method for determining the concentration of growth-promoting compounds in water or the microbial growth potential. This entry describes the assimilable organic carbon (AOC) method and its significance for defining biological stability.

REGROWTH PROCESSES AND GROWTH KINETICS

Regrowth is a complex phenomenon affected by many variables. Key processes in regrowth are the uptake of biodegradable compounds by microorganisms, formation of biofilms on the exposed surface detachment of (micro-)organisms and dead biomass from the pipe wall and accumulation of sediments, respectively. The presence of biodegradable compounds is a major driving force in these regrowth processes but other environmental conditions (e.g., temperature, system hydraulics, and retention time) and physicochemical processes (adsorption, oxidation/reduction, and coagulation/sedimentation) also have significant effects on the extent to which microorganisms multiply. When a disinfectant is added to water before distribution, the situation is even more complex because the concentration of disinfectant generally changes in time and differs among various locations in the system (22).

Bacteria present in the biofilm are released into the water and may be detected in routine monitoring of the microbiological quality of drinking water. Most bacteria predominating in regrowth processes do not seem to constitute a direct hygienic or aesthetic problem (23,24), but their ability to produce biomass under the prevailing conditions is a main cause of the enables Parts of the biofilm sloughing from the surface may settle in pipes at low flow conditions and contribute to the formation of sediments. Biofilms and sediments of decaying biomass are niches for undesirable bacteria including coliforms (25), aeromonads (12), *Legionella* spp. (13,15), *Mycobacterium* spp. (11,14), but also fungi and yeasts may be present (26). Certain invertebrates use biofilms and sediments as a food source (19,20). (See also this Encyclopedia Invertebrates and protozoan in drinking-water distribution systems, Van Lieverloo et al.).

The rate and extent of multiplication of microorganisms in water depend on the concentration and the composition of the available food sources. These food sources provide energy and the elements needed for the biomass synthesis. Heterotrophic bacteria utilize organic compounds as a source of energy and carbon. In addition, certain inorganic compounds are required, in particular nitrogen and phosphorus, and a number of other elements at much lower amounts, for example, sulfur. The need for carbon, nitrogen, and phosphorus can be derived from the gross composition of microbial biomass, $C_5H_7NO_2P_{1/30}$, and the proportion (50%) of organic carbon used for dissimilation (27). Hence, organic compounds serving as a source of energy and carbon are needed in much larger amounts than the inorganic nutrients nitrogen and phosphorus ($C : N : P = 100 : 10 : 1$). Nitrate, a common compound in drinking water, is a good nitrogen source for many aquatic bacteria, although certain types (e.g., *Aeromonas* spp.) require ammonia-nitrogen for growth (28). Phosphate is also a common compound in the aquatic habitat, and it is only needed in very low quantities relative to the carbon source. Hence, the availability of suitable organic compounds will be the growth-limiting parameter for heterotrophic bacteria in most water types. Some studies suggest that phosphate may be growth limiting in certain types of groundwater, which contain a relatively high concentration of organic compounds (29).

The amount of biomass produced on a certain amount of substrate depends on the yield (Y) values of the bacteria for the present compound(s). Generally, 1 mg of substrate

carbon yields 1 mg of biomass (dry weight) during aerobic growth (27). Expressing the yield value as number of bacteria (colony forming units, CFU) is more appropriate for describing regrowth processes. Typical yield values for compounds serving as favorable growth substrates for heterotrophic bacteria (low molecular organic compounds) of 4×10^6 to 2×10^7 CFU have been reported (see later). Hence, utilization of 1 μg of C/L theoretically corresponds with a maximum colony count value of 10^4 CFU/mL. The substrate concentration also affects the rate of growth. This relationship is described by the Monod equation (30):

$$V = V_{max} \times S/(K_s + S) \quad (1),$$

where: V = the growth rate (doublings/hour) in the exponential growth phase at substrate concentration S; V_{max} = maximum growth rate (h^{-1}); K_s = the substrate saturation constant, is the concentration of S at which $V = 1/2V_{max}$. An example of such a relationship is presented in Figure 1, which clearly demonstrates that the increase of the growth rate is less than proportional to the increase of the substrate concentration. However, at very low values for S, that is, $S \ll K_s$ then:

$$V = V_{max}/K_s \times S \quad (2)$$

and the growth rate is linearly related with the substrate concentration S and also depending on the values for V_{max} en K_s, which are constants for specific combinations of organism and substrate. The quotient V_{max}/K_s ($h^{-1} \ldots \mu g^{-1} \ldots L$, the substrate affinity constant is numerically identical to the growth rate calculated for a substrate concentration of 1 μg C/L.

Bacteria representing the indigenous bacterial flora of drinking water have K_s values for easily degradable low molecular weight compounds as low as a few micrograms of C/L. Relatively low K_s values have been also been observed for the high molecular weight compounds amylopectin and amylose (Table 1). *Escherichia coli*, coliforms, and also *P. aeruginosa* have higher K_s values than the typical aquatic bacteria for identical substrates. Still, the K_s values of 13 to 72 μg of glucose-C/L (31,32), and 50 to 150 μg of yeast extract/L (38) as reported for *E. coli* are also relatively low. Despite these kinetics, *E. coli* and *P. aeruginosa* do not belong to the indigenous bacterial community of drinking water. This may be due to the relatively slow growth of these bacteria at temperatures below 15 °C (34) and the very low concentrations of easily available compounds in treated water.

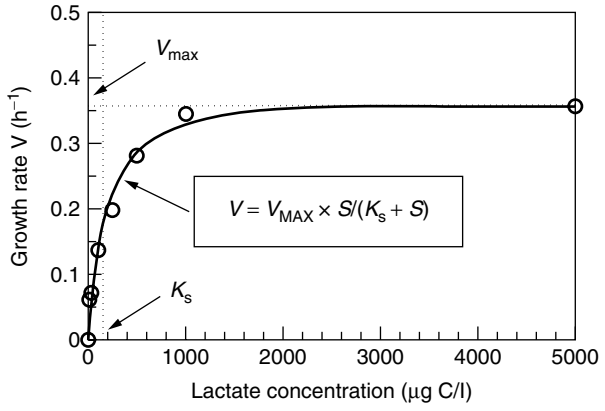

Figure 1. The growth rate of an *Escherichia coli* strain (isolated from river water) at various concentrations of lactate in autoclaved slow sand filtrate ($+PO_4^{3-}$P and NH_4^+-N) incubated at 25 °C. The constants of the Monod relationship (K_s and V_{max}) are given in Table 1.

As a result of maintenance energy requirements, a certain minimum substrate concentration (S_{min}) is required for survival without growth (35). Typical maintenance rates for bacteria due to endogenous substrate utilization range from 0.005 to 0.02 h^{-1} (36), but a much higher value (0.3 h^{-1} at 37 °C) has been reported for *E. coli* (31). The values for the substrate affinity of a number of bacteria presented in Table 1, are below the value of maintenance rate. Consequently, these bacteria are not able to grow at a concentration of 1 μg of C/L of the specified compounds. In practice the situation is more complicated because in most situations, several compounds will be present. Most of the bacteria described in Table 1 are able to utilize a number of substrates simultaneously when present at an individual compound concentration of 1 μg C/L. A mixture of amino acids stimulated the multiplication of *A. hydrophila* at an individual compound concentration as low as 0.05 μg C/L (28).

The growth kinetics as presented in Table 1 demonstrate that low concentrations of easily available organic compounds can cause a rapid and significant growth of bacteria present in treated water. For this reason, the method for assessing the regrowth potential of treated water as developed in the Netherlands was mainly directed at determining the concentration of such compounds.

Assessment of the Microbial Growth Potential of Treated Water

Already at the end of the nineteenth century, studies were conducted on bacterial multiplication in treated water (44). It was observed that the number of culturable bacteria was much higher in stored samples of a high-quality deep-well water with a low concentration of organic compounds (up to 5×10^5 CFU/mL) than in river water samples (4,300 CFU/mL). The assumption was made that the well water obtained from the chalk contained a relatively high concentration of biodegradable compounds because of the absence of bacteria in this water directly after abstraction. On the other hand, it was known at that time that the relatively strong growth in treated water stored in flasks with a cotton was related to compounds present in the air. Also, the difference in growth between well water and river water was most probably the result of the multiplication of a few types of bacteria contributing to the HPC values in well water, whereas many of the bacteria present in river water were not able to grow on a solid medium. These observations show that determining the growth potential using colony counts of the indigenous bacterial community has a number of limitations. In the Netherlands, Beijerinck (45) suggested in 1891 that the growth promoting properties of drinking water be studied by inoculating selected pure cultures in sterilized

samples of the water that was to be tested. He also pointed out the necessity to prevent contamination by volatile compounds. However, no results were presented and it seems that this method did not attract much attention. In 1928 a completely different approach was reported by Heymann (46) who determined the effect of a series of passages of water through sand columns on the concentration of organic compounds, measured as permanganate value. However, this method also did not gain wide application.

Interest in the regrowth phenomenon strongly increased in the Netherlands in the 1970s as a result of the introduction of ozonation and granular activated carbon (GAC) filtration in water treatment for the removal of persistent organic pollutants. In 1978 a method for determining the heterotrophic growth potential of treated water was described, which was based on determining the maximum level of growth of a selected pure culture in samples of water collected and contained in thoroughly cleaned glass-stoppered Erlenmeyer flasks (47,48). Subsequently, this method, which was designated as the AOC method, was improved by including a bacterial strain with the ability to utilize certain carboxylic acids, as produced by ozonation (49). Regrowth phenomena gained also attention in other European countries and in the United States, and a series of methods for assessing the growth potential of drinking water have been developed (Table 2).

Table 2. Characteristics of Methods for Assessing the Microbial Growth Potential of Treated Water

Method*	Mode	Organisms	Parameter	Reference

BFR	Column	Indigenous bacteria	ATP	5,51,52,62

*AOC, easily Assimilable Organic Carbon; BGP, Bacterial Growth Potential; BDOC, Biodegradable Dissolved Organic Carbon; BFR, Biofilm Formation Rate.

Batch tests are most commonly used because such test can be conducted under controlled conditions in the laboratory. These tests give information about the growth potential but the test conditions do not reflect the processes occurring in the distribution system. Another limitation of the AOC and BDOC tests is that the growth potential of treated water may also be affected by the presence of inorganic compounds (e.g., ammonia and sulfides) and methane, which are not included in these tests. A variety of techniques and devices is available to simulate the biofilm formation as occurring in distribution systems, for example, Rototorque system (49), Robbins device, coupon test (50), and a biofilm monitor (51,52). A combination of growth tests, determining the (effects of) concentrations of rapidly and more slowly available compounds, as well as chemical analysis (e.g., for ammonia and methane), may be needed to assess the biostability of treated water. In the Netherlands biostability assessment of water is conducted by using the AOC test and the BFR test (5).

AOC METHOD

Principle of the Test

As explained earlier, easily biodegradable organic compounds may cause significant growth at a level of a few micrograms per liter. Therefore, a test was developed aiming at determining low concentration of these compounds, which were designated as assimilable organic carbon (AOC), derived from earlier descriptions where the terminology "assimilable compounds" was used (46). Assessment of the concentration of easily assimilable

organic carbon (AOC) is based on growth measurements of a mixed culture of two select bacterial strains in a sample of pasteurized water collected and contained in a thoroughly cleaned glass-stoppered Erlenmeyer flask. On the basis of the maximum colony counts of these organisms, the original concentration of substrates is calculated using the yield values of the bacteria for acetate. Hence, the AOC concentration is expressed as μg of acetate-carbon equivalents/L.

Test Strains

The strains used in the AOC test are *P. fluorescens* strain P17, which is capable of utilizing a wide range of low molecular weight compounds at very low concentrations (42) and a *Spirillum* sp. strain NOX, which only utilizes carboxylic acids (43). The general properties of these organisms are described in Table 3, together with another organism specialized in the utilization of carbohydrates (63).

P. fluorescens strain P17 originates from tap water and belongs to one of the most commonly occurring biotypes of the fluorescent pseudomonads in drinking water (64). Growth measurements conducted in drinking water supplemented with mixtures of compounds revealed that the organism can utilize most or all amino acids, a number of carboxylic acids, some carbohydrates and a number of aromatic acids, at a concentration of 1 μg of C/L when present as a mixture (Fig. 2a; 42). In addition, the organism requires a simple nitrogen source and multiplies rapidly on agar media. For these reasons, strain P17 was selected for determining the concentration of easily AOC in (drinking) water (48). The yield factor of strain P17 for acetate-carbon (4.1×10^6 CFU/μg carbon) is used for calculating the AOC concentration from the maximum colony counts (N_{max}, CFU/mL) obtained in the water types tested.

Spirillum species strain NOX had been isolated from slow sand filtrate enriched with 25 μg C/L of oxalate, glyoxylate and formate, respectively (43). The strain is specialized in the utilization of carboxylic acids, including formate, oxalate, glycollate and glyoxylate, which are not used by strain P17. Growth tests conducted with mixtures of substrates with an individual compound concentration of 1 μg of C/L clearly revealed that only carboxylic acids were utilized at this low concentration (Fig. 2b). As a result of its preference for carboxylic acids, the N_{max} value of strain NOX gives information about the concentration of carboxylic acids in the water tested. Yield factors have been determined for acetate and for oxalate, respectively. The yield (CFU/μg of carbon) of strain NOX for acetate is about four times higher than for oxalate-carbon. This difference can be explained by the low energy content of oxalate (27). The organism is used in a mixed culture strain P17 for determining the concentration of easily assimilable organic carbon (AOC) in (drinking) water.

Flavobacterium species strain S12 was obtained from slow sand filtrate incubated at 15 °C after enrichment with 100 μg of starch-C/L (63). The organism is specialized in utilizing carbohydrates, including amylose, amylopectin, maltose, and maltodextrins, which are not used by strain P17 nor by strain NOX. Growth tests conducted with mixtures of substrates with an individual compound concentration of 1 μg of C/L clearly revealed that only certain carbohydrates were utilized at this concentration. N_{max} values of strain S12 therefore give information about the concentration of maltose- and maltodextrin-like compounds in the water tested. Yield factors of strain S12 for starch, maltose, and maltodextrins range from 2.0×10^7 to 2.3×10^7 CFU/μg C (40). Concentrations of

Error bars indicate duplicate measurements.

carbohydrates available for strain S12 in drinking water usually are very low (<1 μg of C/L) and therefore, the organism is not included in the test for determining the concentration of easily assimilable organic carbon (AOC) in (drinking) water. In certain water types however, a significant concentration of carbohydrates may be present, for example, when algal growth occurred in the raw water and/or when a starch-derived coagulant aid is used in water treatment (40).

Other strains can be used for growth measurements to determine the utilization of present or added substrates or to determine the growth potential of the water for a specific organism. Typical examples of such strains include *Aeromonas* species (28), representatives of the coliform group, including *E. coli* (65,66; Fig. 1) and also *P. aeruginosa* (43).

Test Conditions

Sampling and transportation of the samples and sample treatment are essential to obtain an accurate AOC value. For this reason, representative samples of the water to be investigated are collected in duplicate in thoroughly cleaned (including heating at 550 °C for four hours) Erlenmeyer flasks. In these flasks the water samples are transported, pasteurized, and incubated, respectively. Hence, contact with surfaces and air is restricted as much as possible. Pasteurization aiming at inactivating the indigenous bacterial community as present in the water samples is conducted by placing the flasks in a water bath at 90 °C. The flasks are removed from the water bath when water temperature has reached 60 °C and subsequently are placed in an incubator at 60 °C for 30 minutes. After cooling with cold tap water, the test strains are added to

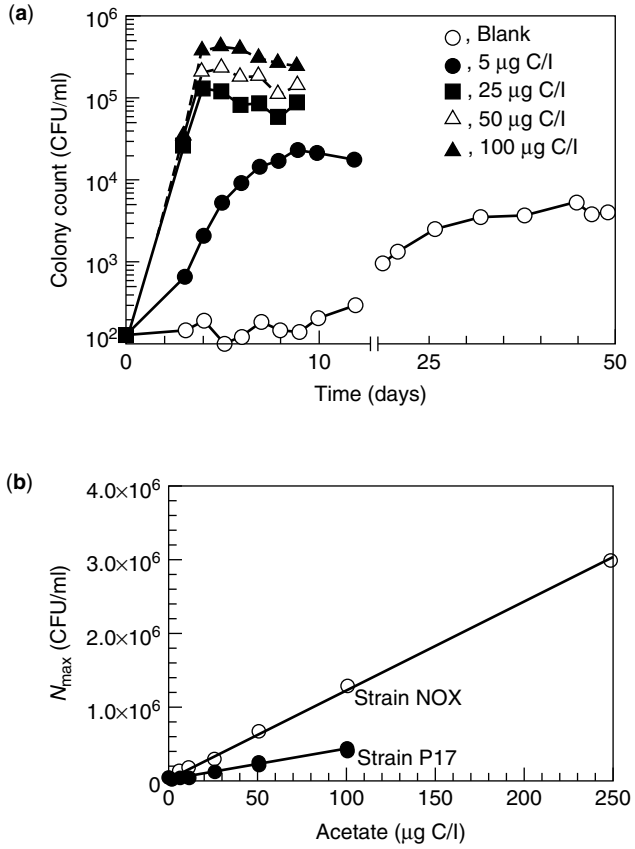

Figure 3. (**a**) Growth curves of *P. fluorescens* strain P17 in pasteurized slow sand filtrate (DOC = 2.3 mg/L) supplemented with different acetate-C concentrations (at 15 °C); (**b**) calibration curves of strain P17 and strain NOX for acetate. Yield values are presented in Table 4.

the flasks. Cultures of the test strains grown in tap water at an initial concentration of 1 mg of acetate-C/L, in which the maximum colony count had been reached are used as inoculum. The inoculum gives is about 50 to 500 CFU/mL in the pasteurized samples. The flasks are incubated at $15 \pm 1\,^{\circ}C$ in the dark, without shaking.

Membrane filters have been used to remove the indigenous bacteria from the samples. However, organic compounds can release from: (*1*) the filters, (*2*) the equipment used for membrane filtration, and (*3*) the flasks in which the filtered water is collected. Furthermore, membrane filtration does not always result in sterile samples because of the presence of very small bacterial cells (ultramicrobes). Hence, application of membrane filters may give unreliable results. Also, autoclaving is not appropriate because it causes a strong increase (three- to fourfold) in the AOC concentration, depending on the water type (unpublished results).

In certain samples, detoxification of the water is required, for example, in the presence of a disinfectant residual, or in the presence of copper. Growth measurements with thiosulphate, used to neutralize a disinfectant residual showed an AOC increase of about 5 μg C/L at a concentration of 10 mg/L. EDTA and NTA do not affect the AOC concentration as determined with strains P17 and NOX (unpublished results). The use of NTA is preferred because this compound is more easily biodegradable in the environment than EDTA.

Growth Measurements and Calibration Curves

The growth curve is determined by periodic colony counts for which purpose water volumes of 0.05 mL are spread in triplicate over the surface of agar medium plates, followed by incubation at 25 °C for 2 (P17) to 3 (NOX) days. A broth agar medium (Lab Lemco Agar, Oxoid) is used routinely, but the R_2A medium 67 has the same recovery for strain P17 and strain NOX (data not shown). Colonies of strain P17 are larger than those of strain NOX and produce a fluorescent pigment on R_2A medium.

The yield (Y) values of strain P17 and strain NOX for acetate are needed to calculate the AOC concentration from the maximum colony counts. Typical growth curves of strain P17 in slow sand filtrate supplemented with different acetate concentrations are presented in Figure 3. N_{max} values were reached after five to seven days at acetate concentrations greater than or equal to ≥ 10 μg C/L, and after about 10 to 14 days at an initial acetate-carbon concentration of 5 μg C/L. Similar experiments have been conducted with strain NOX 43. The relationship between N_{max} values and the acetate concentrations is used for calculating the yield values (Fig. 3b) At acetate-carbon concentrations above 100 μg C/L, the N_{max} value of strain P17 remains below the level expected on the basis of the values observed at lower concentrations (data not shown). This is probably because the cells are larger when grown at higher substrate concentrations. This phenomenon has not been observed with strain NOX. Yield values of a number of test strains are given in Table 4.

AOC concentrations are determined using a mixed inoculum of strain P17 and strain NOX. The AOC concentration is determined from the N_{max} values of each of the strains, using their *Y* value for acetate (Fig. 4). Next to the AOC concentration, information also is obtained about the AOC composition because strain NOX can only grow on carboxylic acids (40).

Figure 5 shows the contributions of strain NOX and strain P17 to the AOC concentration when grown simultaneously in pasteurized slow sand filtrate supplemented with yeast extract. Growth of strain NOX was not enhanced by the addition of yeast extract. The *Y* value of strain P17 for yeast extract is 0.35 μg AOC/μ g YE.

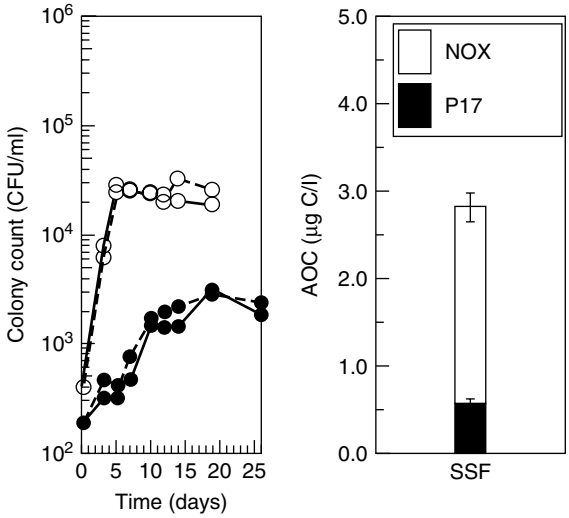

Figure 4. Growth curves of test strains P17 and NOX in slow sand filtrate (SSF) and the AOC value calculated from the N_{max} values of the strains. In these samples the concentration of AOC compounds utilized by strain P17 was less than 1 μg C/L.

Table 4. Yield Values of a Number of Bacterial Strains Used in Growth Experiments (28,40,42,43,48)

Organism	Y value (CFU/μg C) Acetate	Oxalate	Glucose	Starch	Lactate

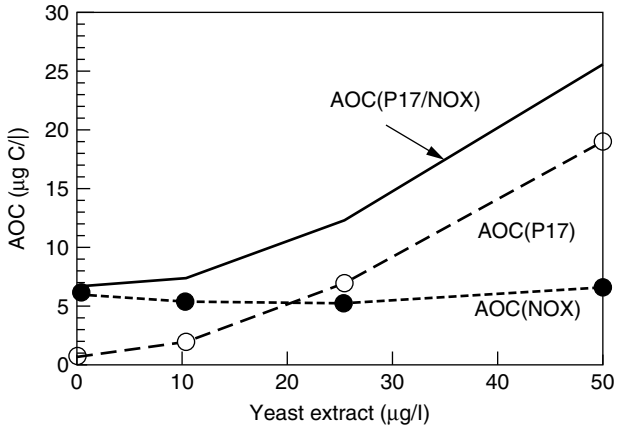

Figure 5. AOC concentrations at various concentrations of yeast extract added to slow sand filtrate. AOC-P17 is the AOC concentration derived from the N_{max} values of strain P17 grown in the presence of strain NOX; AOC-NOX is the AOC concentration calculated from the N_{max} values of strain NOX. AOC-P17/NOX is the total AOC concentration.

Effect of Separate Growth of Test Strains

Both strain P17 and strain NOX are able to utilize carboxylic acids. In a mixed culture, there is competition for these substrates. When grown separately, compounds available to the two strains are used by both strains. Figure 6 shows the AOC concentrations determined in two different water types by the individual strains and by growth as a mixture, respectively. In both water types, the AOC concentration mainly consists of compounds available to strain NOX (carboxylic acids). From these results, it can be calculated that 45 to 66 % of the compounds potentially available to strain P17 were utilized by strain NOX when grown as a mixed culture. In addition, a small fraction of the compounds available to strain NOX is utilized by strain P17 when grown as a mixed culture.

(**a**) water after ozonation; (**b**) ozonated water after GAC filtration. 1(P17), strain P17 alone; 2(NOX) strain NOX alone; $1+2$, AOC calculated from 1 and 2; P17/NOX, strains P17 and NOX grown as mixed culture. Error bars give standard deviations.

Reproducibility and Repeatability of AOC Determinations

A large number of AOC determinations have been conducted since the development of the method. In all cases, the test was done in duplicate sample flasks. Hence, information is available about the reproducibility of the test. Figure 7 shows the Relative Standard Deviations (RSD, %) of a total of 430 AOC tests, conducted within a one-year period, most of which with an AOC value below 25 µg C/L. The STD values were below 10% for 60% of all samples tested. In 10% of the samples STD values were greater than 35% (Fig. 7b). The repeatability of the test is shown by the constant yield values of the test strains for acetate and the constant AOC values obtained for one particular slow sand filtrate over a period of more than 15 years (with values <5 µg C/L) (results not shown).

Comparison of Described AOC Procedures

The AOC test as described earlier, has been adapted by a number of researchers to improve its use as a monitoring tool (55,60). A major adaptation is the use of small-capped containers, in combination with a single measurement in a container (in triplicate) after a defined incubation period. Table 5 compares the conditions of the AOC test as described in standard methods (6g) with the AOC test that was described earlier. A further adaptation to the procedure described in standard methods is the use of ATP for determining the growth of the test strains. With the ATP analysis, the AOC test can be conducted within two to four days (55).

AOC CONCENTRATIONS IN WATER

AOC Concentrations in Raw and in Treated Water

The AOC test had been developed for assessing the biostability of treated water. However, it is also used in raw water and in water in various treatment stages. A problem observed with the use of the AOC test in raw water is the presence of spore-forming bacteria

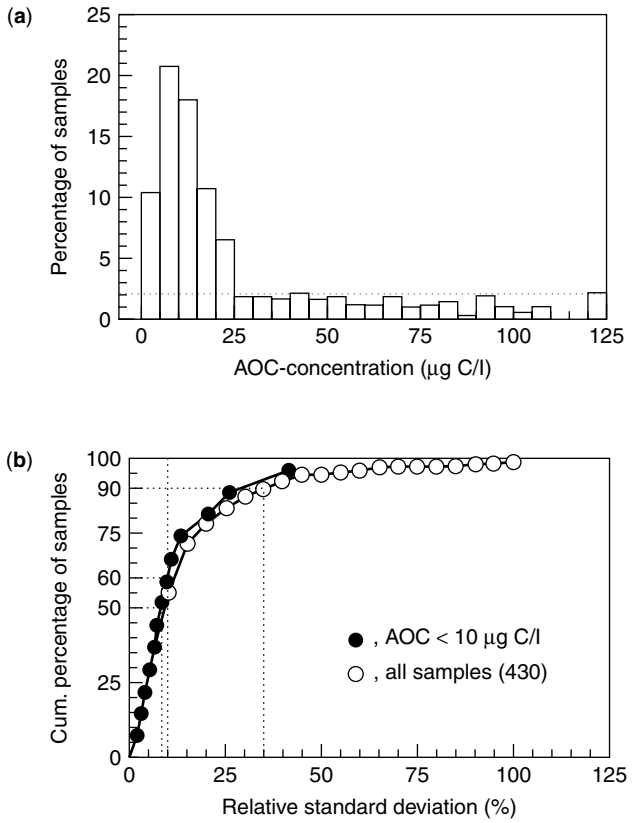

Figure 7. (**a**) AOC concentrations as measured in 430 samples and (**b**) the relative standard deviation (RSD) of the AOC concentrations (relative to the average value of duplicate measurements).

or other types of bacteria surviving the pasteurization procedure. These organisms hamper the AOC test either by growing on the plates and/or by growing in the water samples and thus consuming an unknown part of the substrates potentially available to the test strains. Pasteurization at a higher temperature (e.g., 70 °C for one to two hours) can be applied to eliminate this problem.

Typical AOC concentrations in river (Meuse) water ranged from about 50 µg C/L to 400 µg C/L, depending on the season, with the highest concentrations in spring and in late summer (Fig. 8a). About 70 to 90% of these AOC concentrations was available to strain P17, indicating that the substrates available to strain P17 (e.g., amino acids, peptides, carbohydrates, etc.) were present in much higher concentrations than the carboxylic acids. The concentration of dissolved organic carbon (DOC) was 3.2 to 4.2 mg/L and the AOC concentrations were 1.5 to 10% of the DOC concentration.

In a survey conducted in 1986 to 1987 (53), AOC concentrations observed in drinking water in the Netherlands ranged from 1 to about 60 µg acetate-carbon equivalents per liter (Fig. 8b). The highest values were observed in surface-water supplied with ozonation a treatment ste. In all types of treated water the fraction available to strain NOX was the largest proportion of the AOC concentration, indicating that carboxylic acids were the predominating compounds. The AOC concentration utilized by strain P17 was less than 1 µg C/L in most samples of treated water. The data presented in Figure 8b and many observations conducted since then clearly demonstrated that the AOC concentrations in treated groundwater water in the Netherlands usually are below 10 µg of C/L. Also, in surface water supplies with slow sand filtration as the final treatment step such low AOC concentrations were found.

AOC concentrations in treated water are only a small fraction (<1.7%) of the DOC concentration (Fig. 9). The lowest AOC/DOC ratios have been observed in groundwater supplies, in which AOC concentrations usually were below 10 µg of C/L. Minimum values for the AOC/DOC quotient were all close to 0.1%.

AOC values in treated water observed in the Netherlands are low in comparison to values reported in other countries. Several surveys conducted in the United States revealed that AOC concentrations in treated water

Table 5. Comparison of AOC Procedures

Test Characteristic	AOC (Original Method)	AOC in Standard Methods (69)
Containers	Borosilicate glass Erlenmeyer (1 L); glass stoppered	Borosilicate glass vial (45 mL) with TFE-lined silicone septa
Sample volume	600 mL	40 mL
Surface/volume (cm^{-1})	0.63 (equivalent to pipe diameter of 6 cm)	1.5 (equivalent to pipe diameter of 2.7 cm)
Test strains	P17 and NOX	P17 and NOX, separate growth
Biomass parameter	Colony count	Colony count or ATP (55)
Sample treatment	30 minutes at 60°C	30 minutes at 70°C
Addition of chemicals	none	Thiosulphate (50 mg/L)
Incubation period	≥14 days	9 days
Calculation of AOC	N_{max} values in duplicate flasks	Average of colony counts in triplicate vials on days 7,8, and 9
Result (units)	µg of acetate-c equivalents/L	µg of acetate-C equivalents/L

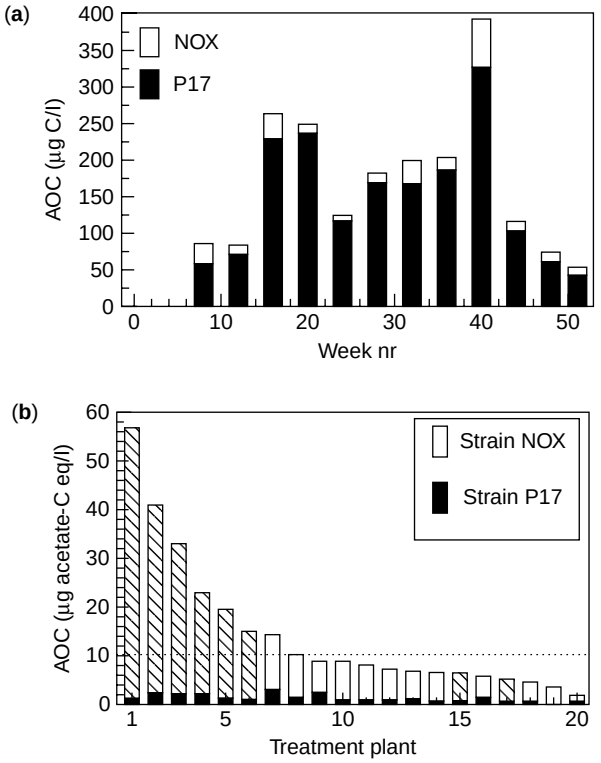

Figure 8. (**a**) AOC concentration in river water in a one year period. (**b**) AOC concentrations in treated water of 20 different treatment plants. Hatched bars represent treated surface water; open bars represent treated groundwater. Groundwater was treated without chemical disinfection. Nrs. 15 and 17 are slow sand filtrates. Adapted from D. Van der Kooij, *J. Am. Water Works Assoc.* **84**(2), 57–65 (1992).

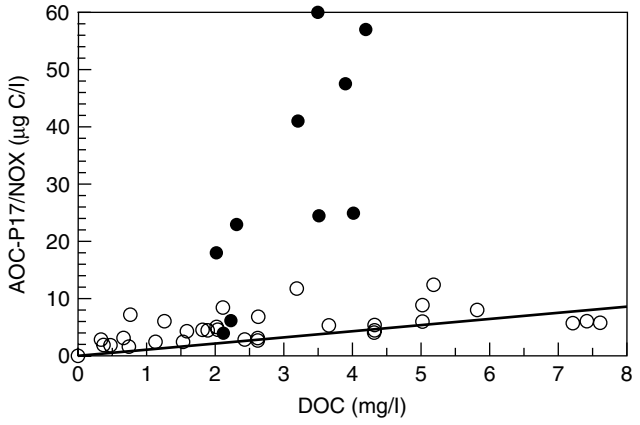

Figure 9. AOC concentrations in treated water as a function of the DOC concentration. Open circles: groundwater supplies; closed circles: surface water supplies. Line shows Lowest AOC/DOC ratios. Data (adapted) from D. Van der Kooij, *J. Am. Water Works Assoc.* 84(2), 57–65 (1992).

ranged from about 20 to 200 or more than 300, respectively (70,71). Median AOC values observed in these studies were about 100 µg C/L. In one of these surveys, the fraction of AOC available to strain P17 exceeded 50 µg C/L in a number of water types. Hence, AOC values in treated water in the United States are much higher than those in treated water in the Netherlands. These differences in AOC levels may be due to differences in water treatment (less biological treatment and addition of chlorine). Also, the AOC test as used in the United States is not identical to the one described in this report (Table 5), but a few comparisons between the test methods did not show large differences between the results (72). Still, the separate growth of the test strain will have an effect in certain water types (cf. Fig. 6).

Effects of Water Treatment

From the differences between the AOC concentration in raw river water and the AOC concentration in treated water, it can be concluded that surface water treatment as applied in the Netherlands can cause an AOC reduction of more than 90%. A variety of processes have different effects on the AOC concentration Fig. 10. The AOC concentration is reduced by biological processes in filter beds when these processes are applied properly and also during soil passage physicochemical processes such as coagulation/sedimentation and adsorption also can reduce the AOC concentration of water. On the other hand, oxidation processes clearly cause an increase of the AOC concentration. The effect of ozonation is related to the degradation of large molecules of natural organic compounds, such as fulvic and humic acids, into low molecular compounds, as has been demonstrated in studies, using advanced chemical analytical techniques. AOC concentrations increase with increasing ozone dosage (74,75,76).

The effect of biological filtration processes on the AOC concentration is of major importance in achieving a biologically stable drinking water. In the Netherlands such processes are included in all water treatment plants, either as rapid sand filtration, GAC filtration, slow sand filtration, or soil passage of surface water (river bank filtration, artificial dune recharge). Fig. 11 shows

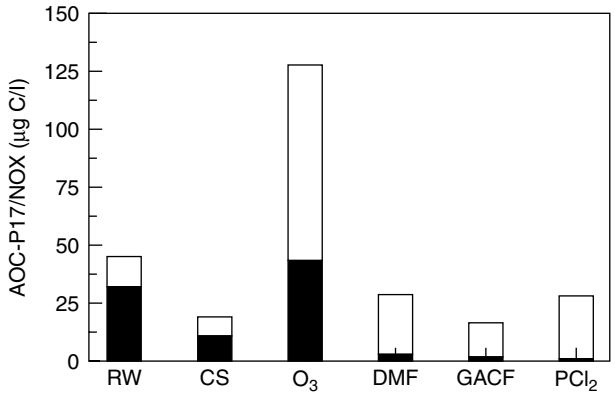

Figure 10. The effects of water treatment on the AOC concentration. RW, raw water river Meuse water after storage in open reservoirs; CS, coagulation/sedimentation; O_3, ozonation; DMF, dual media filtration; GACF, granular activated carbon filtration; pCl2, postchlorination. The water is distributed after postchlorination. Black bar represents the AOC fraction utilized by strain P17.

that the AOC reduction decreases with decreasing AOC concentration in the influent.

From the data shown in this figure, it can be calculated that the AOC reduction in this type of process is negligible at AOC concentrations below 6 μg of C/L. Similar observations have been reported by other investigators (77). Figure 11 also shows that the presence of a chlorine residual in the influent of rapid sand filters decreased the AOC removal, most probably by hampering the biological processes.

Membrane filtration processes have a huge potential in water treatment because of the variety of available membrane types, and the capacity of removing undesirable particles (including bacteria) and dissolved compounds without side-effects on water quality. Ultrafiltration cause an AOC removal up to 84% (from 25 to 3.8 μg C/L) in a surface water treatment, probably by removing particulate compounds of biological origin (78). Reverse osmosis is capable of reducing the AOC concentration to a level below 1 μg C/L. In this water, inorganic nutrients were added to conduct the AOC test (unpublished result 5).

Effects of Distribution

Observations on water sampled from a number of distribution systems have revealed that AOC concentrations may decline rapidly in the distribution system, depending on the initial AOC concentration (Fig. 12). Most likely, biofilm processes play an important role in AOC uptake (53,79). Figures 12 and 13 demonstrate that AOC reduction is very limited at values close to and below 10 μg C/L.

Effect of Storage of Water Samples on AOC and HPC Values

Water samples collected in thoroughly cleaned Erlenmeyer flasks were incubated without pasteurization to obtain information about the effect of the multiplication of the indigenous population on the AOC concentration. Figure 14 shows that the AOC concentration of river water (Fig. 9) collected from a storage reservoir initially followed an exponential decrease. After three days at an AOC concentration of about 10 μg C/L the rate of decrease

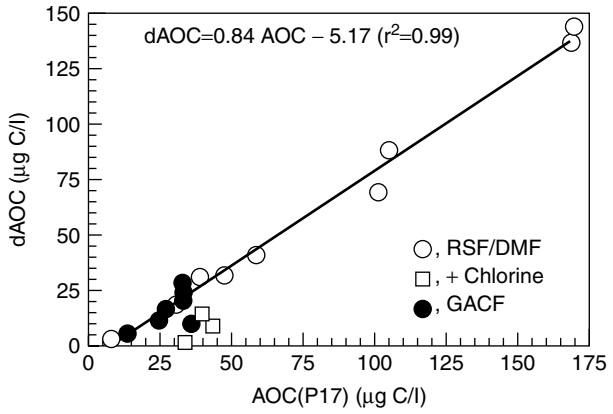

Figure 11. AOC reduction (dAOC) as achieved with biological filtration. RSF, rapid sand filtration; DMF, dual media (anthracite/sand filtration); GACF, granular activated carbon filtration. Adapted from Van der Kooij, 1984 (73).

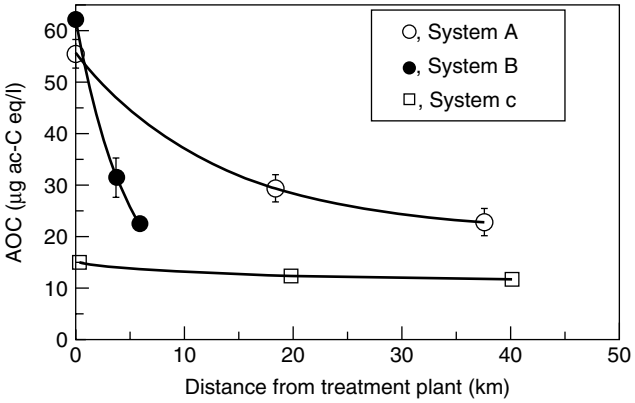

Figure 12. The effect of distribution on the AOC concentration in three different distribution systems. In all cases, ozonation was used as a treatment step. From: D. Van der Kooij, *J. Appl. Microbiol. Symp. Suppl.* **85**: 39S–44S (1999).

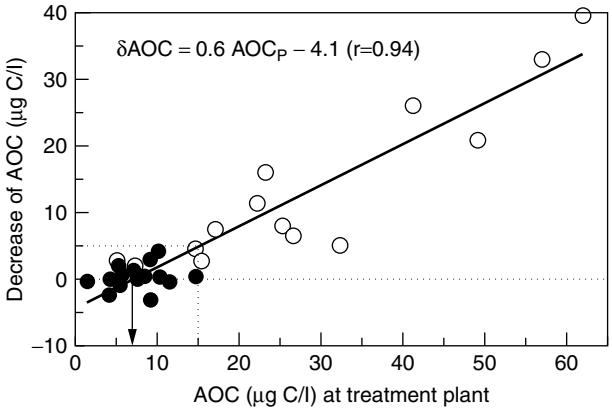

Figure 13. Maximum AOC decrease observed in distribution systems as a function of the AOC concentration of treated water. Open circles: surface water supplies; closed circles: groundwater supplies. Adapted from D. Van der Kooij, *J. Am. Water Works Assoc.* **84**(2), 57–65 (1992).

declined sharply and followed a linear function with time in the test period up to four weeks. In ozonated water, the AOC concentration rapidly declined to a value of 15 μg of C/L. Thereafter the decline became linear with time (Fig. 14(b)). In the stored river water, the fraction of AOC utilized by strain P17 constituted 72% of the initial AOC concentration. In ozonated water the fraction available to strain P17 initially was less than 10% of the total AOC concentration. Obviously, biomass compounds (amino acids, peptides, etc.) predominated in stored river water, whereas carboxylic acids were the major AOC fraction in ozonated water.

The following equations can be used to describe the observed AOC decrease:

Phase 1 (up to five days); exponential decrease with residual:

$$AOC_T = AOC_0 \text{ x } e^{-kT} + AOC_R, \quad (3)$$

Phase 2 (after about 5 days); linear decrease:

$$AOC_T = AOC_5 - Ux(T - 5) \quad (4)$$

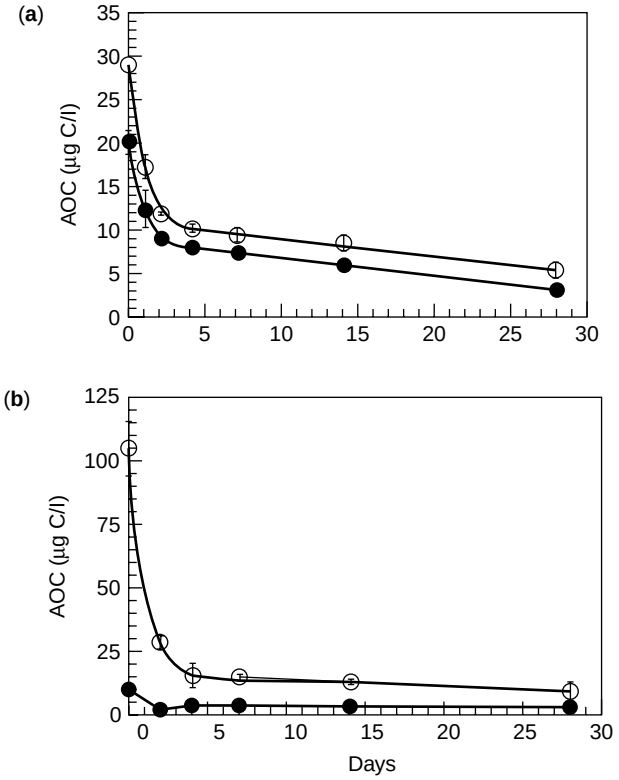

Figure 14. AOC decrease in water samples incubated at 15 °C in thoroughly cleaned Erlenmeyer flasks. (**a**) river water from an open storage reservoir; (**b**) water after ozonation. Symbols: ○, AOC P17/NOX; ●, Fraction of AOC available to strain P17. Error bars give standard deviation of the AOC value (duplicate flasks).

In these equations AOC_T is the AOC concentration at time T, AOC_0, the AOC concentration at the start (zero time), AOC_5 the AOC concentration at day five, and AOC_R, is the apparent residual AOC concentration, respectively. K is the decay constant (d^{-1}) in the exponential phase, and U is the uptake rate ($\mu g \ldots l^{-1} \ldots d^{-1}$) in the linear phase. The constants of the equations for the two water types are given in Table 6.

Simultaneously with the AOC decrease, the numbers of bacteria increase in the water samples during incubation. This increase can be determined with several techniques, including the heterotrophic plate count (HPC), the total direct (microscopic) count (TDC), or the concentration of adenosinetriphosphate (ATP). These techniques all have their specific advantages and limitations. The main limitations of these parameters include: (*1*) the HPC value of a mixed population of aquatic bacteria is always a (small) fraction of the total active population, and requires a long incubation period; (*2*) the TDC values include active and inactive cells, which may also differ greatly in size; (*3*) the ATP test is fast, but the ATP concentration declines rapidly once the maximum level has been attained. For a number of samples, maximum HPC values have been determined in relation to the initial AOC concentration. The results presented in Figure 15 clearly show that there is a good correlation between the AOC concentration and the maximum HPC values, with an average yield of 7.37×10^6 CFU/µg C. Obviously, the compounds serving as sources of carbon and energy for the indigenous population are those compounds used by the AOC test strains P17 and NOX. However, differences between the bacterial communities in the various water types result in different yield values and differences in the fraction contributing to the HPC value influence the N_{max} values.

BIOLOGICAL STABILITY

Comparison of AOC and BDOC

The AOC and BDOC methods are used to assess the biological (in)stability of treated water. Table 2 gives an indication of the difference between these two approaches. AOC values are a small fraction of the DOC concentration of river water and even lower (0.1 to 1%) in treated water. BDOC values may constitute a significant proportion (19 to 54%) of the DOC concentration (3.5 to 13.3 mg/L) of river water (80). Surveys revealed that BDOC concentrations of drinking water from 79 utilities in the United States ranged from 0.01 to 2.4 mg/L and were 0.4 to 52.8 % of the DOC concentration (70). In another study, BDOC values for treated water of 31 plants averaged by site ranged from 0.03 to 1 mg/L and constituted 5 to 21% of the DOC concentration (71). In both studies significant correlations were found between concentrations of AOC and BDOC, respectively. However, the correlation coefficients were

Table 6. Kinetics of the AOC Decrease in Samples (600 mL) of Two Water Types Stored at 15 °C in Thoroughly Cleaned Erlenmeyer Flasks

Parameter*	River Water from Open Storage Reservoir	Water After Ozonation
DOC (mg/L)	3.4	2.9
AOC_0 (at time zero) (µg C/L)	29.1 ± 6.1	105 ± 11
AOC_R (µg C/L)	9.6 ± 0.7	13.2 ± 0.8
K (day^{-1})	0.98 ± 0.11 ($r^2 = 0.99$)	0.90 ± 0.04 ($r^2 = 0.99$)
Uptake coefficient (µg C/L.day)	0.2 ± 0.01 ($r^2 = 0.99$)	0.27 ± 0.02 ($r^2 = 0.99$)

Note: *DOC, dissolved organic carbon; AOC_0 = AOC concentration at time zero; AOC_R = residual AOC concentration; K = exponential decay rate (d^{-1}).

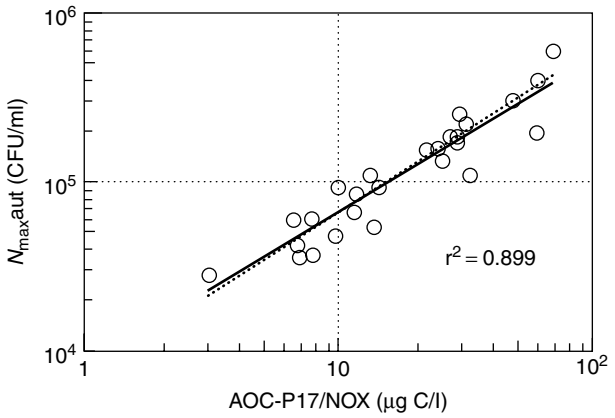

Figure 15. The relationship between the AOC concentration and the maximum colony count (N_{max}) of the autochthonous bacterial community in water samples stored at 15 °C in thoroughly cleaned Erlenmeyer flasks. HPC values were determined using diluted broth agar medium (spread plate method), incubated at 25 °C for 10 days.

relatively low, as a result of the wide range of AOC to BDOC ratios. On average, the AOC concentration was about 20 to 30% of the BDOC concentrations in treated water.

The main reasons for the difference between AOC and BDOC concentrations include:

- the use of an adapted microbial community in the BDOC test;
- the use of a large amount of biomass (bacteria attached to sand) in the BDOC test.

Also, the basis of the methods differ. The AOC concentration gives information about the production of biomass, which is the parameter of concern. The difference between the *Y* values for acetate and oxalate (cf Table 4) implies that the relationship between the amount of utilized organic carbon (BDOC) and biomass formation may differ between water types. In fact, using the *Y* values for oxalate in the AOC test gives much higher AOC values, some of which being close to the BDOC value (70).

From various studies a BDOC concentration of 0.1 to 0.2 mg/L has been derived as a reference value for biological stability (81,82).

The data about growth kinetics (Table 1), suggest that the concentrations of easily biodegradable compounds in treated water should be less than 1 µg of C/L to prevent multiplication. However, complete growth inhibition cannot be achieved and is also not required. The goal is to limit microbial growth to such an extent that water quality deterioration does not occur. Defining an acceptable level of growth is complicated, and may be different for different systems and seasons.

In the Netherlands an AOC value concentration of 10 µg of C/L has been derived as the reference value below which treated water has a very limited regrowth potential. This value is based on the following observations:

1. Samples collected from drinking water distribution systems revealed that AOC concentrations did not decrease at values close to or below 10 µg of C/L (cf. Figs. 12 and 13). Such values are observed in slow sand filtrate and in groundwater supplies in the Netherlands, where rapid sand filtration is the final treatment step;
2. AOC reduction in biological filtration (e.g., rapid sand filtration) is very limited at values below 10 µg C/l. (Fig. 11);
3. AOC concentrations in samples of stored water decline rapidly to a level of about 10 µg C/L (Fig. 14);
4. A statistically highly significant relationship was observed between the AOC concentration and the heterotrophic plate counts as determined on a nutrient poor medium (diluted-broth agar). At AOC values below 10 µg of C/L, the increase of these colony counts during distribution remained limited (53).
5. In a number of water types, the AOC/DOC ratio was as low as 1 µg of C/mg C. Values below this level have not been observed, suggesting that this level is indicative for organic compounds with a high degree of biostability. With DOC values below 10 ppm, this also gives AOC values below 10 µg of C/L.

For limiting regrowth of coliforms in chlorinated supplies AOC concentration of 50 to 100 µgC/l have been derived from extended studies, which indicated that many factors affected regrowth of these organisms (83).

Biofilm Formation Rate

Practical experience in the Netherlands show that the 90-percentile values of the heterotrophic plate counts (22°C, 3 days incubation) remain below 100 CFU/mL in water types with AOC levels below 10 µg of C/L. In groundwater supply this level of AOC is achieved with traditional treatment processes, namely, aeration followed by biological (rapid sand) filtration. In most supplies in the Netherlands the level of 10 µg of C/L is attained, but defining biological stability was found to be more complicated. Even at AOC values below 10 µg C/L and at low heterotrophic plate counts, aeromonads were found to increase in numbers (expressed as CFU/100 mL) (5). Observations indicated that these organisms multiplied in biofilms and in sediment 28. Therefore, a biofilm monitor had been developed for determining the Biofilm Formation Rate (BFR) values of treated water (25,55). Biofilm concentrations are determined by assessing the concentration of adenosinetriphosphate (ATP) with the luciferin-luciferase test. In the Netherlands, the BFR values typically range from less than 1 pg ATP $cm^{-2}\,d^{-1}$ to a value greater that 100 pg ATP $cm^{-2}\,d^{-1}$ (5). Values below 1 pg ATP $cm^{-2}\,d^{-1}$ have been observed in slow sand filtrate and in drinking water prepared from aerobic groundwater. These water types, with AOC values clearly below 10 µg Cl^{-1} represent drinking water with the highest degree of biostability. Higher BFR values have been found in drinking water prepared from anaerobic groundwater, but also these water types had AOC values below 10 µg C/L.

Dosage of acetate at a concentration of 10 μg of C/L to a biofilm monitor gave a BFR value of about 360 pg ATP/cm^2.d. This and other observations showed that a concentration of 1 μg of acetate-C/L causes a BFR value of 35 pg ATP/cm^{-2} . . .d^{-1} (84).

A significant relationship has been observed between the level of regrowth of aeromonads in groundwater supplies and the BFR value of the water leaving the treatment facility. At a BFR value of 10 pg ATP cm^{-2} d^{-1}, the risk of exceeding the guideline value for *Aeromonas* (90-percentile value of 200 CFU 100 mL^{-1}) is 20% (5).

Based on these observations the definition of biostability has been extended and a two dimensional approach is used. Hence, AOC concentrations below 10 μg of C/L in combination with BFR values below 10 pg ATP/cm^2 day represent treated water with a high degree of biostability. Only in a few water types (slow sand filtrate and aerobic groundwater) lower values can be achieved with biological processes.

Materials in contact with treated water

Materials in contact with drinking water can also affect bio(in)stability by releasing biodegradable compounds into treated water. For this reason methods have been developed to test the growth promoting properties of materials. In the United Kingdom the MDOD (mean dissolved oxygen difference) test is used (85), and in Germany a test based on measuring slime production is used (86,87). In the Netherlands the Biofilm Formation Potential (BFP) test is applied, which determines the biofilm concentration (pg ATP/cm^2) on the material as a function of time in a batch test in slow sand filtrate (88). Typical BFP values are below 10 pg ATP/cm^2 for glass and 20 to 50 pg ATP/cm^2 for PVC, whereas values between 500 to 3,000 have been observed for polyethylene materials. Such BFP values can directly be compared with biofilm concentration values as observed on the surface of pipe segments collected from the distribution system. In addition, BFR values as observed in the biofilm monitor also give information about the biofilm concentration, which can be attained on the pipe wall in contact with the water tested. In this way a simple framework is obtained, which enables the assessment and evaluation of the biostability of both water and materials with a consistent approach, the Unified Biofilm Approach.

CONCLUSION

- The AOC method described above has proven to give highly reproducible results. Contamination of the water with biodegradable compounds during sampling, transportation, handling and analysis is a main concern, with glassware and air as potential sources. The described procedures aim at preventing such contamination.
- The two test strains are not capable of utlizing all biodegradable compounds present in a water type. The compounds, which are utilized by the test strains are ubiquitous in water and low AOC concentrations in treated water demonstrate that easily available compounds have been removed.
- AOC concentrations in treated water in the Netherlands are below 10 μg C/l in the groundwater supplies and in most supplies as the result of the application of multiple biological processes in water treatment. The much higher AOC values (median: 100 μg C/l) as reported for treated water in the USA may be ascribed to the absence of biological filtration and the effect of the disinfectant on the AOC concentration;
- A reference AOC value of 10 μg C/l has been derived from effects of biological filtration on the AOC concentration, the AOC decline in distribution systems and the relationship between AOC and HPC values, respectively in unchlorinated supplies. AOC values below 100 or 50 μg C/l have been suggested for limiting coliform regrowth in chlorinated supplies in the USA.
- Even at AOC values below 10 μg C/l, certain microorganisms may multiply in the distribution system. Assessment of the Biofilm Formation Rate in combination with AOC values gives more complete information about the biological stability of treated wate;
- Materials of pipes and reservoirs may release biodegradable compounds into treated water. Assessment of the growth-promoting properties contributes to the selection of appropriate materials.

Acknowledgments

The AOC test has been developed within the framework of the Joint Research Program of the Water Supply Companies in the Netherlands. Many persons, including Ton Visser, Peter J. Oranje, Wim A. M. Hijnen, and Harm R. Veenendaal, have been involved in the investigations aiming at developing and improving the AOC test.

ASTROVIRUSES

SUZANNE M. MATSUI

Palo Alto, California

JOHN E. HERRMANN
University of Massachusetts Medical School
Worcester, Massachusetts

Astroviruses are 28-nm diameter, icosahedral viruses that have a characteristic five- or six-pointed star-like surface structure when viewed by electron microscopy (EM) (Greek. *astron*, star; Fig. 1). Madeley and Cosgrove coined the term astrovirus in 1975 to describe 28-nm diameter round viral particles they observed by direct EM in the stools of infants with diarrhea (1,2). Along with the *Picornaviridae* and the *Caliciviridae*, the *Astroviridae* comprise a third family of nonenveloped viruses whose genome is composed of plus-sense, single-stranded RNA. In addition to humans, astroviruses have been isolated from numerous animal species, including lambs (3), calves (4), deer (5), piglets (6,7), kittens (8), mice (9), dogs (10,11), and turkey poults (12,13).

CLASSIFICATION

Structure

The average diameter given for astroviruses, 28 nm, is based on the measurement of approximately 1,000 negatively stained (phosphotungstic acid) astroviruses in stools (14). The diameter of astrovirus particles may vary, depending on the source of virus and the method of preparation for EM. For example, bovine astrovirus serotype 2 (US2) propagated in primary NBK cells had an average diameter of 34 nm (range 30 to 37 nm) after fixation in glutaraldehyde/1% osmium tetroxide and staining with uranyl acetate (15). Purified preparations of cell culture-adapted human astrovirus serotype 1 particles evaluated by electron cryomicroscopy and image analysis demonstrated a rippled solid capsid shell (330 Å in diameter) with 30 dimeric spikes extending 50 Å from the surface (16). Most of the data regarding the buoyant density of astrovirus particles have been collected using cesium chloride density gradients. However, separation of fecal astrovirus in this medium and further concentration by pelleting disrupts virus morphology (17). Highly purified viral particles are needed for evaluation by electron cryomicroscopy. The inclusion of divalent cations (Ca^{++} and Mg^{++}) has found to stabilize viral particles undergoing isopycnic centrifugation in cesium chloride (16). A gradient of potassium tartrate progressively diluted with glycerol yields a positive-density, negative-viscosity gradient in which virus morphology is maintained and from which viral particles may be pelleted without deleterious effects (17). Peak density for astroviruses in this medium was 1.32 g/mL (17). Buoyant densities of human astroviruses in cesium chloride have ranged from 1.35 to 1.40 g/mL (18–23).

With cell culture-adapted astroviruses, four structural proteins (36.5, 34, 33, and 32 kDa) were identified in astrovirus serotype 4 that was propagated in cell culture in the presence of trypsin (20). It was postulated that the faint 36.5-kDa band might represent a precursor protein that undergoes subsequent processing, in a manner similar to the VP0 protein of enterovirus (24). Two additional proteins with 24 and 5.2 kDa were found by Kurtz (25) in cells infected with astrovirus serotype 1. In CaCo-2 cells infected with astrovirus serotype 1, three astrovirus-specific polypeptides (33.5, 31.5, and 24 kDa) were identified by reactivity with astrovirus serotype 1-specific antiserum (23). In some preparations, a 27-kDa polypeptide was also noted, and it was hypothesized that this may be derived from one of the larger proteins by proteolytic digestion. In studies of human serotype 5 isolated from volunteer fecal specimens, a single 30-kDa structural protein was immunoprecipitated (22).

In astrovirus-infected LLCMK2 cells in the absence of trypsin, a single approximately 90-kDa protein was immunoprecipitated from infected cell lysates with hyperimmune antiserum to purified human astrovirus serotype 2 (26). Pretreatment of the lysates with trypsin resulted in immunoprecipitation of three proteins, a predominant 29-kDa protein as well as a 31- and a 20-kDa protein. These results suggested that the approximately 90-kDa protein may be proteolytically cleaved to yield at least three smaller proteins. In cells infected with human astrovirus serotype 2, grown in trypsin-containing media, Sanchez-Fauquier and coworkers (27) used a neutralizing monoclonal antibody (PL-2) to determine that an approximately 86-kDa protein (P86) is the precursor to VP26, a major component of viral particles. VP29, a minor component of virions and the product of alternative processing of P86, and intermediate proteins ranging from P74 to P35 were also identified in infected cells by PL-2. Although these results suggest processing of P86 to P26 and/or P29 occurs within infected cells, the presence of trypsin in the media impairs optimal interpretation of the data.

Using partially purified preparations of human astrovirus reference strains (serotypes 1 to 7) grown in cell culture, astrovirus types 1 to 4 consisted of three proteins, P1 (~33 kDa), P2 (~33 kDa), and P3 (25 to 28 kDa, depending on serotype), that were immunoprecipitated with homologous rabbit antisera (28). For reference types 5 to 7, three infection-specific proteins were observed in radiolabeled samples, but only P2 and P3 reacted with type-specific rabbit serum (28). In a relatively trypsin-free system, Bass and Qiu (29) found evidence for intracellular processing of the full-length ORF 2 product to a 79-kDa moiety that was incorporated into viral particles. Infectivity was significantly enhanced by treatment of these particles with trypsin, which also resulted in cleavage of the 79-kDa protein to 33-, 29-, and 26-kDa subunits.

Genetics

The genome of astroviruses is a plus-sense, single-stranded RNA of approximately 6,800 nucleotides (nt) in length, excluding the poly(A) tail at the 3′-end. RNA extracted from virions is infectious (30). Infectious RNA also can be transcribed from a full-length cDNA clone of human astrovirus serotype 1 [AVIC (30)]. BHK cells, previously thought not infectable with astrovirus (31), have been shown to support astrovirus replication and maturation when transfected with RNA extracted from virions or transcribed from AVIC. Astrovirus produced in these BHK cells have been shown to infect monolayers of Caco-2 cells in trypsin-containing media.

Complete nucleotide sequences of four strains of human astrovirus are currently available: (*1*) the serotype 1 Oxford reference strain propagated in LLCMK2 cells (32), (*2*) a serotype 1 Newcastle strain recently isolated and maintained in CaCo-2 cells (33–35), (*3*) the serotype 2 Oxford reference strain propagated in LLCMK2 cells (36), (*4*) a serotype 3 strain (GenBank accession AF141381), and (*5*) a serotype 8 strain (37).

During infection of susceptible cells, it has been noted that both the full genomic (6.8 kb) and a subgenomic (2.4 kb) RNA are produced (21,26). The viral genome comprises three open reading frames (ORFs). The two ORFs at the 5′-end of the genome, designated ORF 1a and ORF 1b by the International Committee on the Taxonomy of Viruses [ICTV (38)], encode nonstructural proteins. The third ORF, designated ORF 2, encodes a structural protein and is found at the 3′-end of the genome (32,34,38). This ORF is common to both the genomic and subgenomic

RNA. Sequences of the capsid-encoding ORF 2 are available in GenBank for human serotypes 1 through 8 and for feline, porcine, and turkey astroviruses.

A schematic representation of the astrovirus serotype 1 Oxford reference strain's genome is shown in Figure 2. A 5′-untranslated region of 85 nt precedes ORF 1a, which is 2,763 nt in length. The length of this ORF can vary depending on the method by which the virus was initially isolated. For example, ORF 1a of the Newcastle serotype 1 strain, isolated in Caco-2 is 45 nt longer than the Oxford serotype 1 strain, isolated in primary HEK cells (39). A 73-nt overlap exists between ORF 1a and ORF 1b and contains the sequences critical for (−1) ribosomal frameshifting and translation of ORF 1b. There is an 8-nt overlap between ORF 1b and ORF 2. ORF 2 varies in length among human astroviruses from 2,316 nt for a serotype 4 strain to 2,391 nt in the Oxford serotype 2 strain (36), but for serotype 1 (Oxford) is 2,364 nt. An 80-nt 3′-untranslated region is found between ORF 2 and the poly(A) tail at the extreme 3′-end of the genome. The length of the astrovirus 3′-untranslated region and its predicted secondary structure are similar to those of certain picornaviruses (33), but there is minimal sequence identity between these two viral groups. In a separate study, the terminal 19 nt of ORF 2 and adjacent 3′-untranslated region were found to be highly conserved among all eight human astrovirus serotypes (40). Of note, similarities in sequence and folding of the 3′-untranslated region of human, sheep, pig, and turkey astroviruses, avian infectious bronchitis virus (a coronavirus) and equine rhinovirus serotype 2 (a picornavirus) were observed (36) and it has been suggested that these features may have arisen from recombination events.

The polypeptide sequences of ORFs 1a and 1b were the first indication that nonstructural proteins are encoded by these ORFs. The ORF 1a-encoded protein contains a viral serine protease motif that has features consistent with chymotrypsin-like proteases of other plus-stranded RNA viruses, including RHDV and feline calicivirus (36). An important difference found when comparing the astrovirus protease motif with that of the caliciviruses is the substitution of a serine for a cysteine at the third catalytic amino acid residue. This substitution is seen in several viruses, sobemoviruses, luteoviruses, and arteriviruses, but the putative astrovirus protease bears stronger overall resemblance to the calicivirus protease.

A bipartite nuclear localization signal is encoded downstream of the viral protease motif in ORF-1a (35,36). Recent studies of human astrovirus serotype 1 (Newcastle) have indicated that this signal is functional and directs ORF-1a-encoded proteins to the nucleus (41). Of note, a prior study of cell culture-adapted bovine astrovirus detected viral proteins in the nucleus of infected cells by immunofluorescence (15). Further studies are required to determine the role and importance of nuclear localization in the astrovirus life cycle.

Analysis of ORF 1a sequences of reference serotypes 1 to 7 indicates two distinct genogroups that correlate with serotype (42). Types 1 to 5 (42) and 8 (43) are found in one genogroup (designated A), whereas types 6 and 7 fall into a separate genogroup (B). These phylogenetic associations for ORF 1a sequence are different from that observed for ORFs 1b or 2 in which nearly equidistant clustering of serotypes is found with unrooted phylogenetic trees. Whether these differences are attributable to recombination remains to be studied.

ORF 1b contains a motif consistent with an RNA-dependent RNA polymerase. This motif is highly conserved among astrovirus serotypes 1 to 8 (32,37,42). The astrovirus polymerase motifs are most similar to those of plant viruses, bymovirus, and potyvirus, and can be aligned with other polymerases of Koonin's Supergroup I (44) that includes picornaviruses, caliciviruses, and certain plant viruses (36), although similarities between astrovirus and plant viruses in this region do not necessarily imply a common origin (36).

Regions that may encode an RNA helicase, methyltransferase, or papain-like protease have not been identified in the astrovirus sequences that are currently available. It is unusual for a plus-strand RNA virus with a genome length of greater than 6,000 nt to lack a helicase domain (36,45). Astrovirus may encode a VPg, as suggested by the absence of a methyltransferase-encoding region and the similarity of its RNA-dependent RNA

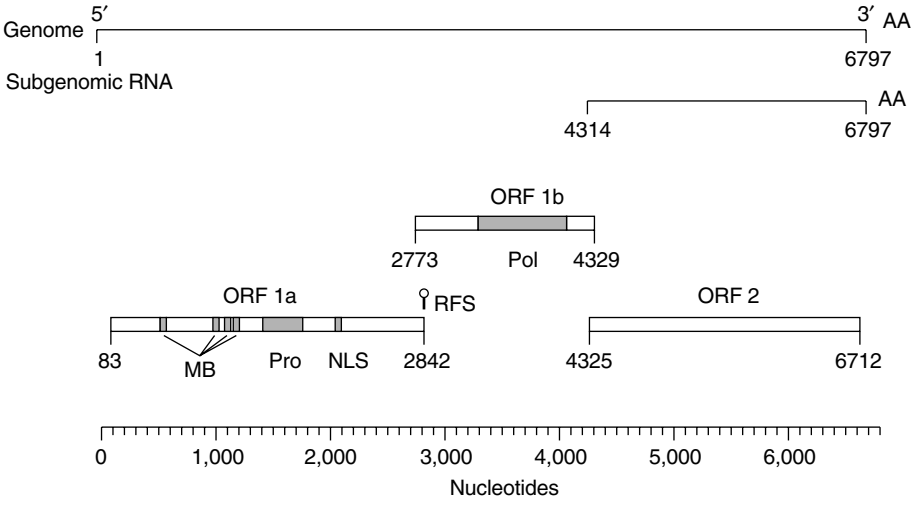

Figure 2. Genome organization of human astrovirus serotype 2 (36). Genomic and subgenomic RNA are depicted in the upper half of the figure. Below this, the three ORFs with predicted locations for transmembrane helices (MB), protease (Pro), nuclear localization signal (NLS), ribosomal frameshift structure (RFS), and RNA-dependent RNA polymerase (Pol) are shown schematically. Nonstructural proteins are likely encoded in ORFs 1a and 1b. At least one structural protein that is most likely a precursor to smaller capsid proteins is encoded by ORF 2.

polymerase with primarily VPg-containing viruses. A convincing VPg domain has not been identified, but it may be located between the putative protease motif and upstream transmembrane alpha-helices, where a serine at aa position 420 that could link the VPg to genomic RNA is found. ORF 1a also encodes an immunoreactive epitope (aa 757 to 899) identified by antisera produced to purified viral particles, but its significance is not known.

The greatest sequence variability is found in ORF 2, which encodes a viral structural protein. A high degree of conservation of the N-terminal 415 (or so) amino acids is observed among the human serotypes (46). In this region, the amino acid sequence for the feline and porcine strains share certain conserved stretches of amino acid residues with the human strains and can be aligned with minimal gaps, whereas the avian strains cannot be aligned easily with the human and other mammalian strains. Beyond this region, there is considerable variability in sequence among the serotypes, requiring gaps to be introduced for optimal alignment. The C-terminal 8 amino acids are highly conserved, particularly among the human strains.

Information regarding processing of the nonstructural proteins is very limited. A preliminary report by Gibson and coworkers (47) noted a "lack of processing" in vitro of ORFs 1a and 1a/1b translation products containing the 3C-like serine protease motif. By contrast, Willcocks and coworkers (41) studied nonstructural protein processing in astrovirus-infected Caco-2 cells by Western blot analysis with antisera specific for the C-terminal 298 aa of the ORF 1a product. They detected proteins of 74, 34, 20, 6.5, and 5.5 kDa, but no full-length ORF 1a product (p101).

In a separate study (48), processing of the ORF 1a product was studied in a cell-free expression. ORF-1a products identified by astrovirus-specific and N-terminal tag-specific antibodies included the full-length 101-kDa protein (p101), an N-terminal cleavage product (p64), and a C-terminal cleavage product (p38). Mutation and deletion analyses indicated the important role of the catalytic triad of the viral 3C-like serine protease (Ser-551, Asp-489, and His-461) in processing of p101.

In summary, the astrovirus genome is organized with the primarily nonstructural proteins encoded by the 5′ two-thirds (ORFs 1a and 1b) and the structural protein encoded by the 3′ one-third (ORF 2). This arrangement resembles the genome organization of caliciviruses (49). However, several features distinguish these two viral families, including differences in the size, number, and processing of structural proteins, the lack of a helicase domain in astroviruses, the use of ribosomal frameshifting to translate the RNA-dependent RNA polymerase, and distinctive morphologic features described in the preceding text. Astroviruses differ from picornaviruses in genome organization, lack of a helicase domain, and use of translational strategies, such as ribosomal frameshifting and subgenomic RNA.

Biology and Antigenic Properties

Astroviruses appear to incorporate specific features of a number of different viruses without strictly resembling any one group and therefore have been accorded a separate viral family, the *Astroviridae* (38). The type species is the human astrovirus. It has recently been proposed by the Astrovirus Study Group of the International Committee on Taxonomy of Viruses that the Family *Astroviridae* be subdivided into two genera, Mammoastrovirus and Aviastrovirus, on the basis of phylogenetic clustering of capsid sequence, host of origin, and target organs. Mammoastrovirus would include astroviruses that infect mammals and primarily cause gastroenteritis. Aviastrovirus would include astroviruses that infect avian species and may cause intestinal as well as extraintestinal illness.

Astroviruses are resistant to many common chemical agents, including chloroform, a variety of detergents (nonionic, anionic, and Zwitterionic) lipid solvents, and acid conditions (pH 3) (20). Human astrovirus retains activity after 5, but not 10, minutes at 60 °C. Viral particles appear to be stable when stored at ultralow temperatures (−70° to 85 °C) for 6 to 10 years (50), but may be disrupted by repeated freezing and thawing. Methanol has been shown to be more effective in reducing astrovirus infectivity than equivalent concentrations of isopropanol or ethanol (51).

When astroviruses were first described during the 1980s, five serotypes of human astrovirus were identified by immunofluorescence, neutralization, and immune EM (52–54). Each strain was isolated from natural infections in the United Kingdom and adapted to growth in cell culture (31). Serotypes 6 and 7 were identified in the United Kingdom in 1989, 1991, and 1992 (55). An eighth serotype is also now described (56).

By serotyping isolates, astrovirus serotype 1 has generally been the most common type found (20,53,55–63), but the predominant serotype may vary depending on location (64). In community-acquired astroviruses studied in Oxford, United Kingdom, between 1975 and 1987 (20), 72% of the astroviruses detected were serotype 1. Serotypes 2 to 5 each accounted for 6 to 8% of the astrovirus strains. A later survey by Lee and Kurtz (55) examined the astrovirus serotypes found in the Oxford region between 1976 and 1992. Serotype 1 was again found most frequently and accounted for an average of 65% of the cases 1991 was the only year in which the number of serotype 2 cases exceeded the number of serotype 1 cases. A third study from the United Kingdom also found a predominance of astrovirus serotype 1 (63). By contrast, a longitudinal study of diarrhea in a cohort of Mexican children found that astrovirus serotype 2 was most common (35%) and serotypes 1 and 5 were least common (4% each) (64).

Animals hyperimmunized with each of the human astrovirus serotypes 1 to 7 raise antisera that appear to react type-specifically in immunofluorescence tests and IEM (20,55,65). Also, rabbit polyclonal antiserum neutralizes astrovirus in a serotype-specific manner by plaque assay (65). All eight serotypes of human astrovirus are recognized by a monoclonal antibody produced by Herrmann and coworkers (55,66). This monoclonal antibody, which does not neutralize virus, is directed at a viral structural protein (57), most likely an epitope within the highly conserved N-terminal half of the ORF-2 product (Geigenmüller and Matsui, unpublished data). An EIA in which the monoclonal antibody serves as a capture

antibody and polyclonal antiserum is used as a detector antibody has been developed (66) and employed in large-scale seroepidemiologic studies described in the following text. A typing EIA that uses serotype-specific reference antisera for antigen capture and the group-reactive monoclonal antibody as detector has been developed to assess the antigenic types of astroviruses found in clinical samples (66). Molecular methods for genotyping clinical isolates by reverse transcriptase polymerase chain reaction (RT-PCR) may also be used, using primers from the more conserved N- or C-terminal regions of ORF-2 (11,59). A high concordance between results of genotyping and serotyping has been observed.

EPIDEMIOLOGY AND CLINICAL DISEASE

The medical importance of astrovirus in humans was established initially in studies conducted in Thailand and Guatemala where astroviruses were found to be the second most common cause (after rotavirus) of viral diarrhea in young children (67,68). This was made possible by the development of a monoclonal antibody EIA that can detect all known human astrovirus serotypes (64,66). This and other improvements in detection techniques, along with increased awareness of astrovirus infection have helped to define the epidemiology of this illness. Astrovirus infections have been found worldwide, primarily, but not exclusively, in young children with diarrhea (19,67–104). Sporadic outbreaks of gastroenteritis because of astrovirus have been reported among elderly patients (79,86,97,105) and military recruits (106). Several studies associate astroviruses with diarrhea in immunocompromised adults (73,81,107,108). Large, foodborne outbreaks, affecting thousands of individuals in Japan, have occurred among otherwise normal school-age children and adults as well (109,110).

Most astrovirus infections are detected in the winter months in temperate regions and in the rainy season in more tropical climates, a pattern that resembles rotavirus infections (20,68,111). Both community-acquired (1,67,82,89,95,112,113) and nosocomial (69,70,76,77,82,83,87,90,95,103,112,114,115) infections have been described. In Australia, astrovirus is the second most common cause of gastroenteritis in children, after rotavirus (61). Infection with serotype 1 predominates, particularly in the winter months when gastroenteritis is common (61,116,117). In a population of Mayan infants, astrovirus was the most common enteric pathogen identified in stool samples collected during a prospective study of oral poliovirus immunogenicity (118).

Astroviruses have been shown to be an important cause of outbreaks of diarrhea in childcare centers among children age three years or less (85,91). In eight outbreaks of astrovirus diarrhea in six childcare centers, 20% of the children with diarrhea shed astrovirus (92). Although each outbreak was associated with a single astrovirus serotype, two distinct serotypes were identified in sequential outbreaks during one winter diarrhea season.

Serological studies indicate that astrovirus infections are common in the United States (111,119), Japan (19), the United Kingdom (60,120), and other areas of the world (63,78,121). In samples of gamma globulin pools collected in the United States, antibodies to all five of the originally identified serotypes of astrovirus are detectable (111). Antibodies to astrovirus tend to be acquired in early childhood. A survey of 87 children less than 10 years old in the Oxford region of the United Kingdom revealed that antibody prevalence rises rapidly from 7% in 6- to 12-month-old infants to 70% by school age. Astrovirus antibodies could be detected in 75% of the 10-year-old children studied. Among young adults (nursing students), 77% had antibodies to astroviruses.

Clinical Symptoms

Astroviruses are a cause of gastroenteritis worldwide. Young children, especially those under six months of age, are the ones primarily affected. However, all ages may be affected. Older children and adults have been involved in outbreaks (109,110), and astrovirus infections have been recognized in elderly, institutionalized patients (63,79,89,105) and in immunocompromised patients (20,73,75,81,122). Human astrovirus infection induces a mild, watery diarrhea that typically lasts for two to three days, associated with vomiting, fever, anorexia, abdominal pain, and various constitutional symptoms that last for up to four days (20,111,123–126). Protracted diarrhea and viral shedding have been observed in some studies (20,107,108). In children, it may not be possible to distinguish diarrhea owing to astrovirus from that owing to rotavirus on clinical grounds alone (20,67,68) and studies of hospitalized children have found astrovirus to be the second most common viral pathogen, after rotavirus (61,116). In general, astrovirus diarrhea is milder and does not lead to significant dehydration or hospitalization (16,64,67,83,85,91,95,126). However, in a significant percentage of rural Egyptian children with astrovirus gastroenteritis severe dehydration was seen (127). In addition, severe infections have been noted in young adults infected with astrovirus serotype 4 (74). Deaths associated with astrovirus infections are extremely rare but have been reported (100,105).

The role of astrovirus in persistent diarrhea remains to be established (103). Prolonged lactose intolerance wand, less commonly sensitivity to cow's milk, have been problems for some patients (76,83,95). Intravenous immunoglobulin may be a useful adjunct in severely immunodeficient patients who fail to respond to conservative measures (107,128), but larger prospective studies are needed to establish the efficacy of this approach.

In animals, as in humans, astrovirus has usually been identified in association with diarrhea, but in ducklings has also been associated with a rapidly fatal hepatitis (129). Avian astroviruses have also been associated with nephritis in chicks (130) and immunosuppression compounding enteritis in turkey poults (131).

Viral Pathogenesis

Pathogenesis of astrovirus infections in humans has been limited to a report of two children with diarrhea that correlated fecal shedding of astrovirus with identification of astrovirus particles in intestinal epithelial cells. This

suggested that virus replication occurs in intestinal tissue in humans (99). Astrovirus particles in the biopsy specimen were localized to the epithelial cells in the lower regions of the villus in a patient with sucrase isomaltase deficiency and in the "exposed surface epithelium" of a second patient who had a severe enteropathy because of sensitivity to cow's milk formula. The significance of astrovirus infection in these patients was not definitive because they had underlying gastrointestinal problems and fecal shedding of *Escherichia coli* 086 or rotavirus. Human volunteer studies have not examined the histological effects of astrovirus-related diarrhea (22,132).

In animals, gnotobiotic lambs given ovine astrovirus showed that mild transient diarrhea was caused by infection of mature enterocytes in the apical two-thirds of villi and subepithelial macrophages, followed by transient villus atrophy and crypt hypertrophy (3,133). Infected intestinal cells were detected by immunofluorescence between 14 and 70 hours after inoculation. Most infected cells were found 14 to 38 hours postinoculation (133) and during this time, aggregates of virus particles along the microvilli or in lysosomes and autophagic vacuoles were observed by EM (133).

Bovine astrovirus infection, which does not result in symptomatic illness, causes infection of M cells and absorptive enterocytes overlying the dome villi of Peyer's patches in the small bowel (134,135). Infected cells were sloughed, replaced by cuboidal cells, and formed an exudate with inflammatory mononuclear and eosinophilic cells above the dome villi. The lamina propria was infiltrated with neutrophils and contained cells with degenerate nuclei. Lymphoid cell depletion was noted in the central region of germinal centers beneath infected dome villi.

These two studies with mammalian astrovirus infections suggest that astroviruses enter cells through the apical surface. In polarized CaCo-2 cells, however, human astroviruses isolated from wild-type infections appear to enter through the basolateral surface (23). Whether or not this result reflects the arrangement of astrovirus receptors in differentiated intestinal epithelial cells in vivo remains to be determined (136).

Entry of astroviruses into cells has also been studied using Graham 293 cells, a transformed line of primary HEK cells (137) that has been frequently used for isolation of enteric adenoviruses. The effects on astrovirus infection of lysosomotropic agents (ammonium chloride, methylamine, and dansylcadaverine) and the ionophore monensin were investigated. All inhibited viral infection, suggesting that a functional endocytic pathway is necessary for delivery of infectious astrovirus into the cytoplasm.

Bovine astrovirus infection in cell culture has also been studied. Bovine astrovirus was propagated in primary NBK cells and the expression of viral antigens was followed by fluorescent antibody probes (15). Immunofluorescence was first detected at 7 hours postinfection in the cytoplasm of infected cells. Shortly thereafter, immunofluorescent granules were identified in the nucleus in a pattern suggesting nucleolar involvement. This was followed by dense immunofluorescent granules appearing in the perinuclear region and diffuse staining of the cytoplasm. This pattern of infection has also been seen in cell cultures infected with human astroviruses (Herrmann, unpublished data).

Modes of Transmission

Human adult volunteer studies indicate that astroviruses can be transmitted through the fecal-oral route, (22,132) although few of the volunteers developed diarrhea with fecal shedding of virus. It appeared that person-to-person spread was responsible for an outbreak of gastroenteritis in Marin County, California, in 1978 (97), that was subsequently shown to be owing to astrovirus type 5 (138,139). Astrovirus diarrhea does not usually develop in adults, but adult caregivers of infected children, including parents, teachers and medical personnel, may become ill (20,109,125,140). An outbreak among military troops has also been described (106). This suggests that these adults may have been exposed to a larger dose of astrovirus or through a variable route (e.g., fomites, contaminated food, or water). Astrovirus has also been detected in water from an area where an outbreak of astrovirus gastroenteritis occurred (141), and 93% of surfers in the United Kingdom had antibodies to human astrovirus serotype 4, compared to 22% of age-matched controls (142). A study of sewage and environmental samples from a water treatment facility in the United Kingdom failed to detect astrovirus RNA by RT-PCR (143). A case of astrovirus gastroenteritis was diagnosed at the end of the sampling period, but occurred outside the surveyed area.

Large outbreaks of astrovirus gastroenteritis occurred in Japan that were thought to be food-borne (109,110). Food handlers should be instructed that shedding of astrovirus in the feces may begin a day before symptoms and continue for several days after diarrhea resolves. In immunocompromised individuals, viral shedding may last for weeks after resolution of symptoms (107,108). In addition, foods, such as shellfish that have been implicated in outbreaks of astrovirus gastroenteritis should be carefully selected and prepared.

RESERVOIRS

Astrovirus infections appear to be species-specific, which suggests that animals are not a reservoir for human infections. Where antigenic relationships among astroviruses of different animal species have been examined, there has been no evidence for cross-reactivity between species (5,6,54,135,144). In general, infection of animals and cell culture is also species-specific. BHK-21 cells support propagation of human astrovirus type 2 (145), and astrovirus isolated from red deer has been shown to infect BEK cells, but serial propagation was not achievable (5). It is likely that not all the animal astroviruses have been extensively tested as serial passage has not been established for astroviruses from lambs (3), red deer (5), kittens (8), dogs (10,146), turkeys (12), and ducks (129). To date, only

bovine (15) and porcine (7) astroviruses have been propagated in cell culture.

DETECTION, OCCURRENCE, AND PERSISTENCE

Methods of Detection

Electron Microscopy. Before immunoassay or PCR methods for astrovirus detection were developed, EM or immune electron microscopy (IEM) techniques were the major assays used, and although insensitive, are still used by some for detection of astroviruses where other assays are not available. EM may also be important for standardizing new detection methods as they are developed. Patients with diarrhea owing to astrovirus frequently shed large numbers of viral particles, 10^{10} per milliliter, or 10^8 viable particles per milliliter (20). IEM techniques are useful to detect lower levels of astroviruses (19,147,148). The sensitivity of EM has been estimated to be 10^6 to 10^7 virus particles per gram of stool.

Diagnosis by EM requires experience, as only 10% of the particles in a given specimen may display the distinctive astrovirus surface star (149). Oliver and Phillips conducted a retrospective analysis of fecal viruses that were originally identified as small, round, featureless viruses by EM alone (96). When complementary immunologic techniques were applied to careful reexamination of the specimens by direct EM, 14 of the 53 samples (26%) first classified as small, round, featureless viruses were shown to be astrovirus. Two caliciviruses and a Norwalk-like virus were also found to be misclassified. Another example of misclassification by direct EM is the Marin County virus, originally classified in 1978 as a "Norwalk-like" virus (97). Subsequent analyses, however, proved that the Marin County virus was an astrovirus (serotype 5) (138,139).

Isolation in Cell Culture. Serial passage of astroviruses in cell culture (primary HEK cells) was first described in 1981 by Lee and Kurtz (31). This was made possible by incorporating trypsin (10 μg/mL) in serum-free growth media (31). After six passages in HEK cells, primary baboon kidney (PBK) cells and a continuous line of LLCMK2 cells could also be infected, but not by direct inoculation of PBK or LLCMK2 cells with fecal derived astroviruses. All five of the serotypes of human astrovirus first described (53) were adapted to growth in LLCMK2 cells.

Direct isolation of an astrovirus from stools in a continuous cell line was first described by Willcocks and coworkers (23) for astrovirus serotype 1. The cell line used, CaCo-2 cells, a continuous line of human colon carcinoma, has been subsequently found to allow isolation of all astrovirus serotypes, including the more recently identified types 6, 7, and 8 (43,55,145). Use of this cell line may allow more rapid isolation and subsequent propagation of wild-type astroviruses (150). Growth in CaCo-2 cells may be also a way to distinguish astrovirus infection from infection with human caliciviruses, viruses that have not been successfully isolated or propagated in cell culture.

Propagation of serotypes 1 to 4 was accomplished in a hepatoma cell line, PLC/PRF/5, a line that was also used to isolate human astrovirus directly from fecal samples (four isolates) (151). Several other cell lines have been tested for astrovirus isolation and cultivation (145). When laboratory-adapted human astrovirus serotypes 1 through 7 were tested for growth in 15 human, 7 simian, and 10 other nonprimate mammalian cell lines, propagation of all seven serotypes was successful in the human cell lines Caco-2, T84, HT-29, and in the African green monkey kidney cell line MA-104. Both primary and secondary African green monkey kidney cells were more effective than Rhesus monkey kidney cells for cultivation of astrovirus. Except for human foreskin cells, all of the other human and simian cell lines supported growth of at least one astrovirus serotype. The only nonprimate cell line that permitted sustained passage of astroviruses was BHK-21 (C13) cell line for astrovirus serotype 2. BHK cells transfected with RNA transcripts derived from a genomic cDNA of human astrovirus serotype 1 have been shown to support viral replication and morphogenesis (30). Of 17 human stool specimens that had previously been shown to be astrovirus positive by ELISA, Caco-2 cells (13 isolates), T84 cells (12 isolates), and PLC/PRF/5 cells (12 isolates) were the cell lines most effective for isolation of human astroviruses from these stool specimens (145).

Enzyme Immunoassay. A group reactive monoclonal antibody (8E7) was developed by Herrmann and coworkers and was used in an enzyme immunoassay (EIA) to capture viral antigen in stools (65,66). In this assay, polyclonal antiserum is used as the detector antibody in an indirect EIA. A modification of this EIA uses a biotinylated polyclonal detector antibody (93). Both EIAs are comparable to IEM in sensitivity (91%) and specificity (98%). EIAs have been useful in rapidly detecting astrovirus antigen in studies where a large number of samples must be assayed (2,67,68,85,112). EIA- and RT-PCR-based methods to type human astroviruses found in clinical samples have been described more recently (59). An astrovirus antigen EIA that uses a group reactive monoclonal antibody [8G4] for both capture and detection (biotinylated) has also been developed (112). The sensitivity of EIA is estimated to be 10^5 to 10^6 viral particles per gram of stool (66,93).

A commercial enzyme immunoassay based on the group reactive monoclonal antibody 8E7 (59) is available for the detection of astrovirus antigen in clinical specimens (IDEIA™ Astrovirus EIA, DAKO Diagnostics). In one survey from Australia, this qualitative assay was found to have a sensitivity of 100% and specificity of 98.6% (117).

RNA Probes and Reverse Transcriptase-Polymerase Chain Reaction (rt-PCR)

Hybridization. The use of nucleic acid probes for astrovirus identification was first described in 1991 (93,152). The sensitivity of RNA probes is approximately equal to that obtained by EIA (93,152), thus for routine diagnosis there is no advantage of probes compared with monoclonal antibody immunoassays for astroviruses in gastroenteritis. The sensitivity is similar, but the probe techniques

are considerably more complex and require more time to obtain results.

Polymerase Chain Reaction. Amplified techniques, such as the polymerase chain reaction (PCR), offer a more sensitive approach than direct hybridization, and PCR applications have been described for astroviruses (81,153,154). The sensitivity in detecting astrovirus infections is improved, and is estimated to be 10 to 100 particles per gram of stool (62). In one study of an outbreak of astrovirus gastroenteritis at a day care center (155), the prevalence of astroviruses determined by EIA varied from 50% in affected rooms to 20% in rooms with older children. Analysis by RT-PCR indicated nearly all children were infected and viral shedding was detectable for weeks despite resolution of symptoms. In addition, RT-PCR detected astrovirus in 32% of the samples tested, compared to a detection rate of 10% by EIA.

The complete sequences of four strains of astrovirus (two serotype 1, one serotype 2 and one serotype 3) are currently available. Oligonucleotide primers selected from sequences at the 3′-end of the genome can amplify astrovirus-specific products from all five reference serotypes (156). Primers derived from the highly conserved RNA-dependent RNA polymerase motif may also be suitable candidates for amplification of different human astrovirus serotypes by RT-PCR (32). RT-PCR has been used also to confirm astrovirus-positive samples detected by EIA (73,81,91,118). Good correlation has been observed between these two methods for detection (78).

Recovery and Concentration. As was discussed earlier, the mode of transmission of astroviruses is considered to be similar to that of other enteric viruses, which includes potential transmission in environmental samples. The environmental samples most commonly assayed are those in which other enteric viruses have been isolated or detected, including surface waters, drinking water, shellfish, and sewage samples. The stability of astroviruses in water also suggests the possibility of transmission by the water route. In dechlorinated water, astrovirus survival was comparable to rotavirus serotype 3 and enteric adenovirus 40/41, both of which can be transmitted through water. Astrovirus and adenovirus were more resistant than poliovirus to inactivation by the addition of free chlorine to the water, but less resistant than human rotavirus or hepatitis A virus (157,158).

Although studies on detection of astroviruses in environmental samples have been very limited in comparison to those for other enteric viruses, the techniques for recovery of astroviruses are similar and follow the same general procedures; extraction, concentration, purification (or removal of inhibitors), and detection. For water samples, this entails adsorption of virus to filters followed by elution and concentration. For the one study on naturally occurring astroviruses in foods (shellfish) (159), virus was extracted from a food homogenate with organic solvents, followed by virus precipitation and nucleic acid extraction for RT-PCR.

Recovery from Water Samples. The first description of recovery of astroviruses naturally occurring in an environmental source was described in 1996, in a sample of sewage polluted water (141). The virus was recovered by passage of 500 L of water through positively charged filters (Zeta plus MKII filters) followed by elution with 0.05 M glycine buffer plus 3% beef extract, and organic flocculation. The final volume of the sample was 50 mL. Viral nucleic acid could not be directly detected in the concentrated samples, but was detected after passage of the samples in CaCo-2 cells. It was estimated that for the wild-type astrovirus strain detected, there was a minimum of 20 astroviruses per liter of in the unconcentrated sample. A second report was published in 2000 (160). Surface water samples were processed using filtration through cartridge filters (type 1 MDS Zetapor cartridge filters) followed by elution with beef extract and concentration by organic flocculation according to the method described for enteric viruses by the Environmental Protection Agency (161). Portions of concentrated samples were inoculated onto monolayers of CaCo-2 cells and tested for astroviruses by RT-PCR. Of 29 water samples analyzed, 15 were positive for astroviruses.

Recovery from Sludge. Because astroviruses have a different capsid structure than enteroviruses, Chapron and coworkers (162) compared the prevalence of human astroviruses in sludges as compared to enteroviruses, using an EPA method designed for other enteric viruses. Using 500 mL of sludge samples collected from sewage plants in the United States from January to June 1999, viruses were concentrated from sludges according to the EPA CFR part 503 regulations (EPA 1992). This procedure uses beef extract elution followed by organic flocculation, and results in a final volume of 20 mL. For detection of viruses, CaCo-2 cells were inoculated and virus detected by RT-PCR/nested PCR. Of 16 sample sites analyzed, 15 were positive for astroviruses and 16 were positive for enteroviruses. This study not only demonstrated that astroviruses can be recovered from sewage sludge, but also showed that astroviruses can be detected in sludge samples by standard EPA procedures for the recovery of enteric viruses.

Recovery from Shellfish. Methods have been described for recovering astroviruses from samples of mussels (163) or mussels and oysters (164) seeded with laboratory strains of viruses, but to date only one report has been published for naturally occurring astroviruses in shellfish. In a three-year study of enteric viruses in shellfish, Le Guyader and coworkers (159) detected astroviruses in 17% of oyster samples and 50% of mussel samples. The mussels were collected from beds frequently contaminated by fecal coliforms. Astroviruses were recovered more frequently from mussels than either hepatitis A virus (13%) or Norwalk-like viruses (35%), both of which have been implicated in shellfish-borne outbreaks of disease. Recovery of astroviruses was accomplished by extracting nucleic acid for PCR from dissected tissues (stomach and digestive diverticula) of shellfish, a method that has been described for recovery of Norwalk virus and Hepatitis A (165). To concentrate virus, the tissues were homogenized in buffered saline, extracted with chloroform-butanol, and precipitated with polyethylene glycol. Viral

nucleic acids were extracted by the phenol-chloroform-water technique and ultimately precipitated with ethanol for use in RT-PCR. As is the case for other enteric viruses, the extracts need to be tested for the presence of PCR inhibitors. A commercial kit that uses a guanidine thiocyanate silica procedure to extract viral RNA directly, without mechanical homogenization of shellfish, is now available (Promega, Madison, Wis.). The virus of interest (astrovirus, Norwalk virus, hepatitis A virus) then can be amplified from the extracted RNA using virus-specific primers in RT-PCR assays (164). Methods for isolation or detection of astroviruses in foods other than shellfish have not been reported.

CONCLUSION

The medical importance of astroviruses as major causes of gastroenteritis has now been well established through clinical and epidemiological studies. The detection of astroviruses in water and shellfish samples, combined with epidemiological evidence for food-borne outbreaks of astrovirus gastroenteritis (109,110) suggests that astroviruses have been spread through environmental sources. With the techniques for detection of astroviruses that are now available, it will be possible to assess the impact of these viruses in food and waterborne gastroenteritis.

BACTERIAL CONTAMINANTS IN RESIDENTIAL ENVIRONMENTS

ELIZABETH SCOTT
Newton, Massachusetts

Over the last thirty years, scientists have drawn attention to a number of actual and potential infection concerns related to the presence of biocontaminants in the home. The list of infections associated with the home includes food-borne infections, shigella dysentery, viral gastroenteritis, common cold virus infections, skin infections, respiratory allergies, and zoonoses associated with domestic pets. In addition, there are specific infection control issues related to the care of infants and young children, the elderly, and other immunocompromised persons in the home. This has prompted an interest in the study of microbial contamination at environmental sites and surfaces in residential settings. Most studies have investigated bacterial contaminants, and there are very few reported studies on fungi or viruses in residential environments.

This article focuses on bacterial contamination at environmental surfaces in domestic settings and the different approaches that have been employed to elicit data on this topic.

BACTERIAL CONTAMINANTS

Studies of domestic bacterial contaminants have largely been conducted under one of the following approaches: (*1*) baseline studies of either multiple or single sites that collect information on a broad spectrum of bacterial species, (*2*) searches focused on collecting data on specific pathogens at environmental sites in the absence of illness in the home, (*3*) pathogen searches at environmental sites related to the presence of a known human illness, (*4*) cross-contamination studies designed to elicit information and understanding on the potential for the transfer of potential pathogens from and via environmental sites, or (*5*) disinfectant studies that attempt to evaluate household disinfectant products under "in-use" conditions in the home.

BASELINE STUDIES

A number of multiple site baseline studies have been conducted in volunteer homes in the United States and in the United Kingdom. In some of these studies, sites and surfaces throughout the home have been examined (1,2), whereas in others, kitchens and bathrooms (3) or kitchens only (4,5) have been examined. There does not appear to be any significant difference in the data based on the regional or national distributions of the homes in these surveys. This is perhaps not surprising as, in general, the lifestyles are relatively similar in the developed world, and most of the homes in these surveys probably fall into a broadly similar socioeconomic distribution. Climatic conditions do not appear to have made a significant impact on the microbiology of surfaces inside the home.

Sampling Techniques

A number of different sampling techniques have been employed. Hard, flat surfaces such as counter tops have been sampled with a combination of Rodac plates (1,2), contact slides (2), and moist cotton swabs (1–5). A "sweep plate" method has been reported for dry fabrics (1) and for premoistened swabs. Kitchen rags and sponges have also been sampled by wetting them with a sterile solution and then collecting a small quantity of this fluid by squeezing it out of the rag or sponge (3,4). Settle plates have been used for air sampling (2) and liquid samples from toilets and waste traps have been collected by pipette and transferred to contact slides in their containers.

The different sampling techniques that have been employed make it difficult to draw conclusions from specific comparisons between the studies. However, as the following sections will show, it is possible to see common trends in the results. While sampling techniques have changed little, laboratory techniques have become much more sophisticated over the period in which these studies took place. In addition to searching for evidence of contamination with *Salmonella* species, more recent studies have specifically looked for pathogens such as *Yersinia, Listeria*, and *Campylobacter*. The role of these organisms in food-borne illness and their culture requirements was not widely known before the last decade.

Bacterial Species

The range of organisms examined in baseline surveys of all sites and surfaces in the home is given in Table 1.

BACTERIAL CONTAMINATION IN DOMESTIC KITCHENS

In total, results for 28 different kitchen sites have been reported, as shown in Table 2. A factor that seems to have a major impact on the type of species and levels of contamination, at any given site, is whether the site is wet

Table 1. Bacterial Species Isolated from Sites and Surfaces in the Home

Enterobacteria
E. coli
K. pneumoniae
Klebsiella spp.
Proteus mirabilis
Salmonella spp.
Citrobacter freundii
Citrobacter spp.
Ent. Cloacae
Ent. Agglomerans
Enterobacter spp.

radiator
Ceramic tiles

or dry. Dry sites can be further divided into food contact surfaces, hand contact surfaces, and general surfaces.

For all kitchen sites, species of *Bacillus* and coagulase-negative micrococci are almost universally present. Results for wet sites indicate some common trends although differing sampling, culturing, and counting techniques are probably responsible for some of the variations in the frequency of occurrence and the levels of contamination for any particular species. Other parameters such as the occurrence of food preparation or cleaning and disinfection before sampling may also impact the data.

Highest recovery for *Escherichia coli* and other coliforms is associated with sinks, sink drains, and to a lesser extent, draining boards. High total and fecal coliform counts of 10^5-10^7 per sample area also have been commonly recorded at sink surfaces (5) and around the rim of the sink drain (3). Counts as high as 10^{11} per sample area for *E. coli* have been recorded from sink surfaces (1). Overall, the recovery of *E. coli* from sink surfaces ranged from 4% to 81% of samples. Recovery of *E. coli* from drains has been somewhat more consistent, ranging from 39% to 65% of samples, probably reflecting the influence of moisture on bacterial survival and recovery.

High total and fecal coliform counts of 10^7 to 10^9 also are associated with sponges, with more than 65% of samples yielding these organisms on occasion (5). The presence of *E. coli* and *Pseudomonas aeruginosa* also has been recorded in baseline studies of these items (1,2,4).

Data for dry sites show a different picture with lower recovery of Enterobacteria and generally, lower coliform counts. Even so, for food contact surfaces, total and fecal coliform counts range up to 10^6 per sample area on counter tops and cutting boards, refrigerators, and kitchen tables. The presence of *E. coli* is recorded on worktops and cutting boards, refrigerator surfaces, cookers, clean cutlery/crockery, and on food shelves. Fecal coliforms have also been recovered from 24% of cutting boards, 20% of kitchen tables, and 10% of refrigerator surfaces in one study (5). *Staphylococcus aureus* was recovered from 7.4% of cutting boards in one study (2) and *Pseudomonas* spp. have been recovered from 37% of refrigerator surfaces.

For hand contact surfaces, sink taps are often found to be contaminated with Enterobacteria. Fecal coliforms have been isolated from about 32% of sink taps with average counts of 10^3 to 10^4 and *S. aureus* has been isolated from up to 48% of kitchen towels (1). Although some studies have found that hand contact surfaces such as handles showed only species of *Staphylococci* and *Bacillus*, average total and fecal coliforms of 10^6 and 10^2, respectively, per sample area have been recorded from the refrigerator handle (3).

General sites such as kitchen floors and kitchen trash barrels generally show low levels of contamination with a range of different organisms and high levels of *Bacillus* and *Micrococci* spp. *Pseudomonas* species have been recovered from 37% of uncarpeted kitchen floors (2) and total and fecal coliforms counts of 10^4 and 10^2 per sample area, respectively, have been recorded (3).

Bacterial Contamination in Domestic Bathrooms and Toilets

Data are available for 25 bathroom and toilet sites, as shown in Table 3. As with sites in the kitchen, the influence of moisture on the occurrence of Enterobacteria and on high levels of contamination is also observed at bathroom and toilet sites. Highest counts have been observed at diaper buckets, face cloths, cleaning cloths, bath surfaces, bath and basin drain rim areas, and drain pipes. Interestingly, toilet water samples generally yield low counts, indicating the effectiveness of toilet flushing as a means of reducing counts here. *Escherichia coli* and other Enterobacteria were most often isolated from the potty, the diaper bucket, the toilet brush, toilet water and toilet bowl, bath surface, bath and basin drain rim areas, and face cloth. One study reported finding *S. aureus* on 44% of towels and 20% of bathroom floors (1).

Bacterial Contamination in General Living Areas

There is little published in the literature on bacterial contamination at general living area. A total of 11 sites have been reported from only two studies (1,2), comprising the following: living rooms (carpet, curtains, upholstery, table, window sill, stair rail, and telephone mouthpiece) and bedrooms (bed sheets, blankets or duvets, carpet, and dressing table).

The predominant organisms at sites in living rooms and bedrooms are species of pseudomonads, micrococci, and bacillus. In general, the incidence of *E. coli* and other Enterobacteria and also *S. aureus* is low at these sites and contamination levels are also low.

Sponges, Rags, and Other Fabrics

A number of bacterial surveys of household sponges, rags, and other fabrics have been published over the last 30 years. It has long been established that dishcloths, tea towels (6) and hand towels (7) can support high levels of bacterial contamination.

Bacterial counts, carried out by both contact plate and serial dilution methods on reusable kitchen rags, have shown that such items are contaminated on average with more than a billion bacteria per rag after only one day's normal domestic use (8). After further use, counts can reach more than 10 billion per rag. Different bacterial species have been isolated from sponges and dishrags (9) including species of *Salmonella*.

Investigations have shown that soiled clothes are heavily contaminated with potentially pathogenic microbes (10,11). Various studies have looked at the potential for biocontaminants to survive the domestic laundry wash processes. One study (12) described the spread of staphylococcal skin infections among families sharing laundry facilities in a closed student community. The machine wash temperatures of up to 149 °F/65 °C were found to be inadequate for disinfection. A review (13) of the changes that have been made to household laundry practices in recent times indicates the impact that these changes have had on textile cleaning and hygiene assurance. Measures to reduce the environmental impact of household washing machines have stressed the ability to reduce bacterial contamination to safe levels.

PATHOGEN SEARCHES

A number of surveys have incorporated isolation methods targeted at specific primary and opportunistic pathogens. Further, some of the organisms isolated in baseline surveys (1–5) may be considered as pathogens, although they were not in that category at the time of sampling. Pathogens isolated in the baseline surveys are *S. aureus, Salmonella* spp, *P. aeruginosa*, *Bacillus cereus*, *Listeria monocytogenes*, *Yersinia enterocolitica*, and *Campylobacter*.

Species of *Listeria* have been detected in 47.4% of 213 houses investigated (14) with dishrags and the area around the bath drain being most frequently contaminated. *Listeria monocytogenes* was present in 21.1% of homes. Highest numbers (10^4 per object) were found in dishrags and washing-up brushes. Lower numbers (up to 10^3 per object) were obtained from kitchen sinks, refrigerator vegetable compartment samples, and toothbrushes.

CROSS-CONTAMINATION STUDIES

For an infection to result from contact with contaminated environmental surfaces, a number of criteria must be in place. These include the presence of an infectious

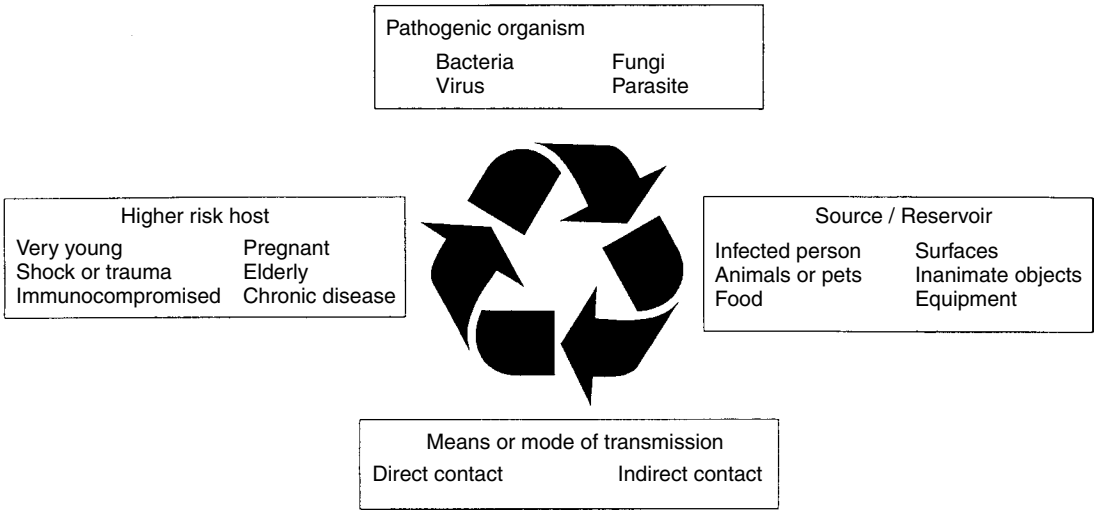

Figure 1. Factors necessary for the transmission of infectious microorganisms via contaminated surfaces.

agent, an environmental source or reservoir for pathogenic contaminants, a means or mode of transmission, and the presence of a host. Although anyone may potentially acquire an infection from a contaminated surface, more often than not, the host is likely to be characterized as at higher risk for infection. When linked together, these criteria increase the probability that disease will occur via contaminated surfaces, as shown in Figure 1 (15).

A number of experiments designed to assess the potential for cross-contamination in the domestic environment have been performed in homes. It should be noted that many other experiments on cross-contamination have been performed in laboratories, under conditions that mimic the home environment and that these are not reported here. Such studies have been reviewed by Scott and coworkers (15).

The microbiological hazards of household toilets droplet production was assessed in the mid 1970s (16). Detection of seeded bacteria and viruses on surfaces in bathrooms after flushing indicated that such organisms had become aerosolized and may present an aerosol infection hazard in older toilet designs. Subsequent studies of domestic toilets and bathrooms have not detected large numbers of toilet contaminants on surrounding surfaces, suggesting that under normal domestic circumstances, flushing is an effective means of removal of bacterial contaminants.

The potential for cross-contamination in kitchens resulting from the preparation of frozen chickens has been examined (17). Raw chickens were seeded with *E. coli* K12 and prepared in 60 kitchens. Cross-contamination occurred in a high proportion of the kitchens examined and contaminants were found on surfaces such as chopping boards, dishrags, and sinks, even after rinsing and washing-up actions occurred. The routine preparation of chicken that is naturally contaminated with *Salmonella* and *Campylobacter* spp. has been found to cause wide dissemination of these organisms to hand and food contact surfaces throughout the home kitchen (18).

ILLNESS STUDIES

Studies in homes with active *Salmonella* infections indicate that environmental contamination may play a role in the development of *Salmonella* infections, especially in young children (19,20). Infecting *Salmonella* serotypes have been isolated not only from human occupants, but also from pets, kitchen sinks and other kitchen surfaces, floors (19,20), and from dishrags (personal communication). In addition, serotypes of *Salmonella* similar to those that have caused infection in the home have been detected in biofilms under the toilet rim several weeks after the infectious outbreak occurred (21). An outbreak of *Staphyloccus aureus* skin infections among families sharing laundry facilities demonstrated the potential cross-contamination risk posed via household fabrics (22).

DISINFECTANT BENEFIT STUDIES

With the growing interest in the positioning of disinfectant products in the home, a number of studies have attempted to evaluate the potential benefit of disinfectants and disinfection processes in reducing microbial contamination at environmental surfaces in the home. This is an area of consumer-related microbiology that is likely to continue to develop in order to fulfill requirements for product development, testing, and support.

In-use tests performed in homes show that the targeted use of household disinfectant products on a range of surfaces can produce substantial reductions in bacterial contamination (3,5,18,23) but that the maximum protection afforded by disinfection is relatively brief; three to six hours after disinfection, contamination levels are only marginally less than those observed at pretreatment (23), indicating that the timing of disinfectant application is a critical factor. In addition, results for the use of detergent and hot water cleaning at fixed surfaces such as counters show that reductions in contamination levels cannot be reliably achieved (18)

and that there may even be an apparent increase in contamination due to surfactant or mechanical break-up and redistribution of cell aggregates (23).

In addition to simple disinfection benefit studies, the data on bacterial contamination and cross-contamination in the home is now being used to develop hygiene practice models for surface cleaning and disinfection, using similar concepts to those employed in the food industry, using the hazard analysis and critical control point concept (HACCP) (15).

FUNGAL CONTAMINATION

There have been a small number of studies investigating the fungal species that are present in the indoor air of houses (24–27). Species of Penicillium, Cladosporium, and Aspergillus are predominant and there is considerable variation concentrations between houses. Studies have indicated a link between the presence of both airborne fungi and airborne bacteria in the home with the incidence of respiratory allergies such as asthma (28,29). In addition to generally damp conditions, factors such as textile floor coverings and indoor storage of organic household waste have been linked to the presence of increased levels of fungal markers in homes (30). Air-conditioning equipment, humidifier reservoirs, dehumidifier drip pans, and showerheads can all harbor molds and mildews. (For more details, see FUNGI AND INDOOR AIR.)

VIRAL CONTAMINATION

There are a number of published studies that indicate that various viral species survive for significant periods on dry surfaces and that contaminated surfaces can play a role in virus transmission in settings such as day-care centers, as reviewed by Scott and coworkers (15). However, at this time, there are no published studies indicating the prevalence of viral species at environmental sites and surfaces in the home.

HYGIENE PRACTICES IN THE HOME

It has been proposed that there are three general categories of sites and surfaces in the home where the risks of bacterial contamination and cross-contamination are highest (2). These are known as

- Reservoirs (toilets, diaper buckets, sinks, drains, etc.) where bacterial contamination is high and there is often the potential for bacterial multiplication.
- Reservoir-disseminators (wet cleaning utensils such as rags, sponges, and mops) where bacterial contamination is high and there is the potential for direct transfer of this contamination to other surfaces whenever these items are used.
- Hand and food contact surfaces (kitchen counters, cutting boards, faucets, handles, laundry, floors, etc.) where there are generally lower levels of contamination but there is a constant potential for cross-contamination to other crucial surfaces such as high-risk foods or the hands.

Effective hygiene practices should include steps to limit the potential transfer of pathogenic microbes from these areas to other more sensitive surfaces such as food and hands. This is especially important when there are people present who are at higher risk for infection (i.e., the young, the elderly, and those who are immunocompromised through existing illness and/or treatment) or when there is potential for increased levels of environmental contamination, such as might occur during incidents of enteric infection in the home. Encouraging the concept that home hygiene is a series of interrelated practices and procedures all based on the same underlying microbiological principles allow the opportunity for a rational approach based on risk assessment (15). The hygiene processes used in the home include the use of soap and detergents, the use of heat (especially for cooking and washing), the use of drying, the use of mechanical action as part of the washing process, and the use of chemical disinfectants. An effective hygiene strategy for the home targets opportunities to prevent or reduce the risk of cross-contamination using effective processes and an understanding of best practices.

CONCLUSION

The study of biocontaminants in the home is a relatively new field but one that is likely to continue to expand, as scientists try to better understand the impact that biocontamination in our immediate living environment has on our overall health. In an era that has already been described as "postantibiotic," there is a growing indication that more emphasis will be placed on effective hygiene practice in our daily life as a means of reducing the potential for infection. But in order to develop effective environmental hygiene practices, we need a better understanding of the nature of the microbial contamination in the environment. At this time, there is a body of data concerning bacterial contamination on surfaces, however, the data are not yet comprehensive and there are many gaps in the knowledge base. For example, there is still little information available on the indoor air quality of domestic dwellings or on the role that the many commensal bacterial species may play in cell-mediated disease and allergic responses. Further, there is even less information about the presence and impact of fungi and algae in domestic settings. There is almost no published data on virus sampling in homes. Viruses are a major cause of domestic infections, and data on the role of inanimate surfaces in the transfer of virus infections would be invaluable in further characterizing the risk posed by contaminated surfaces in the home. To expand the knowledge base in the emerging field of domestic microbiology, further research is needed to complete the picture of biocontamination in the home, to develop and refine risk analysis for environmental surfaces in the home, and to link the potential benefits of hygiene practice in the home, either directly with reduced infections or with other meaningful indicators.

From an agricultural point of view, "soil" refers to the broad environment from which plants obtain mechanical and nutritional support (1). That part of the soil, which is adjacent to the plant root and therefore under its influence is generally denominated as the rhizosphere. As a result of their activity, living roots secrete a wide variety of compounds that alter the physical and chemical properties of their surrounding environment.

Defining the rhizosphere is still a matter of debate, and even more of choice. Throughout the history of rhizospheric microbiology research, investigators have been arbitrarily determining what they consider to be the rhizosphere in their studies. In broad practical terms, the rhizosphere has been considered to be the soil attached to the roots when extracting them from their growth medium, whereas a more restricted view regards the rhizosphere as the relatively small amount of soil particles that remain attached to the roots after they are washed from the residual "bulk" soil. This aspect becomes even more complicated when considering that the qualitative and quantitative distribution of the secreted compounds from the roots is largely influenced by plant species and development, environmental conditions, and location along the roots (2). Hopefully, the increasing exploitation of modern molecular tools by microbial ecologists will be helpful in delimiting the rhizosphere "borders."

In the rhizosphere, bacteria can be enriched by a factor of 100 as compared with their number in the surrounding soil (3). The main factors responsible for this "rhizosphere effect" are the exudation of photosynthetically derived carbon sources (sugars, amino acids, organic acids, phenolic compounds) and the sloughing off of root cap cells and older sections of the cortex (3,4). In turn, these secretions affect bacterial activity and, therefore, the microbial composition of the rhizosphere. Thus, the bacterial population of the rhizosphere generally differs from that present in soil areas not influenced by the roots, not only quantitatively but also in its qualitative composition and distribution (3), although in some studies no differences were observed (5). Table 1 summarizes the effects caused by roots on the rhizosphere.

Among the bacteria living in the rhizosphere, some are able to affect plant growth, either positively or negatively. Rhizospheric bacteria that favorably affect plant growth and yield of many commercially important crops are designated plant growth promoting rhizobacteria (PGPR). PGPR are able to exert positive effects on plants by various mechanisms. These include those that can directly cause plant growth promotion (PGP) by improving seed germination, root development, mineral nutrition, and

Table 1. Factors Derived from the Activity of Living Roots That Influence the Composition of Rhizosphere Microbial Communities

Root Activity	Factors
Secretions/Exudates	Release of low- or high-molecular weight compounds used as nutrients
	Effects on soil solution pH and conductivity
	Release of extracellular enzymes
Lysates	Release of compounds from aging/dead epidermal and cortical cells
Synthesis of mucilage (mucigel)	Changes in hygroscopicity
	Increased root area available for bacterial colonization
	Protection of rhizosphere bacteria from bacterial predators
Respiration	Effects on air composition

Table 2. Modes of Action of Plant Growth Promoting Rhizobacteria (PGPR)

Effects	Mechanisms
Direct effects — Phytostimulation	Production of plant growth regulators (PGRs): auxins, gibberelins, cytokinins
	Biological nitrogen fixation (biofertilizers)
Indirect effects — Biological control	Production of antibiotics and bacteriocins
	Production of cyanide acid (HCN)
	Production of siderophores
	Competition for colonization sites and nutrients
	Systemic acquired resistance (SAR) of the plant against pathogens
	Production of chitinases and glucanases and hydrolysis of fungal cell walls

water utilization (phytostimulation). Others affect plant growth via indirect effects that involve suppression of bacterial, fungal, and nematode pathogens (biological control) (6). The main modes of action of PGPR are summarized in Table 2.

Growing interest in sustainable agriculture has encouraged PGPR research. Many groups are currently investigating possible modes of action of these bacteria at the molecular level using DNA recombinant techniques. However, because of the complexity of the rhizospheric environment and the infinite possibilities of plant-soil-microbial interactions, in most cases, the suggested mechanisms have not yet been fully elucidated. Nevertheless, substantial advances have been made in recent years, as reviewed later.

In this chapter, we will focus mainly on the ecology, modes of action, and utilization of agrobiotechnological inoculants of PGPR that positively affect plant growth by direct mechanisms (phytostimulators). Rhizospheric bacteria capable of improving plant growth by biological control of soilborne diseases, and those able to invade the plant and develop nitrogen-fixing symbioses such as *Rhizobium* and *Frankia*, will not be discussed. Rhizobia will be mentioned only in relation to their interactions with PGPR in the growth promotion of legumes.

MECHANISMS OF ACTION OF PHYTOSTIMULATING BACTERIA

Biological Nitrogen Fixation (BNF)

There are many free-living nitrogen-fixing rhizobacteria contributing fixed nitrogen from the atmosphere to plants, including agronomically important crops (7,8). Bacterial diazotrophs in the rhizosphere belong to a wide variety of genera (Table 3), the most investigated of which have been *Azotobacter* and *Azospirillum*, although many others have been reported to be associated with tropical grasses and rice (7).

Nitrogen fixation by rhizospheric bacteria is sometimes referred to as *associative symbiosis*, and has been extensively estimated by a wide variety of methodologies, including long-term nitrogen balances in soils, estimation of nitrogen contents by the Kjeldahl method, acetylene reduction assay, and the ^{15}N isotope dilution method (9). However, to date, quantification and interpretation of the results have been difficult and controversial. It is estimated that the contribution of nitrogen fixation by free-living rhizobacteria in the rhizosphere of crops such as wheat, sorghum, and maize is in most cases on the order of 1 to 10 kg N ha^{-1} yr^{-1} (10). It may be higher in rice because of the activity of nitrogen-fixing blue-green algae, and in some tropical grasses (7). Although positive, these amounts are, in fact, of minor importance when compared with the amounts of nitrogen fertilizers applied in modern agriculture, which are on the order of 150 to 250 Kg N ha^{-1} yr^{-1}.

Many agriculturally important grasses are associated with endophytic diazotrophic bacteria (Table 3). They have mainly been isolated from plants in which significant BNF has been demonstrated, particularly in some Brazilian sugarcane and rice cultivars (6,11) and in Kallar grass in water logged salty soil in Pakistan (12).

Production of Plant Growth Regulators (PGRs)

Evaluation of the contribution of BNF to plant growth is complicated by the fact that most diazotrophic rhizospheric bacteria and endophytes (Table 3), and many other soil microorganisms, produce a wide variety of PGRs such as auxins, cytokinins, gibberelins, ethylene, and abscisic acid that may alter plant growth (8,13).

A common observation following inoculation with bacteria from the genus *Azospirillum* is an increase in the number of root hairs and lateral roots. This leads to an improved uptake of water and nutrients, resulting in significant increases in crop yields (14). Although it has been proposed that changes in root morphology by *Azospirillum* are caused mainly by the

Table 3. Phytostimulating Bacteria and Their Modes of Action (6–8)

Organisms	Mechanisms
Rhizosphere diazotrophs	
Azospirillum brasilense *Azospirillum lipoferum*	Mainly through production of plant growth regulators (PGRs), mostly auxin. Proliferation of root hairs and branching. Improved mineral and water uptake. Increased nodulation and biological nitrogen fixation (BNF) (by *Rhizobium*) in legumes. BNF: 5 to 10 kg N ha^{-1} yr^{-1} in Gramineae. Increased crop yields in inoculated fields at intermediate fertilizer levels: 10 to 30%
Azotobacter chroococcum	BNF: 5 to 10 kg N ha^{-1} yr^{-1}. Yield increases of 10 to 20% (rhizosphere habitat controversial)
Azotobacter paspali	BNF: increased N-content of about 10% in *Paspalum notatum* cv batatais. Production of PGRs. Proliferation of root hairs and branching
Pseudomonas stutzeri	BNF in rice
Klebsiella pneumoniae and *Klebsiella oxytoca*	BNF in maize and rice. Root hair proliferation in *Poa pratensis*
Enterobacter	BNF in rice
Burkholderia	BNF in maize
Endophytic diazotrophs	
Acetobacter diazotrophicus	BNF in sugarcane (for some cultivars, 50 kg N ha^{-1} yr^{-1}), coffee, and sorghum
Herbaspirillum seropaedica	BNF in sugarcane
Azoarcus	BNF in Kallar grass and rice
Rhizobium leguminosarum bv trifolii	Plant growth promotion in rice
Nondiazotrophic	
Bacillus	Promotion of nodulation and BNF (by *Rhizobium*) in chickpeas and common bean
Serratia liquefaciens and *S. proteamaculans*	Promotion of nodulation and BNF (by *Bradyrhizobium*) in soybean
Pseudomonas fluorescens	Promotion of nodulation and BNF (by *Bradyrhizobium and Rhizobium*) in soybean and peas
Pseudomonas putida	Promotion of nodulation and BNF (by *Rhizobium*) in common bean. Improved phosphate uptake
Pseudomonas putida GR 12.2	Root elongation. ACC deaminase. Production of PGRs

bacterial production of indole-3-acetic acid (IAA) (14,15), production of gibberellins and cytokinins may also be involved (14). Most beneficial bacteria synthesize IAA via the indole-3-pyruvate pathway in which tryptophan is first transaminated to indole-3-pyruvic acid, then decarboxylated to indole-3-acetaldehyde, which is oxidized to IAA. Genes encoding indole-pyruvate carboxylase (*ipdC*) have been isolated from *Azospirillum* (16). An *ipdC* Tn5-mutant of *Azospirillum brasilense* that shows 10% residual IAA production in comparison with the wild type has been obtained and shown to possess reduced ability to promote root hair proliferation (15).

Involvement of ethylene in plant growth promotion has also been investigated. It was demonstrated that a small number of soil bacteria contain the enzyme 1-aminocyclopropane-1-carboxylate (ACC) deaminase. This enzyme hydrolyzes ACC, the immediate precursor of ethylene in plants, to yield ammonium and α-ketobutyrate. Bacteria possessing ACC deaminase activity may therefore grow using ammonium as the sole nitrogen source. The beneficial rhizobacterium *Pseudomonas putida* strain GR 12–2 stimulates root elongation of different plants. This bacterium was found to contain ACC deaminase. Mutants lacking ACC deaminase activity were not able to promote root elongation of canola seedlings, implying that this enzyme participates in root growth promotion by this bacterium (17).

Beneficial Effects of PGPR on the *Rhizobium*-Legume Symbiosis

The effects of PGPR on root hair proliferation and root branching, mineral, and water uptake and growth can also be observed in legumes (8). Positive effects were observed for several *Azospirillum*-inoculated legumes in the field and greenhouse, and under gnotobiotic conditions. The increases in dry-matter production and nitrogen content were attributed to early nodulation, increased nodulation, and higher nitrogen fixation rates, and to a general improvement in root development (18).

Rhizobium infection occurs via the formation of infection threads in the root hairs. Stimulation of nodulation following inoculation with *Azospirillum* may be due to the differentiation of a greater number of epidermal cells into infectable root hairs (19). In addition, *A. brasilense* was shown to cause an increase in the secretion of *nod* gene inducing flavonoids by common bean and alfalfa roots, resulting in the appearance of a greater number of upper nodules following coinoculation with *Rhizobium* and *Azospirillum* in comparison with inoculation with *Rhizobium* alone (20,21).

Several works have been published on the interaction of other rhizobacteria (e.g., *P. putida*, *Pseudomonas fluorescens*, *Bacillus polymyxa*, *Enterobacter* and *Serratia*) with the *Rhizobium*-legume symbiosis (Table 3). Despite data supporting positive effects on nodulation, nitrogen fixation, and yield attributes, little is known about the mechanisms involved in these interactions, but it is likely that in some cases they are similar to those described for *Azospirillum* (8).

Phosphorus Solubilizers

Phosphate deficiency in crops can be diminished by the use of bacteria that act directly as phosphate solubilizers in the rhizosphere, and indirectly by stimulating root excretion of organic acids and/or mycorrhizal associations. Enhanced excretion of organic acids results in increased phosphate solubilization and hence in increased phosphate uptake (22).

Insoluble inorganic phosphorus is largely unavailable to plants, but many microorganisms can bring the phosphate into solution. Species of *Pseudomonas*, *Mycobacterium*, *Micrococcus*, *Bacillus*, and *Flavobacterium* are active in that conversion. These bacteria grow in media with $Ca_3(PO_4)_2$ and apatite as sole phosphorus sources. Not only do the microorganisms assimilate the element, they also render a large portion of it soluble. The many phosphate-dissolving microorganisms found near roots may appreciably enhance phosphate assimilation by higher plants (22).

Inoculation with *A. brasilense* was shown to significantly enhance H_2PO_4 uptake by maize in hydroponic systems, on the order of 30 to 50% over noninoculated controls. In field-grown sorghum and wheat, the increase was in the range of 10 to 30%. In that case, the increases in phosphorus uptake could have resulted from increased root respiration (10).

BACTERIAL FEATURES FOR RHIZOSPHERE COMPETENCE

Inoculation with PGPR is becoming a common practice in agriculture. It is therefore important to understand what microbial traits are involved in rhizosphere competence, which is the relative root-colonizing ability of a rhizobacterium (23). The role of some intuitively defined properties has been not fully demonstrated, with contradictory results found in the literature. In this section, the focus will be on those bacterial features that have received the greatest attention.

Metabolic Versatility

In aerobic environments, most bacteria are highly versatile and can use a large variety of organic compounds as carbon and energy sources. One of the best-characterized examples of metabolic versatility are bacteria belonging to the genus *Azospirillum*. These are free-living nitrogen-fixing rhizobacteria found in close association with plant roots, where they exert beneficial effects on plant growth and yield of many agronomically important crops (14). A variety of carbon sources may be used by azospirilla, (Table 4) for example, salts of organic acids such as malate, succinate, lactate, and pyruvate, and various sugars or amino acids. Under aerobic conditions, oxygen is the preferred respiratory electron acceptor. However, in the absence of oxygen, most strains can use nitrate, nitrite, and nitrous oxide as electron acceptors of the respiratory chain (24,25).

In addition to the monomeric or dimeric carbohydrates, *A. brasilense* and *A. lipoferum* can degrade polymers such as xylan, starch, cellulose, and carboxymethyl cellulose, which are available in the rhizosphere of host plants (26,27). Furthermore, *A. irakense* has been found to grow with pectin as sole carbon source, and some *Azospirillum* spp. are able to grow on methanol or other C1 compounds (25).

Relatively high growth rates and the ability to effectively use a wide range of organic compounds seem to be important factors for rhizosphere competence. However, it was found that rhizosphere and soil bacteria do not significantly differ in their rates and extent of growth in the presence of exudates from soybean seeds and plants (28). In a large study searching for determinants of rhizosphere competence, Jjemba and Alexander (29) could not find a correlation between the growth rate of some of the tested bacteria and their ability to colonize the rhizosphere.

Accumulation of Storage Material

Microorganisms can accumulate a variety of storage compounds such as glycogen, polyphosphate, and sulfur compounds. It is thought that the accumulation of these storage materials enhances competition and survival of bacteria under stress.

A wide variety of microorganisms are known to produce intracellular energy and carbon storage compounds, generally described in the past as being poly-β-hydroxybutyrate (PHB). In recent years, it has been found that in most cases, the polymers are polyhydroxyalkanoates (PHAs)

Table 4. Utilization of Different Carbon Sources by *Azospirillum* spp. (25)

Carbon Source	*A. lipoferum*	*A. brasilense*	*A. amazonense*	*A. halopraeferens*	*A. irakense*
D-Glucose	+	−	+	−	+
Glycerol	+	+	−	+	−
D-Mannitol	+	−	−	+	−
Pectin	−	−	−	−	+
D-Sorbitol	+	−	−	−	−
Sucrose	−	−	+	−	+

Note: + indicates utilization of the carbon source.

comprising copolymers containing different alkyl groups at the β-position (30).

It has been proposed for diverse ecological systems that the accumulation, degradation, and utilization of PHAs by several bacteria may favor their establishment, proliferation, survival, and competition, especially in competitive environments in which carbon and energy sources are limiting factors, such as those encountered in soil and in the rhizosphere (31).

In situ studies of the role played by PHAs on bacteria in the rhizosphere are very scarce, because of the lack of an accurate methodology for measuring their levels. Although mutants unable to synthesize PHAs have been isolated and genetically engineered (32–34), most PHA-negative mutants were examined for their effects on symbiosis and cellular metabolism, whereas their role in rhizosphere competence was not addressed.

Electron microscopy studies of the rhizosphere have shown many bacteria containing PHAs. The C:N ratio of the rhizosphere is estimated at 20. This ratio favors PHA accumulation in *Azospirillum* and *Azotobacter*, and in other rhizospheric bacteria in culture (31).

The possible functions of PHAs in *A. brasilense* strain Cd were investigated, with PHB being the only PHA accumulated by this bacteria (31,35). Degradation and synthesis of the polymer occurred in a biphasic pattern under starvation conditions and were affected by the PHB content of the cells. Under starvation, the survival and respiration rate of bacteria containing about 40% PHB (of total dry weight) were higher than in bacteria containing 5% PHB. Polymer-rich cells fixed atmospheric nitrogen in the absence of exogenous carbon and combined nitrogen. Under stress and adverse conditions, such as UV-irradiation, desiccation, and osmotic pressure, PHB-poor cells died more rapidly than PHB-rich cells. It was concluded that PHB might provide *A. brasilense* with the ability to survive under conditions of starvation and stress, by serving as a sole carbon and energy source (35). Furthermore, in many cases, PHB accumulation is accompanied by flocculation (36), which renders cells highly resistant to desiccation. These properties could conceivably be important for the proliferation of *Azospirillum*, providing a competitive edge over other microorganisms in the rhizosphere (31,35).

In *Rhizobium* bacteroids, PHAs are mobilizable, energy-yielding reserves that provide endogenous carbon substrates for support of nitrogen fixation when exogenous carbon is not available. They may also serve as a carbon and energy supply outside the bacteria (37).

Production of Siderophores

Despite the fact that iron is only a minor nutrient for the growth of most soil microorganisms, it is essential. Although it is abundant in terrestrial habitats, its availability is limited as a result of the low solubility of the ferric ion (1). Therefore, many microbes have developed pathways to obtain it. Many microorganisms overcome this iron unavailability by producing siderophores, specific low molecular weight Fe^{3+}-chelates, and a complementary uptake system, the biosynthesis of which is regulated by the level of available iron (38). There exists a wide variety of siderophores, with organisms producing one or more different kinds. Siderophores are present in the soil and in the rhizosphere, and their utilization is important for the competitive growth of most microorganisms.

Fluorescent pseudomonads produce siderophores termed *pseudobactins*. They seem to play an important role in rhizosphere competition, enhancing their capability as biocontrol agents and as growth promoters (39).

Scher (40) gave indirect evidence of the role of siderophores in competing for iron in *Fusarium*-suppressive soils. In that work, biocontrol of *Fusarium* wilt by *P. putida* was lost when available iron was added, whereas when a Fe^{3+}-chelate with a high binding constant was added, biological control was enhanced. It was also shown that a siderophore-negative mutant of *P. putida* loses its suppressive property against carnation wilt (41). In potato stem cuttings treated with a siderophore-negative mutant with and without the parent strain, the mutant strain multiplied on the cuttings to higher levels when the parent strain was present (42). This indicates that the siderophore produced by the parent strain made iron available to the mutant strain and played an important role in its development.

Azospirillum lipoferum was shown to produce a catechol-type siderophore under iron-starved conditions. In addition to their established role in iron transport, the siderophores exhibited antimicrobial activity against various bacterial and fungal isolates, suggesting that the high-affinity iron uptake system of *A. lipoferum* may be of use in the competition among soil microbes for access to available iron, thereby enhancing its survival in the rhizosphere (43).

Production of Antibiotics

One of the mechanisms used by PGPR, which helps them ensure an ecological edge over other root-colonizing microorganisms, is the excretion of antibiotic substances, which exclude or reduce pressure from competitors on colonized niches. A large array of different compounds showing antibiotic activity against plant pathogens have been isolated from PGPR (44–46). Until now, the bulk of the research on antibiotics was focused on their role in biocontrol, with their significance in rhizosphere competition not being specifically examined.

Kloepper and Schroth (47) demonstrated that five PGPR fluorescent pseudomonads strains that exhibited antibiosis against the soft rot pathogen *Erwinia carotovora*, and several other bacteria isolated from the rhizosphere of radish plants, increased plant growth, but mutants that lacked antibiotic production had no effect. The parent strain, but not the mutants lacking antibiotic production, reduced the number of gram-positive bacteria and fungi in the rhizosphere.

It was shown that the higher the number of *P. fluorescens* on the root, the lower the number of take-all lesions found. When an antibiotic-negative mutant of *P. fluorescens* was tested, there was no suppression of the disease (48). Mazzola and coworkers (49) found that when a phenazine-negative mutant strain of *P. fluorescens* was added together with its parent strain to pasteurized soil to which the take-all fungus had been added,

populations of both the parent and mutant strain were maintained. However, when they were added to untreated soil, the phenazine-mutant population declined, whereas the parent strain proliferated, thereby illustrating the importance of antibiotic production for the establishment of an organism in the rhizosphere.

However, when mutants of *P. fluorescens* defective in in vitro antibiotic production and the parental strain were coinoculated at a 1:1 ratio, no differences in root establishment were found between the strains, suggesting that in this case, antibiotic production contributed little to rhizosphere competence (50).

Resistance to Protozoa

Protozoa are unicellular eukaryotic, generally motile microorganisms. They usually obtain food by ingesting other organisms or organic particles and are found in a variety of habitats, including the rhizosphere. These microorganisms are thought to play a major role in controlling the population of bacteria residing in the soil (51).

The extent of soil colonization by *Rhizobium phaseoli* was shown to be inversely related to the presence of large numbers of bacteria and protozoa. Colonization of *R. phaseoli* was improved upon suppression of protozoa with protozoa inhibitors (52). Casida (53) added representatives of several categories of bacteria to soil to determine which of them might elicit responses from soil protozoa. The protozoa did not respond to *Cupriavidus necator*, a potent bacterial predator, or to *Micrococcus luteus*, one of its prey species. *Cupriavidus necator* also had no effect on the protozoa, showing that in this case bacterial and protozoan predators do not interact. The soil protozoa did not respond to *Arthrobacter globiformis* or to *Bacillus thuringiensis.* Apparently, resistance of these microbes to protozoa enhanced their survival. The addition of *Bacillus mycoides* and *Escherichia coli* caused specific responses by soil protozoa (53).

In summary, addition of bacteria to soil did not cause a general increase in the numbers of protozoa. In other studies, the extent of colonization of a nonsterile rhizosphere by tested bacteria was not correlated to their densities in the rhizosphere containing large numbers of protozoa (29). In view of these findings, it seems that protozoa may reduce the abundance of some species of rhizospheric bacteria; however, its significance in controlling the population of bacteria in the rhizosphere is not yet well understood.

Root Adsorption and Colonization

Bacterial adherence to plant roots is thought to be an important trait in determining rhizosphere competence, and this property has been the subject of a large number of studies.

Attachment to plant roots by some rhizobacteria, including rhizobia, seems to occur in two distinguishable steps: a rapid, weak, and reversible adsorption and a slow, firm, and irreversible anchoring to the plant root surface (54). In the case of *A. brasilense*, it was suggested that an adhesin closely related to the polar flagellum is involved in the first step, and that the second step is mediated mainly by extracellular polysaccharides (54,55).

In the last decade, outer membrane proteins (OMPs) have been proposed to play a role as adhesins in invasion and adhesion processes in various gram-negative bacteria. The major OMPs of *P. fluorescens*, *Rahnella aquatilis*, and *A. brasilense* were suggested to be involved in the adsorption of these rhizospheric bacteria to plant roots (56–58).

Bacteria able to adhere to the root surface are closer to the source of root exudates than are bacteria at some distance from the root. Moreover, adhering cells are presumably more likely to be transported with the extending root. For adhering cells, the root may also serve as a basis of physical support for bacterial proliferation. However, studies carried out on root adhesion have been quite contradictory in supporting the importance of this trait for rhizosphere competence.

Chao and coworkers (59) showed that 82% of the bacteria isolated from the rhizosphere exhibit a positive agglutination reaction with pea roots, in contrast to only 30% of bacteria from bulk soil. However, it was suggested that root attachment by bacteria is, in most cases, a very widely occurring property of low specificity, being greatly influenced by the medium ionic composition (60). Studies carried out with single-gene mutants of *P. putida*, differing in root attachment ability, showed that some agglutinin-negative strains still possess good root colonization ability (61). Recently, Jjemba and Alexander (29) showed that the ability of introduced bacteria to colonize the rhizosphere of soybeans does not correlate with the capacity of low or high densities of these bacteria to adhere to the roots. The aforementioned examples suggest that the ability to attach to the roots is not a crucial determinant for rhizosphere colonization, especially when considering that only a very small percentage of the cells are firmly attached to the roots (62).

Motility and Chemotaxis

Most of the known bacterial species are flagellated by means of polar and/or lateral flagella. Flagella provide the motility needed for the bacteria to reach the most favorable niche and to compete with other microorganisms for these niches. It has been observed that in many cases when competition is absent, bacteria lose their motility and/or flagellation ability (63).

In *P. fluorescens*, many studies have suggested that motility does not affect root colonization following either seed or soil inoculation (64–66). In contrast, De Weger and coworkers (67) found that bacterial motility is required for root colonization of potato by *P. fluorescens*. A comparative study between a wild type and a nonmotile Tn5 mutant of *P. fluorescens* suggested that motility plays a role in the movement of cells along roots more than in the movement from bulk soil toward roots (50).

Many studies have been carried out on the importance of motility for nodulation of legume roots by rhizobia. Although some of them indicated that motility is not essential for root attachment or nodulation, some studies based on competition assays among wild-type and nonflagellated and/or nonmotile mutant strains

suggested that motility confers a selective advantage when competing with nonmotile strains (62,63).

In *A. brasilense*, horizontal and vertical movements in different soil types depend mainly on the presence of plant roots and on the availability of water films in soil (68). On the basis of observation of motile and nonmotile strains of *A. brasilense*, Bashan and Holguin (69) concluded that active motility is needed for interroot travel (movement among neighboring plants) by this bacterium.

Besides locomotive properties, adhesive properties have been attributed to bacterial flagella. As previously indicated, the first step in the root attachment process by *A. brasilense* is mediated by an adhesin closely related to the polar flagellum. *Azospirillum brasilense* cells lacking the polar flagellum were unable to adsorb, and purified polar flagella adsorbed specifically to wheat roots (55).

Strongly related to flagellation is chemotaxis, which allows bacteria to detect and move toward gradients of different compounds. In the rhizosphere, it may be advantageous to respond positively to chemoattractants released by plant roots that may increase metabolic rates.

Some of the most studied PGPR with respect to chemotaxis are those belonging to the genus *Azospirillum* that exhibit positive chemotaxis to a wide variety of compounds such as organic acids, sugars, amino acids, and aromatic compounds (70–72). These bacteria also possess a strong aerotactic response toward reduced oxygen pressure in the root zone when nitrogen fixation is required (73,74).

Using the β-glucuronidase (GUS) reporter system, various *A. brasilense* mutants were investigated for their capacity to initiate wheat root colonization at the root hair zones. Only nonflagellated mutants and a generally nonchemotactic mutant exhibited strongly reduced root colonization ability as compared with the wild type, thus demonstrating the requirement of bacterial motility in the establishment of the *Azospirillum*-plant root association (75).

Conversion into Forms with Increased Resistance Under Stress

Under adverse environmental conditions, some bacteria are able to convert themselves into forms that are more resistant than the vegetative form. For instance, *Bacillus* species, which are known to promote both phytostimulation and biocontrol effects in a wide range of plants (62), are able to form endospores that are highly resistant to desiccation and heat.

Species of *Azotobacter* (e.g., *A. chroococcum*) are known to form heat- and desiccation-resistant cysts endowed with a long life span. This property has been used to prepare nitrogen-fixing liquid bioinoculants useful for a variety of crops (76). Cyst formation was also reported for *A. brasilense* and *A. lipoferum* (77).

Cell aggregation is a widespread phenomenon in the microbial world. Rhizospheric bacteria such as *Rhizobium*, *Pseudomonas*, *Azotobacter*, and *Azospirillum* are able to aggregate and flocculate under both soil and laboratory conditions (58,78,79). There is evidence that this property positively affects bacterial survival under adverse environmental conditions (77,78). In addition, bacterial flocs can be produced on a large scale and be easily separated from the growth medium. This is of great interest for the production of bacterial inoculants.

On the basis of experimental evidence, Neyra and coworkers (80) proposed the generation of inoculants containing intergeneric coaggregates of *A. brasilense* and *Rhizobium leguminosarum* biovar phaseoli to improve the growth of common bean plants.

Despite much evidence indicating that the aforementioned traits improve bacterial survival under laboratory conditions, their real impact on bacterial survival in the rhizosphere has yet to be demonstrated. In addition, these resistant forms are less metabolically active than the vegetative forms, a fact that should be taken into account when preparing bacterial inoculants.

INTERACTIONS OF PGPR WITH BIOTIC AND ABIOTIC FACTORS

Because soil, the milieu in which roots develop, is inherently heterogeneous, and because of their impact on their immediate environment (see the introductory section), beneficial root-associated microorganisms meet a complex habitat. A major component of this habitat is the indigenous microbial populations that vary in structure, spatial distribution, physiology, and impact on the plant's health. Not one methodological approach for studying rhizospheric bacterial communities and their relationship is necessarily better than another, but each, within its own bias, offers a different vantage point from which a more complete and accurate picture of "life in the rhizosphere" can be reconstructed.

The physicochemical parameters that bacterial cells encounter in the rhizosphere are important factors in determining their fate. Such parameters, among others, include hydrogen and redox potentials, water tension and flow, atmospheric composition, viscosity, solution composition, nutrient fluxes, and charged surfaces. Reliable devices enabling precise acquisition of this type of data at the relevant micrometer scale have been successfully applied in microbial ecology (81) and are also being applied to study the rhizopheric environment.

Microsensors

A thorough description of microsensor devices can be found in another article of this book. Briefly, these are mostly microelectrodes responding to specific solutes or gases that, owing to their small tip diameter, are able to perform measurements at the micrometer level. A large variety of microsensors have been developed, such as ones for measuring pH, temperature, carbon dioxide, sulfide, nitrate, nitrite, oxygen, nitrous oxide, organic carbon, and methane (81–83). They have been used to study sediments, sludge, and plant rhizosphere, the latter mainly under flooded conditions (84–86).

Reporter Genes

Soil remediation has been an important incentive for the development of biosensors, namely, reporter genes, cloned under the regulation of a promoter sensitive to

specific deleterious organic or inorganic compounds. The type of genes employed usually yields a colorimetric (*lacZ, gus, xyl*, and *lux*) or a bioluminescent (*gfp*) reaction, or ice nucleation. This approach is also gaining acceptance in rhizosphere studies, with indicator organisms for iron, oxygen, sucrose, and tryptophan already being developed (87–89).

INOCULATION WITH PGPR IN A DENSE MICROBIAL BACKGROUND

Bacterial inoculants, phytostimulators, or biocontrol agents, insomuch as they colonize the rhizosphere and influence plant growth and health, certainly affect indigenous populations. Such effects may stem from direct competition for resources and/or from products of metabolic activity of the introduced microbe, or from indirect factors such as changes occurring in the root system and in exudate release following inoculation. In turn, these indigenous communities may also impede or promote the establishment of the introduced microbe. Although few such studies have been performed, this knowledge is important for increasing the performance of inocula and for evaluating the impact of the introduction of exogenous bacteria on root communities. It may also lead to the isolation of new, efficient PGPR.

Introduced Bacteria and Indigenous Rhizosphere Populations: Support, Interference, or Indifference?

The influence of natural populations on introduced inocula and vice versa is strongly dependent on the systems under study, that is, using PCR-based, culture-independent ribosomal interspacer analysis (RISA); Robleto and coworkers (90) were able to show that inoculation of common bean (*Phaseolus vulgaris* L.) rhizosphere with a trifolitoxin (TFX) antibiotic-producing *Rhizobium etli* leads to a detectable shift in bacterial populations, with bands originating from members of the α-*Proteobacteria* subgroup disappearing.

Plants inoculated with a nonproducing TFX derivative yielded a pattern identical to that of noninoculated plants. Conversely, soil bacteria can reduce PGPR root colonization; Ikeda and coworkers (91) showed that individual strains of soil fluorescent pseudomonads exhibit such deleterious effects on a fluorescent pseudomonad PGPR. Combinations of individually nonsuppressive gram-negative bacteria could significantly suppress subsequent colonization of tomato (*Lycopersicon esculentum*) roots with this particular PGPR, suggesting that less competitive strains may hinder colonization of a competitive strain. An inverse situation was found with *Frankia*, as Knowlton and coworkers (92) reported a significant increase in nodulation of *Alnus rubra* under nonsterile conditions as compared with gnotobiotic growth with *Frankia* alone. Moreover, inoculation of pepper (*Capsicum annum* L.) with a mycorrhizal fungus resulted in a strong reduction of ^{14}C root exudation, altering the composition of the rhizosphere, as detected using a bioluminescent pseudomonad (93).

Such studies are also important for assessing the impact of genetically modified organisms, microbes, and plants alike. Mahaffee and Kloepper (94) investigated whether the introduction of a bioluminescence gene in a rhizosphere isolate of *P. fluorescens* would cause detectable changes in microbial community composition. No such shift could be found by fatty acid methyl ester analysis of 7,200 colonies isolated over a two-year field study.

In contrast, a population shift was observed in the rhizosphere of *Lotus corniculatus* plants engineered to produce opines; increased levels of bacterial strains able to specifically grow at the expense of a particular opine were detected in the rhizosphere of the transgenic plants producing that opine as compared with the wild-type plants (95).

MOLECULAR METHODOLOGY FOR TRACKING INTRODUCED PHYTOSTIMULATORS

Although most studies have been conducted using classical, culture-based techniques, culture-independent modern molecular techniques are being implemented to track introduced bacteria, to monitor their physiological status in situ, to understand their relationship with the surrounding bacterial communities and to analyze these communities. More information about these techniques can be found in another article of this book and in Burdman and coworkers (8).

Reporter Genes

Inocula of engineered PGPR can be tracked using reporter genes such as β-galactosidase (96) or GUS (97,98), the latter being more adequate for direct detection on plant material because X-gal (5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside), the substrate of β-galactosidase, can be cleaved by root enzymatic activities. Newer approaches, combining both markers yielding stronger signals and more sensitive detection systems, such as coupled charge devices (CCD), result in greatly enhanced sensitivity. For example, a 1,000-fold increase in sensitivity was achieved using the bioluminescence *luxAB* gene system in rhizosphere-inoculated *Pseudomonas* spp. as compared with that achieved using the β-galactosidase gene (99).

The green fluorescence protein (GFP), product of the *Aequoria victoria* jellyfish *gfp* gene (100), has been demonstrated as perhaps the most versatile and efficient reporter system; it is highly stable and does not require external or internal reducing power, only illumination to fluoresce. A number of modified proteins have been engineered and exhibit absorption/emission spectral shifts resulting in a change of color, fluorescence intensity, or half-life (101,102). These genes have been successfully used in a number of studies aimed at tracking introduced bacteria on or in roots in various plant species (103,104). Although quantitative uses are possible, bioluminescent-tagged PGPR have mainly been employed for spatial, in situ studies of cell distribution along the root, in conjunction with epifluorescence or confocal laser microscopy. Moreover, the physiological activity of a particular introduced bacterium can be monitored at the single cell level using unstable variants of the GFP protein

in cells containing this particular gene under the control of a ribosomal promoter (105).

Antibodies

Antibodies raised against a phytostimulating bacterium can be particularly useful for quantifying colonization and for obtaining data on the spatial distribution of the inoculum, without relying on reporter genes, which may put a physiological burden on the cell.

The high specificity of monoclonal antibodies (mAbs) raised against specific strains of *A. brasilense* was demonstrated (106). These mAbs were then tested in situ in experiments in which the bacterial strains were coinoculated on wheat roots grown in soil where they could be specifically quantified in different root compartments by chemiluminescent ELISA (106). In situ detection and differentiation of coinoculated *A. brasilense* strains Wa3 and Sp7 was achieved on a background of root-associated bacteria concomitantly stained with 4',6-diamidino-2-phenylindole (DAPI) and rRNA-directed fluorescent oligonucleotides (107).

Polyclonal antibodies (pAbs) have been used to identify rRNA homology group I pseudomonad colonies grown from rhizosphere material (108) and for in situ tracking of each component of a mixed inoculum of *P. fluorescens* in barley roots grown under sterile conditions (109). Schlöter and Hartmann (110) used a monospecific pAb to quantify and track *R. leguminosarum* biovar trifolii R39 inoculated on roots of various legumes and nonlegumes using chemiluminescent ELISA and fluorescein isothiocyanate (FITC)-coupled antibodies, respectively.

rRNA Probes

Characteristic features of the rRNA molecules (16S and 23S) form the basis for the development of oligonucleotide probes designed to match various levels of specificity, from the universal to the species-specific level (111), rendering this tool instrumental in microbial ecology research.

Fluorescence-labeled rRNA-directed probes can be used in conjunction with scanning confocal laser microscopy to detect bacteria in the root system (85,112). They are useful for studying the spatial distribution of targeted groups when applied in conjunction with scanning confocal laser or epifluorescence microscopy, or for direct quantification when cells are extracted from the rhizosphere. However, because in most cases strain-specific probes cannot be designed, tracking a specific strain by this means in a dense bacterial background may prove difficult. When used along with other detection methods, such as specific antibodies directed toward the introduced bacterium, the relationship of the latter with surrounding rRNA-labeled bacterial populations can be observed, as Aßmus and coworkers (107) reported for *A. brasilense* (inoculated on soil-grown wheat).

Furthermore, and because the signal obtained is directly proportional to the rRNA cellular content (113), it is possible to assess the proportion of cells that remain physiologically active. This proportion appears to be greater in the rhizosphere (114,115) than in bulk soil (116).

COMMERCIAL PRODUCTS: PRESENT AND FUTURE

The use of PGPR inoculants has become rather common practice and is on the rise in many regions of the world. Inoculation with PGPR also aims at reducing the application of potentially polluting chemical fertilizers and pesticides (22,117). Various inoculants, referred to as *biofertilizers*, *phytostimulators*, and *biopesticides*, are commercially available under different brand names (10,118,119).

As an example, first-generation (wild-type) *Azospirillum* inoculants for maize (Azogreen®) are commercially available in Europe (Lipha, France). Results from field experiments have consistently shown better utilization of nitrogen fertilizer by maize plants inoculated with *A. brasilense* (P. Wadoux, Lipha, Personal Communication).

Another company, Soygro (Pty) Ltd. (Potchefstroom, South Africa), is producing liquid and peat-based *Azospirillum* inoculants for 150,000 and 12,000 commercial hectares of maize and wheat, respectively, and 500 experimental hectares of sorghum. Field experiments with maize carried out over the last six years have shown yield increases of 10 to 30% above noninoculated plants. In the last few years, *Azospirillum* inoculants have also been applied to legumes in South Africa. Average yield increases of 15 to 30% have been observed, following coinoculation with *Azospirillum* and *Rhizobium*, as compared with inoculation with *Rhizobium* alone (T. E. M. Odendaal, Potchefstroom, Personal Communication).

Large surfaces of maize and wheat in Mexico and Argentina are currently being inoculated with *Azospirillum*, leading to significant increases in yield (J. Caballero-Mellado, CIFN, Cuernavaca, Mexico, Personal Communication). Surprisingly, a company specializing in the improvement of golf courses in the United States (EcoSoil Systems, Inc.) is now using *Azospirillum* to obtain better quality of grass turf.

Important factors that can influence the efficiency of microbial inoculants are summarized in Table 5. Successful field inoculation experiments appear to be those in which researchers paid special attention to those factors, especially to the optimum number of cells in the inoculants and to the appropriate inoculation methodology, whereby an optimum number of cells remained viable and available for root colonization (120).

The main obstacle impeding more intensive and widespread use of PGPR inoculants has been the so-called inconsistency of results in field experiments, which could be explained by the complexity and the variability of the soil-plant-microflora relationship at any experimental site. However, such variability is also the lot of *Rhizobium* inoculants, which have been commercially utilized for about a century, and of chemical fertilizers and pesticides, which are not always efficient in the field.

Biotechnological research objectives aiming at improving bacterial performance should also aim at diminishing inconsistencies. To this aim, the following approach may be taken: first, a large number of strains need to be screened, using selected crop plants grown under laboratory or greenhouse conditions. In the screening assays,

Table 5. Factors Influencing the Efficiency of Microbial Inoculants

Factor	Description
Inoculant quality	Utilization of sterilized (gamma) carriers Optimum bacterial concentration Optimum physiological state of the cells Quality control
Soil cultivation	Cultivation practices leading to reduced natural microbial population Preparation of a weed-free seedbed Light irrigation just after planting/inoculation Tillage implements, prevention of soil compaction (aerobic conditions)
Fertilization	Nitrogen, phosphate: optimization according to the inoculant
Fungicides/Insecticides	Prevention of negative effects on microorganism survival (e.g., physical/temporal separation between application of chemicals and inoculation)
Environmental factors	Soil characteristics at planting: pH, temperature Flooded soil conditions, cool and hail storms that negatively influence bacterial activity

the different strains should be evaluated according to their capabilities to improve germination, seedling vigor, root elongation, root branching, nitrogen fixation, and nodulation in the case of legumes. However, this procedure does not ensure that similar performance will be obtained in soil. Therefore, selected strains need to be further tested in pots and finally in the field. It is necessary to demonstrate, using Koch's postulates, that the selected microorganism is responsible for the observed effect on the plant. One can then proceed toward the development of a commercial product with the best strains.

Another approach should aim at understanding the mechanisms involved in the production of the beneficial plant growth effects seen with certain bacterial strains. Such knowledge can provide a rational basis for the improvement of inoculant production and storage procedures, thus resulting in qualitatively superior products. However, this approach is so expensive that it is not feasible for most agroindustrial products.

Application of genetic engineering techniques for the development of better products with "superior" PGPR strains appears to be the most promising path. Extensive research efforts are being carried out to isolate, clone, and characterize genes involved in bacterial features and activities related to survival, colonization, and plant growth effects in the rhizosphere. Efforts are also being made to fuse reporter genes to those rhizosphere-related genes with the aim of following their activities and expression in situ. However, because of public disagreement and political developments with regard to the release of biologically engineered material to the environment, at the present time, this approach cannot be taken into account for applied purposes.

Development of PGPR products includes paying attention to survival and viability of the bacteria, not only in soil, but also during storage. The aforementioned properties (such as accumulation of storage material, encystation, aggregation, etc.) may be extremely relevant to the success of an inoculant. Carrier optimization also has to be taken into account, as it is expected that a suitable carrier will provide good support and encourage bacterial survival during storage. For the *Rhizobium* inoculants, the most "popular" carrier has been peat. Alternatives may be vermiculite, alginates, and liquid formulations (8). With regard to application technology, more extensive investigations need to be performed in order to compare the performances of seed and soil inoculation.

Growth and development of bacteria under laboratory conditions is now rather well understood. The challenge of the next decade will be to extend this knowledge to microbial growth, survival, and exertion of beneficial effects on the plants in situ, to understand the significance of factors limiting growth (e.g., nutrient limitation, toxic products, protozoa) in the rhizosphere, and the impact of abiotic factors (e.g., temperature, drought, oxygen pressure) on bacterial survival and activity. Moreover, the discovering of specific gene expression patterns in the rhizospheric environment and the understanding of the influence of environmental factors on the essential functions for survival, and on traits involved in colonization and in plant growth promotion, will provide answers necessary for the development of more reliable PGPR inoculants.

BACTERIOPHAGE AS INDICATORS

JUAN JOFRE
University of Barcelona
Barcelona, Spain

The use of indicator organisms to assess the microbiological quality of water is well established and has been practiced for almost a century. Early work focused on the detection of bacterial indicators of fecal pollution, but now it has been extended to bacterial indicators of sewage, indicators of nutrient pollution, and so on. In the last 50 years, bacteriophages have been investigated as indicators for different purposes. The most widely studied is the use of phages infecting enteric bacteria as models in water quality control. Other examples are the use of

bacteriophages infecting *Serratia marcescens* or *Staphylococcus aureus* as tracers of groundwater movement, or bacteriophages infecting *Vibrio parahemolyticus* as indicators of eutrophication in marine waters. The scope of this article is limited to a critical description of the relationship between the presence of bacteriophages of enteric bacteria in water and their possible application as model microorganisms in water quality control. Different authors (1,2) have listed the requisites for a model microorganism. However, some potential extra advantages of bacteriophages as indicators of water quality deserve comment. First, the limited importance, if any, of phenomena such as "stress," "injury," or "reactivation" that frequently lead to misinterpretation of environmental data on bacterial indicators. Secondly, the samples for phage analysis can be conserved for longer periods of time than samples for bacterial analysis before the performance of assays. Finally, the somatic coliphages allow results to be obtained in four hours.

MODEL, INDEX, AND INDICATOR CONCEPTS

The term indicator organism is not clearly defined, which sometimes leads to confusion. Therefore, the concept of model microorganisms as used by other authors (1,2) will be followed. According to this usage, the index and the indicator functions can be attributed to the model organisms.

An index organism is one that is related to the occurrence of the selected surrogate microorganism or microorganisms. The relationship may be direct, such as the index of human viruses or indirect, such as an index of fecal pollution, sewage pollution, or types of fecal pollution (i.e., human or animal). The criteria for an index organism are very similar to those commonly used for bacterial fecal indicators.

The model organisms with an indicator function have a much broader definition. An indicator is basically a model that has behavioral characteristics similar to those of the surrogate microorganism or microorganisms, and has the same or greater resistance to environmental stresses, but that does not necessarily originate from the same source as the pathogen (e.g., feces). This criterion, and others mentioned earlier, define an indicator as a marker for the efficiency of treatments or for the variation in numbers of the surrogate microorganisms in specific environments. In general, the criteria for indicator organisms are less restrictive than the criteria for index organisms (1).

Ideally, a perfect model organism will fulfill both the index and the indicator functions. However, the more is known about fecal pathogens and potential model microorganisms, the more unlikely it seems that a single fecal microorganism fulfilling all criteria under all circumstances, will be found.

BACTERIOPHAGES AS MODEL ORGANISMS IN WATER QUALITY ASSESSMENT

Three main groups of bacteriophages infecting enteric bacteria have been considered so far as potential model microorganisms for various aspects of water quality assessment: somatic coliphages, F-specific RNA bacteriophages, and bacteriophages infecting *Bacteroides fragilis*. Table 1 summarizes some of the features of the three groups of bacteriophages that is more extensively described in the following text.

Table 1. General Features of the Three Groups of Bacteriophages Proposed as Model Microorganisms for Water Quality Assessment

Feature	Somatic Coliphages	F-specific RNA-Phages	Phages of *B. fragilis*
Homogeneity of the group	+	+++	+++
Availability of standardized methods	+++	+++	+++
Occurrence and levels in human feces	++	+	+
Occurrence and levels in animal feces	+++	+	+
Occurrence and levels in urban sewage	+++	+++	+++
Occurrence and levels in abattoir sewage	+++	++	+
Probability of replication in environment	++	+	−
Resistance to inactivation in environment	++	+	+++
Resistance to disinfection			
Chlorination	+	++	+++
Ozonization	ND	+++	ND
UV irradiation	+	+++	++
High-energy radiation	++	+	++
Thermal treatment	+++	+	+++

Note: +++, high; ++, intermediate; +, low; −, very low; ND, no data available.

Somatic Coliphages

Somatic coliphages are bacteriophages, which consist of a capsid containing single-stranded or double-stranded DNA as the genome. The capsids may be of simple cubic symmetry or complex structures with heads, tails, and tail fibers. They are classified into the following families: Myoviridae (dsDNA, long contractile tails, and capsids up to 100 nm), Siphoviridae (dsDNA, long noncontractile tails, and capsids 50 nm), Podoviridae (dsDNA, short noncontractile tails, and capsids 50 nm), and Microviridae (ssDNA, no tail, and capsid 30 nm). All types are found in sewage, although the most abundant are Myoviridae and Siphoviridae (3,4). Somatic coliphages attach to the bacterial cell wall and may lyse the host cell in 20 to 30 minutes under optimum conditions. They produce plaques of widely different size and morphology. The methodology to detect them is very simple and results may be obtained in four hours.

Natural host strains of somatic coliphages include *Escherichia coli* and other closely related bacterial species. Some of these may occur in pristine waters, hence somatic coliphages may also multiply in these environments even in *E. coli* (5,6). Indeed, one of the drawbacks of somatic coliphages is their replication potential outside the gut. However, the contribution of this potential

replication outside the gut to their occurrence in natural environments has never been quantified.

The term *somatic coliphages* covers many types of phage with a wide range of characteristics, including differential resistance to inactivating factors. Moreover, different strains of *E. coli* and different assay media count, different numbers, and types of somatic coliphages (4,7). Consequently, the information available on both the presence and the behavior of somatic coliphages in water environments has to be interpreted very cautiously, because the data reported in the literature had been obtained with different host strains of *E. coli*, media, and assay conditions. To avoid confusion, the term *somatic coliphages*, unless otherwise indicated, will be restricted to phages infecting *E. coli* C as established by standard methods (8) or ISO (9). Bacteriophages frequently used to study somatic coliphage behavior are T-even and T-odd, ΦX147, and PRD-4.

F-Specific RNA Bacteriophages

F-specific RNA bacteriophages consist of a simple capsid of cubic symmetry of 21 to 30 nm in diameter and contain single-stranded RNA as the genome. They belong to the family Leviviridae. They infect bacteria through the sex pili, which are coded by the F plasmid first detected in *E. coli* K12. The F plasmid is transferable to a wide range of gram-negative bacteria. The pili coded by the F plasmid do not form below 25 °C (10). Therefore, the probability of these phages replicating in the environment is small (10). The infection process is inhibited by the presence of RNase in the assay medium, which can be used to distinguish between the F-specific RNA bacteriophages and the rod-shaped F-specific DNA bacteriophages of the family Inoviridae, which also infect the host cell, through the sex pili.

Strains (*Salmonella typhimurium* WG49 and *E. coli* HS) tailored to detect F-specific bacteriophages also detect small percentages of somatic phages. All phages detected by the tailored strains are usually referred to as F-specific bacteriophages. The number of F-specific RNA bacteriophages is the difference between the number of phages counted in the presence and in the absence of RNase in the assay medium. More than 90% of the phages detected in sewage by tailored strains are F-specific RNA bacteriophages. This percentage may be lower in receiving waters.

A standardized method for the detection and enumeration of F-specific RNA bacteriophages is now available (11). Results can be obtained in 12 hours.

F-specific RNA bacteriophages mentioned in this entry are f2 and MS2.

Bacteriophages Infecting *Bacteroides fragilis*

The most abundant bacteriophages infecting *Bacteroides fragilis*, one of the most common bacteria in the gut of warm-blooded animals, belong to the family Siphoviridae, with flexible tails (dsDNA, long noncontractile tails, and capsids up to 60 nm). Phages infecting *B. fragilis* attach to the cell wall of the host bacteria and may lyse the host cell in 30 to 40 minutes under optimum conditions. They produce clear plaques, which do not differ very much in size or morphology. *Bacteroides fragilis* strains differ widely in the numbers of phages that they recover from municipal sewage, but most strains recover bacteriophages that are very similar and belong to the family Siphoviridae. Bacteriophages infecting *B. fragilis* have not been reported to replicate under environmental conditions. The method for detecting these bacteriophages is slightly more complex than methods for detecting the other groups because of the anaerobic nature of the host bacteria. However, a relatively simple standardized method is now being discussed (12). Results can be obtained in 18 hours.

Bacteriophage B40-8 cited in the text belongs to this group.

BACTERIOPHAGES AS INDEXES

Bacteriophages as Indexes of Fecal Pollution

Many studies have been performed on the distribution of bacteriophages specific to enteric bacteria in human and animal feces. Somatic coliphages using *E. coli* C as the host have been isolated in variable percentages (up to 60%) of human stool samples, reaching numbers up to 10^9 plaque forming units (PFU)/g (13,14). The percentages of isolation reported in mammals and birds range from 100% in pigs to 38% in rabbits (14,15) with counts up to 10^7 PFU/g.

F-specific bacteriophages rarely have been isolated from human feces, irrespective of the host strain used. The maximum positive isolation described is approximately 30% (14–16). Such phages have been isolated inconsistently from domestic and feral animal feces, but incidences are in general higher than in humans (15,17), with densities up to 10^4 PFU/g, although usually lower.

Bacteroides fragilis RYC 2056 has been reported to recover phages from 28% of human stool samples, although it also allows the isolation of phages from animals (18), with the maximum incidence, 30%, in pigs with maximum values of 3×10^2 PFU/g. Bacteriophages infecting *B. fragilis* HSP40 have been isolated from 10 to 13% of human stool samples (15,19) with maximum values above 10^8 (19). However, they have not been isolated from animal feces (15,19).

Bacteriophages as Indexes of Sewage Pollution

Bacteriophages of the three groups mentioned earlier are consistently present in raw sewage and sewage effluents. Consequently, sewage pollution will lead to contamination by the three groups.

Most reports indicate that somatic coliphages are the most abundant in raw municipal sewage, with values ranging from 10^6 to 10^7 PFU/100 ml, approximately less than one order of magnitude lower than the numbers of fecal coliforms or *E. coli* (15,20,21). In addition, they are the most abundant in abattoir wastewater, with values that are similar to those found in municipal wastewater, or values that keep the proportion to fecal coliforms as in municipal wastewater (13,22,23). Values from slurries of different animals are also similar.

Numbers in sewage effluents depends on the wastewater treatment. However, they are present in the great majority of sewage effluents.

F-specific RNA bacteriophages rank second in abundance both in municipal raw sewage and in raw wastewater from abattoirs. The most frequent average values range from 5.10^5 to 5.10^6 PFU/100 ml, usually about one order of magnitude lower than values for somatic coliphages (13,17,18,20,22,24,30). The ratios between F-specific RNA bacteriophages and somatic coliphages are of the same order of magnitude in both raw municipal sewage and wastewater from most abattoirs. In some slurries (e.g., cattle) and specific abattoir wastewater, their relative abundance may be lower. Numbers in sewage effluent depend on the treatment, but these phages are always found in wastewater effluents.

Bacteriophages infecting *B. fragilis* RYC 2056 are found in municipal sewage (Europe, Africa, and America), frequently ranging from 10^4 to 10^5 PFU/100 ml, usually one order of magnitude less than F-specific RNA bacteriophages. Their ratio with respect to somatic coliphages and F-RNA bacteriophages is remarkably constant in municipal sewage (18,20). Host strain VPI 3625 has been shown to recover approximately 10^4 PFU/100 ml in the United States (25), whereas strain HSP40 detected approximately 10^4 PFU/ml in some geographic areas, but much lower values in other areas (18,25).

In abattoir effluents, phage numbers detected by host strain RYC 2056 range from 0 to 10^4 PFU/100 ml, but their ratios to somatic coliphages and to F-RNA bacteriophages are significantly lower when compared with urban sewage (18). Numbers in municipal sewage effluents depend on the treatment, but these phages are regularly found in wastewater effluents.

It can be concluded that numbers of the three groups of bacteriophages are fairly constant in raw sewage throughout the world, as are the numbers of bacterial indicators. Furthermore, bacteriophages of the three groups are consistently found in sewage effluents. Consequently, the three groups of phages may be considered as indexes of sewage pollution. On average, all the groups of phage are more abundant in raw sewage than most pathogens.

Studies on the abundance of bacteriophages infecting enteric bacteria in wastewater sludges (biosolids) are relatively scarce. The accumulation of bacteriophages in both primary and secondary sludges is similar to that of bacterial indicators, and the ratios of such indicators to phages do not differ significantly from those in sewage (26,27). The three groups of bacteriophages seem to accumulate in a similar manner (26). However, sludges are subjected to additional treatment before release to the environment. Phage concentrations in treated sludges depend on the treatment (26).

Bacteriophages as Indexes of Human Viruses

Somatic coliphages (28), F-specific-bacteriophages (22), and bacteriophages infecting *B. fragilis* (19) have been proposed as potential indexes of the presence of human viruses in the environment on the basis of their resemblance to human enteric viruses.

Because of the difficulty of enumerating human viruses, studies establishing a correlation between human viruses and bacteriophages are scarce. A certain degree of correlation has been reported between: (*1*) enteroviruses and somatic coliphages in water at the different stages of a water treatment plant (29), (*2*) F-specific RNA bacteriophages and enteroviruses in fresh water (31), (*3*) F-specific RNA bacteriophages and enteroviruses in shellfish (25), (*4*) F-specific RNA bacteriophages and calicivirus in shellfish (32), and (*5*) enteroviruses and rotaviruses and phages infecting *B. fragilis* HSP40 in marine sediments (33).

If bacteriophages are not isolated in all human stool samples tested and if they may originate in sites other than the human gut, there will not be an absolute and unequivocal correlation between the presence of viruses and the presence of the different groups of bacteriophages. However, taking into consideration that bacteriophages infecting enteric bacteria are always present in raw sewage that sewage constitutes the main input of fecal pollution to the environment, and that some phages behave similar to human viruses, the presence of certain phages in given numbers in waters may indicate the presence of human viruses in such waters.

Bacteriophages as Indexes of Human and Animal Pollution

Identifying the sources of fecal pollution is important for water management. One reason, although not fully supported by epidemiological studies, is the perception that there is a higher health risk associated with human fecal pollution than with fecal pollution of animal origin. But, irrespective of the health risk, tracking the origin of fecal water pollution will be a very useful tool for water managers. A range of microorganisms and chemical indicators have been examined as fecal source indicators, including phages.

F-RNA bacteriophages are divided in four main subgroups that can be recognized by serotyping. Studies with a number of isolates indicate that serotypes II and III are mainly isolated from human feces, whereas, serotypes I and IV are usually found in animal feces (34). More recently, it has been shown that the subgroups can be grouped in four main genotypes, which, with few exceptions, show overall comparability with serotypes. Probes for each genotype allow plaque hybridization, and then it is easy to study the distribution of subgroups in water samples. Subgroups II and III predominate in water samples contaminated with human fecal pollution and subgroups I and IV in animal feces and water samples contaminated with animal fecal pollution (25,35,36).

Bacteriophages infecting *B. fragilis* HSP40 are detected in samples with human fecal pollution and are practically absent in samples with animal fecal pollution (15,19), but they are very scarce in wastewater in some geographic areas (18,25). Bacteriophages infecting *B. fragilis* RYC 2056 are found at concentrations ranging from 10^4 to 10^5 PFU/100 ml in municipal sewage of very different geographic origins, and at significantly lower levels in wastewater from abattoirs (18).

More studies are needed on the ecology of these two groups of phages, but they seem to be one of the best ways

of distinguishing human from animal fecal pollution at present.

BACTERIOPHAGES AS INDICATORS

The indicator function requires that resistance to natural inactivating factors and to treatment of the indicator should be similar to or slightly greater than that of the surrogate microorganism or microorganisms. In addition, pathogens are assumed not to replicate in the aquatic environment. Model organisms should not replicate in the environment, and consequently, if there are no new contributions, their numbers in any aquatic environment are assumed to decrease.

The reduction of pathogens and model microorganisms in sewage and environmental waters, on their way from human or animal feces to humans through water and food is a complex process in which many factors interact. There are three major groups of processes:

1. Physical removal by mechanisms such as sedimentation, adsorption, and straining. These processes do not inactivate the microorganisms. They merely transfer the microorganisms to other environmental compartments (sewage sludges, sediments, soils, etc.) where they are inactivated, but from which they can return to the water.
2. Inactivation by direct or indirect effects of physical-chemical factors on the integrity of the organisms. Die-off of phages and viruses in aquatic environments is influenced by many factors, such as suspended matter, sunlight, temperature, pH, and ionic environment. The disinfectants used by man are included in this group.
3. Inactivations as a result of the biological activity of other microorganisms. Antagonistic activity and grazing by protozoa contribute to pathogen removal. The main factor that seems to affect bacteriophages and viruses is the production of antiviral substances.

The relative importance of each of these processes is determined by a great number of variables, which are also interrelated. Two major factors are time and temperature. Each of the earlier mentioned processes is directly and positively affected by time, and the great majority is also directly or indirectly affected by temperature. Removal and inactivation are more rapid at higher temperatures and increase with time.

Separate studies have indicated that there are great differences between the removal and the inactivation of seeded and naturally occurring bacteria, viruses, and bacteriophages. Hence, realistic comparisons of the behavior of the different groups of microorganisms can be made only on data with naturally occurring microorganisms. Unfortunately, extensive studies have not yet been carried out, and those already published are difficult to compare because of differences in detection methodologies. Many studies were performed with a single-seeded phage, which in addition to the shortcoming mentioned earlier may be neither the most abundant nor the most representative of a given group regarding resistance (e.g., the T-even and T-odd bacteriophages among the somatic coliphages). When possible, this article will refer to data based on changes of ratios among the different model microorganisms or simulation experiments with naturally occurring populations.

Removal and Inactivation in Nature

Sedimentation. Sedimentation of microorganisms depends on size, whether they occur singly, in clumps, or are associated with suspended solids, among other factors. In general, removal of microorganisms by sedimentation is more efficient for larger particles. But these then survive better in sediments, because they are bound to solids. However, they may be resuspended into the water column if the sediments are disturbed. Adsorption and aggregation of viruses may also occur. The tendency to be adsorbed to particles has been described to be similar for viruses and somatic coliphages (37). At least in waters with a high fecal pollution, the three groups of bacteriophages suggested as model microorganisms settle similarly (38). However, their survival in sediments is expected to depend on the type of microorganism.

Adsorption to Soil. Adsorption of pathogens and indicators to soil particles plays an important role in their removal from water as it moves through the soil. Soil type and composition, ionic environment, pH, moisture content, temperature, microorganism species, or strains all interact to affect the adsorptive capacity and die-off rate in soil of pathogens and model microorganisms.

Data on the presence of bacteriophages in groundwater and on the comparison of numbers of bacteriophages, viruses, and bacterial indicators are scarce, and most often only presence/absence is given, and consequently, results from different reports are very difficult to compare. Various studies performed across the globe indicate small and nonsignificant differences among the frequencies of isolation of the three groups of bacteriophages. Thus, in a nationwide study performed in United States, F-specific bacteriophages were more frequently isolated (18%) than somatic coliphages (7.6%) in concentrate equivalents of 4.5 L (39). F-specific coliphages were isolated 18.9%, *B. fragilis* phages 17.1%, and somatic coliphages 10.4% of time in 100-ml samples of groundwater in Spain (40).

Most model studies on the behavior of bacteriophages in soil were done with F-specific RNA bacteriophages, mostly MS2 and f2, both belonging to subgroup I. A number of studies have consistently shown that F-specific RNA bacteriophages adsorb soil particles poorly and survive better in groundwater than enteric viruses. As a result, the F-RNA phages have been recommended as an indicator of human virus transport in soil and of their presence in groundwater (41–43).

Inactivation. Susceptibility or resistance to inactivation in the environment can be estimated either by studying the ratios between the different microorganisms naturally occurring in sewage and water environments with remote pollution or through the performance of experiments that are modeled on what happens in nature.

Data available on phage inactivation in the environment frequently seem contradictory. This may be because of the fact that various phages have been studied under different experimental conditions and using diverse detection methodologies. Phages generally survive longer in aquatic environments than most bacterial indicators, with the exception of clostridia. Differences between the survival of phages and bacterial indicators seem to be greater in seawater than in fresh water, in warm water than in cold water, and in areas with abundant sunshine than in areas with scarce sunshine. Somatic coliphages and bacteriophages infecting *B. fragilis* survive better than F-specific RNA bacteriophages in most water environments, mainly in those with more inactivating power. These assertions are supported by data on relative abundance of the different groups of microorganisms in different aquatic environments (20,25,38,44–46) and by results of model experiments (24,47,48).

Data available from experiments with seeded cultured viruses and bacteriophages indicate that phage survive more similarly to human viruses than bacterial indicators (24,47).

Removal and Inactivation by Wastewater Treatment

Wastewater treatment processes, especially the biological processes, are diverse in design and operating conditions. If we consider the different bacteriophage detection methodologies used in different studies, it is not surprising that data in the literature on bacteriophage removal by wastewater treatment processes vary widely. Presumably, the bacteriophage removal rate is lower than that of bacterial indicators and closer to that of animal viruses. However, the proportion of phages removed depends on the treatment process and, in some cases, on the group of bacteriophages studied.

The removal of bacteriophages by primary treatment is usually inefficient and erratic, and data reporting ranges from 10 to 90% without significant differences in the removal rate of bacterial indicators and bacteriophages, or between the different groups of bacteriophages (49,50). However, treatment with lime shows a clear difference, because fecal coliforms, the most sensitive of the indicators suffer a 99.85% reduction, and phages infecting *B. fragilis*, the most resistant of the phages, display a 91.8% reduction (50).

Most data on secondary treatments are related to the activated sludge process. Again, available information is very variable. Pathogen and indicator reductions depend on many factors that may have a differential effect on the various pathogens and model organisms. Well-operated plants remove from 90 to 99% of bacteria and viruses (21,51). The different groups of bacteriophages are also removed in similar percentages (21,50,51).

The typical concentrations of the different indicator microorganisms in secondary effluents maintain the same relative proportion as in raw sewage.

Effluents from activated sludge plants may be further in, that is, lagoons, oxidation ponds, and wetlands; filtration, coagulation, and sedimentation; and disinfection. Lagoons, oxidation ponds, and artificial or natural wetlands may be particularly useful in warm and temperate climates to further treat secondary effluents. Again, information is very variable and partial, but in all these systems bacterial indicators are removed more efficiently than somatic coliphages (52,53). Seeded polioviruses and phage MS2 behave similarly (54). Data comparing the three groups of bacteriophages are very scarce, but all were inactivated more slowly than the bacterial indicators and the differences in their removal are smaller than differences between their removal and the removal of bacterial indicators (55).

Filtration, coagulation/filtration, and postprecipitation processes are frequently used to remove suspended solids from secondary effluents and precipitation (postprecipitation) to remove N and P compound from secondary effluents. Filtration alone has little effect on the removal of bacteria and viruses. But coagulation/filtration and (post)precipitation have a significant effect on the reduction of microorganisms, improving the removal obtained by activated sludge by 90–95%. The reduction of viruses, bacterial indicators, and bacteriophages appears to be similar (21,56).

Removal and Inactivation by Drinking Water Treatments

Most data on the presence of bacteriophages in drinking water refers to somatic coliphages. These have been isolated in tap water samples in the absence or in the presence of low levels of fecal coliform bacteria in both developing and developed countries. Many of these samples containing somatic coliphages contained residual-free and combined chlorine (1,57,58). After filtering nine samples of 20,000 liters of drinking water, no enteroviruses were isolated, somatic coliphages were isolated in two samples and F-specific RNA bacteriophages in one sample in Canada (59). In a three-year study performed in Israel on 1,136 tap water samples, the percentages of positive isolations were 0.7% for fecal coliforms, 5.6% for somatic coliphages, 7.1% for F-specific bacteriophages, and 5.0% for *B. fragilis* phages (40). In Spain, in 410 samples including finished water from a drinking water treatment plant and tap water samples the percentages were 0.5% for fecal coliforms, 1.5% for somatic coliphages, 2.2% for F-specific bacteriophages, and 5.2% for phages infecting *B. fragilis* (7,40).

Precise quantification of bacteriophage removal in drinking water plants is difficult to achieve, either because of the low levels of naturally occurring bacteriophages in source water or because of the treatment removes all the bacteriophages. Bacteriophages are more difficult to remove than coliform bacteria. Their comparative removal depends on the proportion of physical removal (coagulation, sedimentation, and filtration) and chemical disinfection. Physical removal procedures frequently used in drinking water treatment plants such as flocculation-sedimentation and filtration have little effect on removal of bacteriophages, less than 0.5 logs, in comparison with the removal of bacteria including *Clostridium* (29,58,59). Removal of bacteriophages by disinfection is greater than physical removal. Bacterial indicators are inactivated more efficiently than bacteriophages, with the exception of clostridia, which may be more resistant than phage.

Levels of the three groups of phages seem to be reduced similarly by physical removal. In contrast, their removal by disinfection depends on the procedure. The difference in the fecal coliform removal and the most resistant group of bacteriophages in a given plant may be of several orders of magnitude. Thus, prechlorination followed by flocculation removed phages infecting *B. fragilis* 1.5 logarithmic units, when fecal coliforms removal was 4.9 logarithmic units (60). The differences in the extent of removal of the different phages will be greater as the treatment plant increases in complexity and will depend on the type of disinfectant (7,59).

Bacteriophages are expected to behave more similarly to human viruses than bacteria, and many drinking water treatments provide water without fecal indicators that still contain infectious bacteriophages. It is suggested that the presence of bacteriophages of any of the three groups in drinking water indicates a potential risk of viral pollution, and bacteriophage tests have been proposed as additional criteria for drinking water safety (1).

Inactivation by Sludge (Biosolid) Treatment

Wastewater treatment generates huge amounts of biosolids, where pathogens and indicators accumulate. According to their destination, sludges receive different treatments, the most frequent being storage, digestion, and, to a lesser extent, disinfection by pasteurization, irradiation, or lime treatment.

The survival of viruses and bacteriophages in sludge during storage depends on the temperature, as occurs for human viruses. At 4 °C all survive quite well, whereas at higher temperatures F-specific bacteriophages inactivate more rapidly than somatic coliphages and bacteriophages infecting *B. fragilis*, the difference being significant at 37 °C (26).

Different kinds of digestion processes are used to reduce the amount and improve the quality of sludges. Bacteriophage f2 has been reported to survive more successfully than enteroviruses and rotaviruses to both mesophilic and thermophilic digestion (61).

Inactivation by Disinfection

Disinfection is used both in wastewater and drinking water treatment. It is in these processes that major differences in removal are given between pathogens, including different strains or types of the same pathogen, between pathogens and indicators, and between indicators themselves. Resistance of phages will only be compared with that of bacterial indicators because our knowledge of comparative resistance with respect to other pathogens such as *Giardia* and *Cryptosporidium* is very limited and because the methods to determine their viability are difficult to perform. The difference in sensitivity to a given disinfection process deduced from experiments with pure cultures, especially those seeded with the very different types of somatic coliphages, may not reflect what happens in the real world. Moreover, contradictory results comparing a given virus and a given bacteriophage, for example, f2 and poliovirus, appear in the literature. These inconsistencies probably reflect differences in the type of water, viral strain studied, and methodology used.

Chemical Disinfectants. The most widely used disinfectants for water and wastewater are chlorine, chloramine, chlorine dioxide, bromide, bromine chloride, iodine, ozone, and peracetic acid.

The available information on the effectiveness of these disinfectants are with laboratory-grown strains. Bacterial indicators, with the exception of spores of clostridia, are usually more sensitive to free chlorine than with viruses and bacteriophages. But viruses and bacteriophages differ in their sensitivity. Thus, among viruses, human rotaviruses and hepatitis A virus (HAV) rank among the most resistant and polioviruses and SA11 among the most sensitive (62). Among phages, B40-8 infecting *B. fragilis* is more resistant than MS2 and f2, which are more resistant than polioviruses (63). In the presence of 2 ppm of free chlorine, B40-8 is as resistant as HAV (62). Data on somatic coliphages are very variable, but this variability may depend on the morphological type. Thus, some of them are very sensitive and others significantly more resistant than f2 and similar to SA11 (64).

Comparative data on the chlorinated secondary effluents referring to naturally-occurring pathogens and indicator microorganisms are scarce, but in spite of the fact that they were obtained in different treatment plants and even on different continents, they show a similar pattern of inactivation. The difference of inactivation of coliform bacteria and fecal streptococci with respect to inactivation of phages is higher than in drinking water. This fact probably indicates than phages are more resistant to monochloramines than bacteria. Regarding bacteriophages, those infecting *B. fragilis* are the most resistant, followed by F-specific RNA and finally, somatic coliphages. Enteroviruses rank between F-specific RNA bacteriophages and bacteriophages infecting *B. fragilis*. Sulfite-reducing clostridia behave similar to the most resistant bacteriophages (24,65,66).

Available data on the effect of ozone on bacteriophages are scarce and contradictory. Since the aggregation state of microorganisms is a key factor in determining inactivation by ozone, data on naturally occurring viruses and phages are essential to assess the effect of ozone on these microbes. The effect of ozone in finished drinking water is difficult to measure, because usually ozone inactivates all microorganisms to such an extent that they are never detected.

Very few data exist on removal of phages from secondary effluents by ozonation and, again, they are contradictory regarding the comparative resistance of bacterial indicators, viruses, and phages. Thus, some studies indicate that bacteria are more sensitive than viruses and phages, but other studies indicate the contrary. These contradictions may be because of the fact that these studies were done with laboratory-grown microorganisms.

Radiation. Different types of radiation are used for disinfection. The most frequent are UV radiation, which is used for low-turbidity water (drinking water, secondary

effluents, shellfish depuration water, etc) and gamma and electron-beam irradiation, for water and sludges respectively.

UV radiation is extensively used for disinfecting drinking water and secondary effluents. Viruses and bacteriophages are less sensitive than bacterial indicators, although there are broad ranges of sensitivities between the strains of each group of microorganisms. Moreover, binding to suspended solids protects both viruses and bacteria. Therefore, data obtained with seeded drinking water cannot be extrapolated to secondary effluents. F-specific RNA bacteriophages are more resistant to UV irradiation than fecal coliforms, fecal streptococci, most human viruses, bacteriophages infecting *B. fragilis*, and selected somatic coliphages (63,67,68).

Few experiments have been performed with naturally-occurring phages. F-specific phages have been reported to be 2.3 times more resistant than *E. coli* in secondary effluent (67). Other studies reported removals from filtrated secondary effluents of between 2 and 3 logs for fecal coliforms, fecal streptococci and somatic coliphages, between 1 and 2 logs for F-specific RNA bacteriophages and intermediate values for *B. fragilis* bacteriophages (55); and between 1 and 2 logs for fecal coliforms, fecal streptococci and somatic coliphages from coagulated secondary effluents (69). F-specific RNA bacteriophages thus appear to be the most suitable indicator to evaluate UV radiation effects.

Gamma and electron beam radiation are slightly more effective in eliminating *E. coli* than in eliminating somatic coliphages in sewage (70). The only data comparing the different groups of phages are on phages seeded in distilled and tap water, which indicates that MS2 is more sensitive to ionizing radiation than phage B40-8 infecting *B. fragilis*, and this is more sensitive than somatic coliphage ΦX147. In this case, MS2 is as sensitive or more than *E. coli* (71).

Heat Treatment. Levels of fecal microorganisms in sludges are lowered mainly through thermal treatment, either by mesophyllic and thermophilic digestion or by even pasteurization. Bacterial indicators are more sensitive to heat treatment than viruses and phages, which in turn differ in their resistance/sensitivity to heat. Thus, bacteriophage f2 is more resistant than rotaviruses and enteroviruses, but less so than parvoviruses (61). Data comparing the resistance of naturally occurring phages of all groups to pasteurization are not available. Data available for thermophilic and mesophyllic digestion do not allow to differentiate the thermal effect from chemical effects (61).

Accumulation and Depuration of Fecal Pathogens by Shellfish

The presence of fecal pathogens and indicators in shellfish, providing there is no replication, depends on many factors, but, briefly, it is the result of accumulation and/or depuration.

There is no relationship between the levels of bacterial indicators and viruses in the water and their concentrations in shellfish, where most of them accumulate. The extent of accumulation depends on many factors, such as water characteristics, physiological status of the animal, and the identity of the microorganisms. Bacteriophages accumulate in shellfish in a similar manner (25,72,73).

Many studies have also shown differential rates of reduction of bacteria and viruses in depurating shellfish, with bacteria generally being reduced more rapidly. In depuration experiments with heavily contaminated oysters and mussels, F-specific bacteriophages are depurated much less efficiently than *E. coli* and similarly to polioviruses (74,75).

Numbers of fecal bacteria, viruses, and bacteriophages in shellfish collected in areas with different pollution levels are in agreement with the earlier assertions. All the three groups of bacteriophages are found in shellfish grown in waters with low levels of fecal pollution in amounts that indicate that they accumulate and survive longer than bacterial indicators, and more similar to human viruses (24,32,73). Data on somatic coliphages should be considered cautiously, because they may be able to replicate in shellfish (6).

CONCLUSION

Bacteriophages infecting different enteric bacteria have a number of characteristics that make them potential useful model organisms in water quality control and assessment. Three groups of bacteriophages that infect enteric bacteria are under consideration as potential model microorganisms. These are somatic coliphages, F-specific RNA bacteriophages, and bacteriophages infecting *B. fragilis*. Bacteriophages belonging to the three groups of phages are irregularly found in feces, but they are very consistently found in sewage, in numbers that usually exceed the numbers of pathogens by several orders of magnitude. Standardized methods for detecting and enumerating the three groups of bacteriophages are presently available. Methods for detecting and enumerating bacteriophages are simple and can be carried out by any well-trained microbiologist. They do not need sophisticated equipment and can be performed in standard routine microbiology laboratories. They are relatively inexpensive and definitive results can be obtained quickly.

Bacteriophages had been proposed as indicators of the presence of fecal pollution, sewage, human viruses, and human and/or animal fecal pollution. If bacteriophages are not found in all stool samples and if bacteriophages have a chance to originate in other sites than gut, there will not be an absolute and unequivocal correlation between the presence of bacteriophages and the presence of fecal pollution, sewage, human viruses, and human and/or fecal pollution. However, if bacteriophages are always present in sewage, and if sewage, raw or treated, constitutes the main input of fecal pollutants into the environment, the presence of given numbers of certain bacteriophages in waters will indicate the likely presence of the surrogate fecal microorganism or microorganisms.

Moreover, bacteriophages may be used to indicate the behavior of pathogens other than bacteria during the processes of removal and inactivation in nature, water,

and sludge treatment processes. In general, the behavior of bacteriophages resembles more to the behavior of persistent pathogens (i.e., animal viruses and protozoa) than the behavior of currently accepted bacterial indicators, although different groups of bacteriophages show different degree of persistence to different removing processes and resistance to different inactivating factors.

Each one of the three groups of bacteriophages proposed as model organisms has advantages and drawbacks. Somatic coliphages are the most abundant, and the method for their detection and enumeration is the most simple and fast, with results available in one working day. On the other hand, they are a heterogeneous group with important differences in resistance to inactivation among its members, and it has been reported that they may replicate outside the gut. This fact is without any doubt the main shortcoming of somatic coliphages. However, the contribution of this potential replication in the different water environments has never been quantified. Because of the ease of the method for their detection and their abundance, this potential contribution should be estimated before rejecting them as model organisms for water quality control.

F-specific RNA bacteriophages rank second in abundance and they are a homogeneous group. The method for detecting them is simple and fast, although not as much so for the somatic coliphages. They offer good perspectives as index organisms for viruses in groundwater and to monitor some water treatments, for example, UV disinfection. On the contrary, their persistence in surface waters, mainly in moderate and warm climates, seems low, and their resistance to some inactivating treatments is low or intermediate as compared with persistent virus or protozoa.

Bacteriophages infecting *B. fragilis* rank third in abundance. They are a homogeneous group. They are more resistant than the other groups of phages to most inactivating factors and treatments and they do not seem to be able to replicate outside the gut. The method for their detection requires anaerobiosis and results are available only after 18 hours. Their low numbers constitute their main drawback.

In view of the present knowledge, it seems unlikely that we can find a single group of bacteriophages fulfilling all the requirements to be used as an universal indicator, but this seems to be true for all the potential microbial indicators. Now that standardized methods are available, more research in the ecology of these groups of bacteriophages should be done to guarantee the best choice for the various potential applications of bacteriophages as model microorganisms.

BACTERIOPHAGE: BIOLOGY AND GENETICS

SCOT E. DOWD
USDA-LIRU
Lubbock, Texas

Bacteriophages (phage), by definition, are viruses that infect bacteria. In general, phages have a proteinaceous outer shell with an inner core containing their genetic material. They usually infect a host bacterium by attaching to the bacterial cell via specific host receptor proteins and injecting their nucleic acids into the bacteria. The phages then use the chemical energy and biochemical machinery of the host to produce new phage particles. The phage is ultimately released from the bacterial cell by budding or extrusion from the plasma membrane or even complete lysis of the host cell. Phages are in most instances, host-specific, with particular phage infecting only certain bacterial species. Since their discovery in 1915 by the British investigator Frederick W. Twort, and the introduction of the term *bacteriophage* by Felix Hubert d'Herelle (1), bacteriophage have become important tools, not only in the studies of bacterial genetics and cellular mechanisms but also in the field of environmental microbiology. Similar to other disciplines, phage are used primarily as models or surrogates to assess the fate of pathogenic human enteric viruses, as pathogen indicators, as vectors for transport of genetic information, and even as biocontrol agents.

Unlike molecular biology that makes use of the phage as tools for genetic engineering, environmental microbiologists more often use phage such as MS2, PRD1, and PhiX174, which structurally and biochemically resemble human pathogenic enteric viruses, such as *Poliovirus*. These spherical bacteriophage are used as indicators or model viruses not only because they have similar size and shape to important human pathogenic viruses but more importantly because they are much easier and less expensive to assay. The coliphage MS2, in particular, has been used extensively as an indicator and model for enteric viruses such as *Poliovirus*, which is a member of the *Picornaviridae* family. Table 1 lists

Table 1. Comparison of the Phage MS2 and the Enterovirus Poliovirus

Feature	MS2 *Leviviridae*	*Poliovirus* *Picornaviridae*
Particle		
Weight (Mdalton)	3.9	8–9
Diameter (nm)	24	27[b]
Isoelectric point	~3.9	~8.2[a]
Major capsid proteins, number	1	4
Symmetry	Icosohedral	Icosohedral
Enveloped	None	None
Triangulation number	T = 3	T = 1
RNA		
Sense (positive sense acts as mRNA)	Yes	Yes
Molecular weight (Mdalton)	1.2	2.5
Monocistronic	No	Yes
Overlapping genes	Yes or No	No
Replication form infectious	No	Yes
Multiplication		
Translation sequential	Yes	No
Cleaved precursor	No	Yes
RNA enters preformed capsid	No	Yes

some of the similarities and differences between MS2 and *Picornavirus*.

Many of the specific areas where phages are important in the field of environmental microbiology are covered in other entries of this encyclopedia and therefore will only be mentioned briefly in this entry. The main purpose of this section is to describe the basics of bacteriophage structures, taxonomy, and genetics. This section concentrates on the spherical coliphage MS2 and the tailed lambda phage. The lambdoid phage may be important in environmental exchange of genetic material between bacteria, which could be important in many disciplines within environmental microbiology including bioremediation, in which the transport and exchange of genetic material can help to increase the ability of naturally occurring bacteria to metabolize pollutants. The lambdoid phage may also prove to be important in the environment, where genes encoding virulence factors such as Shiga toxin and antibiotic resistance may be transferred from one bacterium to another. Such events could create a potentially pathogenic strain from an otherwise innocuous variety.

TERMINOLOGY

Basic terminology for virus and phage include the following:

Capsid	The protein shell that encloses and protects the nucleic acid of the phage
Structural units	The smallest functional equivalent building units of the capsid
Nucleocapsid	The capsid together with its enclosed nucleic acid
Virion	The complete infective virus particle

These structures are highlighted in Figure 1.

TAXONOMY

The International Committee on Nomenclature of Viruses was established in 1966 to develop classification schemes for viruses and phages (6). Since its establishment, there has been dispute over the taxonomic systems proposed by the committee. One such system acts as an all-embracing scheme for the classification of viruses and phages into subphyla, classes, orders, suborders, and families (Table 2). In this type of scheme, descending hierarchical divisions would be based on characteristics such as nucleic acid type, capsid symmetry, and presence or absence of an envelope. Although the debate over classification schemes continues, David Baltimore (7) devised a scheme for classification of viruses and phage, which is now coming to be widely accepted. This scheme is based on the relationship between the viral or phage genome and the viral or phage mRNA. Table 3 shows the major families of bacteriophage grouped according to the Baltimore scheme.

The taxonomic nomenclature used to describe bacteriophage is different from that used in the naming of animal and plant viruses. Animal and plant viruses are typically named in one of three ways: (*1*) after the disease; (*2*) after the discoverer of the virus; or (*3*) after the location where the virus was discovered. Viruses are also classified at the family (*-viridae*), genus (*-virus*), and species level.

Originally, bacteriophages were only classified into families. Exceptions now exist to this rule. Phages unlike plant and animal viruses are named exclusively with numbers and letters. For instance, PhiX174 was the 174th virus characterized in the 10th group of a large set of phage being classified, with phi (ϕ) being the symbol that stands for phage. For instance, three genuses *Chlamydiamicrovirus*, *Microvirus*, and *Spiromicrovirus* are grouped into the family *Microviridae*. The *Leviviridae* are not only broken down into genuses but subgroups as well. In the past, classification of the *Leviviridae* was based on serotyping, so classification schemes based on six serogroups also exist. In the National Center for Biotechnology Information's GenBank (October 1999), the genera designations *Allolevivirus* and *Levivirus* are listed under *Leviviridae* along with their serogroupings. Bacteriophage taxonomy continues to develop, mainly assisted by the rapid development of genetic sequencing technologies. For instance, the genome of a typical phage can reasonably be determined in a matter of

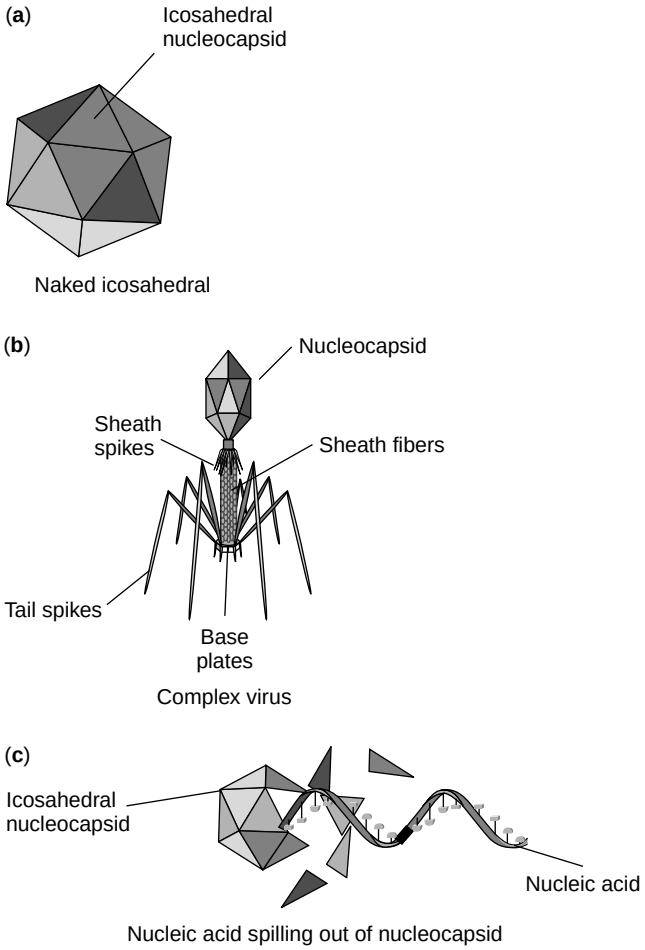

Figure 1. Schematic view of general bacteriophage and virus structures. (**a**) Naked icosahedral structure, which is the basic shape of many phage including *Leviviridae* and *Microviridae*. By definition, an icosahedron is composed of 20 facets, each shaped as an equilateral triangle, 12 vertices, 6 fivefold axes of symmetry passing through the vertices, 10 threefold axes extending through each face and 15 twofold axes passing through the edges of an icosahedron. Caspar and Klug (1962) later defined all possible polyhedra by determining that because an icosahedron has 20 equilateral triangular facets, each of which is identical, there must be 20 T structure units, where T is the triangulation number given by the rule: $T = Pf^2$, where P is any number of the series 1, 3, 7, 13, 19, 21, 31 and f is any integer. Typically, for viruses the P value is 1 or 3. Morphological units can be clustered as 20 T trimers, 30 T dimers, or considered individually as 60 T monomers. (**b**) Represents a complex structure such as *Myoviridae* possess. Indicated in this figure are the major features such as the tail spikes and base plates. (**c**) Represents a nucleocapsid with the nucleic acid spilling out.

days. Similarly, improvements in other molecular and biochemical techniques are continuing to provide tools that allow for structural and topological characterization of viruses and phages at the angstrom level of resolution.

STRUCTURE AND PATHOGENESIS

The architecture of bacteriophages and viruses in general is an elegant molecular structuring of protein subunits,

Table 2. Phage Families and Genera of Bacteriophage

Major Bacteriophage Families	Genus Example	Examples of Species (Host Organisms)
Myoviridae	*Myovirus*	• T4, T2, T6, Wphi, P2, 186, Ac3, Acm1 •(*Escherichia coli*), • PBSX, PBS2, beta22, 2C, (*Bacillus* spp.), • S-WHM1, S-PM2, N1 (Cyanobacteria), • PSP3 (*Salmonella* spp.), • Twort (*Staphylococcus* spp.), • RL1RES, RL2RES (*Rhizobium leguminosarum*), • HP1, S2, HP1 (*Haemophilus influenzae*), • A118, A500, A511 (*Listeria monocytogenes*),
Siphoviridae	*Siphovirus*	• Lambda, 21, T5−933W (*E. coli*) • A118 (*Listeria monocytogenes*) • B40−8 (*Bacteroides fragilis*) • FC1 (*Enterococcus* spp.) • phi-41 (*Lactococcus lactis*) • phi-C (*Staphylococcus aureus*) • psiM2 (*Methanobacterium thermoautotrophicum*) • SFI11 (*Streptococcus thermophilus*
Podoviridae	*Podovirus*	• T7 H-19B, N4, (*E. coli*) • phiAAU2 (*Arthrobacter aureus*) • B103, phi29, H1, NF, Phi-15, Phi-29, (*Bacillus* spp.) • Cf16 (*Xanthamonas campestris*) • Cp-1, CP-7 (*Streptococcus pneumoniae*) • K11 (*Klebsiella* spp.) • Kvp18 (*Kluyvera* spp.) • LP7, P22, PS119 (*Salmonella* spp.) • Phi-13 (*Staphylococcus aureus*) • Phi H (*Halobacterium salinarium*) • Phi-vML3 (*Lactococcus* spp.) • P1 *Mycoplasma* spp.) • phage V, Phage X (*Shigella flexneri*)
Microviridae	*Microvirus*	• PhiX174, G4, S13, ST-1, U3, alpha 3, G14, PhiK (*E. coli*, *Salmonella* spp., *Shigella*) • PhiCPG1 (*Chlamydia psittaci*)
Corticoviridae	*Corticovirus*	• PM2 (*Alteromonas* spp.) • O6N-58P (*Pseudomonas*)
Tectiviridae	*Tectivirus*	• PRD1 (*E. coli*, LT2, *Acinitobacter* spp., *Pseudomonas*, and *Vibrio*), • PR3, PR4, PR772, L17 (*E. coli*) • AP50 (*Bacillus anthracis*)

which provides the basis for infectivity, specificity, and self-assembly. The requirements of self-assembly and host infection specificity have generated a remarkably wide array of phage viroid structural organization and geometric designs. Nevertheless, certain common features and general principles can be applied to most phages.

The description by Watson and Crick of the molecular structure of DNA (8) was followed by yet another macromolecular structural elucidation. Crick and Watson (9) reasoned that the small genomes of viruses could encode for only a few proteins from which they had to build their protein shells. They predicted that to use identical subunits to construct such a shell, it would, by necessity, possess a cuboidal symmetry. These predictions were later confirmed in principle and the basic symmetrical structure of viruses were shown more precisely to be icosahedral. Although not the only shape employed, an icosahedral structure is utilized by a wide variety of bacteriophage and animal viruses. The basic shapes of bacteriophage are schematically depicted in Figure 2, and, Table 4 lists the structural properties for the various phage families. In addition to the variety of structural types found among the various bacteriophage families, there is also a variety of nucleic acid types. Table 5 provides information on the nucleic acids for the various bacteriophage families.

Morphologically, phages can be classified into several groups:

1. Naked icosahedral such as MS2virus, and phiX174
2. Naked helical such as Xf2, Pf1, and v6
3. Enveloped icosahedral such as phi6
4. Enveloped helical of which there are no known bacteriophage
5. Complex such as T4 and lambda

PATHOGENESIS

Bacteriophage can be considered pathogenic to bacteria and thus they follow infection processes common to viral pathogens, including attachment, penetration, and release. Table 6 provides information on the pathogenesis variables of phage families.

Table 3. Baltimore Classifications for Bacteriophage

Kind of Genome	Single- or Double-stranded	Genome Sense (if single strand)	Naked or Enveloped	Families
RNA	SS	Positive	Naked	*Leviviridae*
			Enveloped	N/D
		Positive but reverse-transcribed	Enveloped	N/D

BASIC GENETICS OF RNA AND DNA PHAGE

Because of the relatively simple genomes, rapid replication, simple assay procedures, and ease of manipulation, early bacteriophages such as lambda became the favorite tool of many molecular microbiologists. Phages also allowed for genetic manipulation of their hosts, quickly becoming a necessary tool for molecular microbiologists. Because of their utility and the need for basic understanding, bacteriophage genetics was quickly unraveled and now serves as a model for genetic control and as a mechanism for protein expression. In this section, we will

describe the genetics of two bacteriophages: MS2, a single-stranded RNA coliphage, and lambda, a double-stranded DNA coliphage.

RNA Phage: MS2

As noted earlier, MS2 is physically similar to the enteroviruses such as *Poliovirus*. Because of this and its easy assay procedures, MS2 soon became the classic model of choice of environmental microbiologists in disinfection and survival experiments such as aerosol or groundwater viral survival and UV exposure modeling. MS2, or more precisely the F+ coliphage of which MS2 is the model organism, have also been used extensively as indicator viruses. Indicators are nonpathogenic microorganisms whose presence in an environmental sample indicates that human pathogens may also be present.

As mentioned, MS2 is a small, icosahedral bacteriophage containing a single-stranded linear RNA molecule. The MS2 capsid is composed of a single protein except for a single copy of an accessory protein known as the A-protein (maturation protein). MS2 is a male-specific phage that usually infects F^+ or *Hfr* strains of *E. coli*. F+ refers to bacteria that possess the F-plasmid, which encodes for the F-pilus, a conjugation structure that allows for transfer of genetic material between two bacteria. MS2 attaches to the sides of the pilus using the A-protein and injects its genetic material into the hollow conjugation tube, allowing migration of the phage RNA up through the conjugation tube into the host bacterium.

Because the RNA of MS2 is coding sense (positive-stranded RNA), it serves as its own mRNA, and once it gains entrance to the cytoplasm of the host bacterium, it can immediately begin production of a new phage. MS2 codes for four known proteins, the coat protein, the A-protein (maturation protein), the replicase protein, and the L protein (lysis protein). Figure 3 shows the genetic map of MS2 indicating the relative positions of these genes. Two of the genes are coded within one reading frame, while the second two are coded in another. To further conserve on the size of the genome, the L-protein's reading frame overlaps with that of the coat and the replicase proteins.

Fiers and coworkers (10) were the first to determine the complete sequence of the 3,569 ribonucleotide bases of the MS2 genome. Even if the sequence information, mapping of open reading frames, and the RNA polymerase binding sites is given, the regulation of the genome and

Table 6. Pathogenic Characteristics of Bacteriophage

Phage	Host Adsorption Site	Virus Attachment Structure	Localization of Infection	Release Method
Tailed phage	Cell wall, capsule, pili, flagella, Surface protein	Tail	Nucleoplasm periphery	Lysis

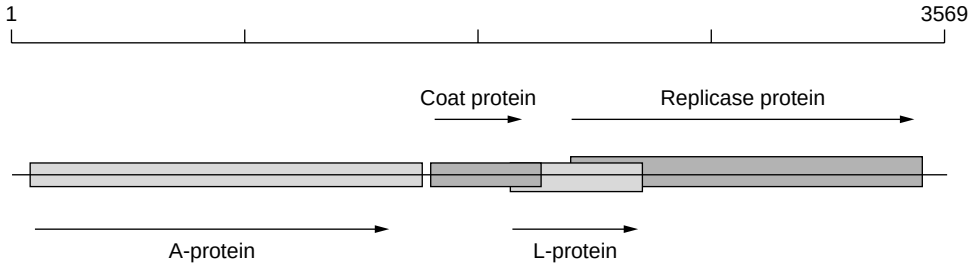

Figure 3. Schematic view of the MS2 genome showing the four encoded proteins. Note that there are two open reading frames that overlap. The replicase gene overlaps the lysis (L) protein and the L-protein overlaps the coat protein. The assembly (A) gene does not overlap with any of the other genes. The arrows indicate the reading direction of each gene and the scale at the top indicates the relative length of the genome.

its four encoded proteins is still difficult to understand without an understanding of the secondary structure of the MS2 genome. It is the secondary structure that actually controls expression of the four encoded proteins. By using secondary structure to control expression levels of individual proteins, the MS2 genome adds elegance and economy, forgoing the need to encode for additional regulatory proteins that would increase the size of the genome. Regulation is accomplished through a process known as translational coupling. Translational coupling refers to a gene arrangement in which the translation of one protein coding sequence on a polycistronic mRNA (coding for more than one gene) is required for the translation of the second downstream or upstream coding sequence.

To grasp the concept of how MS2 uses the secondary structure of its RNA, it is important to realize that ribosomes, which translate the MS2 RNA genome into proteins, have an inherent ability to relieve mRNA secondary structure (disrupt hydrogen bonds). However, this can only occur when the ribosome is bound to mRNA and actively moves along during scanning or translation. Thus, ribosomes are unable to relieve secondary structure before binding and scanning. Thus, nucleic acid secondary structure of mRNA can prevent initiation of macromolecular synthesis but does not inhibit initialized synthesis (11). This regulatory system based on secondary structure controls the production of the A-protein (attachment/maturation protein), the replicase protein, and the L-protein (lysis protein) of MS2. The fourth protein is the coat protein, which is for the most part freely transcribed as it is needed in higher concentrations than the other proteins.

In the case of the A-protein, its coding region is preceded by an untranslated leader of 130 nucleotides, which folds into a cloverleaf, (three stem-loop structures) covering the A-protein's translation initiation region. Thus, as the coat protein is translated and the ribosome moves into the coding region of the A-protein, the cloverleaf structure is dissolved exposing the A-protein ribosomal binding site, allowing binding of a ribosome and translation of the protein. Groeneveld and coworkers (12) indicated that translational starts of the A-protein gene only take place before reannealing of the cloverleaf structure and after translation of the capsid protein.

The replicase protein is required for the formation of the negative-strand template RNA. Replication of phage RNA into a negative strand is a necessary process for the phage to generate its genome. The replicase and three host-derived proteins combine to form a holoennzyme, which converts positive-strand RNA into negative-strand RNA (RNA-dependent RNA polymerase). These negative-stranded RNAs are then converted back into positive-stranded (original sense) RNA genomes, which are packaged into capsids during maturation of the phage. Similar to the A-protein, the expression of the replicase also is controlled by the RNA tertiary structure and translation of the coat protein, although the replicase is located downstream of the coat protein. Thus, as the coat protein is translated and the ribosome dissolves the secondary structure around the coat protein termination site, it exposes the ribosomal binding site of the replication enzyme, allowing for its translation.

The L-protein is encoded in a different reading frame than the coat protein. In addition, the reading frames of these two proteins overlap. Thus, after the ribosome completes translation of a coat protein and relieves the secondary structure that obscures the L-protein initiation site, it is required to release the mRNA, move backward (upstream) to the now exposed binding site of the L-protein, and initiate translation in a new reading frame. It is reasonable to assume that if the ribosome does not quickly find this new open reading frame, or it diffuses in the wrong direction after release from the stop site of the coat protein that the secondary structure (hairpin loop) that blocks translation, can quickly reform (13). Thus, RNA secondary structure regulates translation of the L, A, and replicase proteins and represents the primary form of repression, that ensures the proper balance protein expression.

This mechanism of genetic regulation may be more important for the L-protein than for the A or replicase proteins, as a premature accumulation of the L-protein would cause lysis of the host cell before sufficient coat protein has been made and all phage effectively packaged. In essence, overexpression of the lysis protein lowers the burst size (number of phage produced per bacterium). By nature, the binding affinity for the polymerase is relatively low at the L-protein ribosome binding site. Decreasing this affinity further can also delay or even

prevent accumulation of the L-protein, which in turn can inhibit subsequent lysis of the host cell (11).

Competition for ribosomes is another control method used during translation of A, L, and replicase. The ribosome leaving the coat protein gene can only bind to one of these additional protein genes. Thus, competition for ribosomes represents yet another level of control (11). Three levels of expression control in MS2 include the RNA secondary structure, consensus of ribosome binding sites, and competition for ribosomes during or after translation of the coat protein ensures that proper ratios of the other three proteins encoded by MS2 are achieved.

It is interesting to note that MS2 can self-assemble in vitro with no special enzymatic process involved (14,15). During this maturation process, the coat proteins accumulate around the positive-strand RNA, and the capsid shape begins to form automatically. Finally, the A-protein is added at one end and the virion is completed. The A-protein is required in the mature phage for attachment to the host pilus during infection and injection of the genetic material. At this point during the phage life cycle, sufficient L-protein has accumulated and the cell wall of the host is considerably weakened. As the strength of the wall is compromised, water tension causes the eventual bursting of the host cell and release of the now complete phage particles (11).

DNA Phage: Lambdoid Phage

Andre Lwoof discovered lambdoid phage at the Pasteur Institute, Paris, France. He discovered that certain isolates of *Bacillus* spp., when exposed to ultraviolet light, ceased dividing and then burst open, releasing hundreds of bacteriophage particles. Later in collaboration with Jacob and Monod, he showed that these bacterial strains carried the bacteriophage in a dormant form, termed a *prophage*, and that the phage could be induced to switch from the lysogenic (nonproductive) to the lytic (productive) cycles. Lambda has since become one of the most studied and best understood models for genetic control. Even today, many of the intricacies of the genetic control of lambda are still being elucidated. The genetics of lambda has been extensively studied and provides a valuable model for regulatory control of gene expression.

Similar to MS2, the lambdoid phage can infect *E. coli*, replicate, synthesize new phage, lyse the host cell, and release progeny phage as part of a lytic growth cycle. Unlike MS2, however, lambda can also infect the bacterial cell and its DNA and can then become integrated in the host cell's genetic material, where it is propagated as a part of the bacterial chromosome. Whether the lambdoid phage enters the lysogenic cycle or the lytic cycle is dependent on many factors including the health of the host cell and the multiplicity of infection (MOI). In the case of the discovery of the phage, Lwoff had exposed the host bacteria to UV light, which ultimately signaled the lysogenized phage that its host was in danger. In response to the signal, the lysogenized phage was induced into the lytic cycle. Many forms of stress send signals to the lysogenized phage causing it to leave its dormant stage and enter into a lytic cycle. In the event that the host cell is in a vegetative state, the lambdoid phage does not receive the required stress-related signals and remains incorporated in the host genome. In either case, whether the phage goes into a lytic cycle or stays in the lysogeny cycle, the phage is still able to ensure its own survival and propagation, making it a very successful parasite of *E. coli*.

Structure. The lambdoid phages are considered "complex," meaning that in addition to their icosohedral capsid (which is like MS2's capsid), they also possess an additional tail-like structure that is used for attachment of the phage to the host cell during infection. The more complex structure of a lambdoid phage can be contrasted to the simple structure of the MS2 capsid (Fig. 2). The lambdoid virion has an isometric head with two major capsid proteins, E and D, two minor proteins B and C, and portal proteins W and FII. The capsid is attached to a long flexible tail composed of several proteins, culminating in a single fiber of J, which recognizes the outer membrane, maltose porin protein LamB (2,3).

The genetics of bacteriophage lambda is well known, and most of this section will deal with the prototypical lambda phage genetics. Lambda has a genome of about 46 kb. In the capsid, the lambdoid chromosome is a linear dsDNA molecule usually with 12 nucleotide ssDNA cohesive ends. Table 7 provides the major genes found in lambda phage along with the function of the encoded proteins.

Early Infection. Relying on diffusion, as opposed to any directed locomotion or motility, the lambdoid bacteriophage attaches to the LamB receptor protein, which is located in the bacterial cell outer membrane and which was later discovered to be the maltose porin. LamB protein is responsible for transporting maltose from the environment into the cell. Following contact between the J-protein on the tail of the lambdoid phage and the host cells LamB protein, a conformational change results in the injection of the phage DNA through the core of the hollow tail structure, through the LamB core, and ultimately into the cytoplasm of the host cell. On entry into the bacterial host cell, the linear genome circularizes as the complimentary

Table 7. Major Proteins Encoded by Lambdoid Phage

Genes	Function
nul, A	DNA packaging
W, B, C, D, E, FII	Head formation
Z, U, V, G, T, H, M, L, K, I, J	Tail formation
int, xis	Integration, excision
exo, bet, gam	Recombination
cIII	Stabilization of cII
N	Early antitermination
cI	Repression (primary)
cro	Repression (secondary)
cII	Turn on cI, *int*
O, P	Replication
Q	Late antiterminator
S, R, Rz	Lysis

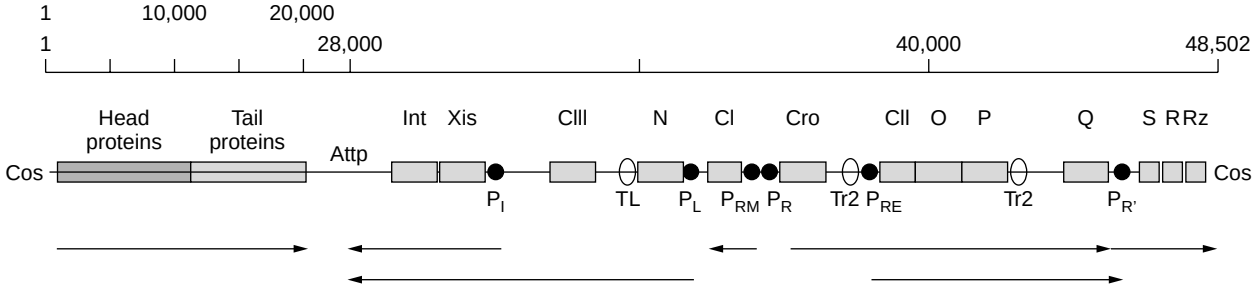

Figure 4. Schematic view of the lambda genome showing the major genes associated with the control of the lysogenic or lytic decision. To the left end of the genome, the bp scale indicated on the top of the figure is condensed to provide clarity to the early genes. Arrows toward the bottom indicate the direction of transcription, which originates from promotors (P). The genome is laid out as it would be in the nucleocapsid before the sticky ends (cos) join after entry into the host. Note the location of the attP site where integration with the host genome occurs.

3′ overhanging cos sites (sticky ends) present on each end of the phage genome hybridize with each other and are sealed by DNA ligase to form a circular genome.

During early infection, several components contribute to the decision of whether the phage will enter the lytic or the lysogenic cycle. These components include three promoters (P_L, P_R, and P_{Rm}), two operators (O_L and O_R), and a group of regulatory proteins (cI, cII, cIII, cro, and N). The location of these components on the phage genome can be seen in Figure 4. An introductory overview of these factors is as follows:

- P_L, P_R, and P_{Rm} are promoters responsible for transcription.
- O_L and O_R are regulatory protein binding sites.
- cI is the major regulatory protein and is transcribed from two different promoters (P_{Rm} and P_{RE}). cI represses transcription from P_L and P_R but allows transcription from P_{Rm}.
- cII and cIII encode activator proteins, which cooperatively bind DNA regulatory sites and enhance transcription of the cI gene from P_{RE}.
- cro is a repressor, which competes with cI to bind the O_R sites.
- N encodes an antiterminator protein, which acts by replacing rho factor for host cell RNA polymerase. It modifies host RNA polymerase activity and prevents termination at the termination sites (T_L, T_{R1}, and T_{R2}).

After circularization of the phage genome within the host cell, the bacterial genetic machinery, considering the newly introduced circular DNA to be "self," begins transcription and translation from the phage genome. As can be seen from Figure 4, this primarily results in the production of three proteins. Transcription and translation from P_R (rightward) leads to production of cro, with transcription termination at the right transcription terminator site (T_{L1}). Transcription and translation from P_L (leftward) leads to production of N and termination at the right transcription terminator site (T_R). There is also a lower level of transcription and translation of cI originating from P_{Rm} (leftward) because P_{Rm} is a weak promoter (16).

Thus, N, cro, and to a lesser extent cI are produced in the cell soon after injection of the phage DNA. The N protein is an antiterminator, which associates with the terminators T_L, T_{R1}, and T_{R2} and consequently allows transcription of longer mRNA. Additional phage proteins are transcribed once sufficient N is produced, including cII from rightward transcription and cIII from leftward transcription. The N protein performs its antitermination function through a complex interaction with several host proteins, RNA, and the host RNA polymerase. Thus, there was an increase in the concentration of N, cro, cI, and now the production of two new proteins, cII and cIII. These events lead the bacteriophage to the next stage in the Lambda infection termed the *decision-state*.

Making the Decision Between the Lytic and Lysogenic State. At this point in early infection, lambda must make the choice between a lytic and a lysogenic cycle. The decision is controlled by the regulators and operators of lambda, but is ultimately decided by the environment and consequently by the physiological state of the host. For example, if the host is experiencing any stress such as DNA damage, starvation, and so forth, the lytic pathway is favored. In other words, if the host has been damaged by radiation from ultraviolet light or is experiencing a limited supply of a growth factor such as tyrosine, the phage presumably decides to move onto a more suitable host. Recent research has revealed that the regulatory molecule responsible for the lytic-lysogenic signal may be Guanosine tetraphosphate (ppGpp) (17), which is a nucleotide that is synthesized by *E. coli* cells in response to amino acid or carbon source starvation. Too low and too high levels of ppGpp resulted in less efficient lysogenization. If the host is growing, and more importantly, dividing normally and has not been exposed to any harmful chemicals or DNA-damaging radiation, the phage considers the bacteria to be a good host, and the lysogenic cycle is more likely to be chosen. Lambda makes this decision using a very elegant mechanism of genetic balance among operators, promoters, and regulatory proteins, centered around the intracellular levels of the cI protein. If the phage can produce sufficient cI before too much cro is built up, it will

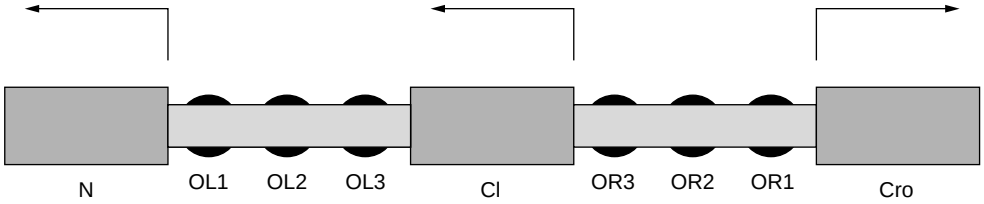

Figure 5. Schematic view of the focal area of the operator sites to which cro and cI bind. Arrows indicate the direction of transcription. O_L and O_R both have three binding sites for cI, and each binds one cro or cI dimer as described in the text. As indicated in the text, cI first binds to O_{L1} and O_{R1} and then to the other operator sites in a cooperative manner. The carboxy-terminal domains of the repressor (cI) dimers mediate this cooperativity. Cro has the opposite affinity binding first to O_{R3}, which represses transcription of P_{RM}.

enter lysogeny. The phage genome will be integrated into the bacterial genome as a prophage. If too much cro is produced before cI reaches the critical level, the cell enters the lytic cycle, resulting in expression of phage structural genes, replication of the phage genome, production of mature phage, and lysis of the host cell.

Cro and cI compete for binding sites on O_R. This is the operator that ultimately decides the fate of the bacteria and the bacteriophage. Two properties of the O_R region enable it to provide sensitive regulation of the phage life cycle. First the O_R region has three binding sites for cI or cro, which from left to right are termed O_{R3}, O_{R2}, and O_{R1} (Fig. 5). Secondly, cro and cI, while they bind to the same locations on the O_R, do so with different affinities for different binding sites. The cI repressor binds with affinity $O_{R1} > O_{R2}$, $>O_{R3}$; binding of cro is with an affinity O_{R3}, $>O_{R1}$, $>O_{R2}$. Occupancy of sites O_{R1} and O_{R2} by cI facilitates the constitutive production of cI from P_{RM} as required for lysogenic growth, while precluding transcription of cro from P_R. Similarly, cro bound to O_{R3} inhibits transcription of cI from P_{RM}.

Transcription of cI originating from P_{Rm} by itself cannot compete with the transcription of cro during early infection. If the levels of cro reach a threshold level before cI is able to turn off its synthesis by binding the O_R sites, then the phage becomes committed to the lytic cycle. There is, however, a very strong cascade of genetic events and kinetic reactions, which tip the balance back toward cI if cellular conditions are adequate (18). For instance, proteins cII and cIII assist cI in at least two ways: they stabilize and protect cI from degradation by host proteases such as RecA and they interact with two additional promoters on the lambda genome (P_I and P_{RE}) (19,20). P_I is the promoter in charge of the proteins needed for lysogeny (int and xis) and P_{RE} is important in the decision-state of lambda. P_{RE} is located just downstream to the left of the cII gene and controls leftward transcription of a cro antisense RNA and the cI mRNA (positive-sense). Thus, additional cI is transcribed from P_{RE}, which becomes a stronger promoter when associated with cII/cIII (21,22), which stabilizes cI and is thought to be the sensory molecule for multiplicity of infection (MOI). MOI is the number of phage that infect a cell at one time. It has been observed that a high multiplicity of infection enhances the expression of the cIII and cII genes, progressively delays lysis time, and increases the rate of lysogenization (23).

Lysogenic Decision. Lysogeny in lambda is characterized by events that lead to integration or incorporation of the lambda genome into the host chromosome. Integration is accomplished through site-specific recombination between the lambda genome and the host chromosome. A lambda-encoded recombinase enzyme known as integrase (Int) mediates the recombination event. Int, together with several host and phage accessory proteins, inserts the phage genome into the host chromosome using specific sites in both genomes known as attachment sites (att) (24). The attachment sites on both genomes, attB for the bacteria and attP for the Phage, share 15 bp of identical sequence. It is important to realize that even during optimum environmental conditions, a substantial fraction of lambda enter the lytic cycle. Some conditions, such as high multiplicity of infection or the presence of divalent cations or cyclic AMP can increase the proportion of cells that go toward lysogeny.

Thus, in what may be considered a rare occasion when the concentration of cII builds up, transcription of cI is enhanced and intracellular levels of the cI repressor protein rise in relation to cro lambda enters the lysogenic cycle. The cI protein binds to O_R and O_L, preventing transcription of all late infection (structural, reproductive, lysis) phage genes from the early promoters P_L and P_R. At this point, the level of cI protein is maintained automatically by a negative feedback mechanism at P_{RM}. Protein cII, during the time when it successfully upregulated expression of cI, also turns on the promoters that control the prophage *int* gene (25).

Integration is very efficient and requires no external energy sources. As the lambda DNA and the host chromosome come together, they form an integration complex, which mediates synapsis and strand exchange. The integration complex consists of the attB, attP, the bivalent DNA binding protein Int, and host proteins. The host proteins include DNA gyrase, which introduce negative supercoils into DNA (26), integration host factor (IHF) that bends attP DNA (27,28), and Fis, which assists in integration (29). Int cleaves each strand at attB and attP, creating strand exchanges by joining broken ends from each (30). Following the initial exchange, there is a "resolving" exchange between the other two DNA strands, resulting in an integrated phage genome.

At this point, the genome of the prophage is almost completely shut down. The cI protein has accumulated and is bound to the operator sites on the phage genome.

There is a balancing act between cI production from the P_{RM} promoter and the normal degradation of cI by the host. As long as cI is the only protein being expressed from the phage genome, the result is a lysogenized *E. coli* bearing an integrated lambda prophage (31).

Lytic Decision. In order to enter the lytic growth cycle, cro must bind to the three operator-sites in O_L and O_R, repressing all transcription from P_L and P_R. This binding ultimately prevents expression of N, which consequently prevents expression of cII and cIII. Thus, cro turns off all early gene expression. During early infection, the transcript from P_L, which produces cro and cII, also produces three other proteins, which accumulate in the host. O, P, and Q proteins are essential for the development of the lytic cycle. Q is an antiterminator, which allows RNA polymerase to override the termination signal downstream of $P_{R'}$ so that it can transcribe the lysis genes (S, R, and Rz) and the structural and accessory genes (Nu1, A, W, etc.). O and P are utilized for replication of the phage genome. Thus, at the point where the lytic decision for the phage genomic DNA replication is well under way owing to the background levels of the O and P proteins, the copy number of late genes available for activation is increased.

Replication of the lambda genome early in the lytic cycle is bidirectional (Theta-form replication) and initiates from an origin within the *O* gene. Protein O recognizes the four 19-bp palindromes of the origin and protein P binds to the host-derived primase DnaB, recruiting it into the replication complex. Ultimately during viral DNA replication, multigenomic tails of double-stranded DNA are spun out from rolling circles. These long pieces of DNA containing repeated lambda genomes become substrate for DNA packaging (16). During rolling, circle as the DNA is spooled out, it is cut into correctly sized pieces by a phage-encoded enzyme called *Ter*. Ter cuts at the cos sites releasing mature phage lambda DNA ready to be packaged into the phage head.

Morphogenesis is the process of phage particle assembly that takes place in the host cell nucleoplasm periphery and includes formation of the phage capsid, condensation of DNA, packaging of the DNA into the capsid, and attachment of the tail. Morphogenesis results in mature phages that are capable of infecting a new host. During morphogenesis of the phage particles, there is a concurrent buildup of lysis proteins, which ultimately results in lysis of the host cell and release of the infective lambda particles into the extracellular environment. Lambda has at least two lysis genes, *S* and *R* (32). Protein R is an enzyme that cleaves between N-acetylglucosamine residue bonds similar to the action of lysozyme. Protein S is a holin-like protein, which disrupts inner membranes of the host, allowing *R* access to the N-acetylglucosamine in the murein layer. Ultimately, the infection cycle results in the production and release of 50 to 100 infective phage particles per lysed cell (33).

Induction: The Switch from Lysogenic to Lytic. Lysogeny, once established, is relatively stable. The cI repressor continues to stimulate its own synthesis and the inserted prophage is passively replicated as part of the bacterial chromosome. A delicate equilibrium exists between stable lysogeny and induction. Induction is the stimulation of transcription resulting in excision of the phage genome from the host chromosome and, ultimately, movement into the lytic cycle. The health of the host and its responses to environmental stimuli determine whether the phage will remain within the host genome or enter the induction process. The primary mechanism that controls induction is the availability of cI. Physiological stress such as UV damage results in the activation of a host cell SOS response. The expression of the genes in the SOS regulatory network is controlled by a complex circuitry involving the RecA and LexA proteins (28,34–36). As indicated aRecA's normal substrate is LexA but it also nonspecifically degrades cI (lambda repressor), stimulating the dormant prophage to enter the lytic cycle.

The nonspecific cleavage of cI by aRecA renders it inactive and it falls off the operator sequences O_L and O_R. This allows *E. coli* RNA polymerase to transcribe the gene for cro and Xis and Int, which were under repression by cI. The Xis and Int proteins interact to form an excision complex, which more or less reverses the integration process and effects induction of the prophage from the host chromosome. From this point, the lambda genome circularizes and follows a lytic infection cycle as described previously. It should be noted that induction is irreversible. One probable explanation is that in a lysogen there is a MOI of only one (the prophage itself). After induction, the lytic cycle, as described previously, leads to morphogenesis, lysis of the host cell, and release of progeny phage particles.

CONCLUSION

Bacteriophages have been and will continue to be used by environmental microbiologists as indicators and model organisms. Simple and inexpensive assay procedures create a remarkably easy system that can provide a wealth of information not only about the environmental fate of the phage themselves but also as a model system for the study of eukaryotic viruses. From their use as airborne indicators of fecal pollution, as models for studying the subsurface transport of viruses in aquifers, as indicators of fecal pollution in surface and drinking water, as vectors for the transmission of genetic information between species of bacteria and as simple models to help unravel the complexities of genetic control, bacteriophage have been instilled into the core of most aspects of microbiology.

BACTERIOPHAGE DETECTION METHODOLOGIES

SURESH D. PILLAI
Texas A&M University
College Station, Texas

NENA NWACHUKU
United States Environmental Protection Agency
Washington, D.C.

Bacteriophages are viruses that infect bacterial cells. A variety of different bacteriophages or phages (as they are commonly referred to) that infect different bacterial cells have been reported in the literature. Phages that infect the coliform group of bacteria are termed coliphages. Coliphages that infect coliform bacteria that contain the F-pilus or sex pilus are termed male-specific phages or F-specific phages. According to the International Standards Organization (ISO), the F-specific RNA bacteriophages are defined as, "bacterial viruses which are capable of infecting a specific host strain with F-or sex-pili to produce visible plaques (clearance zones) in a confluent culture lawn grown under appropriate culture conditions. The infectious process is inhibited, however, by concentration (40–400 μg/mL) of RNase in the plating medium" (1). The ISO defines somatic coliphages as "bacterial viruses which are capable of infecting selected *Escherichia coli* host strains (and related strains) by attachment to the bacterial cell wall as the first step of the infectious process. They produce visible plaques in a confluent lawn of host bacteria grown under appropriate culture conditions" (2). Bacteriophages that infect *Bacteroides fragilis* are defined by the ISO as "bacterial viruses which are capable of infecting selected *Bacteroides fragilis* host strains by attachment to the bacterial cell wall as the first step of the infectious process" (3). Various studies have shown the usefulness of bacteriophages as indicators of fecal pollution caused by viruses. Coliphages may be good indicators of enteric viral pollution because they are found in relatively high numbers in human and nonhuman feces, are persistent in the environment, do not multiply in the environment, and the cost of coliphages assay is only a fraction of an enterovirus tissue culture assay. Recently, coliphages also have been suggested as conservative indicators of enteric viruses because of their similarities in size, transport, survival, persistence, and high densities in sewage and septic samples. Bacteriophages that infect the *Bacteroides fragilis* also have been suggested as potential indicators of fecal pollution (4). *Bacteroides fragilis* is an obligate anaerobe found in high concentrations in human feces, and thus the presence or absence of these phages may be indicative of fecal pollution in a sample. One salient feature of using Bacteriodes phages is that because these bacteria are reportedly present only in human feces, the presence of these phages in a sample may be a strong indication of human fecal pollution. The use of bacteriophages such as coliphages as indicators of fecal pollution is based on the assumption that their presence in water samples denotes the presence of bacteria capable of supporting the replication of the phage (5). Bacteriophage as an indicator has an advantage. The detection method is simple and inexpensive and the results usually are available within 8 to 10 hours. This chapter provides an overview of some of the methods that have been used to detect and enumerate bacteriophages, especially the coliphages and the *Bacteriodes* phages in

environmental samples. The methods that have been described pertain to only those assays in which the primary purpose is to determine the microbiological quality of an environmental sample. The reader is advised to consult other entries in this encyclopedia for a detailed discussion on the classification of bacteriophages, their occurrence, their persistence, and the rationale for using phages as indicators of fecal pollution.

RECOVERY OF BACTERIOPHAGES FROM GROUNDWATER AND DRINKING WATER

One of the primary issues confronting the detection of bacteriophages, especially the male-specific coliphages in environmental samples is the potentially large volume of samples that needs to be analyzed. The rationale for employing large sample volumes is based on the premise that enteric viruses are normally present in very low numbers. There are various procedures for the recovery, detection, and enumeration of bacteriophages (2,6–8)). These protocols vary in terms of the recommended volumes to be analyzed, sample processing methods, and the recommended host bacteria. The terminologies used in these procedures are based on the distinguishing characteristics of the procedure, of the original publication, or of the agency that published it. For example, the "AWWARF method" is based on a membrane filtration (MF) approach developed by Sobsey and coworkers (9), whereas the "Environmental Protection Agency (EPA) methods" rely on the concentration of large-volume (500 gal) samples and smaller (100 and 1,000 mL) samples. The "ISO method" differs from the other methods primarily in the use of *B. fragilis* as the host bacteria.

MF Technique

The MF method of Sobsey and coworkers (9) was based on a field-tested protocol that compared the recovery of male-specific coliphages in several source waters with concentrations of fecal-indicator bacteria. Erb and coworkers (10) reported on the detection of low concentrations of male-specific coliphages in swimming pool waters using the MF method. However, they had to adjust the sample pH to 3.5 before filtration to achieve efficient recoveries. They have reported that humic acids in the water samples could interfere with adsorption of phages to the filter. The MF-based method is unique in that it relies on the use of widely available inexpensive membrane filters and filtration apparatus along with manageable sample volumes (1,000 mL).

Procedure

1. A water sample (1,000 mL) initially is supplemented with $MgCl_2$ to obtain a final concentration of 0.05 M $MgCl_2$.
2. The sample is filtered through a 47-mm (0.45 μm pore size), cellulose acetate membrane at a flow rate not exceeding 100 mL per minute.
3. The F-specific coliphages adsorbed to the membranes are eluted using 3 mL of a high pH buffer (3% beef extract V; 0.3% Tween 80; pH 9.5).
4. The sample concentrate is neutralized as soon as possible with 0.1 M HCl.
5. This sample concentrate then is used for the bacteriophage analysis using appropriate host bacteria.

In the original method, the host bacterium *Salmonella typhimurium* (strain WG 49) was employed for the detection of F-specific coliphages. This particular host strain is resistant to nalidixic acid and kanamycin and contains an *E. coli* plasmid (F′42lac : Tn5) that is responsible for pili production and thus susceptible to infection by F-specific coliphages (6). The host strain is grown in a medium containing 1% tryptone, 0.1% glucose, 0.8% NaCl, 0.03% $CaCl_2 \cdot H_20$, 0.015% magnesium sulfate, 100 mg/L nalidixic acid, and 20 mg/L kanamycin sulfate. The concentrations for the top and bottom agar were 0.7% and 0.5%, respectively. Although the original protocol suggested the use of *S. typhimurium* WG49 as the host bacterium, the authors indicated that there may be interferences by somatic Salmonellaphages. There is concern that the plasmid is not stable within the host bacterium and thus false negatives could arise if the WG49 strain is used. This has led to the use of alternate host bacteria such as *E. coli* 15597 as a tool to screen for male-specific phages. Theoretically, it is possible to use any other suitable host bacteria and exploit the advantageous features of this protocol. In laboratory studies, the observed decrease in phage recovery with increase in sample volumes was attributed to the accumulation of "deposits" on the filter surface. Sobsey and coworkers (9) recommended that sample volumes should be small enough to prevent deposit accumulations (or the use of 90-mm diameter filters). Sobsey and coworkers (9) suggested that the filters could be placed "face down" onto agar media containing lawns of the specific host bacteria. To aid in the detection of the enumeration of the plaques, the use of tetrazolium dye (0.03% final concentration) was suggested.

The MF method has been used to screen groundwater serving public water supply wells along the Texas-Mexico border region. In this study, 17 wells were sampled over a span of three months, however, none of the samples were positive for male-specific coliphages. The protocol was as follows:

1. Groundwater field samples (1,000 mL) were collected in sterile containers filled under optimum conditions. The samples were adjusted initially to 0.05 M $MgCl_2$ using sterile $MgCl_2$ and thoroughly mixed.
2. The samples were then filtered through a sterile 0.45-μm pore size filter at the rate of 100 mL per minute.
3. A sterile polypropylene tube was placed beneath the membrane and 5 mL of a beef extract elution solution (3% beef extract V; 0.3% Tween 80; pH 9.5) was added to the membrane. After five-minute incubation, this solution was filtered through the membrane (by vacuum application). To quickly bring the pH of the buffer to neutrality, 770 μl of 0.1 M HCl was added to the tube containing the eluate.

4. This concentrated solution was then used for the bacteriophage analysis. Aliquots (0.5 mL) of the solution were used in conventional double agar overlay techniques for phage enumeration using host bacteria specific for F-specific phages (*E. coli* ATCC 15597) and somatic phages (*E. coli* ATCC 13706). Parallel studies, using spiked groundwater samples, showed very high phage recoveries.
5. In this protocol, a filter-elution step (to elute the viruses off the filter) was employed, rather than "laying the filter facedown" on an agar plate. This avoided problems associated with the plaque visibility and the need to use tetrazolium dyes for plaque contrast purposes.

The U.S. EPA ICR Protocol

The U.S. EPA published a standardized procedure for the enumeration of somatic and male-specific coliphages in the implementation of the Information Collection Rule (ICR) (7). In this procedure, water samples are passed across and in between a positively charged 1 MDS filter (CUNO Inc., Meridien, CT). However, for source water, the total amounts of sample that can be filtered through the 1 MDS filter will depend on the water quality in terms of suspended solids. The recommended sample volumes are 200 L for source water and 1,500 L for finished water. However, samples up to 1,500 L were used for groundwater-monitoring purposes (11).

ICR Method

Sampling

The routine precautions that one employs normally when sampling for enteric viruses are followed such as flow rate (not exceeding 3 gallons per minute) (7). Also, if the water to be sampled contains a disinfectant such as chlorine, a 2% sodium thiosulfate as a neutralizing agent is injected continually into the sampling stream at a rate of 10 mL/gal (2.6 mL/L or 30 mL per minute at a flow rate of 3 gal per minute). The filter cartridge along with the filter is then aseptically packed in sterile foil and transported to the laboratory on ice, and processed as soon as possible.

Sample Processing

1. Filters are eluted initially using one liter of sterile beef extract glycine solution (1.5% beef extract V, 0.05 M glycine in water, pH 9.4). The filter is soaked in the elution solution for 15 minutes. The solution then is forced from the housing into a sterile 2-L beaker using nitrogen gas or positive air pressure. (It has been found that this particular step in the protocol is too cumbersome, prone to significant errors, and possibly could lead to cross-contamination). Currently in our laboratories, the elution solution is added to the filter holder and rocked back and forth for 15 minutes using a rocking platform.
2. The eluate is then poured into a sterile 2-L beaker, the pH adjusted to 7.0–7.4 using 1 M HCl, and the solution stirred for 15 minutes. Forty milliliters of the eluate is mixed with 4 mL of glycerol and the sample is stored at −80 °C until the sample is flocculated and further concentrated (details of these steps are presented elsewhere in the encyclopedia).
3. The bacteriophage assay is then performed on the concentrated sample using the appropriate host bacteria and the conventional double agar overlay method.
4. There is concern that the exposure of phage to high pH during the sample processing could lead to significant loss of phage recovery. This has forced researchers to explore alternate sample processing approaches.

ISO Method for Detection and Enumeration of Bacteriophages

The method for the detection of F-specific bacteriophages already is an official standard for the ISO, whereas the method for the detection and enumeration of somatic phages and *B. fragilis* phages currently is in the final stages of approval (Juan Joffre, Personal Communication). The detection and enumeration method for F-specific RNA bacteriophages can be applied theoretically to all kinds of water, sediments, and sludges where necessary after dilution. The ISO method recommends a preconcentration if necessary for samples that may harbor low numbers of bacteriophage.

ISO Method for the Enumeration of F-Specific RNA Bacteriophages. The sampling, transport, and storage of water samples are to be handled in accordance with the ISO, ISO 8199 (ISO 5667-1, ISO 5667-2 and ISO 5667-3 (1,11–13). The method recommends the use of *S. typhimurium* WG 49, *E. coli* K-12 Hfr, or *E. coli* HS (pFamp) R (14). The host cultures are grown in tryptone yeast extract glucose broth (TYGB) at 37 °C. The quality control check of the *S. typhimurium* strain (WG49) is performed by screening for the presence of lactose-negative colonies (which would indicate plasmid segregation) and inhibition zones around antibiotic disks impregnated with kanamycin and nalidixic acid. Less than 8% of the cells should be lactose-negative with no inhibition zone around the nalidixic acid disk and an inhibition zone around kanamycin disks of less than 20-mm diameter. The ISO method clearly details the protocol for samples containing high bacterial background, samples with low phage counts, and a presence/absence test. The salient feature of the protocol is that the method suggests confirmatory steps when sampling new sources, when there is an unexplained overabundance of F-specific bacteriophages, or when there is indication that somatic phages ("large, circular, clear plaques with smooth edges") are being isolated. For confirmation purposes, the protocol recommends plating aliquots of the sample (in parallel) on a series of plates containing RNase at a final concentration of 40 μg/mL. The appropriate volume of a stock solution is added to soft agar just before adding the top layer. The protocol suggests that at times the RNase concentration may need to be as high as 100 μg/mL for selectivity.

Protocol

1. Semisolid (soft agar) TYGA media (50 mL) in bottles are melted and placed in a 45 °C water bath. (Because nalidixic acid is heat-stable, this antibiotic could be added before autoclaving to prevent background flora interferences). To these bottles, 0.5 mL of calcium-glucose solution ($CaCl_2 \cdot 2H_2O$ 3 g; glucose 10 g; water 100 mL) and 2.5-mL aliquots are distributed into sterile capped tubes.
