Giardia lamblia is a flagellated protozoan first documented in 1966 as a causative agent of waterborne intestinal disease in the United States (5). *Giardia* forms an environmentally resistant cyst, which allows for the extended survival of the parasite in surface and treated drinking water. *Cryptosporidium parvum*, the protozoan responsible for cryptosporidiosis, is ubiquitous in surface water supplies and is resistant to conventional disinfectants (chlorine and chloramine) used in water treatment (6–12). The organism forms an environmentally resistant oocyst that permits prolonged survival in the aquatic environment. The Interim Enhanced Surface Water treatment Rule (13) lowered the turbidity limits to 0.3 nephelometric turbidity units (NTU) (in 95% of four-hour samples) as a means to control (by physical removal) *Cryptosporidium* in treated drinking water. A well-operated conventional water treatment plant is thought to remove 99–99.9% or more of the Cryptosporidium oocysts in water. Sedimentation (or clarification) processes play an important role in removing the majority of oocysts during the treatment process, with the remaining organisms removed by filtration. Backwashing of filters result in a major recyclable waste stream within a plant that can impact the source water quality. Solids (including microbes) retained on a filter can be recycled back to the source water if no further treatment is provided for the SFBW.

Table 1 summarizes the occurrence of protozoa reported by various studies. Rose and coworkers (14) reported *Cryptosporidium* at 686,900/100 L and 2,430,600/100 L in two samples collected from backwash water of rapid sand filters. Colbourne (15) reported *Cryptosporidium* at 1,000,000/100 L in the SFBW during an investigation following an outbreak of cryptosporidiosis in England. Supernatant from a settling tank treating the SFBW still had *Cryptosporidium* in the range of 100,000/100 L a few days after the outbreak. During this outbreak, 30% of the distribution system drinking water samples were positive for *Cryptosporidium*. The outbreak was attributed to dumping of animal wastes containing *Cryptosporidium* that were concentrated on the filters because of the continued recycle of spent filter backwash water.

It should be noted that measurement of Cryptosporidium oocysts in SFBW is very difficult as a result of the presence of large amounts of particulate material and interfering chemicals. Because Cryptosporidium oocysts are measured using an immunofluorescence microscopic technique, the large amount of particulate material minimizes the sample that can be analyzed to volumes typically less than one Liter. The small volume analyzed results in large multiplication factors when reporting counts per 100 L. The presence of interfering chemicals, particularly coagulation polymers, causes the fluorescent antibodies used in the immunofluorescence assay to nonspecifically stick to particle surfaces, increasing the likelihood that algal cells or other particles to be mistaken for Cryptosporidium oocysts. The reader, therefore, should be aware that the variability in the results that follow is highly influenced by the analytical methodology and the experience of the microscopist.

A survey of 66 water treatment plants in 14 states, found *Cryptosporidium* levels 57 to 61 times higher in the initial backwash water than in the corresponding raw water (7 to 108 oocysts/100 L) (8). *Giardia* was 12 to 16 times higher in the initial backwash water than compared to the corresponding raw water levels (4 to 32/100 L). *Cryptosporidium* was found in SFBW samples; the same time as it was found in the filtered plant effluent samples. This observation confirms the finding of Colbourne (15) that a filter can continue to concentrate protozoa, a few of which can be released into the filter effluent. On the basis of a survey of water treatment plants in 17 states, Rose and coworkers (7) reported a geometric average *Cryptosporidium* concentration of 217/100 L in SFBW samples.

Cornwell and Lee (16,17) documented the fate of *Giardia* and *Cryptosporidium* in two plants in Pennsylvania employing different type of treatment trains. One plant (Plant 1), employing direct filtration treated raw water from a combination of surface water, deep and artesian wells, and springs. SFBW at Plant 1 was treated in a clarifier before it was recycled back to the head of the plant. For the first sampling event, raw water *Cryptosporidium* level of 6/100 L increased to 40/100 L after addition of the clarified SFBW recycle stream that contained 141/100 L oocysts. The SFBW contained 902/100 oocysts indicating an 84 percent removal of oocysts in the backwash clarifier. *Giardia* in raw water at 3/100 L increased to 7/100 L after the addition of clarified SFBW recycle stream containing 86/100 L cysts. The SFBW contained 1,350/100 L cysts resulting in a 94% removal in the clarifier. For the second sampling event, *Giardia* was not found in raw water, SFBW, or clarified SFBW samples. However, raw water *Cryptosporidium* level of 140/100 L reduced to 45/100 L after the addition of clarified SFBW stream consisting of 750/100 oocysts. The low levels of oocyst in the clarified water compared with both the raw water and recycle stream, is attributed to the inaccuracies of the immunofluorescence method. SFBW contained 850/100 L oocysts, indicating only a 12% removal of oocysts in the backwash clarifier.

The Plant 2 received source water from an impounded reservoir, a spring and three wells, and employed adsorption clarification, and mixed media filtration. In addition to SFBW, a wastewater clarifier treated other

waste streams (clarifier flush water, sand bed filtrate, filter-to-waste, and clarifier- to- waste) generated with in the plant. Supernatant from the wastewater clarifier was recycled back to the head of the plant. As was the case in Plant 1, monitoring at Plant 2 consisted to two sampling events. The raw water *Cryptosporidium* level of 13/100 L increased to 30/100 L after addition of wastewater clarifier recycle stream containing 80/100 L oocysts. The influent to wastewater clarifier contained 16,613/100 L oocysts in the SFBW and 2,600/100 L oocysts in the adsorption clarifier flush. *Giardia* in raw water at 290/100 L decreased to 160/100 L after the introduction of wastewater clarifier supernatant that contained 70/100 L cysts. The SFBW contained 16,513/100 cysts, whereas the adsorption clarifier flush contained 5,200/100 L cysts.

For the second sampling event, protozoa were analyzed in the individual and combined raw water and wastewater clarifier supernatant samples only. Raw water *Cryptosporidium* and *Giardia* levels of 20/100 L and 60/100 L, respectively, increased to 476/100 L and 79/100 L, respectively, after the addition of the wastewater clarifier supernatant stream. *Cryptosporidium* in the

clarifier supernatant was observed at 420/L; whereas, *Giardia* was below detection level.

Karanis and coworkers (18) reported the occurrence of *Cryptosporidium* in raw and SFBW samples by using two separate sample collection techniques at a treatment plant in Germany. By using a continuous flow centrifugation method, eight out of 12 raw water samples showed *Cryptosporidium* in the range of 0.8 to 109/100 L. Using the same method, *Cryptosporidium* was observed in 8 out of 11 the SFBW samples ranging from 1 to 69/100 L. Using cartridge filters, 33 out of the 39 SFBW samples were positive for *Cryptosporidium* ranging from 0.8 to 252/100 L. At another plant in Germany, *Cryptosporidium* was reported at a level of 150/100 L in a SFBW sample that was collected 10 minutes after the start of the backwash cycle Karanis and coworkers (19).

States and coworkers (20) reported results of a fifteen-month protozoa monitoring study of raw, settled, filtered, and SFBW samples at the Pittsburg Drinking Water Treatment Plant. In raw water, *Cryptosporidium* (11 out of 15 samples) and *Giardia* (9 out of 15 samples) were observed at geometric mean levels of 43/100 L and 42/100 L, respectively. In contrast, only *Cryptosporidium* (2 out of 15 samples) was found at a geometric mean level of 0.4/100 L in filtered water. For the SFBW samples, *Cryptosporidium* (8 out of 15 samples) and *Giardia* (2 out of 15 samples) were detected at geometric mean levels of 321/100 L and 59/100 L, respectively. On the basis of the data, the level of *Cryptosporidium* in SFBW samples was approximately 7.5 times higher than that observed in raw water samples.

In the most comprehensive study of protozoa in SFBW waters, Arora and coworkers (21) collected paired raw and SFBW samples six times from 25 water systems across the United States. Source waters included: rivers (18 sites), creeks (3 sites), and reservoirs or lakes (4 sites), and were collected on the same day as the SFBW samples. SFBW samples were collected either from holding tanks (immediately following a filter backwash to avoid settling of solids) or by compositing a number of equally spread samples during the backwash cycle. *Giardia* and *Cryptosporidium* were analyzed by the immunofluorescence assay (IFA) (10) and, *Cryptosporidium* was analyzed by the cell culture polymerase chain reaction (CC-PCR) method that measures live and infectious oocysts (22).

Giardia and *Cryptosporidium* were detected using the IFA method in 30% and 11% of the raw water samples, respectively (Table 2). The adjusted (for recovery) geometric mean for *Giardia* and *Cryptosporidium* in the raw water samples was 420 and 470 per 100 L, respectively. *Giardia* and *Cryptosporidium* were detected in 8.1% and 4.7%, of the 148 SFBW samples, respectively. The adjusted geometric mean for *Giardia* and *Cryptosporidium* in SFBW samples was 3,200 and 3,100 per 100 L, respectively. The adjusted SFBW protozoa levels (geometric mean for positive samples) were approximately seven times higher than raw water levels.

To account for peak occurrences of protozoa (that might overwhelm treatment), the 90th percentile of *Giardia* and *Cryptosporidium* occurrence in raw water, and SFBW samples was determined. Although these levels were approximately 3 to 4.5 times higher than the geometric mean, the ratio of protozoa in SFBW was still approximately seven to eight times higher than in the raw water. This ratio is reasonable if, for example, a plant uses 2% of its total production to wash the filters, then the expected protozoa levels would be 50 times higher in the SFBW compared with the raw water (assuming no removal of cysts or oocysts during the coagulation/sedimentation process). However, if one assumes that coagulation and sedimentation removes between 1 and 2 logs of protozoa, then levels in the backwash water would range between 0.5 and 5 times the raw water level.

A total of 122 raw water and 121 SFBW samples were analyzed by both the IFA and CC-PCR methods. Infectious *Cryptosporidium* were detected in six raw water (4.9%) and nine SFBW samples (7.4%) (Table 3). Occurrence of live *Cryptosporidium* in the SFBW samples indicates the organism can penetrate treatment barriers to at least the

Table 3. Summary of *Cryptosporidium* Detection for Paired SFBW Samples

Assay	Raw $n = 122$	Backwash $n = 121$
Positive flotation IFA for *Cryptosporidium*	13.1%	5.8%
Positive CC-PCR for infectious *Cryptosporidium*	4.9%	7.4%

point of filtration and be present in the filter backwash water. The results highlight the need to carefully handle the disposal or recycle of SFBW to minimize the public health impact from infectious protozoa.

A comparison of detection of *Cryptosporidium* oocysts in raw water showed that 11% of the samples positive by IFA and 4.9% positive by CC-PCR (Table 3). This result is not surprising since IFA detects all oocysts, dead or infectious. However, infectious *Cryptosporidium* were detected in more SFBW samples (7.4%) than total oocysts detected by IFA (4.7%). These results probably are a reflection of the splitting of samples containing very low numbers of oocysts between the IFA and CC-PCR assays; the additional sample handling and potential loss of oocysts required for IFA method; and possibly, the higher sensitivity of the CC-PCR assay than the IFA technique (22).

Overall, *Giardia* was detected in raw water samples at least once for 18 sites (72%), and for 78% of the positive sites, *Giardia* was observed more than once. *Giardia* was detected in SFBW samples at seven sites (28%) with two sites positive, more than once. *Cryptosporidium* was detected in raw water samples from 16 sites (64%) at least once by either the IFA or CC-PCR methods, and a number of times, at 25% of the positive sites. *Cryptosporidium* was detected in the SFBW samples by IFA or CC-PCR methods at 10 sites (40%), with three of these sites positive, more than once.

OCCURRENCE OF OTHER WATER QUALITY PARAMETERS

Besides protozoa, other water quality parameters (dissolved organic carbon, disinfection by-products, metals, etc.) can also impact water treatment and/or water quality upon recycle of the SFBW. Because finished drinking water is typically used for filter backwashing, the presence of disinfectants and disinfection by-products (DBPs) can increase the overall DBP levels in treated water upon recycling of the SFBW. These increased DBP levels can impact water utilities at the borderline for the new DBPs maximum contaminant limits (23). Use of metallic coagulants in water treatment can introduce aluminum and iron to the raw and other metals such manganese and zinc can increase upon continual recycling. Recycling of these metals can be either beneficial (e.g., coagulation) or harmful (e.g., increased zinc loading on wastewater treatment plants), depending on site-specific water quality and treatment. Table 4 summarizes the average and 90th percentile results for a number of water quality parameters measured in raw and SFBW samples. The impact of wash water recycle ranged from an average threefold (for dissolved organic carbon) to a 92-fold (for trihalomethanes) compared to raw water samples. Peak levels (measured as the 90th percentile of occurrence) could further impact recycled water (Table 4).

TREATMENT STRATEGIES FOR SFBW

The level of treatment required for SFBW before recycle will vary from site to site, depending on the treatment process and water quality objectives. A reasonable assumption may be to treat the SFBW to the level of the raw water quality. Various treatment options are available to water treatment plants, which include equalization, sedimentation, filtration, and chemical oxidation.

Equalization

Equalization of the recycle flow involves reusing a constant amount of backwash water over a period. To achieve equalization, a backwash holding tank of sufficient size is necessary to store all the water used to wash the treatment filters until it can be recycled. The size of this holding tank will depend on the projected number of filters to be washed, the volume of water used to wash a filter, and the rate of recycle. If a plant, for example, used 2% of the total water produced to backwash the filters, and metered the recycled backwash water at a constant 2% of the plant production, these rates would be equalized. The advantage of this approach is that (*1*) changes in raw water quality (related to recycle) are minimized because the treatment process always experiences the same mix of raw and backwash

Table 4. Chemical Parameter of Raw and SFBW Samples

Parameter	Raw Water			Backwash Water			Increase (fold)	
	Range	Average	90%	Range	Average	90%	Average	90%
Dissolved organic carbon, mg/L	0.7–5.4	2.4	4.0	0.8–191	8.0	15.6	3.3	3.9
Trihalomethanes, μg/L	ND-21.8	0.6	0.7	ND-198	55.0	95.5	91.7	136.4
Haloacetic acids-6, μg/L	ND-21.5	1.9	3.4	ND-211	45.5	94.7	24.0	27.9
Bromide, mg/L	ND-0.68	0.033	0.04	ND-0.46	0.027	0.06	0.8	1.5
Aluminum, mg/L	ND-8.7	0.57	1.35	ND-145.8	14.8	44.2	26	32.7
Iron, mg/L	ND-1.8	0.83	1.78	ND-132	9.1	27.6	11	15.2
Manganese, mg/L	ND-3.0	0.09	0.17	0.01-17.9	1.4	3.9	16	21.8
Zinc, mg/L	ND-0.2	0.02	0.09	ND-1.0	0.1	0.30	5.0	3.2

water and (*2*) contaminants in the backwash water are diluted (about 50-fold) with the source water. However, the cost and space requirements for the holding tanks can be expensive.

Sedimentation

Once a holding tank is constructed, removal of solids from the backwash water can be achieved by: (*1*) allowing sufficient time for settling or (*2*) accelerating settling through the addition of polymeric coagulants. In the absence of chemical treatment, there was no reduction of SFBW particles with a detention time of 36 minutes and a overflow rate of 1.3 gpm/ft^2 (3.3 m/h) (21). When chemical treatment was applied (as either an anionic, cationic polymer, or ferric chloride), particle counts were reduced by about 1 log and turbidity levels were lowered by more than 90%. Polymeric pretreatment reduced *Giardia* and *Cryptosporidium* levels by greater than 2 log and *Clostridium* and *Bacillus* levels by more than 2.5 and 1.5 log, respectively. On the basis of the 7- to 8-fold increase in protozoa levels observed in SFBW, the authors conclude that sedimentation with chemical addition is adequate treatment to control the risk of *Cryptosporidium* in recycled wash water. These results were similar to Cornwell and Lee (16) who reported that a nonionic polymer was effective in increasing particle removals to more than 90% at overflow rates of 0.2 to 0.3 gpm/ft^2 (0.5 to 0.75 m/h).

Dissolved Air Flotation

Dissolved Air Flotation (DAF) may be a viable clarification process depending on the quantity of solids in the SFBW. McTigue and coworkers (24) reported a 1 log turbidity removal from SFBWs ranging in turbidity from 20 to 200 NTU without any addition of a polymer. Overall, DAF with polymer worked as well, or better than sedimentation with polymer. On an average basis, DAF with polymer removed 2.5 log of turbidity and particles from SFBWs.

Filtration

Removals of *Giardia* from 1.5 to 5.1 log and *Cryptosporidium* removal of 1.5- to 5.2-log have been reported for conventional coagulation/sedimentation/granular media filtration studies (10,25–27). Similar removals (*Giardia:* 2.9 to 5 log; *Cryptosporidium:* 1.3 to 5.9 log) have also been reported for direct filtration (25,26,28,29). However, because of the particle concentration of SFBW, a filtration option would have to be preceded by clarification.

Other filtration processes have been used of treatment of SFBW, including a backwashable depth filter, bag filters, and membrane filters (21,24,30–33). Using nylon (2.0 μm nominal rating) filters in the backwashable depth filter, removal of *Cryptosporidium* (3 log), *Giardia* (1.2 log) and *Clostridium* (1.5 log) was achieved at a flow rate of 6 gpm (23 L/min). A polybutylene terephthalate (PBT) filter with a nominal rating of 5 μm resulted in lower removal efficiencies (*Cryptosporidium*, 3 log; *Giardia*, 0.5 log; and *Clostridium*, 1-log removals). Goodrich and coworkers (31) reported *Cryptosporidium* removal ranging from 0.3 to 3.2 log for bag filtration. Membrane filtration (micro- and ultrafiltration) can remove protozoa more than 3.5 log (24,30–33) reported over a 3-log removal of particles and more than 2.5 log of turbidity from six separate SFBW samples by filtration and microfiltration. Again, because of the particle concentration of SFBW, these options would have to be preceded by clarification.

Disinfection

Because of the increased dissolved organic carbon and other oxidant demand-producing compounds in SFBW samples, clarification is typically necessary before a disinfection option. Arora and coworkers (21) examined the oxidant demand for potassium permanganate, chlorine dioxide, and ozone for SFBW samples from five water utilities and showed that the potassium permanganate demand was approximately 5.5 times higher for SFBW with particles than in samples without particles. The presence of particles in the SFBW samples increased the chlorine dioxide demand by a factor of 4. Maintenance of an ozone residual was not possible in nonclarified SFBW samples. Because clarification alone is sufficient to control concerns regarding recycle of *Cryptosporidium* oocysts in SFBW in most circumstances, the addition of a disinfection option would only be necessary in specialized cases.

Once oxidant demand-causing particles have been removed from the SFBW, inactivation of *Cryptosporidium* oocysts is possible with ozone, chlorine dioxide, or ultraviolet light. A 2-log reduction of *Cryptosporidium* with ozone may require 5 mg min/L (3) of disinfection at pH 8 and temperature of 20 °C, but may require 115 mg min/L (34) of chlorine dioxide disinfection under similar conditions. Ultraviolet (UV) technology for control of *Cryptosporidium* has shown that UV doses as low as 3 mJ/cm^2 resulted in inactivation greater than 4 logs (35).

PAUCITY OF NUTRIENTS AS A SEVERE ENVIRONMENT

The inhabitants of severe environments are the products of evolutionary processes. For the earliest life on this planet, only where conditions were favorable could life be successful, but after the development of energy trapping mechanisms, great diversity arose. This variety of life-forms included organisms that had adapted or evolved to grow in harsher environments; these would have a niche with little competition from the not so specialized forms of life. To the extent that it is physically and chemically possible now that the world biomass is high, severe environments have become inhabited by evolved and adapted specialist organisms. Prokaryotes have invaded severe environments of different kinds very effectively. For example, they have invaded environments that are too hot or cold for the majority of organisms. Living when the temperature is extreme requires a series of special adaptations. A larger variety of special adaptations are needed for the range of nutritional deficiencies that are found in nature. Many such habitats are occupied with prokaryotes, and primarily and consistently by oligotrophs.

To understand the oligotrophic state, two topics are especially important and are generally not covered as part of microbial ecology because of their physical and

chemical nature; these will be treated here. One concerns the thermodynamics of a cell because a living organism must be viewed as an engine that needs an external supply of reactants to provide energy that can be manipulated for cellular use; and the other concerns the diffusion of small molecules up to a cell.

WHAT IS AN OLIGOTROPH?

Oligotrophic bacteria live most of the time in nutrient-deficient environments. Of organisms inhabiting such environments, the prokaryote oligotrophs are the most numerous. As compared with the multicellular Eukarya, the domains of Bacteria and Archaea and single-celled Eukarya have many more members that inhabit severe environments. This is no doubt because the lifestyles of single cells are less restricted by such an environment, and these cells are capable of adapting more easily than multicellular organisms to nutritional limitation. Let us compare oligotrophs with a very different extremophile, a pathogen. Both inhabit severe environments, one dealing with poor nutrition and one dealing with a host's sophisticated defense mechanisms. The pathogen's way of life is just as relevant as the oligotroph's to the topic of life in extreme environments, but each copes with totally different problems. Obviously, if some essential nutrient is completely missing, the oligotroph cannot grow, but its forte is surviving if nutrients are sometimes missing or if they are generally present in only very low concentration. Life may be possible, but only if the inhabitants have the physiological adaptations needed to endure such conditions.

Evolutionary theory designates the precursor of the three domains of Bacteria, Archaea, and Eukarya as the Last Universal Ancestor (LUA). In its time, the development of methanogenesis and oxygen-producing photosynthesis had not occurred. Then carbon compounds of intermediate oxidation state were formed abiotically either by geologic and astrophysical forces or by fallout from interplanetary material. At that time, life on this planet must have been sparse (1–4). This was an oligotrophic world. In today's biosphere, oxygen-producing photosynthesis supplies both the organic material and the oxidant so that many trophic levels in the food chain are possible and the biomass of the world is many orders of magnitude higher than that and much of the world is eutrophic. Still there remains a vast habitat that has little exploitable fixed carbon. Although an oligotrophic environment refers to all nutrients, most usage only refers to insufficiencies of oxidizable carbon compounds.

The largest habitat of a carbon-sparse is the deep seas (5). At the surface where there is light and carbon dioxide, there is usually a deficiency of nitrogen and phosphate, because the nitrogen and phosphorus are ordinarily depleted through consumption by photosynthetic organisms. These elements then pass through the food chain and eventually fall to the oceanic depths. This process maintains oligotrophic conditions throughout the water column. On the other hand, eutrophic conditions are usually prevalent near shores due to runoff. However, where there are upwelling currents of the deep ocean waters or when and where the thermal stratification of water layers ceases (and the thermocline temporarily disappears), then the mixing (turnovers) brings nitrogen and phosphate to the illuminated surface and growth is perfuse. In contrast, the bulk of the oceans have been described as biological deserts. Although these waters are clear, they still may contain more biomass than the rest of the world because their volume is so large. There, many varieties of small bacteria eke out their existence and persist. These generally are small marine bacteria and have been called ultramicrobacteria, oligobacteria, nanoplankton, picoplankton, and a number of other names. Deep freshwater lakes may also be oligotrophic and provide habitat for freshwater oligotrophs, depending on the geology of the surrounding watershed and on other factors, such as the absence of agriculture in the adjacent terrain.

Agricultural fields generally are regularly fertilized and much biomass is generated so that the food chain leading from the primary producers may have enough active stages that only a few recalcitrant compounds remain (6,7). During agricultural cultivation, nitrogen and phosphorus are replaced by fertilization, although they may be washed away (or metabolized to gaseous N_2). Typically, when agricultural activities cease, the environment becomes largely oligotrophic and the succession in the resulting ecosystem depends on nitrogen fixation, carbon availability, and soil formation. But even with land in crop production or in mature climax forests, oligotrophic bacteria persist, growing slowly on compounds left behind by organisms closer (metabolically) to the site of primary production.

A most interesting oligotrophic environment is the distilled water reservoirs in chemical and biological laboratories (8–10). In many cases, *Caulobacter crescentus* can be found there. This heterotroph must be able to find enough carbon compounds and enough nitrogen, phosphorus, sulfur, and trace elements coming by elution from the glass, by failures of the water purification processes, from resources contains in the gas phase, and from plasticizer and are able to survive and grow. Their persistence shows that they have attacked and solved the formidable biochemical and bioengineering problems of such an existence.

HISTORY OF THE FIELD

Nomenclature

The term "oligotroph" has been used since Weber coined the term in 1907 (11), but was brought to the attention of microbiologists when Jeanne Poindexter (8,9) used it to contrast with her new term "copiotrophs." In concept, the former class of bacteria is devoted to a life in a perennially sparse environment and the latter to environments with generally higher level of nutrition.

"Copiotroph" and "eutroph" are terms more or less equivalent to "zymogenous" or "allochthonous," as used by Winogragsky in 1924. His term "autochthonous" is approximately equal to "oligotrophic bacteria" (but it actually means of indigenous origin). These organisms are characterized, in large part in modern usage, by their

inability to grow in high levels of nutrients. They are not characterized solely by an exceptional ability to use low concentrations of substrates. In fact, the ability to use a substrate has a lower limit imposed by the physics of diffusion and not by biological constraints (see following text).

From Bacteriology to Microbial Physiology to Molecular Biology and Microbial Ecology

Microbial physiology had its start from the work in the last century of Pasteur and colleagues at the Institut Pasteur in Paris and from Robert Koch and colleagues in Berlin. During the first half of the twentieth century, progress shifted to Holland and then to America with Henrici at Minnesota. But the real shift occurred at the time of World War II and shortly thereafter with the development of molecular biology [stemming from Luria and Delbrück's work (12)], the principles of microbial genetics, and the appropriate methods needed for the study of bacterial genetics. At the same time, the studies of microbial ecology developed built on the earlier studies primarily of the Dutch school. In the postwar era the progress was fantastic, but it is only since the 1990s that the two microbiology branches of molecular biology and microbial ecology have fused together. Now, molecular biological tools and concepts allow microbiological ecology to be studied effectively. With respect to the so-called oligotrophic bacteria, there is much left to be done, but much is shortly to be accomplished given the state and applicability of the complementary sets of tools now available from molecular biology and microbiological ecology.

Work in the Last Half Century

Before discussing the problems of life in low nutrient conditions and oligotrophy, it is necessary to highlight several research areas investigated since 1940, in which the concept of the "oligotroph" would be appropriate. This section is just to give the highlights, key conclusions from the studies, and the key researchers; further discussion will be presented later.

1. Morita, who was Zobell's student, spent his career in studying marine organisms that persisted for a very long time under starvation conditions. Although there were some changes of the starving vegetative organisms, it was particularly significant that the cells became smaller and that the survival remained high. Most of his studies were of a marine vibrio (see section The Marine *Moritella* Ant-300; 13).
2. Jeanne Poindexter studied of the survival of a freshwater organism, *C. crescentus* (8–10). It grows in extremely low nutrient conditions. She was the first investigator to unearth a number of biological facets during her studies of *Caulobacter* growth in a variety of conditions. This organism differentiates into a swarmer cell and a stalked cell during every cell generation. This circumstance gave the opportunity to study differentiation of a bacterium to give insight to the developmental processes that take place in metazooans and plants. It was the utilization of this organism by Shapiro (14,15) that was important in meshing the ecological biology with the molecular biology of differentiation. (see section The Prosthecate Bacterium *C. crescentus*).
3. Ensign and his students studied a gram-positive soil microorganism that undergoes morphological changes during its culture cycle. In the stationary state it becomes a coccus instead of a rod. (15; see section The Jointed Bacteria, *Arthrobacter* spp).
4. Button and his group (16–21) are marine microbiologists. They isolated a number of marine organisms that appeared initially to be obligate oligotrophs. *Cycloclasticus oligotrophus* RB1 was the organism chosen for detailed study, and although it could not be grown when isolated, it was cloned in an interesting way. This was done by an MPN (most probable number) method that they called the dilution culture technique. (see section A Marine Ultramicrobacterium *C. oligotrophus* RB1).
5. The fifth development came from my laboratory (22–25) and concerned *Escherichia coli*, a nominal copiotroph. We developed a way to study bacterial growth very sensitively through a long light path cuvette in a spectrophotometer linked to a computer. With it we could study growth at very low substrate concentrations. We were able to show that even the organism *E. coli*, which was not thought to be an oligotroph and in fact had been touted as the premier example of a copiotroph, had actually no lower limit to the concentration of glucose in which it could grow. As efficiently as diffusion kinetics would permit, it takes up a monosaccharide, glucose, from the environment and converts it into cell mass. This was important in redefining the contrast between an oligotroph and a copiotroph. The implication is that even a copiotroph's uptake system is so efficient that a sugar molecule that collides with the cell is taken up before it can diffuse away and thus uptake is close to 100% efficient (see section Uptake at Low Concentrations by a Presumptive Copiotroph, *E. coli*).

CLASSES OF OLIGOTROPHS

The first review of the oligotrophs was by Kuznetsov and coworkers (26). They divided oligotrophs into four classes: (*1*) those that are only initially cultivatable; (*2*) those that could be isolated initially on poor medium, but then become culturable on rich medium; (*3*) those that are only cultivatable on special "poor" medium; and (*4*) those that cannot be cultivated but can be observed with a microscope.

Because of the recent studies by Pace and by those who learned techniques in his laboratory (5,27,28), it is quite clear that there are myriads upon myriads of organisms in nature that we cannot grow in the laboratory and therefore belong to Kuznetsov's class 4. These insights were obtained mainly by using hybridization with probes against portions of the 16S rDNA to identify the

phylogenetic location of the bacterium under inspection. Many of these are quite different from microorganisms that have been cultured. Electron micrographs show that the morphology of these is highly variable (5). Most of these "unculturables" would be true "obligate oligotrophs." Although some DNA molecules may have come from dead organisms that had grown elsewhere, most must have come from in situ obligate oligotrophs. Although we do not understand their basic physiology, we can infer that, with few exceptions, these organisms must have grown in the environment in which they were found.

WHAT PROPERTIES MUST AN OLIGOTROPH HAVE?

In 1978 a workshop was held (29) to consider "Strategies of microbial life in extreme environments" and the subcommittee on "Life under conditions of low nutrient concentrations" summarized from available knowledge and from just thinking about the problem what such oligotrophs must be like. I must summarize these considerations here and add more from work in the subsequent 25 years in the laboratories of Poindexter (8–10), Morita (13), Colwell (30), Button (16–21), Egli (31–36), Pace (5,27,28), and Koch (22–25).

- Oligotrophs should be able to efficiently scavenge their environment of nutrients. For this they should have a high surface-to-volume ratio. Not only should they be small for this reason, but also they should be nonspherical (37). Actually, some are spherical, possibly for simplicity in formation during growth. They should have a high volume-to-biomass ratio and active transport systems that can accumulate substances against a high concentration gradient. These "permeases" generally should be ready to function and the range of transport systems should suffice for the range of types of molecules that are likely to be encountered in the relevant oligotrophic environment. The energetics of active transport systems can depend on the type [respiration and ATP-linked generation from proton motive force (PMF)] and on the degree of coupling of the symporters or antiporters to the relevant ion gradients. Again, the choices depend on a balance of cost and upkeep versus utility to the organism. The prime problem of the cell is to acquire substrates, and developing enzymes to metabolize them is probably a less immediate problem. To summarize, they should have the ability to consume a variety of substrates that *might* occur and be able to do so promptly at any time. They must do so efficiently and waste little in maintaining and assembling an adequate transport system during the time a particular transport system is not needed.
- Oligotrophs should be able to husband their resources. Although suspended in an aqueous environment as in the high-seas environment mentioned in the preceding text, nutrition may be almost continuous but infinitesimal, but in most oligotrophic environments life is one of feast and famine. However, not as suggested for the life of *E. coli* (38), but one where the feast is very spartan and the famine supplies poor resources in terms of both quality and quantity (Poindexter chooses the word "fast" instead of a limited "famine"). To the degree that it is biologically possible, the oligotroph should (*1*) decrease its metabolism, (*2*) decrease any turnover, and (*3*) block any futile cycles. In addition, it should (*4*) have stored up some reserves to help it through the severest part of the famine. It should do this even at the expense of not engaging in certain amount of cellular growth. Clearly, all of these prohibitions are "judgment calls," but they appear to be built into the physiology and genetics of the species and kind of oligotroph being considered. The oligotroph must engage in metabolic processes, and their kinetic control to conserve resources is much more sophisticated than the mechanisms of copiotrophs. *Bacillus subtilis*, in an all-or-none way, carries out the sporulation pathway at great expense to itself and then, also in an all-or-none way, can revert to vegetative growth. *Escherichia coli* responds to a rapidly imposed starvation. The apparently simple choice of how not to grow too fast is seemingly both with and against the dictum of Darwin and the dogma of ecologists that an organism's goal is to increase its inclusive fitness. If it grew at the limit of its current resources, then it would not be able to form reserves for future needs, but the organism has no way of knowing the time when the near-famine state will become a total-famine state. In principle, evolutionary processes have selected for those varieties of organisms that do not grow too fast and do not extensively store accumulated resources as reserves. Somehow they must have a strategy, encoded in their genes, based on the past experience of earlier generations.
- Among the endogenous resources consumed during starvation, ribosomes and associated factors are generally used, whereas poly-hydroxy-butyrate (PHB) and glycogen are stored only in some bacteria. Degradation of ribosomes is a general strategy because a cell during growth needs many ribosomes, but during starvation a cell possesses an excess over its needs. When little protein synthesis is ongoing, degradation of currently unneeded proteins and ribosomes can permit specific proteins to be produced that can enable the cell to prolong its survival (see section Conservation of Current Resources for Future Use).
- Although a bacterium cannot pursue multiple strategies, a bacterial population can. I have discussed (39) reasons for believing that bacteria have built-in mechanisms to increase the rate of special mutations in regions of specific genes that are easily reversed when the need has passed. This can be done by having a tandem series of doublets or quadruplets in relevant genes. Thus, in a population of millions or more bacteria, there are mutations that are due to slippage and mismatch repair in these tandem repeats that turn on or off genes in which they are present and allow an individual organism to cope with an environmental challenge. When the environmental challenge is no longer present, the culture can revert in the same mutational way, and

the original genotype can be selected. So this type of mutational mechanism provides temporary help.

- Many organisms that appear to be obligate oligotrophs can be "coaxed" into becoming facultative oligotrophs or copiotrophs (these would be a subset of Kuznetsov's second category). In the reverse direction, copiotrophs seem to be converted to oligotrophs during slow growth. I have the impression from the literature and from my own experiments (25) that copiotrophic cells growing in slow chemostat culture slowly become converted to having a slower maximal rate of growth but also a higher efficiency of uptake. Although the topic of viable but nonculturable (VBNC) cells is currently in a state of flux with supporters and detractors, it would seem to be merely a difference in degree and strategy from characters expressed in other organisms, particularly oligotrophs.

WHO LIVES IN OLIGOTROPHIC ENVIRONMENTS AND WHO DOES NOT?

The biology of four oligotrophs and one copiotroph are explored in this section, in large part, to document and extend the conclusions mentioned in the previous section.

The Marine *Moritela* Ant-300

The in-depth study of Ant-300 in the laboratory of Morita involved many students and many years (13,40,41) and is probably the most completely documented case of an oligotroph. The starting point for Morita's studies was the observation that this vibrio on starvation for a carbon source changed progressively to small coccal-shaped form. Obviously, two processes are ongoing during the early phases of starvation. One process was that the starving rods divided to form smaller coccal-shaped organisms; this is similar to what is seen with *Arthrobacter* species (see following text). Moreover, similar behavior was observed with *E. coli* (3). In the latter case, the cells are long and wide in rich medium, whereas they become smaller in poor medium, although they maintain their proportions in the length and width dimensions. In the case of this vibrio, the culture increases in both viable and total count about fourfold in the first week of starvation as the cells become smaller. Thus, although the size of the individual cell decreases as cell division takes place, they are substantially all alive.

Thus, the first response is that the cells become smaller but still can form a colony and are alive by all the criteria used in microbiology. Subsequently, after the first week, some cells died using these assays, but the number of small round particles remained constant for many weeks, indicating little cell lysis. Therefore, there is an increase in the proportion of particles of the dimensions of starved living cells that cannot be induced to give rise to a colony. The viable count eventually plateaus after the decrease in viability of 1,000-fold (41). This is typical of the response of many bacteria to environmental challenges. It is speculated from electron microscopic studies (40) that the live particles are the ones that retain a less dense region in the center of the cell than do the bulk of the particles. This lighter appearance in electron microscopes is usually characteristic of DNA-containing regions. Moreover, the cells that appear not to form colonies have a periplasmic space that is a higher percentage of the total cell volume.

These same cellular changes could be duplicated by growing the organism in continuous culture at progressively slower dilution rates. During the starvation of particles of the dimensions of coccal cells, various cellular components generally decreased.

The Prosthecate Bacterium *C. crescentus*

Caulobacter is a genus of prosthecate bacteria. This aerobic heterotroph occurs in freshwaters and soils of low organic content. The dividing cell is asymmetric. One part, the stalked half, remains attached to a surface and continues to grow and divide; but the other part, the swarmer cell, carries out few biosyntheses. Instead it swims around, until it finds a place to reside. Then, it sheds its flagellum and in its place grows a stalk with holdfast material to hold it to the substratum. In poor, usually phosphate-deficient medium, the stalk continues to grow, generation after generation. The new region formed with every generation is separated by a partition from the earlier portion (42). The stalk appears to be an extension of the cell envelope, and two functions have been assumed for it: to function as an absorptive organ with a surface containing very little volume and to allow the cell body to be further from the surface of attachment. With a long stalk attaching it to a solid surface, the flow around the cell body bathes it with a fresh environment and thus the cell is better able to sequester resources (42).

Much of the behavior and the kinds of habitats in which *C. crescentus* is found are consistent with the niche of specialization to grow in a severely nutritionally limited environment. However, *C. crescentus* is not a strict obligate oligotroph. There is reason to believe that even fresh isolates from nature are not truly obligate oligotroph. This comes from the use of an effective technique used by microbiologists for isolating the species. The sample from the oligotrophic environment is plated on an agar that has a certain small amount of peptone, tryptone, and so on. Colonies that grew rapidly are identified the next day and colonies that have subsequently emerged are picked several days later. Many of these turn out to be *C. crescentus*. Consequently, it can be concluded that these organisms had obviously not been killed or destroyed by the nutritional supplement. Many other species of genus *Caulobacter* are more difficult to grow and thus some of them may be oligotrophs that are more obligate than *C. crescentus*.

Another conclusion that *C. crescentus* has copiotrophic tendencies can be drawn because the organism is currently under intense molecular biological study in the laboratories of Shapiro and those of her erstwhile students (14,15). The studies in these laboratories depend on the ability to grow cultures to quite a high density to allow molecular biologists to perform the many kinds of experiments and measurements of their trade. Because it now grows to high density, it can be concluded that the organism never really had an obligate oligotrophic status

or has modified its apparent obligate character during culture.

The Jointed Gram-Positive Bacteria, *Arthrobacter* spp.

Study of this oligotroph has been carried out in Ensign's laboratory (43–45). Arthrobacters grow as a chain of rods and have received their name because the junction between rods is usually at an angle. Consequently, they resemble the joints in a human limb or, more realistically, the legs of a spider. This articulation between chains is a result of the division process in which a septum is completed across the cell and then split into two, but the last few bonds may be split more slowly. Other gram-positive rods under certain conditions do the same thing. The organisms are found mainly in soils. Although the jointed chains of rod-shaped cells are useful for taxonomy, it is argued that this is not its characteristic form in its natural environment, which is usually nutritionally deficient. Under such conditions, the cells continue to divide until they appear coccoid. These coccoid cells are small, but not of a full resting form like a spore because they appear to grow and divide as coccoids, although they are more resistant to environmental stresses. Enough is known about wall growth in *E. coli* so we could engineer a recombinant form to convert it from a rod to a coccus, as occurs naturally for the *Arthrobacter*. Probably it could be done in several different ways. But it is not clear why this change in *Arthrobacter* takes place. I have argued that the change in surface-to-volume ratio would not increase the effectiveness of diffusion very much, although a small change could be biologically important. The more likely explanation is that in dividing to become smaller, the same amount of cytoplasm and nucleoplasm will be present in more "propagules" in the small coccoid form.

Their maximum growth rate in rich medium is not very fast, say a doubling every two to three hours. The low maximum rate is usually attributed to their inability to deal with saccharides. This makes some sense. In general, in the decomposition chain of vegetable biomass, the acid-soluble fraction of the cells is consumed first, then the reserve polysaccharides and proteins, and lastly the lignins. In these stages, the more and more recalcitrant compounds are enriched and organisms growing at the later stages have to deal with a different distribution of resources. So the arthrobacter, like *B. subtillis*, may commonly meet succinate in its environment and not sugars simply because the latter has been consumed first and the dicarboxylic acid, succinate, is a product of the degradation of aromatic and fatty compounds. Conversely, *E. coli* grows faster on certain sugars than it does on succinate. So the question of why the growth rate is slower cannot be explained on a biochemical basis. Poindexter's review (9) suggests that their inability to grow rapidly may be the reason that they can thrive in soils compared with the failure of an organism like *E. coli* to grow in this environment.

During starvation RNA and protein are degraded. This process is discussed further in the section Conservation of Current Resources for Future Use.

A Marine Ultramicrobacterium *C. oligotrophus* RB1

The fourth organism to be discussed is *C. oligotrophus* RB1—it was isolated and studied by Button and coworkers (16–21). He is a marine microbiologist and his group isolated marine oligotrophs that appeared to be obligate, at least initially. Cloning was performed by an MPN (most probable number) method that he called the dilution culture technique. In this technique, seawater was filtered and sterilized. Seawater contains a low level of nutrients; this could be demonstrated when the sterilized seawater was inoculated with a small fraction of the unsterile seawater and the number of organisms increased and in some weeks, the cell count returned to its original value as measured by flow cytometry. With this as a start, they used smaller inocula and subcultured by the same technique until they had a monoculture. One of the organisms generated by this type of subculture was named *C. oligotrophus*; it was studied extensively and it was found that it could be grown to high titers with aromatic compounds as carbon substrate (19).

Button's group isolated many cultures in this fashion from oceans in several parts of the world. Many of the strains could not be grown initially on high nutrients, but after culture and subculture in the laboratory, most could grow to higher titers. When cloned, their nutrition could be studied, and it was clear that a number could grow to high density on the appropriate substrates. Many of these cells appear to be less dense than a typical vegetative cell of a growing copiotroph. Thus the main point is that this organism uses low levels of carbon sources more effectively than many other organisms and has designed its biology to yield a small cell with a smaller, simpler, and specialized genome, little protein, and a high proportion of water so that the small cell is larger than would be expected from its protein content.

Fast Rate of Uptake at Low Concentrations by *E. coli*, the Presumptive Copiotroph

Escherichia coli is a gram-negative rod and has been considered the prime example of a copiotroph. When it is cultured in a glucose-limited chemostat and diluted into very low glucose minimal medium, it takes up glucose at such a fast a rate that it can be calculated that if it had no outer membrane the uptake would be the theoretical maximal rate limited by physical diffusion (23–25).

Consequently, the important experimental question is how close can bacteria come to this theoretical limit. To test this experimentally, I used the apparatus that Wang and I (22) had constructed to attack a related question. It was concluded from the uptake kinetics and by fitting the data to a variety of models that the cells of strain *E. coli* ML308 when cultured in a glucose-limited low dilution-rate chemostat for a month were, indeed, very efficient during batch growth in very low concentrations of glucose. The measurements and the subsequent calculations showed that if the outer membrane could have been stripped off the cells, then uptake at the cytoplasmic membrane would be at the theoretical level of the physically fastest possible consumption. But because of the extra obstacle to diffusion due to the diffusion resistance in the penetration

of the porins of the outer membrane, the ultimately fastest limiting rate for intact gram-negative cells is a little less than the theoretical limit. For more details, see (25).

PHYSICAL CONSIDERATION FOR SURVIVAL UNDER STARVATION OR OLIGOTROPHIC CONDITIONS

Two major topic are considered in this section. The first is the necessity of maintaining the energy within the cell. This mainly depends on the cell possessing and using ways to block dissipation of energy sources. The other is to consider the role of diffusion in the oligotrophic environment.

Control of Energy Metabolism

Consider a stripped down bacterium with no regulatory or control mechanisms. This hypothetical entity is like a car without a steering wheel, brakes, or accelerator. As long as energy is available, the bacterium can generate protonmotive force and ATP, say, from the respiration of glucose with oxygen and grow while the car engine could burn gasoline and the wheels would turn. The cell can carry out synthetic biochemistry and grow, synthesizing or importing from the environment all the necessary macromolecules for the cell's life, and the car would move. When the energy supply is no longer available, thermodynamic laws will require that the system should approach the equilibrium state. This, for the bacterium, means that almost all macromolecules would hydrolyze to their constituent amino acids, monosaccharide, fatty acids, nucleic acid bases, and phosphate. The reactions go toward dissolution because the concentration of water is high in living systems and provides the water that splits the macromolecules to their constituents. The car would just coast to a stop.

Although any system spontaneously moves toward equilibrium, net synthesis of a part of a system can occur only when the overall free energy of formation of the system is negative; that is, if the positive free energy for the synthesis (uphill part) is overcome by the negative free energy (downhill part) of the energy-supplying portion of the cell's metabolism. For biological systems, this is when an adequate chemical energy source is present within the cell at a sufficient concentration. When the high-energy sources are absent or only present at an infinitesimal concentration, the net reaction is still "downhill" as it always must be, but now the equilibrium-free energy state to which the system is driven is toward hydrolysis and the state of nonlife.

This is the issue relevant here. When the concentration of the internal energy source, ATP, is near zero and in the absence of a membrane protonmotive force, the system will spontaneously proceed toward the reversal of the synthetic paths. For example, if the forward direction of a particular reaction is the addition of an amino acid to a growing peptide chain by virtue of energy from a charged tRNA and from GTP, these two substances will not be present in the absence of metabolic energy, but uncharged tRNA and GDP will be available and the reverse process could happen. It might be slow. More extreme hydrolysis of a protein by ribosomes and associated factor would charge the tRNA and other steps would generate free amino acids. Because there are many steps, including sequential reactions, the reversal of most or many metabolic reactions during starvation would be slow, but eventually would drive the system backward. For a whole-cell this must lead to death and destruction. The relevant point here is that bacterial cells must have active mechanisms equivalent to brakes and clutches. This is an entirely unstudied aspect of microorganisms in general and of oligotrophs in particular.

Possible Processes That Would Speed Destruction of a Cell Faster Than the Default Rate

Enzymes are very efficient and effective machines, but they are not perfect. The default situation of reversal of the synthetic machinery in the absence of metabolic energy would occur if each energy-coupling enzyme had a single specificity and transduced energy with 100% efficiency. On the other hand, if the specificity and the coupling to energy source was not complete, there would be some spontaneous downhill hydrolysis reactions and the system would dissipate its macromolecular structures faster.

Probably much more important, the cell does possess energy-dissipating hydrolases (proteinases, nucleases, etc.). Their purpose to the cell would be to degrade and turn over cellular constituents as a proper aspect of cell metabolism and as part of the normal cell cycle. There are also enzymes that were made for export to the periplasm or to the environment to break down resources found there to create nutrient molecules that the saprophytic cell could use. However, portions of these enzymes may fail to be extruded from the cell and remain in an active state inside the cell; in this case degradation would be enhanced. There are hydrolytic enzymes residing in the periplasmic space of gram-negative organisms that have a nutritional function, but if given time during starvation, they may degrade some other constituents of the periplasmic space and its surfaces.

Bacteria Have Genetic Factors That May Function to Enhance Survival in a Given Environment

The point has been made that most of the genome of a typical organisms such as *E. coli* is not used under a single given growth condition (46–49). In fact, the majority of the genome may represent temporarily nonfunctioning DNA. This includes sequences left by genetic pathogens that inhabited and functioned in an ancestor and are no longer viable. In this age of complete sequencing of genomes, it is clear that there is much genetic information in cells that is not being used at any time. Probably most of it collectively serves a role when the cell is subject to one of many challenges that have occurred many times in the history of any species, including starvation and coping with a nutritionally deprived environment. Work from a number of laboratories with particular organisms and particular environmental challenges have been presented in the literature. This, of course, includes responses to starvation. But although many genes and many enzymes have been located in these studies, it is clear that the microbiologist is nowhere near a full accounting for the functions of the bacterial genome.

DIFFUSION LIMITATION OF UPTAKE

A bacterium is much more nutritionally limited than an animal in being able to seek out nutrients. Motile chemotrophic microorganisms do some hunting, but only to a limited extent. In fact, coliforms cannot move faster toward nutrients than small molecules can diffuse to the cell (38,48,50).

The kinetics of diffusion (50) of nutrients to the cell from the bulk medium depends on Fick's law. His law can be expressed in either of two forms. If we idealize the shape of a cell into a sphere, the mathematics using Fick's second form becomes simpler. The first biological application of Ficks's law, applied in the 1930s, concerned the adsorption of virus onto bacteria (51). Later, Delbrück (52) extended the treatment and obtained

$$C = C_o\left(\frac{1-a}{R}\right)$$

for the concentration, C, at a distance r from the cell center, where C_o is the concentration in the bulk phase at a long distance from the cell. The distance at which C becomes zero is a. The radius of the spherical cell is indicated by R. If there is complete consumption of every molecule that diffuses to the surface (which is the best that a cell can do), then at the surface of the cell, $C = 0$ when $a = R$. If uptake is less efficient than this physical limit, then a is less than R and C will be greater than zero at the surface, and the gradient of concentration at the cell surface in this case is less.

The rate of uptake of the cell is the quantity of interest. To obtain this information, we substitute the equation for concentration, given in the preceding text, into Fick's second law written for spherical geometry, carry out the mathematics, and end up with:

$$\frac{dq}{dt} = 4\pi DaC_o$$

where dq/dt is the rate of substance uptake by a cell and D is the diffusion constant of the nutrient in the medium. In an earlier paper (37), I have rearranged this equation to calculate the theoretical efficiency of the cell, E, as D/a^2. The efficiency is defined as the equivalent number of cell volumes of medium that are depleted of resource per second by diffusion to the surface if there is complete consumption by the cell.

BIOLOGICAL CONSIDERATIONS FOR SURVIVAL IN A NUTRITIONALLY POOR ENVIRONMENT

Both oligotrophs and copiotrophs must survive in a poor nutritional environment, but the former have evolutionarily "chosen" to specialize and persist in the chronic starvation condition and may not persist in other nutritionally richer environments for extended periods. The copiotrophs on the other hand will not successfully compete and survive indefinitely in a low nutrient environment. Consequently, each type must have been "tuned" to their particular environments by evolution to be better. So we should next consider those factors that would aid in either endeavor. It must be noted that except for chemostat or turbidostat culture, there are no environments that are truly constant and consequently organisms can reasonably "expect" upswings and downswings in the nutritional state of their immediate environment and as the result of evolution have "planned" to capitalize on and exploit the upswings and survive starvation and other down swings.

Conservation of Current Resources for Future Use

Many oligotrophs and copiotrophs, but not all, "choose" to synthesize polymers and form inclusion bodies to store carbon, nitrogen, and/or phosphorus, presumptively for later leaner times. This makes good sense if the cell could not use available resources for immediate growth because of some other constraint. This is the problem of heterotrophic dual nutrition (39,53), which has been discussed in a number of papers by Egli (31) and has been mathematically modeled (54). An example of this is cases in which some, but not all, of the needed nutrients are available in the environment at a given time. However, if the resource could have been used for immediate growth and the production of additional propagules and instead is used for storage material this would appear, at first, to be a bad strategy. But maybe not! Specifically, if future starvation could lead to cell death, additional metabolic reserves might postpone death enough to survive the starvation period. Parahydroxy benzoic acid is a common storage form. There is an alternative strategy to storing PHB. This strategy is used in some cases and may be a better approach sometimes. This was first discovered in *E. coli* (55). It was found that on starvation, the cells would break down ribosomes and use them for purines, pyrimidines, amino acids, and for carbon, nitrogen, and phosphorus for growth and metabolic energy, while keeping only a small fraction of functional ribosomes for new protein synthesis for the time when adequate resources might materialize.

A related phenomenon is that in slow dilution rate chemostat culture in the steady state, the organism keeps many more ribosomes than it can currently use. However, if a fluctuation occurs to greatly enrich the environment, these ribosomes come to function in seconds, presumably so that the organism can grow quickly after a shift up (38). So for multiple reasons, having extra an ribosome, but not too many, is an effective hedge against either future condition becoming either poorer or better.

Multiple Pumps

Cells can have a variety of mechanisms present in the cytoplasmic membrane (and in the outer membrane of gram-negative cells) for transport. The simplest class would be the transport mechanisms called "facilitate diffusion." These equilibrate the concentration of specific compounds across the membrane so that the concentration on both sides of the membrane tend to approach each other. Secondly, there are mechanisms that use metabolic energy to actively bring into the cell against a concentration gradient molecules from the environment. These active transport mechanisms are generally necessary under

nutritionally poor conditions. But then the cost of manufacture of the more complex mechanism, the necessary additional genetic apparatus, and the energy expenditure for function must be taken into account. Moreover, there may be energy consumption even if there is no substrate present (idling). This would constitute a continuing loss to the cell. There are other considerations as well; the transport units must be numerous and distributed on all sides of the cell surface. Because the cell frequently has many substances to import, this leads to competition for the space on the cell surface.

There is another quite different aspect — in most oligotrophic environments in addition to the total concentration of carbon compounds being low, it is the fact that it is usually composed of multiple and varied substances. So resident organisms must again choose to adopt different strategies depending on whether there are many kinds of substances or whether there is a single or only a few kinds of homologous resources. It may happen that a class of similar chemical species is present and can be accumulated by a single kind of pump. Egli has emphasized that multiple pumps for carbon compound are generally needed, but it must be emphasized here that different environmental habitats call for different allocation of membrane surface and competing bacteria may succeed or fail on this basis. It was pointed out earlier that oligotrophs should be constitutive in their synthesis of pumps so that they will be ready when the substrate enters their environment and not waste the time to induce the permeases and incorporate them into the membrane in response to sensing the compound in the environment, but this can be overdone.

Failure to Use Certain Environmental Sources

A cell that has many pumps has the costs discussed in the last paragraph, but there are more issues. A pump not functioning because of lack of exogenous substrate may act to allow cellular resources to exit the cell. A way to avoid this problem is to not form the pump or not install it in the cellular membrane. This may protect the cell, but may also prevent it from growing rapidly in a richer environment. This may be the critical reason also why oligotrophs do not grow fast in rich medium.

The Necessity of Surviving in Multiple Habitats

There are many species of bacteria that form the basis of Bergey's manual. Modern molecular biology and microbial ecology have shown that these known types are only a small fraction of what is "out there," as most of the world's organisms have not been cultivated. Most of these, no doubt, represent organisms adapted toward particular habitats quite different from that provided by the usual culture media in the laboratory.

There is a particularly important class of sequential adaptations: these are multiple adaptations that serve to aid an organism to grow because its habitat must necessarily vary from time to time. Many microorganisms must adapt serially to a number of habitats as aspects of their growth strategy. For example, *E. coli* must get to a new host before the current host dies of old age. To survive in nature, *E. coli* must adapt: (*1*) to the environment of the mammalian colon; (*2*) to that of wastewater and soil; (*3*) to the upper gastrointestinal tract of some other mammal, and (*4*) finally, to the large intestine of the new host. *Escherichia coli* must succeed in all to be passed from host to host and survive indefinitely. Although I have argued that much of what is known of the molecular biology of this organism bespeaks of adaptation to the ileum (the most distal part of the small intestine; 63), it must necessarily do well enough in each of these stages to persist in nature. Recently, there has been interest in organisms that have two alternate lifestyles: living in an environment as a saprophyte (nonpathogen) versus their living as pathogens inside of an animal or a plant host. We are beginning to understand the ways they switch from one growth mode to another.

References to Reviews in Related Areas

The study of oligotrophs overlaps the field of starvation survival. I will take the term "starvation survival" to include not only starvation of particular nutrients, but also survival in the stationary state, and the growth of organisms at low dilution rates in continuous culture and life in an oligotrophic nutritional environment. The key reviews and monographs of the field of starvation survival are Fletcher and Floodgate (56), Kjelleberg (57), and Morita (13). Related fields have to do with organisms that are in the shutdown state (58) and the viable but not culturable (VBNC) (30) state. The issue of VBNC is current and important. Particularly relevant are the studies of Matin (59) and Kolter (60). See References 61 and 62 for how *E. coli* survives during starvation.

Questions Not Answered Here That Need to be Addressed

This article has delved into the evolutionary principles, biophysics, biochemistry, and microbiological physiology of oligotrophs. This article has not provided answers to the following question areas:

1. Why don't all bacteria grow in any environment that has, at least, an infinitesimal concentration of necessary nutrients?
2. What are the mechanisms that increase chance of death when, at best, only slow growth can occur?
3. Are there threshold phenomena such that at too low nutrient concentrations, no growth can occur because all energy metabolism is spent in maintenance?
4. Are some organisms that appear to be obligate oligotrophs really experimental artifacts (48) because the organisms are destroyed, for example, osmotically when nutrients are added by the microbiologist? Does death occur because uptake is then too rapid that the cell's osmotic pressure becomes too large and causes rupture of the cell? Alternatively, does a rich medium under aerobic conditions produce lethal free radicals?
5. Are there two special biologies for oligotrophs and for copiotrophs or is there a continuum biologies for a continuum of habitats and niches? This is of basic microbiological interest.

Acknowledgments
I wish to thank Don Button, Tom Egli, Anne Glover, and Jeanne Poindexter for the inspiration to write this review.

OXYGEN: EFFECT ON MARINE MICROBIAL COMMUNITIES

NIELS PETER REVSBECH
KAI W. FINSTER
University of Aarhus
Aarhus, Denmark

Oxygen is a master variable in nature that governs the distribution of organisms. Oxygen is produced by the oxygenic photosynthesis of cyanobacteria, algae, and plants. It is consumed by the, predominantly biotic, oxidation of organic matter previously formed by photosynthesis. A significant amount of oxygen is also used for the oxidation of reduced inorganic compounds such as ammonium, ferrous iron, reduced manganese, and sulfide; oxygen thus has an important impact on the major element cycles. Animals and plants almost exclusively depend on the presence of oxygen for their respiration, and microorganisms that do not require oxygen therefore dominate the anaerobic world. The effect of oxygen distribution on the biota is most easily seen in waterlogged systems where the low solubility and diffusivity of oxygen in water results in steep oxygen gradients in stagnant environments such as sediments. The low solubility also means that water bodies with a high consumption rate of oxygen periodically may turn anoxic with dramatic effects on fish and other organisms.

Microorganisms have adapted to different oxygen regimes and on this basis are defined as aerobic, microaerophilic, or anaerobic (1,2). Aerobic bacteria thrive at oxygen concentrations of 200 to 300 μM (equal to air saturation) while microaerophilic bacteria proliferate at lower oxygen concentrations, and they are often inhibited when concentrations approach air saturation at 200 to 300 μM O_2. Anaerobic bacteria, in contrast, are harmed by oxygen and are unable to grow with oxygen as electron acceptor. The presence or absence of oxygen also governs the mineralization pathways of complex organic matter, such as polysaccharides, and on the kinds of bacteria involved. While some pure cultures of aerobic bacteria can completely oxidize cellulose to CO_2, the same process in anoxic marine environments requires at least three physiologically specialized kinds of bacteria. The energy available to these anaerobes is much less than when oxygen is used as electron acceptor as oxygen reduction is the thermodynamically most favorable process (3). The electron acceptors used by anaerobes (e.g., NO_3^-, Mn^{4+}, Fe^{3+}, SO_4^{2-}, CO_2) are transformed to reduced products that may be eventually oxidized with oxygen. These products include ammonium, which is produced by dissimilatory nitrate reducers (4); hydrogen sulfide, which is produced by sulfur- and sulfate-reducers (5); methane, which is produced by methanogens (6); and reduced metals such as ferrous iron and reduced manganese, which are produced by metal reducers (7,8).

Historical Record of O_2 in the Sea

Considerable controversy exists about the evolution of oxygenic photosynthesis, but there is general agreement that the first oxygenic phototrophs were cyanobacteria-like organisms, as all oxygenic photosynthesis in the present world is performed by cyanobacteria (including the prochlorophytes) and the chloroplasts of eukaryotes that are closely related to cyanobacteria. Well-preserved fossil stromatolites usually thought to be affiliated with ancient cyanobacterial communities have been dated as far back as 3.5 Ga, but it should be kept in mind that even some modern cyanobacteria may perform anoxygenic photosynthesis (9). Cyanobacteria-like filamentous microfossils in stromatolites could be ancient relatives of

Chloroflexus-like organisms that perform only anoxygenic photosynthesis, but the morphological variation in filamentous and unicellular bacteria in stromatolites as old as 2.6 Ga (10) points to an origin of cyanobacteria older than that.

The precipitation of large banded iron formations (11) at about 2.7 to 1.8 Ga (i.e., 2.7 to 1.8 billion years ago) indicates that the oceans were being oxidized during that period, and the change in isotopic composition of carbon (12) and sulfur (13) at 2.8 to 2.7 Ga support the initiation of a considerable O_2 production. Banded iron formations older than 2.7 Ga are also found, and even the oldest known rocks (3.8 Ga) from the Isua formation in Greenland contain small banded iron formations (11). The highest rates of iron deposition occurred around 2 Ga. It is possible that some of the older banded iron formations were caused by the activity of iron(II) oxidizing phototrophic bacteria (14), but some scientists also assume that oxygenic phototrophs were present in the ancient microbial communities at about 3.8 Ga (15). Although there is good evidence for initiation of oxygenic photosynthesis no later than 2.8 Ga this does not mean that the oceans were predominantly oxic. The continued extensive precipitation of banded iron formations until about 1.8 Ga indicates that they were in fact predominantly anoxic at least until that time, and it is possible that only a thin surface layer of the oceans were oxic until the oxygen concentration in the atmosphere rose to considerable levels. It is even possible that the bottom waters of the oceans became sulfidic after the precipitation of dissolved iron and remained so until the O_2 concentration in the atmosphere presumably reached >10% of present day levels at about 1.0 to 0.6 Ga (12–13).

OXYGEN TOXICITY

In general, organisms that respire with oxygen grow faster and to higher densities than organisms that use alternative electron acceptors. However, the advantages of aerobic respiration come with a price. Oxygen reduction forms intermediates of extremely high reactivity that cause damage to many cell constituents, including lipids, sugars, amino acids, and polynucleotides. These intermediates are superoxide radicals, hydrogen peroxide, and hydroxyl radicals. The hydroxyl radicals, which are produced when superoxide radicals react with hydrogen peroxide, are responsible for most of the damaging effects of oxygen. The extreme reactivity of these compounds supported the evolution of a suite of detoxification and repair mechanisms (16–18).

Despite the devastating effect of oxygen metabolites, multicellular eukaryotes have "learned" to exploit them to their own benefit. One example is the so-called "respiration burst" of phagocytically active cells, during which the massive production of oxygen radicals helps kill invasive bacteria. Secondly, plants use hydrogen peroxide in the oxidation of phenols, which serves for the synthesis of lignin (17). However, in the prokaryotic world reactive oxygen intermediates generally represent a threat to cell integrity and consequently cells respond by means of several integrated detoxification systems. The different systems are discussed in detail elsewhere (17) and will only be described very briefly here.

Superoxide dismutase (SOD) catalyzes the dismutation of superoxide radicals into O_2 and H_2O_2:

$$O_2^- + O_2^- + 2H^+ \rightarrow O_2 + H_2O_2$$

The presence of SOD in organisms was originally interpreted as a major adaptation to aerobic respiration, and thus as a key to distinguish between aerobic and anaerobic organisms (19). Early studies supported this hypothesis as SOD activity was exclusively found with aerobic or facultatively aerobic bacteria. However, later investigations identified SOD activity in anaerobes such as *Desulfovibrio desulfuricans* (Norway 4), *Desulfotomaculum nigrificans*, and *Clostridium perfringens* (20,21). Recently, it has been proposed (22) that the SOD activity, which observed in many anaerobes, is only putative, and actually represents superoxide reductase activity instead (see below).

The possible role of H_2O_2 splitting enzymes (e.g., catalase) in oxygen detoxification was recognized by Gottstein in 1893 (23), who observed the production of gas when certain bacteria were treated with H_2O_2. The reaction is described by the following equation:

$$H_2O_2 \rightarrow H_2O + 0.5O_2$$

Catalase thus detoxifies a product of the SOD reaction. As for SOD, early reports correlated the presence of catalase with the ability to use oxygen, but as for SOD this generalization was overruled by later discoveries.

In contrast to SOD, superoxide reductase (SOR) detoxifies superoxide radicals without formation of molecular oxygen and thus avoids production of a potential source of new superoxide radicals. Instead, SOR reduces superoxide radicals to hydrogen peroxide that is further reduced to water by peroxidases. It seems that this detoxification reaction is particularly well suited for the needs of anaerobes (22), and thus SOR rather than SOD is expected to be found in anaerobes. The presence of SOR in organisms that lack SOD was confirmed by complete genome analysis. It was concluded (22) that the presence of SOR in anaerobes "indicate(s) that anaerobic microorganisms possess a mechanism for detoxifying reactive oxygen species that is independent of the SOD-catalase-based system of the aerobic world."

THE DISTRIBUTION OF OXYGEN IN WATER AND SEDIMENT

The vast majority of the oceanic water column is well oxygenated, and the water circulation suffices to keep even the deepest parts oxic with some exceptions such as the Cariaco Trench. Some open-water areas such as the upwelling areas outside Peru and Namibia may, however, experience periodic anoxia. Because of high primary production in these areas anoxia or very reduced oxygen concentrations may occur either at some depth in

the water column (the so-called oxygen minimum zone), or in the bottom waters (24). Isolated water bodies such as the Black Sea and fjords with a sill may have permanently anoxic deep waters (25), while estuarine areas that are stratified by gradients in temperature and salinity as, for example, the Danish straits, may experience periodic anoxia (Fig. 1; 26).

While marine waters are predominantly oxic, the reverse holds true for the sediments. Oxygen usually penetrates to a depth of a few mm in coastal sediments (27), and only sediments from deep oligotrophic oceans have homogeneous oxygen penetrations exceeding a few centimeters (Fig. 2; 28). It is, however, important to realize that oxygen locally may penetrate to considerable depths because of infauna. Burrowing fauna may maintain a thick layer of oxidized sediment (i.e., with a high content of particulate oxides and hydroxides of Fe^{3+} and Mn^{4+}) while the majority of this oxidized sediment at any given time is anoxic (29). The difference between oxic and oxidized conditions in a bioturbated sediment is illustrated in Figure 3 by profiles of redox potential and oxygen. As illustrated to the right in Figure 3, such sediments are also characterized by a large spatial variability in the distribution of oxic and oxidized conditions. The effect of the fauna on the reoxidation processes depends on the feeding and burrowing strategy of the animals. Some animals may make burrows down to a sediment depth of 2.5 m (30), but usually the affected layer is considerably thinner (0.5 m or less).

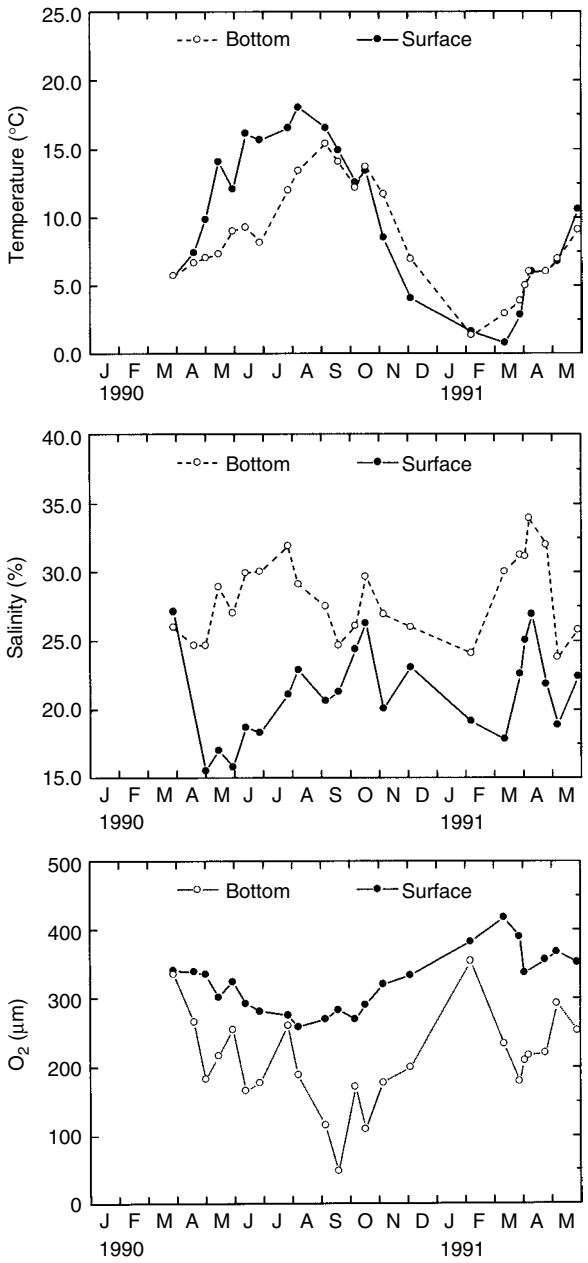

Figure 1. Changes in surface and bottom water temperature, salinity, and oxygen concentration through the seasons in the middle of Aarhus Bay at a water depth of 16 m. Owing to the density gradient caused by the differences in temperature and salinity, the water column was permanently stratified and the bottom water went almost anoxic in September. Redrawn with permission from B. Aa. Lomstein and T. H. Blackburn, Havforskning fra Miljøstyrelsen **16**, 1–74 (1992).

OXYGEN AND PHOTOSYNTHESIS

Oxygenic Photosynthesis and Photorespiration

The activity of oxygenic phototrophs may lead to elevated concentrations of oxygen in water masses with high photosynthetic activity (31). The effect of photosynthesis on the chemical microenvironment is, however, much more pronounced in shallow-water sediments. Profiles of oxygen, pH, and gross photosynthetic activity (for a description of methods see 29) are shown in Figure 4 for an illuminated marine cyanobacterial mat (Fig. 4a) and for a diatom-inhabited sandy sediment (Fig. 4b). Although oxygen reached a peak concentration of 1,540 µM (corresponding to supersaturation with pure oxygen gas) at a depth of 0.2 mm in the cyanobacterial mat, the sediment was anoxic below 1.6 mm depth. The high photosynthesis (CO_2 assimilation) rates in the upper 0.4 mm resulted in a pH as high as 10.3, although the pH at 3 mm depth was about 7. The effects of the photosynthetic activity in the diatom community (Fig. 4b) were less dramatic than in the cyanobacterial mat because of a lower population density.

The effect of very high oxygen concentrations on marine heterotrophic bacteria is poorly studied, but high oxygen concentrations affect phototrophs themselves as high oxygen promotes photorespiration. The ribulose-bi-phosphate-carboxylase (RUBP) that mediates carbon dioxide fixation in the Calvin cycle of all oxygenic phototrophs is also an oxygenase. When RUBP functions as an oxygenase ribulose-bi-phosphate is oxidized and no carbon is fixed. The dual function of the "most important enzyme in the world" may serve as a protection against photooxidation. Many marine photosynthetic organisms can accumulate bicarbonate. In combination with an intracellular carbonic anhydrase, such an active accumulation of bicarbonate may suppress photorespiration at even very low external concentrations (32,33).

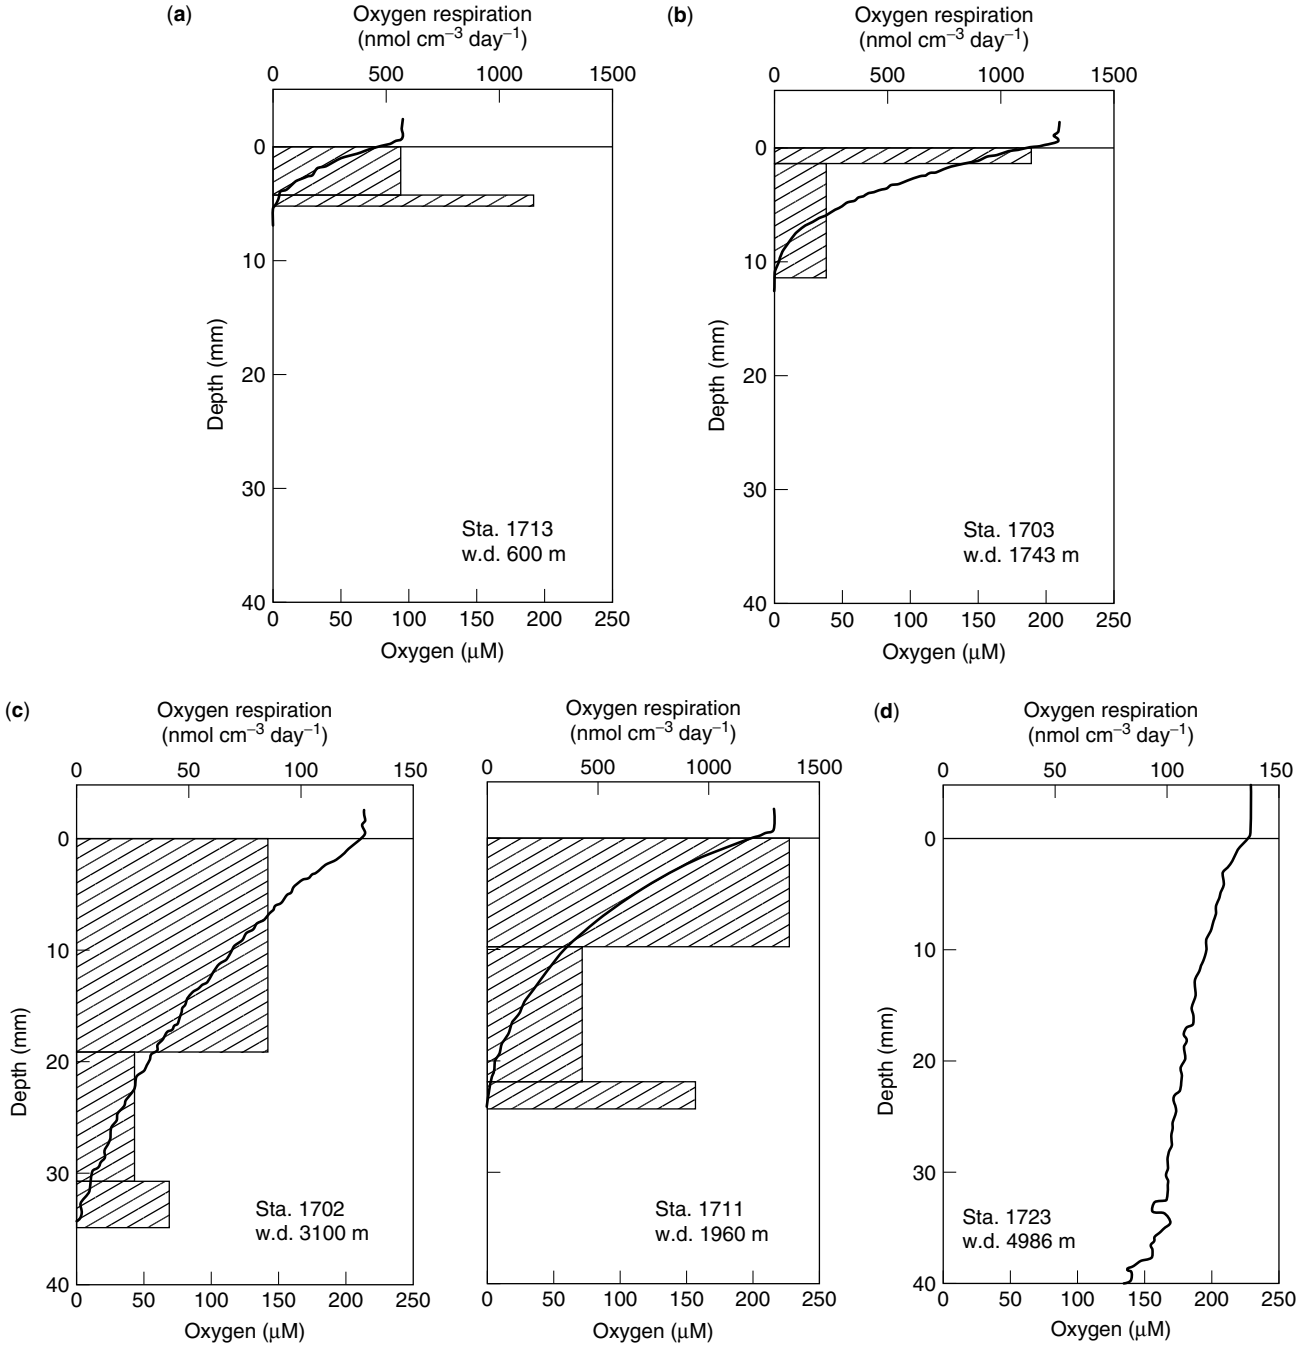

Figure 2. Oxygen microprofiles as measured *in situ* by oxygen microsensors in sediments along a transect in the Atlantic Ocean with water depths ranging from 600 to 4,986 m. The hatched bars illustrate oxygen uptake rates as calculated from the oxygen profiles by a diffusion-reaction model. Reproduced with permission from R. N. Glud et al., Deep-Sea Res. **41**, 1,767–1,788 (1994).

Experimental evidence (34,35) and diffusion-reaction models (36) indicate that photorespiration may balance a major part of the gross photosynthetic activity in benthic photosynthetic communities (Fig. 4), where conditions of high O_2 and low CO_2 (high pH) favor this process.

Anoxygenic Photosynthesis

Some cyanobacteria can perform anoxygenic photosynthesis in the presence of sulfide and then shift to oxygenic photosynthesis when sulfide is depleted (37,38). The oxidized sulfur product of this anoxygenic photosynthesis is elemental sulfur (37) or thiosulfate (39). Most anoxygenic phototrophs are, however, dependent on a reduced electron donor such as hydrogen sulfide to perform photosynthetic activity. Anoxygenic phototrophs are thus often found in a an anoxic layer below the oxygenic phototrophs where some infrared light is still present (40). Microbiology textbooks often show a typical zonation of

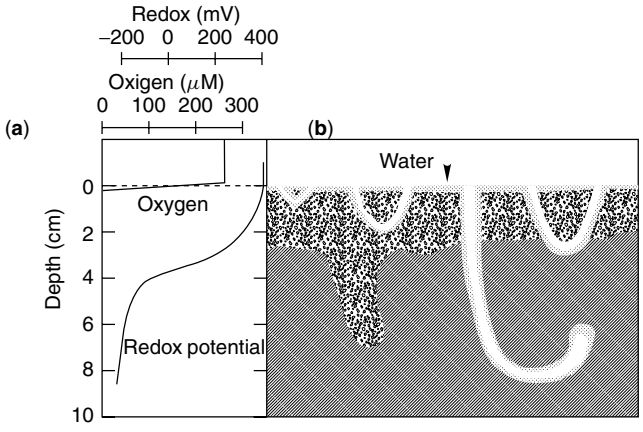

Figure 3. A: Oxygen and redox profiles in a coastal marine sediment as measured by electrodes. The sediment had a thick (but heterogeneous) oxidized layer because of the activity of the infauna, which periodically and locally oxidized the reduced ferrous and manganese minerals. In insert B are shown oxic sediment (dotted areas near sediment surface and around burrows), oxidized (redox potential > 0) but anoxic sediment (cloudy areas), and reduced (redox potential < 0) sediment (dark hatched areas). The oxygen and redox profiles are representative for the position shown with an arrow. Reproduced with permission from N. P. Revsbechand B. B. Jørgensen, *Adv. Microb. Ecol.* **9**, 293–352 (1986).

cyanobacteria followed by a purple layer covering a black sulfidic sediment. However, often the picture in nature is less clear. As an example, immobile purple bacteria (*Thiocapsa* sp.) are often found mixed with diatoms at sandy beaches. It has long been known that purple nonsulfur bacteria are facultative anaerobes that grow well in the dark as ordinary chemoorganoheterotrophs, but it was assumed that anoxygenic purple sulfur bacteria were strict anaerobes that could only be active under anaerobic conditions. The work of Kämp and Pfennig (41) showed that these bacteria are much more versatile, and that purple sulfur bacteria may even respire with oxygen using either organic or inorganic electron donors. The presence of purple sulfur bacteria in periodically oxic microenvironments is thus not surprising. Like many other microorganisms with a diversified metabolic potential the purple sulfur bacteria cannot compete with more specialized bacteria under constant environmental conditions. Grown under constant chemolithoautotrophic conditions in the dark *Thiocapsa* was thus outcompeted by thiobacilli (42). Anoxygenic phototrophs can generally not synthesize bacteriochlorophylls when oxygen is present, but planktonic phototrophs of the genus *Erythrobacter* (43) actually require oxygen to be active. Bacteriochlorophylls from such anoxygenic phototrophs are quite abundant in fully oxic oceanic waters (44). However, there are also reports of benthic anoxygenic phototrophs that produce pigments under oxic conditions (45). Because of the general inability to produce bacteriochlorophylls under oxic conditions, it was assumed that the vast majority of anoxygenic phototrophs could not perform photosynthesis when oxygen is present. This assumption was, however, based on a traditional culture approach with constant illumination and continuously reduced conditions. Experiments with purple sulfur bacteria grown under cycles of illumination and oxygen mimicking the conditions in the surface layer of sediments with presence of

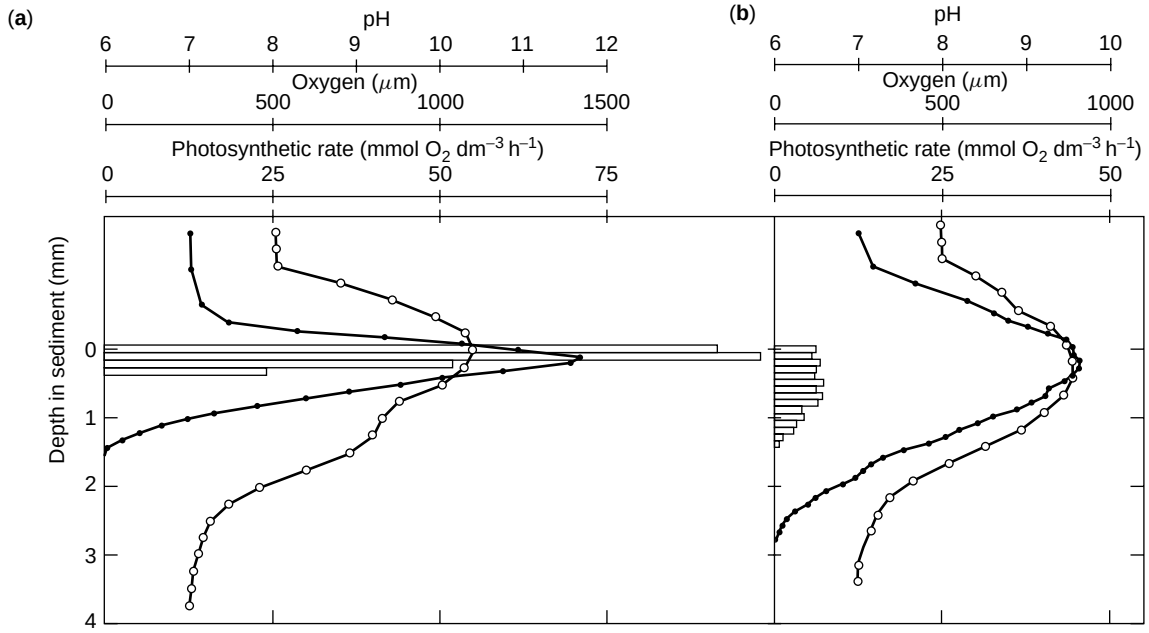

Figure 4. Profiles of oxygen (●), oxygenic photosynthesis (bars), and pH (ϒ) in a marine cyanobacterial mat (**a**) and a diatom-inhabited sandy sediment (**b**) during illumination at 1,000 μmol photones $m^{-2}s^{-1}$. Note the extreme pH values and concentrations of oxygen in the only 0.4-mm thick photic zone of the cyanobacterial mat in Figure 4a.

oxygenic phototrophs have shown that anoxygenic photosynthesis based on bacteriochlorophyll synthesized during anoxic periods continued during aerobic periods (46). Purple sulfur bacteria living in close association with diatoms on sandy beaches may thus be active during the oxic daytime hours, oxidizing elemental sulfur accumulated during the anoxic periods, or oxidizing periodic pulses of reduced sulfur compounds originating from deeper strata (47).

Oxygen and the Nitrogen Cycle

Nitrogen Fixation. Nitrogen fixation is restricted to the prokaryotic domains *Bacteria* and *Archaea*. No convincing evidence has been given for eukaryotic nitrogen fixers. Almost (48) all known nitrogen-fixing enzymes, the nitrogenases, are highly oxygen-sensitive (49,50) and it was consequently believed that nitrogen fixation was associated with bacteria that live under anoxic conditions or create anoxic conditions at the sites where nitrogen fixation takes place. Some examples are (*1*) anoxygenic phototrophs including species of the genera *Chlorobium* and *Chromatium*; (*2*) obligately anaerobic bacteria such as sulfate-reducers, clostridia, and methanogens, (*3*) oxygenic cyanobacteria that protect their nitrogenases within specialized anoxic cell structures (heterocysts), and (*4*) bacteria that are protected from a generally oxic environments by the action of a host organism such as the symbiotic association between the terrestrial *Rhizobium* sp. and legumes.

From soils it has been known for a century that *Azotobacter* may fix nitrogen under fully aerobic conditions (51). Until recently this ability has been explained by intracellularly near-anoxic conditions, caused by a combination of high respiration rates and a thick layer of extracellular polymeric material, which was supposed to slow down the diffusive supply of oxygen to the cell. Recently, however, it has been shown that protective proteins are responsible for the insensitivity to oxygen of the nitrogenase in *Azotobacter* (52).

The root-symbiont *Azoarcus* sp BH72 uses different respiratory pathways at high and low oxygen concentrations, respectively, to protect the nitrogenase (53). Apparently, nitrogen-fixing cells use a cytochrome oxidase under fully aerobic conditions, whereas cells that fix nitrogen under microaerophillic conditions use a quinol oxidase instead. Whether there is interdependence between the oxygen regime, the type of terminal oxidase, and the nitrogen-fixing state needs to be elucidated. Oxidases may also play an important role in regulating the oxygen concentration in nitrogen-fixing nonheterocystous marine cyanobacteria (50).

Nonheterocystous cyanobacteria have developed a series of different mechanisms to minimize the deleterious effects of oxygen on nitrogen fixation. These include behavioral and metabolic strategies as well as physical barriers (50). Additionally, nitrogenase itself may have the capacity to reduce oxygen. It has been shown that Fe-protein of the nitrogenase could reduce oxygen to H_2O_2 and water *in vitro* when the concentration of the Fe-protein was at least four times higher than the oxygen concentration. When the concentration of oxygen exceeded the concentration of the Fe-protein, hydroxyl radicals were formed that inactivated the nitrogenase (50).

A behavioral strategy is utilized for O_2 protection by the nonheterocystous cyanobacterium *Plectonema boryanum*, which fixes nitrogen during illumination by separating the process temporarily from photosynthesis (54). It has been demonstrated that two different kinetics of oxygen uptake were expressed during the photosynthetic (P) and nitrogen-fixing (N) phases, respectively. The K_m value for oxygen in P was 71.4 μM, while the K_m value for oxygen in N was only 13.5 μM. The organism was not able to fix nitrogen in the absence of oxygen. Thus, oxygen-dependent respiratory energy generation was obligatory for diazotrophic growth of this species, and the lower K_m for oxygen uptake during nitrogen-fixation indicates intracellularly low oxygen concentrations that would allow a functional nitrogenase. Other nonheterocystous cyanobacteria use the dark phase for nitrogen fixation and the light phase for photosynthesis (49,50).

In the open-ocean environment, *Azotobacter*-type organisms are not known and the absence of planktonic cyanobacteria with heterocysts suggested that cyanobacterial nitrogen fixation apparently did not occur. It was therefore a revolutionary finding when it was reported that the marine filamentous cyanobacterium *Trichodesmium* fixes nitrogen under oxic conditions (55,56). *Trichodesmium* may occur in gigantic blooms in the oceans, and the discovery of its nitrogen fixation was crucial for the understanding of the global nitrogen budgets. The nitrogen fixation in *Trichodesmium* is only taking place during illumination, which could be expected to suppress the process by oxygenic photosynthesis. *Trichodesmium* grows in loose aggregates, but microsensor investigations have not shown anoxic sites in the aggregates, and it is likely that *Trichodesmium* protects its nitrogenase in a similar way as *Azotobacter*, but other mechanisms are also possible (55). Recently, it was shown that nitrogen fixation in *Trichodesmium* is under circadian control (56). It was discovered that the transcription of the *nifHDK* gene (nitrogenase), the transcription of the *psbA* gene (constituent of PSII), and the transcription of the *psaA* -gene (constituent of PSI) are under control of a circadian rhythm, and that they are temporally separated over the diel cycle. It was concluded that a phase separation between the expression of photosynthesis genes and nitrogen fixation genes, which is clearly maintained by the circadian rhythm, could be one of the underlying mechanisms that allows oxygen-sensitive nitrogen fixation to proceed in *Trichodesmium* IMS 101 during illumination. Both *Trichodesmium* and *Plectonema* (see earlier section) thus seem to be able to accomplish a temporal separation of oxygenic photosynthesis and nitrogen fixation during the light period.

The nitrogenase from the thermophilic *Streptomyces thermoautotrophicum* is very different from all other known nitrogeases and the mechanism of nitrogen fixation mechanism is also highly unusual (48). The perhaps most striking difference is that this nitrogenase is not adversely affected by oxygen, and the mechanism of nitrogen fixation actually involves oxygen and superoxide. Reduction of acetylene to ethylene by nitrogenase is usually used

to measure the activity of nitrogen fixation in natural samples, but this organism does not produce ethylene. The question of whether similar unusual nitrogenases are found also by mesophilic organisms remains to be answered.

Nitrification and Denitrification

The oxidation of ammonium to nitrite by ammonium-oxidizing bacteria, such as *Nitrosomonas* and *Nitrosospira*, and the subsequent oxidation of nitrite to nitrate by *Nitrobacter*- type bacteria are oxic processes. Ammonium may also be oxidized by nitrite by the so-called anammox process (57) originally discovered in a wastewater treatment plant, but the end-product of this process is nitrogen gas. It is not yet known how important the anammox precess is in nature, but there are strong indications that it may occur in some marine sediments.

As nitrification is an aerobic process, nitrite and nitrate may be produced in both the pelagic environment and in the oxic surface layer of sediments. An example of a NO_x^- (i.e., $NO_2^- + NO_3^-$) profile in a marine sediment as measured with a microscale NO_x^- biosensor (58) is shown in Figure 5 together with an oxygen profile. The oxygen penetration in this coastal sediment was about 3 mm, and nitrification in the layer caused an elevation of the NO_x^- concentration from 4 μM in the overlying water to almost 10 μM at 2-mm depth. Nitrate consumption in the anoxic layers below 3-mm depth caused a decrease to zero at a depth of about 5 mm (59). In most nonphotic sediments, the majority of the NO_x^- consumption is due to denitrification. Denitrification is a predominantly anoxic process, but calculations performed on many profiles indicate that some denitrifying activity may occur at oxygen concentrations of a few micromolar (60). Denitrifying bacteria are facultative anaerobes (although exceptions to this general statement my be found (61)),

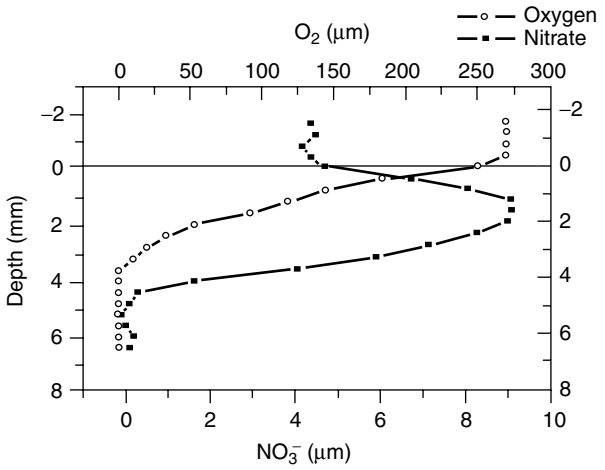

Figure 5. Profiles of O_2 and NO_x^- in a Danish coastal marine sediment. There was a production of NO_x^- in the oxic layer down to 3-mm depth producing a small peak in NO_x^-, and denitrification depleted NO_x^- at a depth of 4 to 5 mm. Redrawn with permission from N. P. Revsbech et al., in J. Buffle and G. Horvai, eds., In situ monitoring of aquatic systems: Chemical analysis and speciation, John Wiley & Sons, **2000**, pp. 195–222.

and as the energy yield by oxygen respiration is much higher than by denitrification, only few bacteria exhibit denitrification at high oxygen concentrations when grown in pure culture (62). It is possible that the aerobic denitrification exhibited by a few laboratory strains is caused by mutations that would have reduced competitiveness under natural conditions.

The highest nitrifying activity is often found near the oxic-anoxic interface (e.g., 63) where there is a high diffusive supply of ammonium from anoxic layers. It should therefore be expected that nitrifying bacteria are microaerophilic and exhibit a chemotaxis toward low oxygen as is well described for some sulfide-oxidizing bacteria (64). However, nitrifying bacteria predominantly live in immobile aggregates and do not follow changes in gradients of oxygen and ammonium. One possible reason that nitrifiers do not optimize their metabolism by chemotaxis is that they may rely on density-dependent intracellular signaling with homoserine-lactones within aggregates to be able to respond to changing availability of ammonium (65).

EFFECT OF OXYGEN ON THE IRON AND MANGANESE CYCLES

Much work has been conducted on microbial iron reduction in marine sediments (7), but the importance of microbial oxidation of Fe^{2+} in this environment has only been poorly explored because of methodological difficulties in distinguishing between chemical and biological contributions. At neutral pH iron oxidation may be biologically mediated, but the purely chemical oxidation of Fe^{2+} is so rapid at neutral pH that much and probably most Fe^{2+} oxidation in the marine environment is nonbiological. Bacteria-like *Gallionella ferruginea* overcome competition with rapid chemical iron oxidation at circumneutral pH by microaerophilic growth in environments with opposing oxygen and iron gradients where stable diffusion conditions for oxygen and ferrous iron prevail (66) or in environments with an advective supply of reduced iron (67,68). In marine environments biological iron oxidation has only been reported from hydrothermal vent sites (69,70), where the vent water may contain up to 1,000 μM Fe^{2+} and 20 μM Mn^{2+}. Large fluffy mats of precipitated iron oxides, which often consist of sheaths and filaments reminiscent of *Leptothrix ochracea* have been found in the surrounding of the vents. This suggests that the precipitated iron oxides may be of biogenic origin.

Ferrous iron oxidizing bacteria are extremely difficult to isolate in axenic culture (68). A recent publication (71) report on the isolation of a facultatively aerobic nitrate respirer from brackish sediment that oxidizes ferrous iron with nitrate as electron acceptor. It could be demonstrated that the strain also was able to grow by aerobic iron oxidation in opposing ferrous iron and oxygen gradients. Facultative iron oxidizers may be preferentially isolated with nitrate as electron acceptor instead of oxygen as chemical oxidation of iron with nitrate does not occur.

Reduced manganese in the form of Mn^{2+} ions is quite soluble at circumneutral pH, but in contrast to ferrous

iron, the spontaneous chemical reaction of Mn^{2+} with oxygen is very slow. Only above pH 8 does the chemical oxidation of Mn^{2+} become significant (72). Comparison of Mn^{2+} fluxes toward the oxic zone of a sediment and Mn^{2+} fluxes from the sediment and into the overlying water implied a 1,000 times higher oxidation rate in the sediment than would be the case by purely chemical oxidation with oxygen (73). Thus, at circumneutral pH, Mn^{2+} oxidation in sediments may be biologically mediated. Many bacteria catalyze the oxidation of Mn^{2+} with oxygen (74) and insoluble manganese oxide precipitate on the outside of Mn^{2+}-oxidizing cells (68). Manganese oxide encrustations may protect cells against grazing by protozoa, viral attack, or detoxify oxygen radicals (68). Despite the active involvement of bacteria in Mn^{2+} oxidation, growth-linkage to this process has not been observed. Manganese-oxidizing bacteria may be important for the formation of manganese nodules that are found on the surface of many deep-water sediments (75).

OXYGEN AND THE SULFUR CYCLE

Sulfide-Oxidizing Organisms

We currently have only a limited understanding of sulfide oxidation in the surface layers of marine sediments, where the overwhelming part of the sulfide formed by sulfate reduction is oxidized. Some hydrogen sulfide is oxidized chemically with oxygen or by aerobic chemolithotrophs and anoxygenic phototrophs, and these oxidations have been studied extensively (42). In most marine areas only little sulfide is, however, oxidized directly by oxygen. It reacts instead with oxidized iron and manganese compounds that are subsequently reoxidized with oxygen by either burrowing fauna (Fig. 3) or by strong turbulence in the overlying water and resuspension and repositioning of the sediment (76). In some areas the predominant electron acceptor for sulfide oxidation seems to be nitrate that is either used directly near the sediment-water interface or is transported to deep layers by gliding bacteria of the genera *Thioploca* or *Beggiatoa* (24,77).

Chemolithotrophic thiobacilli are probably the major aerobic sulfide oxidizers in nature. Many species of this genus are well characterized physiologically and phylogenetically, and the major biochemical pathways of sulfide oxidation have been elucidated (78,79). However, much interest has been attached to the larger sulfide-oxidizing bacteria of the microaerophilic genera *Beggiatoa* and *Thiovolum*, as they exhibit unique physiological and tactic characteristics (80). However, only a limited number of *Beggiatoa* strains have been cultured, and no *Thiovolum* isolates have been obtained yet. Our knowledge about the physiology of these large sulfide-oxidizing bacteria is thus still very incomplete.

Beggiatoa spp. often covers the surface of reduced marine sediments, where they oxidize sulfide and organic compounds diffusing upwards with oxygen diffusing downwards. The sediment surface may be totally white because of the mats of *Beggiatoa*, but often only depressions in the sediment are covered, resulting in white flakes on a gray-brown sediment surface. However, *Beggiatoa* is also present in the areas with an oxidized surface, but most filaments there are found at the oxic/anoxic interface located at some depth in the sediment. At least the cultivated *Beggiatoa* strains are microaerophilic, and exhibit a tactic response toward low oxygen (64,81). The fact that beggiatoas in nature have the ability to accumulate at the oxic/anoxic interface rather than "getting lost" in the anoxic sediment may be a result of negative sulfide taxis (64). *Beggiatoa* spp. do not have the enzyme catalase to protect them against hydrogen peroxide formed as a reduction product of oxygen, and they actually do not tolerate high oxygen concentrations for extended periods of time (82). There is evidence that some (uncultured) *Beggiatoa* sp. may reduce nitrate (83), and such a capability may explain some observations of occurrence that do not seem to be associated with an oxic/anoxic interface (84). The taxis toward low oxygen concentrations makes it possible for *Beggiatoa* to maintain a very high density at the oxic/anoxic interface and thereby to be very efficient in the oxidation of hydrogen sulfide. Profiles of oxygen and sulfide measured in sediment covered with *Beggiatoa* (Fig. 6) show how oxygen and hydrogen sulfide overlap in an $<$ 100 μm thick layer. Oxygen and sulfide are continuously supplied to this thin layer by diffusion from above and below, respectively, and the turnover-time for the sulfide and oxygen pools within the overlap zone is about 1 s, which is several orders of magnitude faster than by a purely chemical oxidation. Comparable studies with pure *Beggiatoa* cultures in an agar-stabilized gradient system showed that the sulfide-oxygen overlap zone was almost 1 cm in the absence of bacteria and about 0.1 mm in the presence of *Beggiatoa* (82).

Theoretically, an organism such as *Beggiatoa*, with a typical diameter of about 10 μm, should experience a relatively lower diffusive supply of oxygen and electron donors (85) than, for example, thiobacilli, with a typical size of 1×2 μm. The explanation for the success of some large bacteria in nature is always that the large size confers some advantage that is greater than the loss in fitness owing to inferior diffusive supply. The largest bacteria known (up to 750 μm in diameter) are thus nitrate-accumulating sulfide oxidizers that, by virtue of their size, can store a large amount of nitrate in an internal vacuole (86). The advantage of large size for *Beggiatoa* is poorly studied, but it may involve factors as the ability to store large amounts of sulfur intracellularly, rapid gliding mobility, reduced predation, and increased tolerance of the community to hydrodynamic stress. A study of a sulfidic coastal sediment showed that grazing resulted in a succession from unicellular motile bacteria-like *Thiobacillus* and *Thiovolum* over thin *Beggiatoa* species to large *Beggiatoa* with a diameter of about 30 μm (87).

Thiovolum has a somewhat different strategy than *Beggiatoa*, with which it is relatively closely related (86). Both rely, at least partly, on the oxidation of sulfide, but where *Beggiatoa* may form a well-defined oxidation zone within the sediment or at the sediment surface (Fig. 6), *Thiovolum* is able to move this oxidation zone up into the water-phase. It is able to form veils, which separates

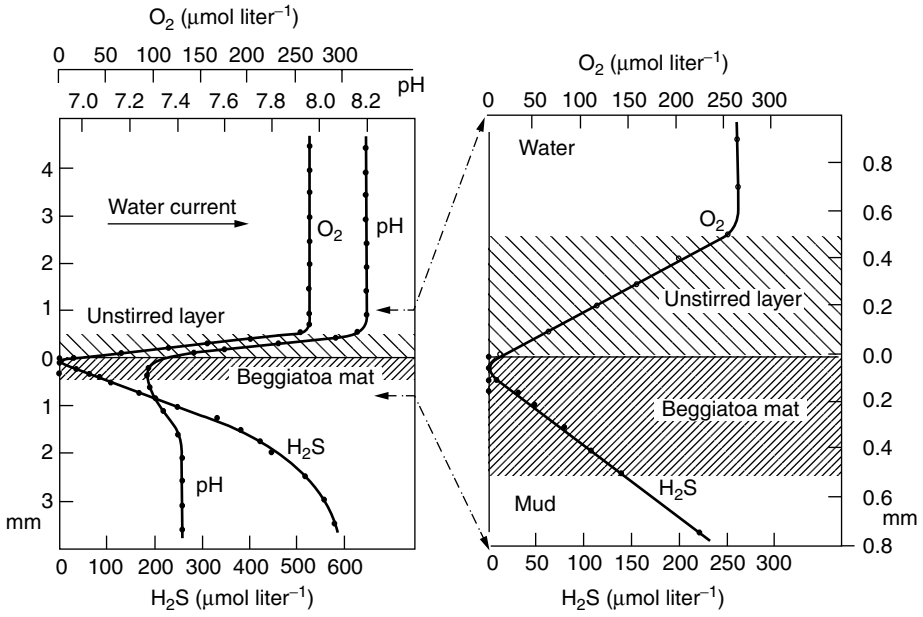

Figure 6. Oxygen and hydrogen sulfide distribution in a marine sediment covered with a Beggiatoa mat. Panel A to the left shows O_2, pH, and dissolved sulfide (H_2S) over a depth scale of several mm, and the enlarged panel (B) to the right shows that the overlap zone between sulfide and oxygen was < 0.1 mm. Reproduced with permission B. B. Jørgensen and N. P. Revsbech, *Appl. Environ. Microbiol.* **45**, 1,261–1,270 (1983).

anoxic, sulfide-containing water on one side of the veil from oxic water at the other side (80). The veils are kept together with filaments of extracellular polymeric material. By forming veils in the water the *Thiovolum* cells avoid competition from other bacteria. The veil can disintegrate into individual cells that may subsequently aggregate to form a new veil at another location when the conditions for *Thiovolum* deteriorate as a result of competition from colonizing organisms or because of lowered oxygen or sulfide availability. Colony formation in *Thiovolum* is unique. It is used not only to separate sulfide and oxygen so that a well-defined oxidation zone can be established, but also to create a water current through the veil by flagellar movement of the individual bacteria. Consequently, substrate availability is increased by a factor of about 40 above that possible by molecular diffusion (88).

Oxygen and Sulfate-Reducing Bacteria

Sulfate-reducing bacteria were originally described as highly oxygen-sensitive obligate anaerobes, and their distribution was asserted to be restricted to permanently anoxic environments. However, this has proven untrue (86). Over the last two decades reports have accumulated that document the presence of large numbers of viable sulfate-reducing bacteria in permanently or temporally oxygenated environments such as oxidized surface sediments (87), seawater (88), photosynthetic microbial mats (89–91), and associations with the rhizoplane of marine macrophytes (92,45). These observations indicate that sulfate-reducers must have developed mechanisms to cope with toxic oxygen radicals (see earlier section). Indeed superoxide dismutase and catalase were detected in a wide variety of "strict" anaerobic bacteria, including sulfate-reducing bacteria (93,13,94). In addition, the presence of polyglucose in several species of sulfate-reducers was interpreted as an adaptation to the periodic occurrence of oxic conditions in the environments from which they were isolated, typically the oxic–anoxic interface of microbial mats (95). The mechanism of polyglucose mediated oxygen tolerance has not yet been identified. Recently, it has been proposed (96) that polyglucose may stabilize NADH oxidases and prevent them from rapid inactivation in the presence of oxygen. It was also shown (96) that polyglucose containing *Desulfovibrio*-species were able to reduce oxygen at much higher ambient concentrations than *Desulfovibrio*-species that lack the ability to synthesize polyglucose.

However, sulfate-reducing bacteria may not only tolerate oxygen (97), they may also use it as an electron acceptor (98,99). It has thus been shown that several stains from different genera are able to use oxygen. Although energy is conserved (ATP formed) by the electron transport, none of the strains examined thus far can grow with oxygen as sole electron acceptor (100). Results from experiments with *Desulfovibrio vulgaris* CNS (101–103) even suggest that some sulfate-reducers can oxidize sulfide to sulfate in the presence of oxygen. The mechanism proposed involves an initial biologically mediated oxidation of sulfide to elemental sulfur and concomitant reduction of oxygen followed by the bacterial disproportionation of elemental sulfur into sulfate and sulfide. Recent investigations have also demonstrated that some sulfate-reducing bacteria are microaerophilic and exhibit a positive O_2 taxis toward low oxygen concentrations (104,105). The reason for such a positive aerotaxis is obscure, as no hitherto isolated sulfate-reducer can grow with oxygen as electron donor. However, a positive chemotaxis toward oxygen may enable freshwater sulfate-reducers, which naturally live under sulfate-limited conditions, to find the zone (oxic-anoxic interphase) where intermediately oxidized sulfur compounds, such as thiosulfate or elemental sulfur are formed. As mentioned above, sulfate-reducers may even actively participate in

the formation of these compounds, which then serve as substrates for growth.

There have been reports of extremely high sulfate reduction rates in the oxic layers of microbial mats, where a high supply of electron donors could originate from oxygenic photosynthetic activity of the cyanobacterium *Microcoleus chtonoplastes* (106). The initial findings of high aerobic sulfate reduction rates have not, however, been supported by more controlled experimental evidence. It is difficult to explain how an energetically inferior process could occur at high rates when it has to compete with oxygen-respiring microorganisms for the same substrates.

ANALYSIS OF OXYGEN AT A SCALE RELEVANT TO THE WORLD OF MICROORGANISMS

This review has shown several examples of microscale profiles of oxygen in microbial communities (Figs. 2–6), without going in any detail about the techniques available to obtain such information. These techniques have just been reviewed extensively (107,108), and only a very short description will therefore be given here. All the oxygen profiles shown in the figures were recorded with electrochemical oxygen microsensors such as the one shown in Figure 7. The gold cathode within such a sensor reduces oxygen entering through the silicone membrane to OH^-, and the current resulting from this reduction is proportional to the amount of oxygen being reduced. Because of a tip diameter of only a few micrometers, diffusion of oxygen to the tip is a very efficient means of transport as compared to advection, and the signal from such sensors is therefore almost ($< 2\%$) unaffected by changes in water flow. Even changes in diffusion coefficient of the analyzed medium do ordinarily not affect the reading to any significant extent. Sensors can be made with tip diameters down to 1 μM, and 90% response times can be down to 0.1 to 0.2 s. Commercial suppliers of such oxygen microsensors are Unisense A/S, Aarhus, Denmark, and Diamond Electrodes Inc, Ann Arbor, Michigan. An alternative is to use optic fibers with a tip coating that exhibits an oxygen-dependent fluorescense. Such sensors cannot be made as small as the electrochemical sensors, and they also react considerably slower to changes in oxygen concentration, but they have the advantage of being completely insensitive to water flow and diffusivity. Such optical sensors (optodes) are sold by Presense, Regensburg, Germany. A two-dimensional set of information about the distribution of oxygen may be obtained by use of so-called planar optodes, where a transparent sheet is covered with the same fluorescent material as used in ordinary oxygen optodes. The planar optodes may, for example, be helpful when the oxygen dynamic at the bottom of a biofilm (growing on the planar optode) is studied. Planar optodes are at present not commercially available.

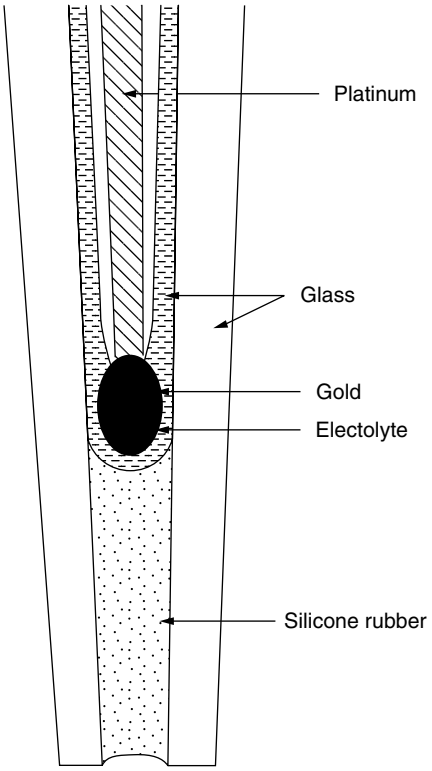

Figure 7. Oxygen microsensor with a tip diameter of about 5 μm. This type of sensor and similar microsensors for other chemical species may be used to analyze the chemical microenvironment in microbial communities.

CONCLUSION

Oxygen is a crucial chemical species for all microorganisms, whether it functions as the optimum electron acceptor for energy generation or has the role of a dangerous poison that has to be detoxified. Microbiologists generally distinguish between aerobic and anaerobic microorganisms, but it is becoming increasingly clear that the previous dogmas about the detrimental effects of oxygen on organisms such as sulfate-reducers that were thought to be strict anaerobes have to be reconsidered. Many "strict" anaerobes are actually equipped with defence mechanisms against oxygen or may even to some extent be able to use oxygen as an electron acceptor. The dogma about the detrimental effect of oxygen on the nitrogenases of nitrogen-fixing prokaryotes also has to be modified, as nitrogen fixation has been described to occur under fully aerobic conditions. The development of analytical techniques that allow for resolution of microscale chemical gradients of oxygen (and other relevant chemical species) has made it possible to observe exactly where oxygen is present and also at which rates it is being metabolized. The rise of molecular microbial ecology has at the same time enabled visualization of the presence and distribution of specific kinds of microorganisms, even when these microorganisms cannot be cultured. Together these powerful in situ techniques offer an outstanding opportunity to study the ecological niches of microorganisms, but whenever possible such studies should be combined with detailed physiological studies of pure cultures.

OXYGENASE ENZYMES: ROLE IN BIODEGRADATION

JOHN D. HADDOCK
Southern Illinois University
Carbondale, Illinois

The global carbon cycle is necessary for life on earth. Inorganic carbon that is fixed and transformed into biochemical compounds by metabolic processes must eventually be mineralized to carbon dioxide, so that it will be available to subsequent generations of living organisms. Biodegradation and mineralization of natural and artificial organic compounds through catabolic pathways occurs both in the presence (aerobic) and in the absence (anaerobic) of molecular oxygen (O_2), producing energy and carbon for metabolism and growth of prokaryotic and eukaryotic microorganisms. Molecular oxygen can support aerobic biodegradation in two ways: (*1*) as a terminal electron acceptor for oxidation of organic compounds via pathways linked to aerobic respiration and (*2*) as a reactant in catabolic reactions resulting in incorporation of one or both oxygen atoms into organic substrates. The latter function is important for biodegradation of relatively inert organic compounds and is catalyzed by a class of enzymes known as oxygenases (1,2). Oxygenases act in conjunction with other enzymes such as dehydrogenases, hydrolases, and aldolases, by catalyzing one or more steps of the microbial biodegradative pathways that channel substrate carbon

into the central metabolic pathways. Since the discovery of the first oxygenase by Hayashi approximately half a century ago (3), the functions of these enzymes in numerous biodegradative pathways have been well established and their properties extensively described. An appreciation of the scope of the interest in oxygenases can be gained by consulting the many excellent review articles, book chapters, and books that have been published (4–16). In addition, comprehensive information about the roles of oxygenases as well as other enzymes of the biodegradative pathways can be found on the web site of The University of Minnesota Biocatalysis/Biodegradation Database (*http://www.labmed.umn.edu/umbbd*).

An oxygenase can be defined as an enzyme that catalyzes a chemical reaction between molecular oxygen (O_2) and a substrate, usually an organic compound, resulting in the formation of a product that contains one or both of the oxygen atoms. Oxygenases are found in many species of prokaryotes (bacteria) and eukaryotes (e.g., yeast, fungi, algae, plants, and animals), where they perform a variety of metabolic functions. In higher eukaryotes, they play important roles in detoxification and excretion of organic pollutants, metabolism of drugs, and biosynthesis of sterols, hormones, and other physiologically active compounds. In some species of yeast, fungi, and bacteria, oxygenases act in concert with other enzymes in catabolic pathways that catalyze reactions resulting in the breakdown and mineralization of stable organic compounds that enter the environment through natural processes and human activities. Major sources of these compounds include natural seeps and accidental spills of unrefined and refined petroleum, lignin, terpenes, and other secondary metabolites produced by plants and artificial organic compounds produced via synthesis of industrial chemicals. Contributions from the latter source increased dramatically during the twentieth century with the industrial revolution and human population explosion. Deliberate application of agricultural pesticides, release of industrial and domestic wastewater, exploitation of fossil fuels and leachates from industrial waste dumps, leaking pipelines, and chemical storage tanks have contributed to the presence of large amounts of recalcitrant toxic organics in the environment. Oxygenases that participate in the biodegradative pathways of microorganisms allow their cells to obtain carbon and energy for growth and metabolism of organic compounds that would otherwise be useless or even harmful to the organism.

Artificial organic compounds are produced by chemical synthesis, rather than by biochemical reactions, and many possess combinations of functional groups and chemical bonds that are not found in nature. Biodegradative pathways of these xenobiotic compounds may not exist in nature or mineralization may be incomplete and dead-end metabolites may be released into the environment. Research is currently being conducted to speed up the evolution of biodegradation pathways using the recently developed tools of molecular biology to produce oxygenases and other biodegradative enzymes with broader specificities for their substrates (17). The goal is to increase the rate of mineralization of troublesome organic pollutants such as atrazine and polychlorinated biphenyls (PCBs) (18,19).

The two main functions of oxygenases in catabolic pathways are activation of otherwise biochemically inert compounds via catalysis of hydroxylation reactions and cleavage of cyclic compounds so that they can be metabolized by central metabolic pathways (20). Biodegradation of cyclic hydrocarbons requires both hydroxylation and ring cleavage. Substituents (e.g., chloro, nitro, and sulfono groups) that chemists add to already stable organic compounds may retard biodegradation of a compound by inhibiting the activity of oxygenases as well as other enzymes of the biodegradative pathway. In some instances, the activity of oxygenases results in the removal of the inhibitory substituent and enhanced degradation of the product. For example, biphenyl 2,3-dioxygenase is the first enzyme of a catabolic pathway for degradation of biphenyl (21,22). In *Burkholderia* sp. strain LB400 this enzyme catalyzes the addition of molecular oxygen to some *ortho*-substituted PCBs, resulting in the spontaneous elimination of the chloro substituent from the *ortho* position of the ring (23). Other examples include dioxygenase-mediated elimination of fluoro, chloro, bromo, iodo, and amino substituents from aromatic rings of *ortho*-substituted benzoates (24–26), *para*-chloro substituent from 4-chlorophenylacetate (27), and monooxygenase-mediated elimination of *para*-chloro and *ortho*-chloro substituents from chlorophenols (28).

Biodegradation pathways involving oxygenases are utilized by bacteria, yeast, and fungi, but the broad diversity of biodegradative enzymes in bacteria has attracted the most attention because of the potential for biotechnological applications involving bioremediation and industrial uses such as production of chiral synthons for synthesis of single-enantiomer drugs and industrial chemicals (13,29). This article will highlight the activities of bacterial oxygenases that catalyze the incorporation of molecular oxygen into naturally occurring and artificial organic compounds. The types and basic functions of oxygenases will be discussed first, followed by an examination of their roles in the degradation of various classes of organic compounds.

Traditionally, oxygenases have been described as either monooxygenases or dioxygenases, on the basis of the number of molecular oxygen atoms contained in the product of the reaction (Table 1). Monooxygenases catalyze the addition of one oxygen atom, whereas dioxygenases catalyze the addition of both oxygen atoms to the substrate (S) as shown (30).

$$S + \frac{1}{2}O_2 \xrightarrow{\text{monooxygenase}} SO \quad (1)$$

$$S + O_2 \xrightarrow{\text{dioxygenase}} SO_2 \quad (2)$$

One limitation of this classification scheme is that some oxygenases do both, depending on the substrate. For example, the toluene dioxygenase of *Pseudomonas putida* F1 catalyzes the addition of one atom of molecular oxygen to the methyl group of 2- and 3-nitrotoluene (38), whereas

Table 1. Examples of Biodegradative Oxygenases

Reaction and Representative Enzyme	Enzyme Cofactor	EC Number[a]	Reference
I. Monooxygenation			
A. Hydroxylation			
Pentachlorophenol monooxygenase	Flavin	1.14.13.50	31
Camphor 5-monooxygenase	Heme iron	1.14.15.1	32
Alkane monooxygenase	Nonheme iron	1.14.15.3	33
B. Baeyer-Villiger monooxygenation			
Cyclohexanone monooxygenase	Flavin	1.14.13.22	34
II. Dioxygenation			
A.1. Hydroxylation			
Toluene dioxygenase	Nonheme iron	1.14.12.11	35
A.2. Hydroxylation/decarboxylation			
2,4-D/α-ketoglutarate dioxygenase[b]	Nonheme iron	1.14.11.-	36
B.1. Aromatic ring cleavage, intradiol			
Catechol 1,2-dioxygenase	Nonheme iron	1.13.11.1	3
B.2. Aromatic ring cleavage, extradiol			
Catechol 2,3-dioxygenase	Nonheme iron	1.13.11.2	37

[a]Enzyme Commission number (Nomenclature Committee of the International Union of Biochemistry and Molecular Biology).
[b]2,4-D, 2,4-dichlorophenoxyacetic acid.

the 4-methoxybenzoate monooxygenase of *P. putida* DSM1868 catalyzes the addition of both atoms of molecular oxygen to the vinyl group of 4-vinylbenzoate (39). However, in these and other examples (40), the atypical activity of the enzyme occurs with nonphysiological substrates, whereas with physiological substrates (usually the one that lends its name to the enzyme) one or both atoms of molecular oxygen are added when the reaction is catalyzed by a mono- or dioxygenase, respectively.

Mono- and dioxygenases may be further described based on whether the oxygen atom(s) of the product is present as a hydroxyl group(s) substituent of one of the carbon atoms (hydroxylase) or whether oxygen is inserted between a carbon-carbon bond (Table 1). A monooxygenase that inserts an oxygen atom between a carbonyl carbon and an adjacent carbon atom of aliphatic compounds (open chain and cyclic) is called a *Baeyer-Villiger monooxygenase* (BVMO) because the product is the same as that produced by the Baeyer-Villiger reaction familiar to organic chemists. Dioxygenases that insert both oxygen atoms between two carbon atoms of an aromatic ring are called *ring-cleavage dioxygenases* because the product is acyclic with the oxygen atoms present in two carboxylate groups or in a carboxylate and a carbonyl group of the product. Two hydroxyl groups must already be present as substituents of aromatic substrates for ring cleavage to occur, however. Intradiol ring-cleavage (also called *ortho ring cleavage*) dioxygenases catalyze the cleavage of the ring between two adjacent (vicinal) hydroxyl groups, whereas extradiol ring-cleavage (also called *meta ring cleavage*) dioxygenases catalyze the cleavage of the ring adjacent to only one of the hydroxyl groups. The first oxygenase discovered was a bacterial intradiol ring-cleavage dioxygenase that catalyzed formation of *cis*, *cis*-muconic acid from catechol (1,2-dihydroxybenzene) (30).

Mono- and dioxygenases employ cofactors at their active sites, which are involved in binding molecular oxygen prior to its incorporation into the organic substrate (Table 1). These cofactors also perform a mechanistic role in catalysis by activating molecular oxygen or the substrate, thus facilitating the reaction between the two. Flavin adenine dinucleotide (FAD) or flavin mononucleotide (FMN) or some form of iron (heme or nonheme) is the most common cofactor. Additional reactants and products may also be involved; these will be described with the specific examples discussed later.

MONOOXYGENASES AND THEIR ROLES IN BIODEGRADATIVE PATHWAYS

Most monooxygenases found in biodegradative pathways catalyze the addition of one atom of molecular oxygen to their substrates, whereas the other oxygen atom is reduced to a molecule of water. Two reducing equivalents (electrons) are also required and are usually supplied by the coenzymes reduced nicotinamide adenine dinucleotide (NADH) or reduced nicotinamide adenine dinucleotide phosphate (NADPH).

Monooxygenases are involved in the degradative pathways of open-chain and cyclic aliphatic compounds and aromatic compounds. The enzymes are structurally diverse in that the number of protein components and the number and type of cofactors vary, depending on the source of the enzyme. The following discussion will focus on only a few of the monooxygenases that have been described, but will illustrate that a range of catalytic activity and diversity of composition of the enzyme protein components and cofactors exists in different microorganisms.

Hydrocarbons are chemically inert and addition of oxygen activates the compounds for further degradation, as illustrated for linear alkanes, compounds that

are major constituents of petroleum. Monooxygenase-catalyzed hydroxylation of alkanes often occurs at a terminal methyl group (41). (In the following reactions, all reactants and products may not be depicted.)

$$R{-}CH_3 + O_2 + 2e + 2H^+ \longrightarrow R{-}CH_2OH + H_2O \quad (3)$$

The products are water and an alcohol that is oxidized to a fatty acid in reactions catalyzed by an alcohol dehydrogenase and an aldehyde dehydrogenase.

$$R{-}CH_2OH \longrightarrow R{-}CHO \longrightarrow R{-}COOH \quad (4)$$

The fatty acid is then coupled to coenzyme A (CoA) and mineralization proceeds via the β-oxidation pathway and the Krebs cycle.

$$\begin{array}{l} R{-}COOH \longrightarrow R{-}COCoA \longrightarrow Acetyl{-}CoA \\ \qquad\qquad\qquad\qquad\qquad\qquad\quad \downarrow \\ \qquad\qquad\qquad\qquad\qquad\qquad\quad CO_2 + H_2O \end{array} \quad (5)$$

Some alkane monooxygenases also hydroxylate the methyl group of straight-chain fatty acids, producing ω-hydroxy fatty acids.

$$\begin{array}{l} CH_3{-}(CH_2)_n{-}COOH + O_2 \\ \qquad\qquad\qquad\quad \downarrow \\ CH_2OH{-}(CH_2)_n{-}COOH + H_2O \end{array} \quad (6)$$

The hydroxylated carbon is then oxidized producing a diterminal carboxylic acid. Further degradation proceeds via β-oxidation and the Krebs cycle as described in equation (5). Branched alkanes are also degraded by alkane monooxygenase–mediated pathways, but less efficiently because branching hinders subsequent degradation reactions (42).

Less commonly, degradation pathways for alkanes involve a monooxygenase-catalyzed attack at a subterminal carbon position producing a secondary alcohol (7,41). Oxidation of the subterminal hydroxyl group by a dehydrogenase-catalyzed reaction produces a ketone.

$$\begin{array}{l} R{-}CH_2{-}CH_3 + O_2 \longrightarrow R{-}CHOH{-}CH_3 \\ \qquad\qquad\qquad\qquad\quad \downarrow \\ \qquad\qquad\qquad\qquad\quad R{-}CO{-}CH_3 \end{array} \quad (7)$$

The ketone is a substrate for a BVMO that inserts one atom of molecular oxygen between the carbonyl carbon and the adjacent carbon on the side with the longest alkyl group, producing an ester (43).

$$R{-}CO{-}CH_3 + O_2 \longrightarrow R{-}O{-}CO{-}CH_3 + H_2O \quad (8)$$

The ester is then hydrolyzed in a reaction catalyzed by an esterase producing an alcohol and acetic acid.

$$R{-}O{-}CO{-}CH_3 + H_2O \longrightarrow R{-}OH + CH_3{-}COOH \quad (9)$$

These products are then mineralized through pathways involving β-oxidation and the Krebs cycle as shown in equations (4) and (5).

Two types of monooxygenases that hydroxylate linear alkanes have been characterized. The alkane monooxygenase of *Pseudomonas oleovorans* is a multicomponent enzyme system consisting of the catalytic hydroxylase, an electron transport protein (rubredoxin) and an NADH: rubredoxin oxidoreductase (reductase) (44) (Fig. 1a). The three components together constitute a short electron transport chain containing flavin and iron redox centers that are reduced and oxidized as electrons are transferred from NADH to the enzyme's active site. The reductase, which contains FAD, oxidizes NADH and passes the electrons to rubredoxin, which contains two ferric iron ions that accept the electrons from FAD (45,46). The electrons are then transferred from rubredoxin to the hydroxylase that contains a diiron cluster at the active site, which binds and activates molecular oxygen during hydroxylation of alkane substrates (47). The hydroxylase is associated with the cell membrane, whereas the electron transport components are located in the cytoplasm. This enzyme system initiates the degradation pathways of $C_6{-}C_{14}$ *n*-alkanes (48). In addition, the enzyme hydroxylates the methyl group of $C_6{-}C_{12}$ fatty acids (Eq. 6). The alkane monooxygenase of *Corynebacterium* sp. strain 7E1C (49) has a different structure than that of *P. oleovorans*, though the product of the reaction is the same for both enzymes. In *Corynebacterium* the enzyme appears to consist only of a reductase and a hydroxylase component (Fig. 1b). The reductase is a flavoprotein, whereas the hydroxylase is a cytochrome P450, which contains iron bound to the protein as heme. Nonheme iron is also present in the hydroxylase component. The heme iron binds and activates molecular oxygen during catalysis. This type of monooxygenase

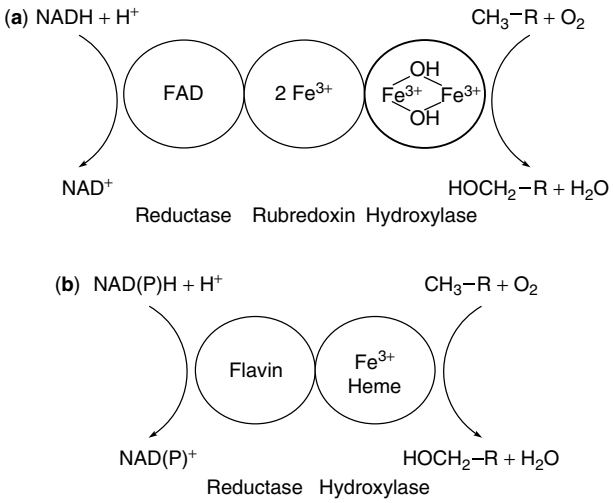

Figure 1. Proposed arrangement of the protein components of alkane monooxygenases of: (**a**) *Pseudomonas oleovorans* and (**b**) *Corynebacterium* 7E1C. R-alkyl or carboxyalkyl.

is also present in some species of *Candida*, a yeast that grows at the expense of alkanes (41).

Methane monooxygenases of methylotrophic bacteria (bacteria that utilize methane as a growth substrate) also hydroxylate longer chain *n*-alkanes in a process called *cooxidation* (50). These bacteria utilize methane but not the longer chain *n*-alkanes for growth. Methane monooxygenase catalyzes the oxidation of methane to methanol as the first step in the methane degradation pathway, but it has a relaxed substrate specificity and fortuitously oxidizes a wide range of substrates in addition to alkanes, including chlorinated alkanes, alicyclic, and aromatic hydrocarbons (51,52). The hydroxylated products are not further metabolized by the methylotrophs and further degradation is dependent on the enzymes of pathways expressed by other microorganisms in the environment. The methane monooxygenases of *Methylosinus trichosporium* OB3b and *Methanococcus capsulatus* (Bath) are three-component enzyme systems consisting of a reductase containing FAD and a 2Fe-2S cluster, a small protein without cofactors and a hydroxylase with properties similar to those of the alkane monooxygenase described earlier (14).

A BVMO that inserts an oxygen atom into C_4-C_{14} methylketones has been purified from *Burkholderia* (*Pseudomonas*) *cepacia* (43).

$$\begin{array}{l} CH_3-(CH_2)_{1-11}-CO-CH_3 + O_2 \\ \qquad\qquad\qquad\quad \Big\downarrow \\ CH_3-(CH_2)_{1-11}-O-CO-CH_3 + H_2O \end{array} \qquad (10)$$

This enzyme may participate in alkane degradation pathways involving subterminal hydroxylation as the first step (see earlier). The enzyme is a homodimer with a molecular weight of 123,000, contains FAD as a cofactor, and is specific for NADPH as the source of reducing equivalents.

Alkenes, also known as olefins, are unsaturated hydrocarbons containing a double bond between two carbon atoms of a hydrocarbon chain, which may also be degraded by pathways involving alkane monooxygenases (41,53). As with alkanes, terminal and subterminal hydroxylation of alkenes have been shown and a variety of hydroxylated compounds are produced, depending on the site of attack by oxygen. Degradation following subterminal hydroxylation of alkenes may involve a BVMO and an esterase as described for subterminal hydroxylation of alkanes (41). An epoxide is produced when the double bond is the site of attack, however.

$$R-CH_2-CH=CH_2 + O_2 \longrightarrow R-CH_2-\underset{\diagdown\,\diagup}{\overset{O}{CH}}-CH_2 + H_2O \qquad (11)$$

Epoxides may be hydrolyzed to diols spontaneously or via a reaction catalyzed by an epoxide hydrolase.

$$R-CH_2-\underset{\diagdown\,\diagup}{\overset{O}{CH}}-CH_2 + H_2O \longrightarrow R-CH_2-COH-CH_2OH \qquad (12)$$

In contrast, the epoxide produced from propene by *Xanthobacter* sp. strain Py2 is carboxylated producing acetoacetate which enters central metabolic pathways via acetoacetyl-CoA (54).

$$CH_3-\underset{\diagdown\,\diagup}{\overset{O}{CH}}-CH_2 + CO_2 \longrightarrow CH_3-CO-CH_2-COOH \qquad (13)$$

Alicyclic hydrocarbons (cycloalkanes) contain three or more carbon atoms arranged in a cyclic structure. They are major components of petroleum and are the fraction most resistant to biodegradation (55). Isolation of pure cultures of microorganisms capable of utilizing alicyclic hydrocarbons as sole carbon sources is difficult (56). However, a *Nocardia* sp. (57), a *Pseudomonas* sp. (58), and a *Xanthobacter* sp. (59) capable of growth on cyclohexane have been isolated. The aerobic degradation pathway for cyclohexane involves initial hydroxylation to cyclohexanol in a reaction catalyzed by a monooxygenase (Fig. 2). The soluble (i.e., not membrane bound) *Xanthobacter* sp. enzyme was partially purified and appeared to be composed of three components, including a cytochrome P450 type hydroxylase (hemoprotein), a ferredoxin, and a ferredoxin reductase (59). The latter two components transfer the required reducing equivalents to the catalytic hydroxylase component. These characteristics are similar to those of cytochrome P450 camphor 5-monooxygenase (32). In the second step of the pathway, cyclohexanol is oxidized to cyclohexanone in a reaction catalyzed by a dehydrogenase, then cyclohexanone 1,2-monooxygenase inserts one atom of molecular oxygen into the ring producing ε-caprolactone (55). The purified cyclohexanone monooxygenase, a BVMO of the *Xanthobacter* sp., contains FAD and FMN and is a monomeric protein with a molecular weight of 50,000. The enzyme is specific for NADPH as a source of reducing power, but has a broad substrate specificity for cyclic alkanones containing four to eight carbons. Straight-chain alkanones are not substrates (34).

Whereas a few bacterial strains capable of growth on alicyclic compounds in pure culture have been described, the predominant pathway for degradation of alicyclic hydrocarbons in the environment is thought to involve cooxidation and commensal interactions (60). Cooxidation occurs when a carbon source that does not support growth of an organism is partially oxidized by catabolic enzymes of a biodegradative pathway for a growth substrate having a similar chemical structure (50). Commensal interactions among the members of a mixed microbial population may then complete degradation of the cooxidation product(s) (56). Thus, the complete biodegradative pathway is not present in one organism and two or more organisms acting in concert are needed for mineralization of the starting compound. In the case of alicyclic hydrocarbons, an organism that contains a broad-specificity hydroxylase that allows it to grow on alkanes may initiate degradation by hydroxylating

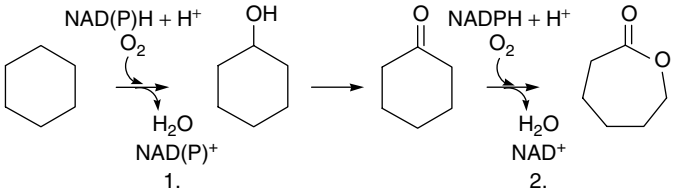

Figure 2. Involvement of monooxygenases in the degradation of cyclohexane. (*1*) Reaction catalyzed by cyclohexane hydroxylase. (*2*) Reaction catalyzed by cyclohexanone 1,2-monooxygenase. Hydrogen substituents on the ring carbon atoms are not shown.

the alicyclic hydrocarbon to a cyclic alcohol, which is then oxidized to the corresponding cyclic ketone (cycloalkanone), as describe earlier for cyclohexane. The cycloalkanone then serves as a growth substrate for other organisms containing a BVMO, esterase, and enzymes involved in β-oxidation (61). Cooxidation of alicyclic hydrocarbons has been studied in bacteria such as *Mycobacterium vaccae* JOB-5 (62) and *Pseudomonas aeruginosa* 473 (63), which do not utilize them for growth, but can initiate their degradation via hydroxylation and oxidation to cycloalkanones while growing on linear alkanes. Methylotrophs that contain a broad-specificity methane monooxygenase also carry out the initial hydroxylation of alicyclic hydrocarbons, as described earlier for alkanes (51,64). Alkyl-substituted alicyclic hydrocarbons are more predominant in petroleum than unsubstituted alicyclics and their degradation may be initiated by monooxygenases that hydroxylate either the alkyl group or the ring (55).

Terpenes are produced by plants and released into the environment on a large scale. They constitute a class of hydrocarbons containing many different acyclic, monocyclic, and bicyclic monoterpenes, which contain 10 carbon atoms (Fig. 3), as well as more complex structures such as diterpenoids (C_{20}) and triterpenoids (C_{30}). Terpenes have been shown to be degraded primarily through monooxygenase-mediated pathways. Hydroxylases and BVMOs similar to those of the degradation pathways of petroleum hydrocarbons are often involved (65). However, a pathway has been proposed for the degradation of abietic acid, a diterpenoid present in paper pulping wastewater, by *Pseudomonas abietaniphila* BKME-9, which involves hydroxylation of the aromatic ring of a proposed intermediate by a dioxygenase (66).

Hydroxylation of the C-8 methyl group of linalool by a soluble P450 monooxygenase ($P450_{lin}$) of *P. putida* PpG777 initiates the degradation of this acyclic monoterpene (Fig. 4) (67). The product of the reaction is an alcohol that can be also be oxidized to the aldehyde, 8-oxo-linalool, by the hydroxylase. The second hydroxylation reaction was hypothesized to produce an unstable gem

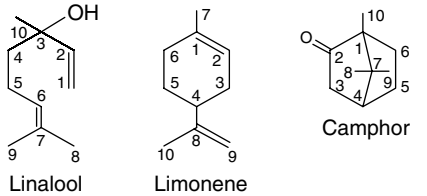

Figure 3. Examples of acyclic (linalool), monocyclic (limonene), and bicyclic (camphor) monoterpenes. Numbering schemes for the carbons atoms are shown.

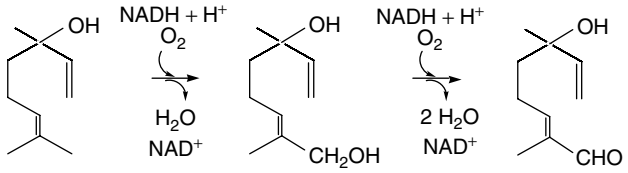

Figure 4. Hydroxylation and oxidation of linalool in reactions catalyzed by linalool 8-methyl hydroxylase of *P. putida* PpG777 (after Ullah and coworkers (67)).

diol that dehydrates spontaneously to the aldehyde. An alcohol dehydrogenase, which oxidizes the alcohol to the aldehyde, is also present in this organism. The aldehyde is likely oxidized to a carboxylic acid followed by β-oxidation. Linalool 8-methyl hydroxylase consists of three separate protein components containing redox centers: a reductase oxidizes NADH and passes the two reducing equivalents to the catalytic hydroxylase component via a small molecular weight electron carrier named *redoxin*. The reductase contains FAD as a redox center, the redoxin contains a 2Fe-2S iron-sulfur redox center, and the P450 hydroxylase contains ferric iron (Fe^{3+}) coordinated by a molecule of heme and a thiolate ligand at the active site. The properties of this enzyme are very similar to those of camphor 5-monooxygenase (see later). There is evidence for an alternate pathway that involves hydroxylation of the C-10 methyl group in this organism (65).

Several pathways have been described for the bacterial degradation of limonene (68). One pathway involves hydroxylation of the C-7 methyl group in a reaction catalyzed by a membrane-bound hydroxylase (69). A less-common pathway involves two monooxygenases: one that produces an epoxide and one with BVMO activity (68,70) (Fig. 5). The activity of limonene 1,2-monooxygenase in cell extracts of *Rhodococcus erythropolis* DCL14 was dependent on FAD, suggesting that the enzyme utilizes it as a cofactor during catalysis.

One pathway for biodegradation of camphor involves hydroxylation at C-5 and two BVMO-catalyzed reactions (Fig. 6). Hydroxylation is catalyzed by camphor 5-monooxygenase, also known as cytochrome $P450_{cam}$. This soluble enzyme has been purified from *P. putida* PpG786 and has been studied as a model for mammalian cytochrome P450s involved in a variety of metabolic reactions (32). The enzyme consists of a flavoprotein reductase, a 2Fe-2S iron-sulfur protein, and a cytochrome P450 hydroxylase with properties similar to those described earlier for linalool 8-methyl hydroxylase (67). Two different BVMOs catalyze the insertion of oxygen into the two rings, leading to cleavage of both rings. The

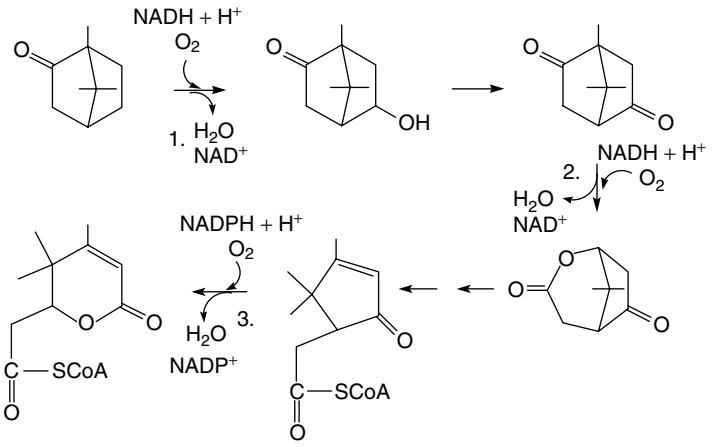

Figure 6. Involvement of monooxygenases in the degradation of camphor by *P. putida* (after Ougham and coworkers (72)). (*1*) Reaction catalyzed by camphor 5-monooxygenase (cytochrome $P450_{cam}$). (*2*) Reaction catalyzed by 2,5-diketocamphane 1,2-monooxygenase. (*3*) Reaction catalyzed by 2-oxo-Δ^3-4,5,5-trimethylcyclopentenylacetyl-CoA 1,2-monooxygenase.

first enzyme, 2,5-diketocamphane 1,2-monooxygenase, is a two-component enzyme consisting of a reductase with a molecular weight of 36,000, which oxidizes NADH, and a monooxygenase, containing FMN, which is a homodimer with a molecular weight of 78,000 (71). The second BVMO of the pathway, 2-oxo-Δ^3-4,5,5-trimethylcyclopentenylacetyl-CoA 1,2-monooxygenase, consists of a single protein component containing FAD, is specific for NADPH, and is a homodimer with a molecular weight of 106,000 (72).

Monooxygenases are also involved in the degradation pathways of aromatic ring compounds. The benzene ring is one of the most abundant and stable chemical structures present in organic compounds, plant lignin being a major source in nature (2). Biodegradation of aromatic compounds requires cleavage of the ring and metabolism to products that enter the central metabolic pathways. However, aromatic ring cleavage catalyzed by dioxygenases is a reaction that requires the presence of two hydroxyl group substituents on the ring. Thus, many of the biodegradation pathways involve hydroxylation by monooxygenases and/or dioxygenases and transformation to the dihydroxylated aromatic compounds (ring-cleavage substrates) such as catechol, protocatechuic acid or gentisic acid (Fig. 7b). For example, phenol, 2-hydroxybenzoic acid (salicylic acid), 3-hydroxybenzoic acid, and 4-hydroxybenzoic acid (Fig. 7a) are transformed to ring-cleavage substrates in reactions catalyzed by phenol hydroxylase (73), salicylate hydroxylase (74), 3-hydroxybenzoate hydroxylase (75), and 4-hydroxybenzoate hydroxylase (76), respectively. These enzymes utilize FAD as a cofactor and oxidize NADH to provide the necessary reducing equivalents for addition of one atom of molecular oxygen to the substrate and reduction of the other oxygen atom to water. Cleavage of aromatic rings will be discussed later in the section on dioxygenases.

In addition to hydroxylation of an aromatic ring, monooxygenases may hydroxylate alkyl substituents attached to the ring. Catabolism of toluene provides examples of the different ways that monooxygenases (and dioxygenases) participate in biodegradation pathways of aromatic compounds. Five different pathways have been described for the aerobic biodegradation of toluene (77). One pathway is initiated by a monooxygenase that catalyzes hydroxylation of the methyl group (Fig. 8), three pathways involve monooxygenases that hydroxylate the aromatic ring at the *ortho*, *meta*, and *para* positions, respectively (Fig. 9), whereas only one pathway is initiated by a dioxygenase that catalyzes dihydroxylation of the ring (Fig. 10).

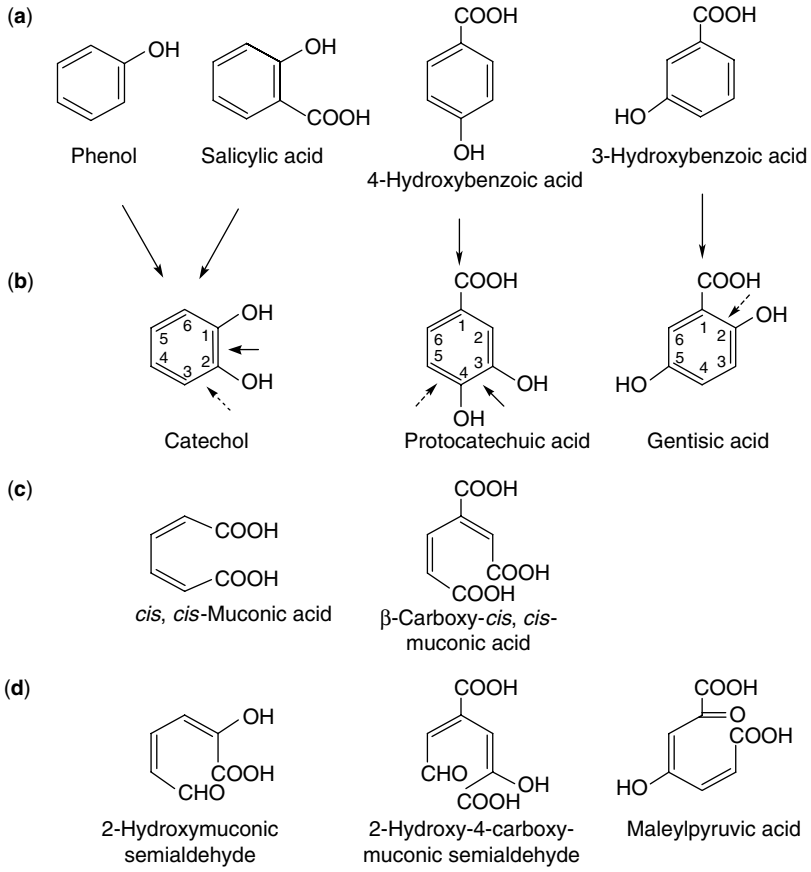

Figure 7. Transformation of aromatic hydrocarbons to common ring-cleavage substrates. (**a**) Examples of compounds that are hydroxylated in reactions catalyzed by monooxygenases. (**b**) Ring-cleavage substrates common to many pathways for degradation aromatic compounds. The positions in which intradiol (solid arrows) and extradiol (dashed arrows) ring cleavage occurs is shown. (**c**) Intradiol ring-cleavage products of dioxygenase-catalyzed attack on catechol and protocatechuic acid. (**d**) Extradiol ring-cleavage products of dioxygenase-catalyzed attack on catechol, protocatechuic acid, and gentisic acid.

The TOL plasmid of *P. putida* mt-2 encodes a pathway for biodegradation of toluene as well as xylenes and some substituted derivatives (78). Hydroxylation of the methyl group is the first step of the TOL pathway for biodegradation of toluene and *meta*- and *para*-xylenes (Fig. 8). The reaction is catalyzed by xylene monooxygenase, a two-component enzyme consisting of a reductase and a hydroxylase. The reductase is a monomer with a molecular weight of 42,000 and contains FAD and a 2Fe-2S iron-sulfur cluster as redox cofactors (79). The size of the membrane-bound hydroxylase component was calculated to be 41,650 from the deduced amino acid sequence (80). It probably contains a catalytic diiron cluster like that of the hydroxylase component of the related alkane monooxygenase (47,81) (Fig. 1). Two dioxygenases catalyze dihydroxylation and cleavage of the ring in subsequent steps of the pathway (82).

Burkholderia cepacia G4 contains a toluene 2-monooxygenase that catalyzes hydroxylation of the ring at the *ortho* position, producing *ortho*-cresol (83) (Fig. 9, reaction 1a). This enzyme also catalyzes the second ring hydroxylation (reaction 1b). The soluble enzyme was purified and shown to consist of a multisubunit hydroxylase ($\alpha_2\beta_2\gamma_2$, molecular weight 211,000) containing diiron clusters, a reductase containing FAD and 2Fe-2S iron-sulfur cluster, and a small molecular weight protein, lacking metals or organic cofactors, that enhanced enzyme activity 10-fold (84). These properties are similar to those described (or predicted from gene sequences) for alkane hydroxylase (47), soluble methane monooxygenase (85), and xylene monooxygenase (80). Ring cleavage in this pathway is catalyzed by an extradiol ring-cleavage dioxygenase (reaction 1c) (86).

Toluene 3-monooxygenase of *Ralstonia* (*Pseudomonas*) *pickettii* PKO1 catalyzes hydroxylation of the ring at the *meta* position, producing *meta*-cresol (Fig. 9, reaction 2a). Analysis of the genes encoding the enzyme suggests that it is comprised of a catalytic hydroxylase component plus a reductase and a ferredoxin (87). The second ring hydroxylation reaction of strain PKO1 is catalyzed by phenol/cresol hydroxylase (reaction 2b), a simple monooxygenase that contains only FAD as a cofactor (88). Cleavage of the ring is catalyzed by an extradiol ring-cleavage dioxygenase (reaction 2c) (89).

Toluene 4-monooxygenase of *Pseudomonas mendocina* KR1 catalyzes hydroxylation of the ring at the *para* position, producing *para*-cresol (Fig. 9, reaction 3a). The composition of the enzyme is similar to that of toluene 2-monooxygenase described earlier (90,91). Hydroxylation of the methyl group is catalyzed by *para*-cresol methyl hydroxylase, which is not an oxygenase as the hydroxyl group is derived from water. The second ring hydroxylation reaction of this pathway (reaction 3b) is likely catalyzed by 4-hydroxybenzoate 3-monooxygenase (cf. Fig. 7). This enzyme has been purified from a variety of bacteria. The enzyme of *Corynebacterium cyclohexanicum* is a

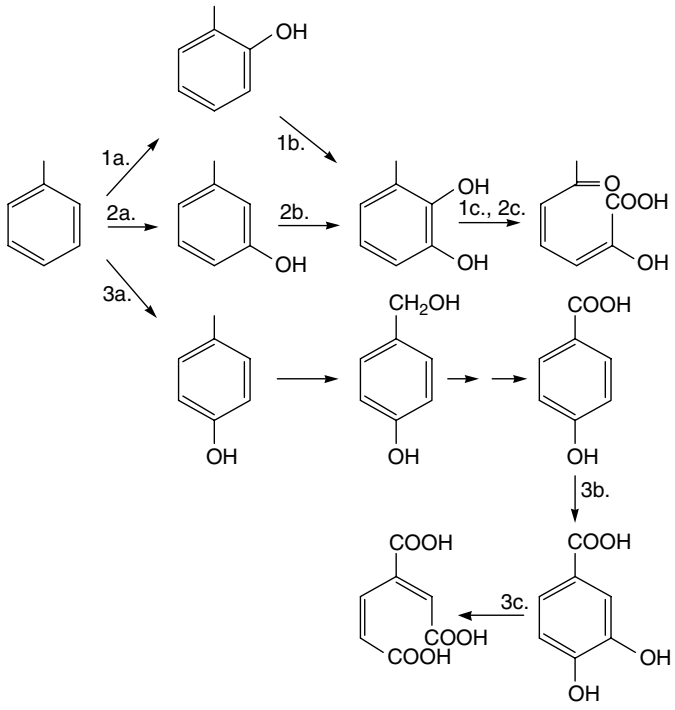

Figure 9. Three toluene biodegradation pathways that are initiated by monooxygenases that catalyze hydroxylation of the *ortho* (1a), *meta* (2a) and *para* (3a) ring carbons. The next reaction of pathways 1 and 2 involves a second monooxygenase-catalyzed ring hydroxylation reaction (1b and 2b), whereas pathway 3 involves methyl group hydroxylation with water rather than O_2 as the source of oxygen. The second ring hydroxylation of pathway 3 is catalyzed by a monooxygenase (3b). Ring-cleavage dioxygenases for pathways 1 and 2 catalyze extradiol cleavage of the ring (1c and 2c), whereas pathway 3 involves intradiol cleavage (3d). Molecular oxygen and other reactants have been omitted for clarity.

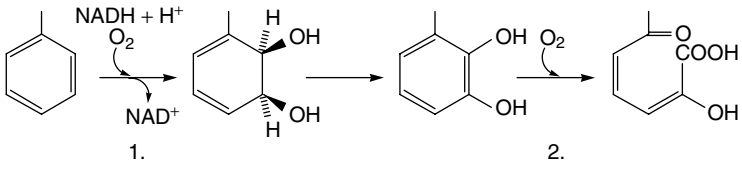

Figure 10. Involvement of dioxygenases in the pathway for the degradation of toluene. (*1*) Dihydroxylation reaction catalyzed by toluene dioxygenase. (*2*) Extradiol ring-cleavage reaction catalyzed by 3-methylcatechol 2,3-dioxygenase. (Absolute stereochemistry is not intended.)

monomeric flavoprotein (molecular weight of 47,000) that contains FAD as a cofactor and obtains reducing equivalents from NAD(P)H (92).

Monooxygenases participating in the biodegradation pathways of numerous other aromatic compounds, such as phenol, chlorophenols, nitrophenols and anthranilic acid are equally interesting, but will not be discussed here because of limited space.

DIOXYGENASES AND THEIR ROLES IN BIODEGRADATIVE PATHWAYS

Dioxygenases catalyze the addition of both atoms of molecular oxygen to their substrates, which are usually aromatic compounds. Two different types of dioxygenases participate in aromatic biodegradative pathways: those that catalyze dihydroxylation of aromatic rings of

compounds that lack two ring hydroxyl groups and those that catalyze cleavage of dihydroxylated aromatic rings. Examples of both reaction types are found in the toluene degradation pathways previously discussed (Figs. 8 and 9).

As previously discussed, aerobic degradation pathways for a large number of different aromatic compounds, especially for aromatic hydrocarbons, converge on a few common dihydroxylated intermediates that are substrates for ring-cleavage dioxygenases (Fig. 7b). The hydroxyl groups may be located on adjacent carbons (*ortho*), as for catechol and protocatechuic acid, or they may be located *para* to each other on the ring, as for gentisic acid. Ring-cleavage dioxygenases insert both atoms of molecular oxygen into the ring either between the hydroxylated carbon atoms (*ortho* or intradiol ring cleavage) or between a hydroxylated and a nonhydroxylated carbon atom (*meta* or extradiol ring cleavage). Many aromatic hydrocarbon biodegradation pathways involve extradiol ring cleavage as shown for three of the previously discussed toluene biodegradation pathways (Figs. 8 and 9). Extradiol ring-cleavage dioxygenases contain nonheme ferrous iron (Fe^{2+}) as a cofactor that binds and activates molecular oxygen during catalysis (4). Pathways involving intradiol ring cleavage are also common. These enzymes contain nonheme ferric iron (Fe^{3+}) as a cofactor that activates the aromatic substrate during catalysis. Both types of enzymes may be composed of one (α) or two different protein subunits ($\alpha\beta$) present in a variety of stoichiometries, depending on the organism in which they are found. For example, catechol 1,2-dioxygenase (intradiol cleavage) of *Alcaligenes eutrophus* CH34 is an α_2 homodimer with a molecular weight of 76,000 (93), whereas catechol 2,3-dioxygenase (extradiol cleavage) of *P. putida* mt-2 is an α_4 homotetramer with a molecular weight of 140,000 (37). Protocatechuate 3,4-dioxygenase of *Brevibacterium fuscum* (intradiol cleavage) is an $(\alpha\beta)_6$ heterododecamer with a molecular weight of 315,000 (94). Reactions catalyzed by aromatic ring-cleavage dioxygenases do not require externally supplied reducing equivalents, so reduced coenzymes and accessory electron transfer proteins are needed.

Aromatic ring hydroxylating dioxygenases initiate biodegradation pathways for aromatic hydrocarbons and many aromatic compounds that lack hydroxyl groups needed for ring cleavage. Hydroxylation of the ring is accompanied by the addition of two reducing equivalents, resulting in a product with both hydroxyl groups located on the same side of the ring (*cis*), as illustrated in the fifth known pathway for bacterial toluene degradation (Fig. 10). *cis*-Dihydrodiol dehydrogenases catalyze the second step of most pathways, which rearomatizes the ring producing substrates for ring-cleavage dioxygenases. Ring-cleavage products are then metabolized to intermediates that enter the central metabolic pathways.

Toluene dioxygenase catalyzes dihydroxylation of toluene in *P. putida* F1 (95). This enzyme system is composed of three protein components: a catalytic hydroxylase and two electron transfer proteins (ferredoxin and reductase) that supply reducing equivalents to the hydroxylase (Fig. 11). The reductase oxidizes NADH and transfers the electrons to the ferredoxin, which transfers the electrons to the hydroxylase. The reductase contains FAD as a redox cofactor, whereas both the ferredoxin and hydroxylase contain a 2Fe-2S iron-sulfur cluster as a redox cofactor. The hydroxylase also contains mononuclear ferrous iron, which has been proposed to bind and activate molecular oxygen as part of the catalytic mechanism of various hydroxylases (96). The reductase and ferredoxin components are monomers with molecular weights of 42,900 and 11,900, respectively. The hydroxylase is an $\alpha_2\beta_2$ heterotetramer with a native molecular weight of 151,000. This arrangement is typical of dioxygenases that act on benzene and biphenyl, though differences in the number of hydroxylase subunits have been reported (97,98). Dioxygenases that catalyze hydroxylation of the carboxylated aromatic compounds benzoic acid and phthalic acid lack a separate ferredoxin component, but the reductase contains a 2Fe-2S redox cluster, in addition to flavin, as a redox cofactor (97).

Additional examples of aromatic compounds that are dihydroxylated via multicomponent dioxygenases include biphenyl and PCBs, naphthalene, phenanthrene and other polynuclear aromatic hydrocarbons, heterocyclic aromatic compounds such as dibenzo-*para*-dioxin, dibenzothiophene, and carbazole, and 1,1,1-trichloro-2,2-bis(4-chlorophenyl)ethane (DDT). The dihydroxylated products of some of these substrates are illustrated in Figure 12. In some cases, the initial product of the hydroxylase is unstable and spontaneously rearomatizes without the aid of a dehydrogenase, as shown for the product formed from dihydroxylation of dibenzo-*para*-dioxin (Fig. 12d).

A final example of the roles of dioxygenases in biodegradation pathways is shown in Figure 13. 2-Aminobenzene sulfonic acid is oxidized to 3-sulfocatechol by 3-sulfocatechol 2,3-dioxygenase. The *cis*-dihydrodiol product

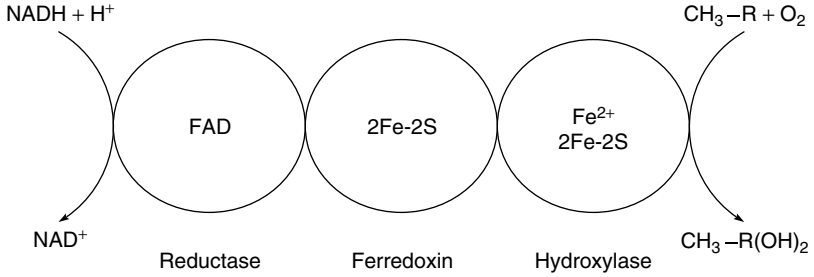

Figure 11. Proposed arrangement of the protein components of toluene dioxygenase of *P. putida* F1. R = C_6H_5 (phenyl).

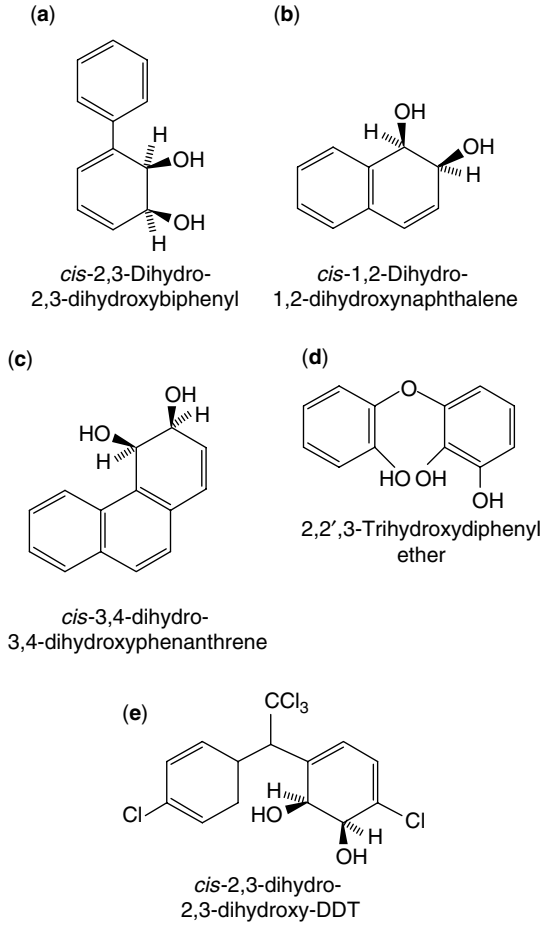

Figure 12. Products of dihydroxylation of some bi- and polycyclic aromatic compounds. The dioxygenase substrates are: (**a**) biphenyl, (**b**) naphthalene, (**c**) phenanthrene, (**d**) dibenzo-*para*-dioxin, and (**e**) DDT. (Absolute stereochemistry is not intended.)

of this reaction is unstable and spontaneously rearomatizes, eliminating the amino group as NH_3^+ and producing 3-sulfocatechol. The aromatic ring of 3-sulfocatechol is cleaved by 3-sulfocatechol 2,3-dioxygenase (intradiol ring cleavage), also producing an unstable intermediate that reacts with water producing 2-hydroxymuconic acid and bisulfite (99). This example illustrates that reactions catalyzed by a hydroxylase and a ring-cleavage dioxygenase can eliminate potentially inhibitory ring substituents and form a product (2-hydroxymuconic acid) that can be further metabolized via central metabolic pathways.

CONCLUSION

Over the past 50 years, a large body of evidence obtained from laboratory studies conducted with pure cultures and under optimized conditions indicates that the involvement of oxygenases in biodegradative pathways is common in nature. There is also evidence that these pathways are operational in the environment and contribute to the functioning of the global carbon cycle (100,101). It is likely that oxygenases play a crucial role in the survival of micooorganisms by allowing them to utilize chemically stable, and sometimes toxic, compounds as growth substrates. This probably accounts for the diversity of structure and catalytic mechanisms of these enzymes and promises that many oxygenases with novel properties and activities remain to be discovered.

The process of evolution has selected for oxygenases that play specific roles in sometimes complex biodegradative pathways involving the oxidation of naturally occurring organic compounds to carbon dioxide and water. Enzymes, including oxygenases, are usually very specific for their substrate(s) and the type of reaction they catalyze. Oxygenases are often tolerant of structural variation in the chemical structures of substrates, however, and may attack xenobiotic compounds that pose hazards to environmental health. Complete pathways for mineralization of xenobiotics may evolve in micooorganisms via the processes of mutation, rearrangement of genetic elements, recombination and genetic exchange among cells in the environment, as well as through genetic engineering and selection in the laboratory (102–104). Thus, biochemical constraints on the mineralization of pollutants may be circumvented and the potential exists for mineralization via biodegradative pathways that involve steps catalyzed by oxygenases.

PALEOLIMNOLOGY: SUBFOSSIL ALGAE OTHER THAN DIATOMS AND CHRYSOPHYTES

BYRON C. SHUMATE
THOMAS L. CRISMAN
University of Florida
Gainesville, Florida

It is a standard practice in paleoecological studies to use biological remains to infer past environmental conditions. Chitinous animal remains (cladoceran exoskeletons and dipteran mouth parts), ostracods, and mollusks preserve well, can be numerous in lacustrine sediments, easily identifiable, and are sensitive to environmental fluctuations (1). Plant pollen is widely used for reconstruction of terrestrial plant communities. Aquatic plant macrofossils are commonly used both to reinforce pollen diagrams and to characterize past macrophyte community structure in littoral zones (2).

Phytoplankton assemblages are represented in the subfossil record by siliceous diatom tests (3) and chrysophyte cysts (4), which are often abundant and well preserved. A broader identification of the phytoplankton community is provided by algal pigments (chlorophylls and carotenoids) and other biochemical parameters in sediments (5–8). These indicators have been used to make statements about primary productivity, salinity, nutrient limitation, water level fluctuation, trophic-cascade dynamics, and watershed–lake interactions.

This article considers the application of other algal remains to paleolimnological studies. These groups, typically the Chlorococcales, Desmidaceae, and Cyanophyta, contain numerous taxa meeting criteria necessary to serve as effective biological paleoindicators (9). Their remains are preserved in sediments and can be identified to specific levels; documented ecological information exists for individual species, and they are sensitive to environmental change.

ANALYTICAL METHODS

There is no standardized technique for the preparation of lacustrine sediments for the analysis of algal remains. Usually, samples are prepared for pollen analysis, and algal microfossils are counted as a secondary component. Palynological (pollen) preparation is typified by the methods of Faegri and Iversen (2). Initially, a fresh sediment is inoculated with known quantities of an exotic pollen, typically *Eucalyptus* or *Lycopodium*, to estimate pollen and palynomorph concentrations. Samples are then treated with KOH or HF to break sediment aggregates and eliminate siliceous material (10). A milder bromoform alcohol solution can also be used instead with no discernible difference (11). An acetolysis step follows to remove cellulose and other refractory organic residues. If the samples are still coarse or clayey, they can then be passed through a fine sieve (12). To facilitate specimen identification, stains such as safranine (13) and gentian violet (9) are sometimes added before microscopy.

Unfortunately, the strong chemical treatments in this method probably dissolve the majority of siliceous and calcareous algal remains. Cronberg (4) recommended addition of *Lycopodium* spores for analytical purposes, but suggests a dilute NaOH treatment for the analysis of blue-green and green algal remains. In most studies targeting specific algal remains, sediments are left untreated (14) or diluted and preserved with glycerol (15) or ethanol (9).

For microscopy, silicone oil is the most common mounting medium (16–18), but glycerine is also used (19). Oil immersion and 1,000X stereomagnification are occasionally required (13,17), but 400X is usually the highest resolution at which routine identifications are made. Counting techniques vary widely. When performed as a component of palynological (pollen) analysis, taxa are enumerated until a significant number of pollen grains and spores is reached. This number typically ranges between 200 (13) and 900 (20). Some researchers highlight the importance of counting slides entirely to counterbalance nonrandom distributions of remains (20). Enumeration techniques are similar in algal-specific studies, but counts are based on numbers of algal specimens (9).

Strategies also vary in the expression of data. Most palynologists report algal remains either as a percentage of the total pollen sum (18) or as a percentage of both pollen and algal totals (21). Algal-specific studies employing this technique report microfossils as a percentage of the total algal sum (9). Most often, concentrations of algal remains are used (13–15). In such investigations, it is important to decide what constitutes an individual. Algal remains are first enumerated taxonomically, and then the counts are adjusted to account for different algal growth forms, especially the separation of single-celled, filamentous,

and colonial taxa. For instance, *Pediastrum* is reported as number of colonies, *Chara* and *Nitella* as number of oospores (13), and *Aphanizomenon* and *Anabaena* as number of akinetes (15).

PALEOECOLOGICAL APPLICATIONS OF ALGAL SUBFOSSIL TAXA

After diatoms and chrysophytes, green algae (Phylum Chlorophyta), especially genera within the Order Chlorococcales, are the most widely studied for their paleolimnological utility (Fig. 1). Oospores of macroalgae (Order Charales), however, are also enumerated. Species of the Family Desmidaceae (Phylum Conjugaphyta) are more resistant and numerous in sediments than the Family Zygnemataceae, and are more widely used (Fig. 2). Within the Cyanophyta, cell walls of *Gloeotrichia* and akinetes of *Anabaena* and *Aphanizomenon* species have been studied successfully (Fig. 3). A few genera of euglenoids, cryptophytes, and dinoflagellates have been of limited value in freshwater stratigraphic reconstructions (Fig. 4). Individual algal groups, their decay-resistant properties, and their application to paleolimnology are discussed later.

Phylum Chlorophyta

Order Chlorococcales. Of the algal groups discussed here, Chlorococcales have received the most attention. Species of Pediastrum, Botryococcus, and Scenedesmus contain sporopollenin, a decay-resistant protein, in their cell walls (22). Silica also is present in the cell walls of some Pediastrum species (23). Palynologists first noticed this durability, and mentioned the presence of green algal remains in their early studies (9).

Most quantitative studies with these algae have been in concert with pollen analyses. Cell counts of Chlorococcales, in conjunction with aquatic pollen, plant macrofossils, and other biological proxies, provide information about the lacustrine setting in which terrestrial pollen was deposited. The first significant studies included temporal trends for *Pediastrum* and *Botryoccocus* species since the last glacial period (16,24–27). Although some presented detailed taxonomic separation, most paleolimnological conclusions were based on total subfossil abundances of Chlorococcales (20). Combined with other paleoindicators, these early studies made inferences about lacustrine productivity, water depth, extent of aquatic macrophyte coverage, and cultural disturbance.

Meanwhile, other paleoecologists were seeking to obtain more precision in their interpretations of green algal remains. Reconstructed algal productivity strongly correlated with silt accumulation in Greenland glacial lakes (28) and those of central Europe (29). These interpretations were verified through limnological investigations and expanded to include nutrient

availability in both subarctic (18,30,31) and temperate (32,33) lakes. Crisman (33) found correlations between subfossil green algae, desmid, and cyanophyte assemblages in lake sediments and terrestrial vegetation succession in Minnesota, implying temporal alterations in watershed-nutrient export. In a Nevada saline lake, Bradbury and coworkers (34) used the presence of *Botryococcus* to indicate past periods of freshwater conditions. *Pediastrum* abundances in the Great Lakes were used in conjunction with analyses of oxygen isotopes, silicate, and deposition of inorganic sediment to infer silt accumulation (13).

Unfortunately, broad geographic interpretations of these subfossil groups have been confounded by regional inconsistencies. For example, Anderson and Brubaker (17) attempted to explain water depth in northern Alaskan lakes as a function of *Pediastrum* frequency. Other researchers found the reverse relationship in Europe (35). Edwards and coworkers (21), however, found no relationship between *Pediastrum* and water depth, arguing that abundance was a function of multiple lacustrine factors and that *Pediastrum* subfossils in a sediment sample indicated, at best, the presence of standing water.

Order Charales. Often referred to as *macroalgae*, species of the order Charales are large, colonial taxa, associated with hardwater and secretion of marl. In sediment records, they are typically represented by oospores. *Chara* remains were noted in palynological studies as early as 1932 (36), and interpretations of their remains are usually conservative. For example, oospores of both *Nitella* and *Chara* species are often used to infer the presence of shallow marshy areas within a particular catchment (9,16). Some studies have equated these species with silty, lentic conditions (20). Eisner and coworkers (18) found abundant remains of *Chara*, *Nitella*, and *Tolypella* species in the sediments of Lake 31, Greenland. Although photomicrographs of the oospores were provided, paleoecological reconstructions were based on other data. In a departure, Yu (13) ran an oxygen isotopic analysis on *Chara* encrustations, marl, and mollusk shells to approximate paleotemperature in Twiss Marl Pond, Ontario. *Nitella* and *Chara* propagules were also enumerated, but, again, were not mentioned in the interpretation.

Phylum Conjugaphyta

Family Desmidaceae. Members of the Desmidaceae, the principal representatives of the order Zygnematales in the subfossil record, often contain pectin, silica, and iron compounds (37) in their cell walls. Their cells are generally thick and resistant to processing techniques used in pollen analysis, although they contain no sporopollenin (9). Taxonomic microfossil evaluations revealed abundant desmid subfossils in early palynological investigations (38–40), but quantitative paleoecological assessments were delayed. Limnological investigations found significant correlations between low-nutrient enrichment and desmid abundance (41–44), a relationship that paleoecologists have used to infer low productivity on the basis of both *Cosmarium* microfossil abundances in Ohio lake and peat bog sediments (9) and *Staurastrum manfeldtii* from the sediment record of Lake Gosciaz, central Poland (45). Conversely, enhanced productivity was inferred from sediments of a South Georgia Island lake on the basis of diatom abundances and sediment organic matter combined with the presence of three desmid species (46). A positive correlation was found between two species of the *S. manfeldtii* complex and species of the cyanophyte, *Anabaena* (49). This relationship was later used to imply nitrogen limitation in the Lake Gosciaz, Poland, and paleoreconstruction using *Staurastrum pingue* and *Staurastrum planctonicum* (19).

Family Zygnemataceae. To a lesser extent, taxa of the family Zygnemataceae have been used in lacustrine paleoreconstructions. Spores from species of *Mougeotia*, *Spirogyra*, and *Zygnema* have been reported in the sediments, but in insignificant numbers (33). Van Geel and coworkers (19) noted the presence of *Spirogyra* among other algal subfossil assemblages during a period of anthropogenic nutrient enrichment in Lake Gosciaz, Poland. Given their scarcity, conclusions were based on other, more numerous algal paleoindicators. Regardless of the relatively sparse literature, some researchers remain optimistic about the Zygnemataceae as paleoindicators, citing their sturdiness, ability to be identified to species, and sensitivity to environmental variables (11).

Phylum Cyanophycota

Also referred to as *blue-green algae* or *cyanobacteria*, the cyanophytes are prokaryotic photosynthetic organisms. They occur in unicellular, filamentous, and colonial forms. Cyanophytes enjoy several competitive advantages over their protist counterparts, including an ability to fix atmospheric nitrogen, control their position in the water column, and toxin production. These attributes have led to their proliferation in stressed environments.

Pectin-containing compounds are abundant in cyanophyte cell walls and sheaths (48), and have imparted a decay-resistant nature to some taxa (9). The species most commonly used in paleoecological studies are from the genus *Gloeotrichia*. On the basis of established positive relationships between cyanophyte abundance and lacustrine productivity (26,41,42,44,49), many studies have used the presence of these remains to infer eutrophication (9,19,50,51).

Other investigations noted that this genus can be seasonally epiphytic, planktonic, and epibenthic (52,53). Combined with other data for subfossil algal taxa, Birks and coworkers (16) used this cyanophyte to infer a past period of dense aquatic vegetation in Elk Lake, Minnesota. Also, given the heterocystic nature of *Gloeotrichia* (54), its heightened presence in late-glacial sediments has been associated with either early successional, nitrogen-poor conditions (55,56) or productivity-induced phosphorus limitation (53).

Cyanophytic akinetes, or spores, also have been used in paleoecological investigations. These decay-resistant structures can remain viable in lacustrine sediments for up to 64 years (57). Akinetes used in paleolimnological investigations typically belong to species of *Aphanizomenon* and *Anabaena*, known for their proliferation under eutrophic conditions, especially nitrogen limitation (58,59). In Lake Arendsee, Germany, akinetes in the sediment record were associated with such conditions (14). Extant *Aphanizomenon* populations proliferated in both light- and phosphorus-limited conditions (60), whereas *Anabaena* species only thrived under phosphorus limitation (61). Such differential responses were used to specify the nature of cultural eutrophication in a paleoecological study of Lake Gosciaz, Poland (19).

Other Algae

Other algal groups are known to preserve in sediments, but their scarcity has made it difficult for any significant conclusions to be drawn from the analysis of their subfossil remains. Euglenophyta are seldom used in studies of lacustrine sediments, in part because of the poor preservation of most taxa (9). However, *Phacotus lenticularis*, which has been associated with water hardness, preserves well because of the high calcium content of its cell wall (62). This species has been used in paleolimnological investigations to denote high alkalinity, and with the presence of other indicators, nutrient enrichment (14). Cryptophytes and dinoflagellates, also of limited abundance in lacustrine sediments, are rarely enumerated. Findlay and coworkers (59) did find relationships of these groups with light limitation and eutrophication in the Canadian Experimental Lakes Area. Both groups were enumerated in a follow-up study, but conclusions were limited because of low abundances (14). Dinoflagellate cysts were also counted by Huber (33) in a comprehensive study of algal remains in Gegoka Lake, Minnesota, but low numbers and identification problems inhibited their utility. Remains of the green alga, *Cladophora*, although numerous in some sediments, are counted as macrofossils when studied (18).

CONCLUSION

Of the subfossil algae surveyed, none have been used alone in paleolimnological reconstructions. Initial investigations combined species of chlorococcales and cyanophytes with the more widely used algal paleoindicators, diatoms, and desmids (23,62). Some investigations relied strongly on subfossil algae (9,19), but the data were mainly complementary to other biological indicators, such as pollen (18,21) or diatoms (14). A key problem associated with the use of these other algal groups is differential preservation of species in lacustrine sediments. Frederick (9) counteracted this through use of Nygaard's (41) compound quotient of lake trophic status, but this topic has not been addressed by later investigators.

Although currently of limited value, utilization of subfossil algae in paleoecological studies has great potential. Most investigations hesitate to draw conclusions unless other, more established proxies indicate similar conditions. However, there is a wide array of algal genera that are abundant, readily identifiable, and possess decay-resistant structures in lacustrine sediments. These genera display clearly defined responses to environmental variables including trophic state, nutrient limitation, and conductivity, but their use as single variable paleoindicators remains problematic until the issue of differential preservation of remains is addressed adequately.

Acknowledgments

The authors offer most sincere thanks to U.A.M. Crisman, who skillfully crafted the figures in this manuscript. Administrative support was capably provided by S. Brinkley and S. Ratnesar.

PALEOLIMNOLOGY: USE OF ALGAL PIGMENTS AS INDICATORS

PIERO GUILIZZONI
ANDREA LAMI
CNR Istituto Italiano di Idrobiologia
Verbania Pallanza, Italy

Algal and bacterial pigments (chlorophylls and carotenoids) are common components of lake sediments and have been under investigation for more than three decades. This article reviews the major pigments, mechanisms for their preservation in the sediment record, and their utility in paleolimnological reconstructions. Current interest in environmental history has focused attention on lake deposits as a medium within which natural (e.g., climate) and anthropogenic (e.g., eutrophication, atmospheric pollution) environmental changes are recorded in historical sequence. Pigments reach the surface of lake sediment both as particulate matter from autochthonous planktonic and littoral organisms, and as transported allochthonous plant matter from the catchment or shoreline.

Similar to a number of chemical and biological subfossil remains (e.g., diatoms), plant pigments can be used to infer environmental changes over different timescales (centuries to millennia). The validity of using sedimentary pigments as an index of past events or processes such as trophic condition and primary productivity depends mainly on the preservation of these relatively labile organic compounds, the extent of differential degradation during and after sedimentation, and the extent of allochthonous sources of sedimentary pigment products. When primary producers die, their remains decompose and are incorporated in the sediments. Physical, chemical, and biological factors are responsible for the sedimentary pool of organic matter (see later), and these are well reviewed

by Brown (1), Swain (2), Leavitt (3,4), and Cuddington and Leavitt (5).

However, rarely are pigments completely degraded and thus such *"biochemical fossils"* in lake sediment cores have proved useful for assessing past environmental changes in many lakes.

Finally, as demonstrated for many paleolimnological records, pigments are a useful tool for delineating historical lake development in which long-term limnological data are often lacking or very rare and the only way to obtain such data is through a paleolimnological perspective. Such an approach has value for lake management and monitoring (6).

PIGMENTS OF ALGAE AND PHOTOSYNTHETIC BACTERIA

Presence and Meaning

Higher plants, algae, and bacteria synthesize a variety of pigmented organic compounds that are used in photosynthetic reactions. Chlorophylls absorb solar energy more efficiently in the red portion of the solar spectrum at wavelengths that do not penetrate into deep water. For this reason, aquatic plants synthesize different carotenoids, which are used as accessory pigments, in so far as they absorb light in a wider range of the spectrum. Table 1 summarizes the main pigments (chlorophylls and carotenoids) and their taxonomic specificity.

Chlorophyll *a* is found in all photosynthetic aquatic organisms, with the exception of some species of autotrophic bacteria. As reported in the following text, its degradation products (phaeophytin *a*, phaeophorbide *a*, and chlorophyllide *a*) are relatively well preserved in lake sediments (11–13).

Carotenoids are also widely distributed in all photosynthetic organisms. Those commonly present in the sediment can be subdivided into two major categories according to their solubility in different solvents (e.g., methanol and petroleum ether): epiphasic (carotenes) and hypophasic (xanthophylls). The principal carotene is β-carotene, which is present in all algal taxa. Yellow xanthophylls display greater diversity than carotenes. The most abundant are lutein, neoxanthin, and zeaxanthin (8,14). In addition to these, there are specific xanthophylls, such as

Table 1. Principal Specific Pigments and Relative Taxa (4,7–10)

Pigment	Taxa
Chlorophylls	
Chlorophyll *a*	Common to all plants
Chlorophyll *b*	Chlorophytes, Euglenophytes, Trachaeophytes
Chlorophyll *c*	Chrysophytes, Pyrrophytes
Chlorophyll derivatives	
Phaeophorbide *a*	Chlorophyll *a* derivative (grazing)
Phaeophytin *a*	Chlorophyll *a* derivative common to all plants
Phaeophytin *b*	Chlorophyll *b* derivative common to all plants
Phaeophytin *c*	Chlorophyll *c* derivative (Chrysophytes, Pyrrophytes)
Carotenes	
α-carotene	Cryptophytes, Chlorophytes, Trachaeophytes
β-carotene	Common to all plants, some bacteria
Xanthophylls	
Alloxanthin	Cryptophytes
Astaxanthin	Invertebrate herbivores, some chlorophytes
Canthaxanthin	Invertebrate herbivores, some filamentous cyanobacteria
Echinenone	Total Cyanobacteria (formerly named blue-green algae)
Fucoxanthin	Siliceous algae
Lutein	Chlorophytes, Euglenophytes, Trachaeophytes
Myxoxanthophyll	Colonial and filamentous cyanobacteria
Oscillaxanthin	Oscillatoriaceae
Peridinin	Dinophyceae
Zeaxanthin	Cyanobacteria
Diadinoxanthin	Euglenophytes
Dinoxanthin	Pyrrophytes, Chrysophyceae
Myxol-2′-o-methyl-methylpentoside	*Oscillatoria limosa*
4-Keto-myxol-2′-methylpentoside	*Anabaena flos-aquae*
Sulfur photosynthetic bacteria	
Isorenieratene	Green sulfur bacteria (*Chlorobium* sp.)
Okenone	Red sulfur bacteria (*Chromatium* sp.)
Licopene	*Rhodospirillum* sp.
Spheroidene, spheroidenone	*Rhodopseudomonas sphaeroides*
Rhodopinal	*Lamprocystis, Rhodospirillum tenue*

fucoxanthin and diadinoxanthin, present in diatoms, myxoxanthophyll and echinenone, present in cyanobacteria, and oscillaxanthin present in filamentous cyanobacteria *Oscillatoria* spp.

In many meromictic lakes, two horizontally stratified populations of sulfur photosynthetic bacteria frequently occur, one near the chemocline and the other at greater depth. Each population contains pigments that are distinctive and group-specific and can be used in paleoecological studies to indicate, for example, changes in the physical and chemical environment.

PRESERVATION/DEGRADATION OF PIGMENTS AND ITS PALEOLIMNOLOGICAL SIGNIFICANCE

Sedimentary Processes and Physical-Chemical Factors

Pigments contain chromophorous groups that absorb visible light and give the molecules their characteristic colors. Double bonds and functional groups constitute attack sites for microorganisms, making the compounds highly sensitive to diagenetic changes (15). Despite this tendency, some pigments may become diagenetically more stable once they have arrived in the lake or sediments. The complete aromatization of the tetrapyrrolic ring of chlorophylls, which transforms them into porphyrines, and the hydrogenation of the C−C double bonds of carotenoids to form isoprenoidal alkanes, are the principal changes stabilizing pigments (16).

Regarding the important question of pigment preservation, many authors have discussed the different behavior of carotenoids and chlorophylls (2,17). First, pigments originating in the catchment usually do not arrive in the lake intact, that is, in their original form. Pigments of autochthonous origin are also rapidly degraded if they are not quickly incorporated into the sediment. For example, it was found that photo-degradation of chlorophyll derivatives in the photic zone of the lakes in Michigan was complete after only three days (18).

Carotenoids degrade more rapidly than chlorophylls in the water column, although once reaching the sediment, they are much more stable than chlorophylls. There is no evidence that carotenoids decompose significantly once buried in sediment; if decomposition does occur, it is similar to that of organic matter as a whole (13). Chlorophyll derivatives (phaeophytin, phaeophorbides, and chlorophyllides) are equally refractory to further decomposition and are always more abundant than nondegraded chlorophyll, which is usually present in high quantities only in newly deposited sediment (2,13).

Pigment degradation is particularly sensitive to the presence of oxygen and light (Fig. 1). In fact, decomposition rates in anoxic sediment are generally less than half of that observed at the water–sediment interface in well-oxygenated environments because of direct oxidation and increased activity of benthic organisms (19–21).

Photooxidation is the most important degradation process for pigments that are deposited in sediment; the half-life of carotenoids and chlorophylls is generally about 0.2 days, but may vary in relation to phytoplankton composition and presence of humic acids and light-absorbing compounds (18,22–24). Invertebrate activity in sediments of shallow lakes may also be important (25,26), as may the general physical-chemical and biological conditions of the water column (20,25).

Sediments of deep lakes usually receive less light or are completely aphotic, and oxygen may also be scarce. Thus, pigment degradation through photooxidation and that mediated by organisms (biological) is less than that of a shallow lake. Pigment conservation might therefore be better in sediments of deep lakes rather than shallow lakes (2,27–29). On the other hand, the longer residence time of the pigments in the water column of deep lakes can offset the favorable preservation environment of sediments.

Thus, under field conditions in which light and oxygen are high (e.g., unproductive holomictic lakes), carotenoids and chlorophylls are rapidly transformed into colorless compounds (30,31). However, preservation of fossil pigments is greater in meromictic than in holomictic lakes (3).

Light absorption by chlorophylls may result in formation of a highly reactive triplet excited-state molecule; this molecule may subsequently undergo redox reactions determining the production of radical species, which in turn cause pigment oxidation. Alternatively, excited chlorophyll may react with oxygen, itself a triplet molecule, to form ground-state chlorophyll and singlet oxygen. The latter reacts rapidly with most compounds containing double bonds (10).

Chlorophyll degradation may also be considerable during algal senescence and appears to result from loss of Mg^{2+} from the heme group (Fig. 2) (type I degradation) (32). Algal decomposition (33,34) produces rapid conversion of chlorophyll *a* (with Mg^{2+}) to phaeophytin *a* (without Mg^{2+}), but cell lysis or viral attack alone are insufficient to convert chlorophyll *a* to phaeophorbide *a*. On the other hand, the mechanism converting chlorophyll and phaeopigments into colorless compounds in the dark (type II degradation) is poorly known.

Biological Factors

Various biological factors and processes cause pigments to degrade before or during their deposition (Fig. 1). Among these are grazing by herbivores, and microbial degradation mediated by temperature associated with cell senescence (1–4,13,24,25,27,35–42).

Daley (33) and Daley & Brown (34) fed live cyanobacteria to *Daphnia* and observed that, at the same time as chlorophyll *a* was converted to phaeophytin and phaeophorbide, there was a 70% loss of total phorbins in 145 hours. Carotenoid degradation also occurs mainly during passage of pigments through the guts of herbivores. However, comparing the degradative ability of freshwater cladocerans and rotifers, Carpenter & Bergquist (43) suggested that grazing causes substantial but nonselective pigment degradation, and that the pigment content per unit of organic matter might increase after passing through the gut of herbivores. Leavitt and coworkers (44) considered grazing by large zooplankton the most important factor that determines the increase in the conservation of pigments and their derivatives in lake sediments.

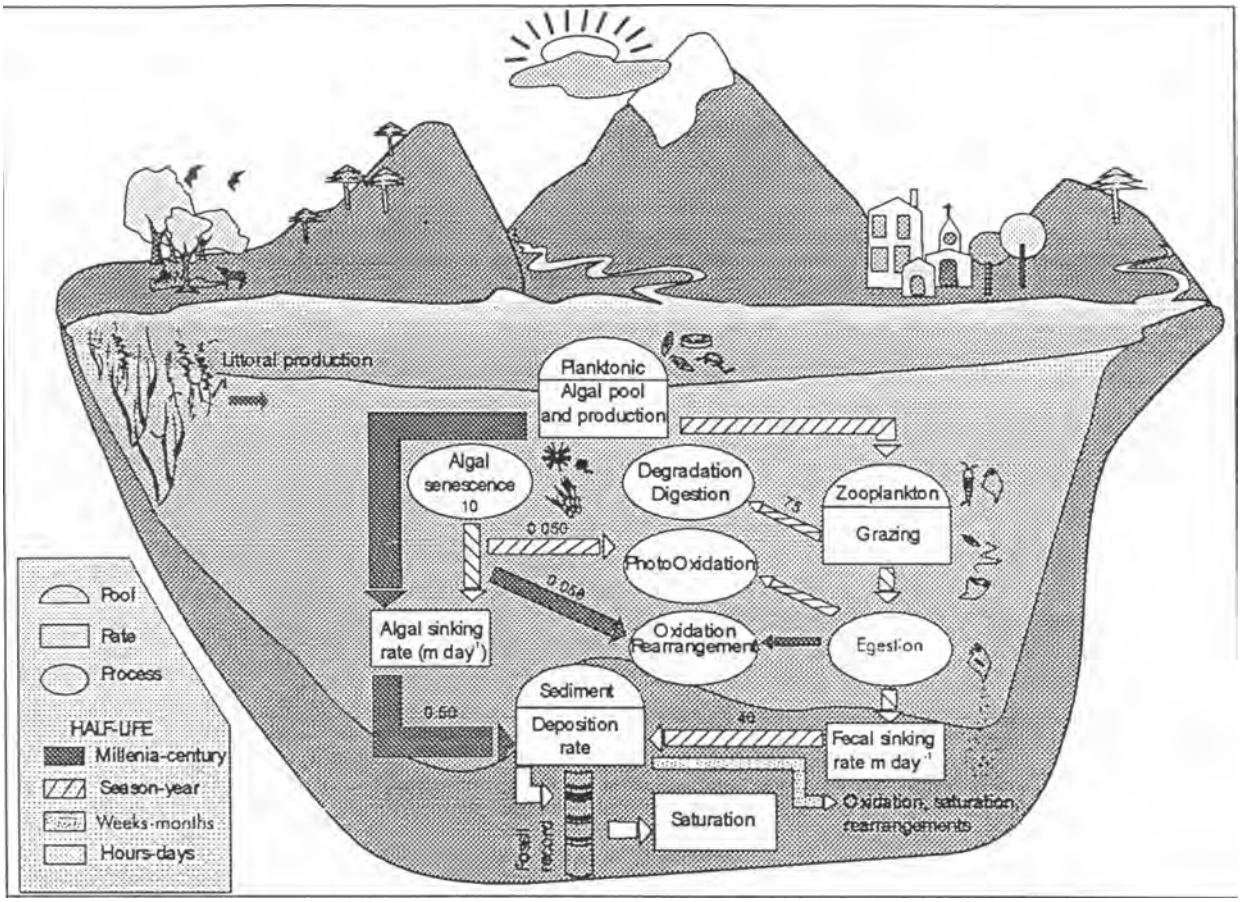

Figure 1. Major fluxes of autochthonous plant pigments in lakes. Sources of pigments: planktonic and benthic production, littoral macrophytes, allochthonous, and sediment resuspension. Model of individual algal cells (summerlike conditions) as they descended through a one-dimensional water column, underwent various loss process, and ultimately were deposited in the sediments. Hypothetical unproductive lake with the following simplified physical parameters: lake depth = 25 m; oxic zone depth = 20; light extinction coefficient = 0.30. Arrow width indicates importance of process (redrawn from P. R. Leavitt, *J. Paleolimnol.* **19**, 109–127 (1993), by permission). Approximate mean values are from K. Cuddington and P. R. Leavitt, *Can. J. Fish. Aquat. Sci.* **56**, 1,964–1,977 (1999). *Note*: Rate coefficients of algal recruitment and senescence are equal (10% day^{-1}). Initial algal abundance, 750 cells. Rate constants are characteristic of the carotenoid β-carotene: photoxidation in $E^{-1} \cdot day^{-1}$ (1 Einstein = 1 mol photons); oxidation in day^{-1}; herbivore grazing in % day^{-1}; pigment digestion (grazing degradation) in % $ingestion^{-1}$; algal sinking and fecal sinking in $m \cdot day^{-1}$. Percentage values implemented as probabilities.

To summarize degradation by herbivores: in general, there can be two concomitant, although different, situations that are not necessarily separable from each other. In one, consumption of algae by microherbivores causes severe pigment degradation (up to and exceeding 80% of initial content (33,34)); in the other, consumption of algal cells by large zooplankton (e.g., *Daphnia*) results in the pigments not undergoing the most effective photochemical degradation as they move through the water column. In the second case, the pigment is in fact excreted by the animal as fecal particles and rapidly sedimented without undergoing any great change (6,24).

Individual Pigment Stability

Chlorophyll *a* degradation is usually greater than that of carotenoids, and may change according to the structure of the food web of the water body (22–24,40,42). Undegraded chlorophylls are generally abundant only when algal remains are rapidly buried in an anoxic, cold environment. In some cases, it is a sensitive indicator of deep-water algal populations (45).

Each algal group has specific pigments with individual characteristics affecting the degree of conservation and degradation in the water column and sediments. Thus, because of selective degradation limits, pigments in sediments can be useful indicators of relative algal abundance (45).

Degradation rate constants of carotenoids, in particular, differ enormously; the ubiquitous β-carotene and phaeophytin *a*, and lutein, are the most stable carotenoids and thus recommended as sedimentary indicators of total algal abundance, whereas peridinin and fucoxanthin are among the most labile (20,24–26,46–48). β-Carotene and

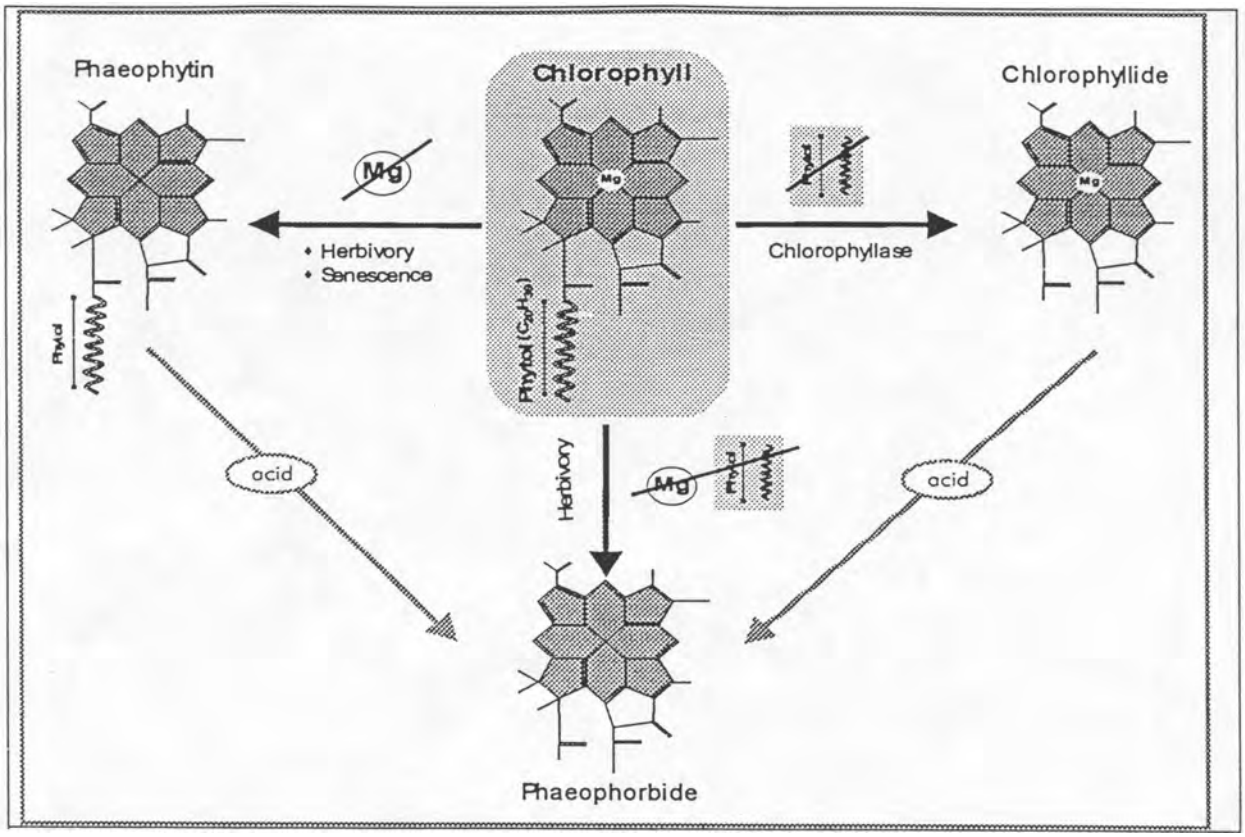

Figure 2. Processes of formation of chlorophyll derivatives (type I reactions). Chlorophyll *c* does not have a phytol chain. Allomers are formed from their respective chlorophylls in the presence of oxygen (from P. R. Leavitt, *J. Paleolimnol.* **19**, 109–127 (1993), by permission).

echinenone degrade less (about half) in anaerobic and aphotic conditions (69) than other pigments and organic compounds in cyanobacteria.

The specific pigments of the dinoflagellates (e.g., peridinin) are rarely conserved in sediments (20,24,25,44,46–48). Likewise, pigments of diatoms and chrysophytes (fucoxanthin and *c*-phorbin) are generally more labile than those from green algae (lutein and *b*-phorbin), Cyanobacteria (zeaxanthin and *α*-phorbin), and cryptophytes (alloxanthin, *β*-carotene and *α*-phorbin) (20,25,68). Lutein-zeaxanthin generally replaces fucoxanthin as the dominant carotenoids in saline lake sediments (50).

Algal Production and Its Relationship with the Sedimentary Pigments: The Importance of Temporal Scale in the Degradation Processes

Despite the various problems associated with conservation of photosynthetic compounds, sedimentary pigments and algal abundance, as well as production remain correlated through time, provided there is no change in basin size and depth, light penetration, thermal and chemical stratification, and deep-water oxygen content (4). Production/trophic state (at the broadest scale), morphometric features (at a narrow range of algal abundance) and foodweb effects (at the finest scale) are the three main hierarchical factors affecting algal production and deposition.

In agreement with Leavitt (4), the general consensus is that the observed relationship between algal biomass and subfossil concentration is site-specific and that the deposition process is regulated by the aforementioned hierarchy of control operating at three temporal phases:

1. rapid degradation in the water column (half-life, $T_{1/2}$ = days)
2. small postdepositional losses in surface sediments ($T_{1/2}$ = years)
3. very slow loss of double bonds in deep sediments ($T_{1/2}$ = centuries)

The fastest reduction in concentration therefore happens when cells die and sink to the sediment (point 1) when, under certain conditions, 99% of chlorophylls and carotenoids may be degraded (48,51). During the process of algal deposition, the principal degradation processes are photooxidation, digestion by herbivorous zooplankton, enzymatic catalysis during senescence, and oxidation either chemical or mediated by microorganisms (Fig. 1).

At the end of this stage, the matter deposited at the water–sediment interface (point 2) continue degrading at a slightly slower rate, which in turn depends on the quantity and type of pigments sedimented (20,46).

Thereafter, much slower degradation processes act at a century-millenium scale (point 3) (52,53). Swain (2) suggested that the long-term conservation of total

carotenoids was similar to that of chlorophylls. Variations in the relationship between these pigment groups thus reflect stratigraphic variation of a series of physical-chemical factors as well as phytoplankton community composition, presuming that there are no significant postdepositional changes.

The fact that individual pigments degrade at different rates according to steps in the settling process (water column, surface sediments, deep sediments) is very important and should always be kept in mind if pigment quantity is to be related to algal biomass. Studies on English lakes (54,55) highlighted the close correlation existing between chlorophyll derivatives and epiphasic carotenoids (carotenes) on the one hand and algal abundance on the other, and proposed an index of lake productivity. Züllig (56) demonstrated a strong correlation between myxoxanthophyll and lake primary production, and reconstructed the recent history of several Swiss lakes, using pigments isolated with a chromatographic technique that he developed. Later, others found a link between oscillaxanthin (the pigment of *Oscillatoria* spp.) and the trophic level of American and English lakes (57,58).

Subsequent studies in the 1970s and 1980s confirmed strong correlations between phytoplankton abundance and fossil pigments in many environments (38,59–67). Such relationships are especially strong for sediments below the first 5 cm of the sediment–water interface, which are not subject to continual processes of diagenesis. Excellent linear correlations between sedimentary carotenoids and algal biomass ($r = 0.90$) were developed for English lakes. Correlations between algal groups and sedimentary fossils were also very good. These results led to the conclusion that most organic matter and pigments were autochthonous in origin, and that pigments could be used as indicators of primary production. The existence of such relationships, especially those between concentrations of sedimentary pigments, algal biomass, and primary productivity rate should be strongest when lake morphometry and water chemistry are relatively constant (5).

Studies on lakes with basins differing in productivity also offer proof of the existence of strong correlations between phytoplankton and fossil pigment abundance. For example, in their examination of the surface sediments of Lake Mead (U.S.A.), Adams and Prentki (67) reported strong correlations between algal production and concentrations of total carotenoids and phaeopigments ($r = 0.97$, $r = 1.0$, respectively). Similar results were obtained by Brenner and Bindford (68) for 97 Florida lakes.

In a similar study of 12 Italian subalpine lakes using inter- and intralake comparison, Adams and coworkers (62), and Guilizzoni and coworkers (66,69) also found an excellent mathematical regression ($P < 0.01$) of surfacial lake sedimentary pigment concentration against current and recently derived measures of primary production. Other studies recorded increased pigment concentrations in sediment as a result of nutrient enrichment and thus increased productivity of the ecosystem (8,70,71).

Although these examples suggest that fossil pigment concentration increases as algal standing crop increases, it should be pointed out that pigment concentrations in sediments of oligotrophic lakes could be lower than expected for the following reasons (2): increased degradation before deposition; lower sedimentation rate in anoxic sediments; high dilution due to the input of allochthonous organic matter low in pigments; low-pigment production per unit of organic matter.

Swain (2) maintains that the correct stratigraphic interpretation of fossil pigments in lake sediments depends essentially on two factors that are highly correlated with trophic status: (*1*) degradation of autochthonous pigments and (*2*) dilution due to a load of allochthonous matter low in pigments.

Post-depositional degradation may obscure stratigraphic interpretations of pigments within a particular "degradation zone" (water-sediment interface), especially if events occur that normally favor increased pigment deposition, such as eutrophication and grazing.

Degradation and dilution processes are more evident in lakes with low productivity and a substantial allochthonous input. In addition, these environments usually have greater light intensity and high oxygen concentrations in the hypolimnion, which encourage photooxidative processes. On the contrary, conditions more favorable to pigment conservation are found in eutrophic lakes and particularly in meromictic environments in which the monimolimnion is invariably anoxic, does not mix and does not have bioturbation (13,37).

As for pigments, mineralization of most organic matter occurs during deposition (72–74). Therefore, if the losses of total organic matter are similar to those of carotenoids and chlorophylls, then concentrations of specific pigments could remain relatively unchanged despite considerable degradation of both fractions. In addition, input of low-pigment organic matter from the watershed would dilute the sedimentary pigment pool, whose temporal concentration variations may be determined by:

- significant inputs of allochthonous organic matter conveying low carotenoid concentrations yielding a high chlorophyll/carotenoid ratio (28);
- type of algal and macrophyte community;
- more or less favorable oxygen conditions;
- differential production of chlorophylls and carotenoids by plants (2).

The final important factor in pigment conservation is sedimentation rate of particulate matter present in the water column, because high sedimentation rate favors rapid segregation of pigments from the water-sediment interface, where physical-chemical conditions are highly favorable for decomposition (2,13,60,66,69,75).

Expression of Data

In all the cases in which phytoplankton and fossil pigments are correlated, researchers have used pigment concentrations (weight × unit of organic matter or moles per gram of organic matter) as a measure of their abundance. From the concentration of sedimentary pigments, then, it is possible to make a more precise

estimate of changes that occurred in phytoplankton abundance during the postglacial period, rather than using as a measure sedimentation flux or pigment accumulation (moles m^{-2} $year^{-1}$). In fact, pigment sedimentation rates (fluxes) are less suitable than fossil pigment concentrations in determining annual changes in phytoplankton community composition (4). However, expressing information as fluxes would have the advantage of being immune from errors of interpretation from decreased pigment concentrations caused by dilution effects of organic matter.

Carotenoids from Sulfur Photosynthetic Anaerobic Bacteria

In recent years, there has been growing interest in carotenoids of photosynthetic sulfur bacteria in sediment (8,9,72,76). The families of photosynthetic bacteria most commonly found in lakes are the chromatiaceans (red sulfur bacteria, e.g., *Chromatium okenii*) and chlorobiaceans (green sulfur bacteria, e.g., *Chlorobium* spp.). Because of the different light requirements and oxygen tolerance of these two groups they occupy different layers of the water column, often corresponding to the chemocline of meromictic lakes, with red bacteria vertically distributed immediately above the greens. McIntosh (77) believed that two bacterial carotenoids, okenone (red sulfur bacteria) and isorenieratene (green sulfur bacteria), were a valuable source of information on, for example, light penetration and the presence of sulfides in the water.

In many closed basins, under strictly anaerobic conditions it is quite common that intense populations of *R. sphaeroides* develop, and thus only yellow spheroidene is found in the sediment. The same bacteria produce red spheroidenone only when oxygen is present, even with severe hypoxin. Züllig (72) suggested that if only spheroidene is present and spheroidenone is absent from sediment, it is to be inferred that the lake was meromictic.

It is not safe to assume that decomposition rates among pigments are always similar. Although many stratigraphic studies were done on the relative abundance of pigments (8,71,72,78), this approach has been discouraged because of selective losses of carotenoids (4). On the contrary, the main changes in the historical record of microbial groups can be traced with success using within-core carotenoid analysis.

Indices Used for Evaluating Pigment Degradation

Various indices are used to highlight the conservation state of pigments. One is the ratio of 430 nm: 410 nm (ratio between the spectrophotometric absorbencies of an acetone extract at wavelengths of 430 nm and 410 nm) that represents the degree of conversion of chlorophyll to phaeopigments as a measure of the state of conservation of pigments in the sediment (79–82). Another common index of pigment degradation involves taking the spectrophotometric reading at 665 nm for the sediment sample before and after acidification with 0.2 M hydrochloric acid to yield the percentage of chlorophyll not degraded to phaeopigments (2).

In addition, it has been proposed (2,35,83) that the CD/TC ratio (chlorophyll derivatives/total carotenoids) is an index of decomposition and of trophic state. A low CD/TC ratio indicates optimum conditions for the preservation of these pigments in the sediment because of high carotenoid concentrations (29). Other authors (13,84,85) also believe that this index can be used in delineating the history of the lake as a measure of allochthonous loading of organic matter versus the autochthonous contribution. A high CD/TC ratio would indicate a major allochthonous load of organic matter. Because of contradictory results, probably linked to site-specific characteristics and the influence of physical-chemical, biological, and morphometric factors (4), the validity of this ratio as an index of pigment degradation is questionable.

RECONSTRUCTING LAKE ACIDITY AND TROPHIC STATUS

Acidification Studies

Studies on atmospheric chemical deposition and lake responses have been conducted since the early 1970s and have shown pronounced acidification throughout the world. Consequently, paleolimnological studies were undertaken to develop quantitative temporal reconstructions of lake pH. Most studies relied on subfossil remains of two algal groups to infer pH: diatoms and cysts and scales of chrysophytes. Such histories were then compared with trends in atmospheric deposition of substances derived from combustion of fossil fuels measured as carbonaceous particles. Some years ago, Guilizzoni and coworkers (80) proposed a new proxy record for lake pH reconstruction based on an easily measurable ratio of total plant pigments: the ratio of absorbance at wavelengths (430 nm and 410 nm) in acetone extract of lake sediments. A high significant linear correlation ($P < 0.001$; $r = 0.71$) between pH in 21 Alpine lakes and the 430 nm:410 nm ratio indicated that acidity greatly influenced the pigment ratio. Stratigraphic analysis of a sediment core from an alpine acid-sensitive lake in Italy (Fig. 3) showed a clear decreasing trend coincident with increased atmospheric pollution as inferred by the carbonaceous particle profile. These data were confirmed both by comparison with existing historical data on Italian thermal electricity production and by pH reconstructions based on diatoms and chrysophycean scale assemblages (80,86,87).

Eutrophication and Climate Change Studies

Paleolimnological studies have provided evidence of the long history of algal development and production in many lakes of Europe and North America based on extraction and identification of characteristic pigments from sediment cores. Many spectacular algal blooms were associated with natural conditions and not necessarily a result of human impact (88,89).

Fossil pigment stratigraphies from two crater lakes in central Italy (Albano and Nemi) served as a good example for tracing the postglacial history of phytoplankton development and primary production (Fig. 4). The two lakes displayed marked similar histories, and these were reflected in all biological (pigments, algal cells, invertebrates) and geochemical records (90,91).

Figure 3. Inferred pH from 430 nm:410 nm pigment ratios and Chrysophyte scales in sediment cores of a high-altitude lake in the Italian Central Alps (Lake Paione Superiore). Graphs of number of carbonaceous particles (No. g dry weight^{-1}) and of the Italian thermal electricity production (Million MWatt h^{-1}) are also indicated.

In general, the concentrations of pigments in Lake Nemi were much higher than those from Lake Albano. Some differences were associated with their distinct bathimetry, catchment size, and topography differences. The presence of the photosynthetic sulfur bacterial carotenoids (i.e., okenone and isorenieratene) in early and mid-Holocene (10,000–5,000 yy BP) was significant (Fig. 4). These pigments, however, were also abundant throughout the Holocene, except in the mid-Holocene where high water turbidity and consequently the low light availability very probably limited bacteria development.

Cyanobacterial pigments (a sum of specific algal carotenoids such as echinenone, oscillaxanthin, myxoxanthophyll, and zeaxanthin) mainly characterized the early phase of the Holocene and the recent past. These periods of high concentrations were phases of fairly high lake productivity with a seasonally anoxic water column separated by oligotrophic colder periods as inferred from diatoms cladoceran and chironomid remains (91).

These high levels of pigments and inferred total phosphorus concentrations are similar to those found in very eutrophic lakes today. The balance of evidence from Lake Albano sediments (e.g., presence of varves, high percentages of planktonic communities) points to substantially higher lake levels during these periods. In contrast, lake level was lower in Lake Albano between 3,000-ky BP and 3,500-yr BP, a period during which a human settlement was established on the shores of this lake and nearby lakes.

Cold episodes are defined by an abrupt decrease in pigment concentrations. Signs of marked changes detected in sediment records in the upper part are mostly anthropogenic; the human impact is superimposed on the sudden, general decrease of all biota during a global cold phase around 3,800 to 4,000 yr cal. BP. An oligotrophication phase and oxic sediments are evident from 3,500-yr cal. BP to 4,500-yr cal. BP.

NEW MARKERS AND SUMMARY OF THE PIGMENT PROXY RECORDS

From the aforementioned, it has been shown how environmental factors can control plant pigment deposition and how a strong theoretical background on in-lake processes is extremely important for paleolimnological interpretation. Indeed, fossil pigments from algae and sulfur photosynthetic bacteria are sensitive proxy-records for a number of environmental parameters such as oxygen concentration, variation in water chemistry and water level (Table 2) and are useful for reconstructing variations in community structure (Table 1).

Past studies on fossil pigments have been mainly focused on lake eutrophication and a few on lake acidification, and most of the advances and developments can be readily transferred to studies of past climate changes. In the context of paleoclimate studies, two pigment markers have been recently discovered: one, scytonemin, produced by benthic algae, can be used to infer past changes in UV radiation (92); The second, tetrapyrrole pigments and aromatic hydrocarbons, are diagenetic products of chlorophylls and carotenoids,

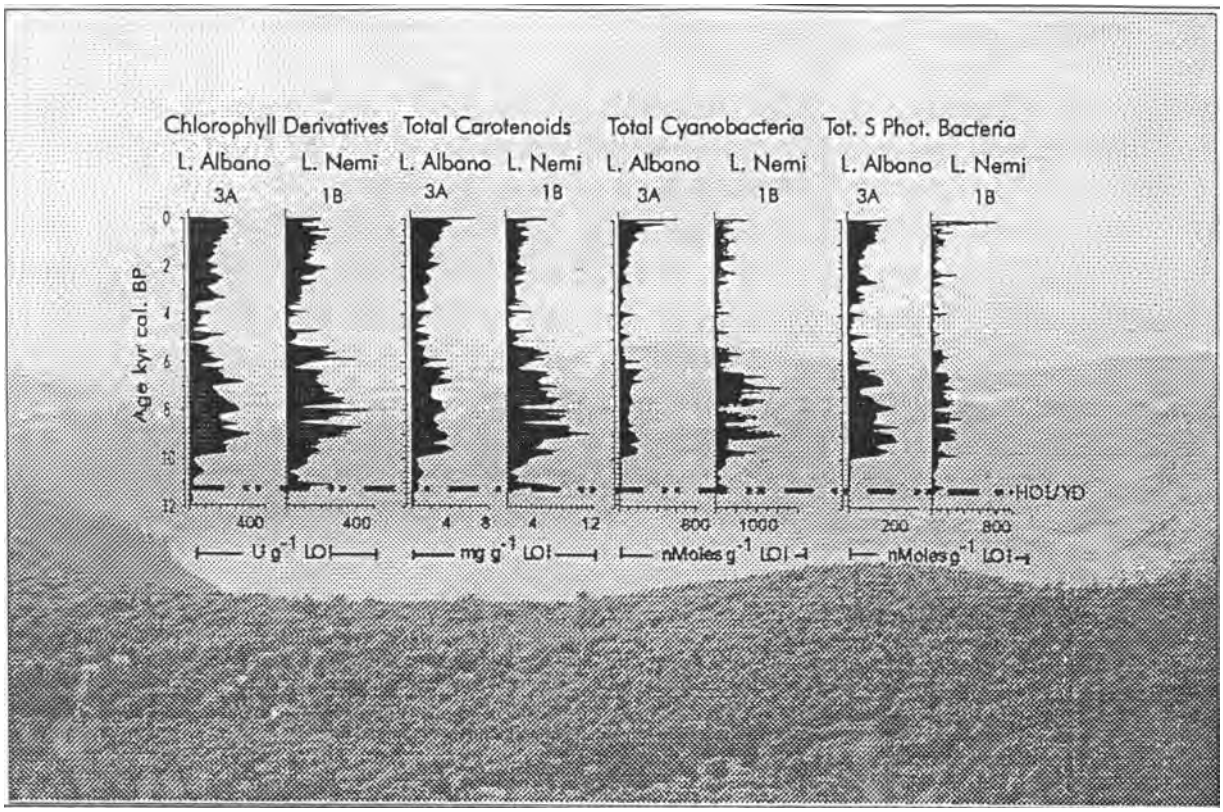

Figure 4. Holocene paleoenvironmental changes from Lakes Albano (*core 3A*) and Lake Nemi (core 1B) sediment cores based on pigments from algae and sulfur photosynthetic bacteria. Total plant photosynthetic pigments (chlorophyll derivatives, total carotenoids) and the group-specific HPLC measured carotenoids (total Cyanobacteria, total carotenoids from anaerobic, sulfur photosynthetic bacteria) are used as valuable indicators of past changes in aquatic productivity and past redox conditions. The evolution of Cyanobacteria populations is inferred from the sum of specific carotenoids (echinenone, oscillaxanthin, myxoxanthophyll, and zeaxanthin). The Holocene/Young Dryas boundary is also indicated.

respectively, may provide valuable information on oceanic circulation and climate (93).

Scytonemin is a pigment produced in the sheaths of certain cyanobacteria when they are exposed to high UV radiation; and two unique pigments (compound A and B) derived from the scytonemin are normally found in lake sediments. Leavitt and coworkers (92), in a study on midlatitude alpine lakes in Canada, found that past UV radiation was greater than that during the present period of anthropogenic ozone depletion of the stratosphere.

Rossel-Melé and coworkers (93), from their study on the so-called "Heinrich" events (cold periods probably resulting from freshwater released from massive melting of the Laurentide ice sheet) (94,95), demonstrated that autochthonous chlorine pigments and the chlorophyll and carotenoid derivatives of continental origin were observed only in this Heinrich sediment layers as a result of reduced bottom water oxygen content. The presence of these biomarkers of potential "source rocks," and their association with better preservation in anoxic conditions suggest that large meltwater input reduced or stopped deep-water formation in the North Atlantic.

Analyses of these pigments requires a technique, that is, the gas chromatography-mass spectrometry, often combined with high performance liquid chromatography (HPLC) to provide diagnostic information on their molecular structures. In turn, this can permit inferences to be made on the sedimentary environment and pathway of pigment degradation (96). This new approach will increase the number of biomarker molecules available for paleoenvironmental and paleoclimate reconstructions.

Because pigments laid down in lacustrine sediments reflect environmental conditions in the lake and its catchment at the time of their deposition, their records allow historical changes in lake trophic status, anthropogenic and natural (climate) changes to be determined, adding greatly to our understanding of development of lakes and associated processes. Such an understanding is necessary for a number of purposes including paleoenvironmental and paleoclimate data, which can be used for predictive models, and for enlightened lake management. It should be considered, however, that any interpretation of the early history of lakes based on pigments stratigraphy is enormously facilitated by any comparison with contemporaneous limnological and historical information. When

Table 2. Summary of the Main, Most Stable, and Most Informative Pigments: Sources, and Their Use as Proxy Records in Paleolimnology (see text)

Pigment	Taxa	Source	Proxy Record for:
Fossil pigments	All plants	Planktonic, littoral	Food-web changes, gross taxonomic composition
β-Carotene, Phaeophytins, and total carotenoids	Plantae, some bacteria	Planktonic, littoral, terrestrial (especially phaeophytin a)	Primary production, and total phototroph abundance
β-Carotene: Chl a	All plants	Planktonic, littoral	Deep algal bloom (low ratio)
Phaeophorbides	Chlorophyll derivatives	Planktonic	Grazing by zooplankton
Astaxanthin, astacene	Zooplankton, few algae	Planktonic	Zooplankton abundance
Vanadyl alkyl porphyrins	Diagenetic product of chlorophylls	Terrestrial	Ancient, organic rich sediments; anoxic conditions
Aryl isoprenoid hydrocarbons	Diagenetic product of carotenoids	Terrestrial	Ancient, organic rich sediments, anoxic conditions
Alloxanthin	Cryptophyta	Exclusively planktonic	Water level (?)
Two lipid-soluble pigments similar to Scytonemin	Certain benthic cyanobacteria	Alpine lake	Past aquatic UV radiation environments
Echinenone	Total cyanobacteria	Planktonic, littoral	Phosphate-eutrophication
Myxoxanthophyll, Oscillaxanthin	Filamentous cyanobacteria	Planktonic	Phosphate-eutrophication
Aphanizophyll	N_2-fixer cyanobacteria	Planktonic	Eutrophication
Okenone, Isorenieratene	Chromatiaceae (*Chromatium. okenii*) Chlorobiaceae (purple and green sulfur, photosynthetic bacteria, respectively)	Planktonic	Anoxia conditions and historical Secchi Disk transparency
Spheroidene, spheroidenone	*Rhodopseudomonas sphaeroides*	Planktonic	Meromictic/Holomictic conditions
430 nm: 410 nm index[1]	All algae	Planktonic, littoral, terrestrial	Acidification, pigment preservation
Chl a: Phaeophytin a; Chl a: β-carotene	All algae	Planktonic, littoral, terrestrial	Pigment preservation

[1]Acetone extract ratio of absorbance at two spectrophotometric wavelengths (430 nm and 410 nm).

these long-term data are available, it is possible to calibrate the pigment record as a paleolimnological indicator and thus accurately reconstruct ecosystem changes and food-web processes in lakes.

PALEOLIMNOLOGY: USE OF SILICEOUS STRUCTURES OF CHRYSOPHYTES AS BIOLOGICAL INDICATORS IN FRESHWATER SYSTEMS

PETER A. SIVER
Connecticut College
New London, Connecticut

Chrysophycean algae are a highly diverse assemblage of freshwater and marine organisms containing well over 1,000 described taxa (1). Although there are exclusively marine orders within the Chrysophyceae (2), as well as groups that have been split from the Chrysophyceae (e.g., silicoflagellates), the majority of the taxa are freshwater and most are euplanktonic in nature. Chrysophytes contain a vast array of morphological types, including unicellular, colonial, filamentous, and palmelloid forms, as well as both mixotrophic and strict photoautotrophic taxa. Even though chrysophytes are more common and can often form large concentrations in ponds and lakes, they can also form substantial populations in streams and rivers (3). As a group, chrysophytes often dominate the spring plankton flora in temperate waterbodies; however, individual species display a vast array of seasonal strategies (4). Chrysophytes can be found in waterbodies from the tropics to the arctic as well as across a wide trophic gradient, although they tend to decline in biomass in the most eutrophic habitats (5). They can form blooms, deep-water (metalimnetic) peaks (6), and are often responsible for taste and odor problems (7). Despite the wide diversity of morphological types and habitats supporting chrysophytes, it is a fact that at the species level many taxa are restricted along an array of environmental gradients (e.g., pH, dissolved salt, and trophic gradients) that make them especially useful as bioindicator organisms (4,8).

As reviewed by Preisig (2), the classification of chrysophycean algae is in a state of flux. Starmach (1) identified three subclasses within the class Chrysophyceae based largely on the number of flagella (none, one, or two) found on cells. Starmach's (1) system of classification was very similar to, and followed closely, that of Bourrelly (9,10). However, as reviewed by Preisig (2), many "uniflagellate" forms are now known to possess a second flagellum, and some species previously thought to be aflagellate can indeed produce flagella. Thus, Starmach's (1) classification scheme has given way to more modern concepts that include a wealth of new ultrastructural, biochemical, and molecular data. Several groups of organisms, including the Synurophyceae, silicoflagellates and pedinellids, have been moved from the Chrysophyceae as circumscribed by Starmach (1) and placed into new classes (11).

A group of chrysophycean organisms possess a covering of siliceous plates, called *scales*, and have historically been referred to as "scaled chrysophytes." Scaled chrysophytes were contained within the family Mallomonadaceae Diesing (10,12) or the family Synuraceae (1) within the class Chrysophyceae. In a classic study, Hibberd (12) recognized that ultrastructural features among some of the scaled chrysophyte genera differed substantially from others, and later Preisig and Hibberd (13,14) formed a new family, the Paraphysomonadaceae, to accommodate scaled chrysophytes with a cell ultrastructure similar to that of *Ochromonas* and *Chromulina*. Andersen (15) then moved the genera not in the Paraphysomonadaceae out of the class Chrysophyceae and placed them in a new class, the Synurophyceae. Thus, today scaled chrysophytes refers to taxa in two different algal classes.

The bulk of the use of chrysophycean algae as indicator organisms has been paleolimnological in nature and is based on siliceous remains of the organisms. Three distinctly different types of siliceous structures, cysts, scales, and bristles, are formed by the organisms and upon death ultimately become part of the sediment record. Because these siliceous structures are species specific they can be used effectively to reconstruct past floras. Cyst and scale remains have been incorporated most widely in paleolimnological studies. Cysts are globose resting stage structures (see later) presumably formed by all members of the Chrysophyceae and Synurophyceae. Scales are only produced by taxa in the family Paraphysomonadaceae (e.g., *Chrysosphaerella*, *Spiniferomonas*, and *Paraphysomonas*) and all members of the class Synurophyceae (e.g., *Mallomonas*, *Synura*, and *Chrysodidymus*). Bristles are specialized siliceous structures formed only by members of the genus *Mallomonas*.

The purpose of this article is to (*1*) introduce the reader to the anatomy and morphology of siliceous scales, bristles, and cysts; (*2*) provide an overview of the distribution of chrysophytes along environmental gradients; and (*3*) discuss how the group has been used in paleolimnological studies.

ANATOMY OF THE SILICEOUS CELL COVERING

All scaled chrysophytes possess a cell covering composed of siliceous plates referred to as scales (Figs. 1 and 2). The scales are sculptured with very specific designs and serve as the primary means of identifying taxa at the species and subspecific levels. Scales of taxa in the family Paraphysomonadaceae, class Chrysophyceae, are more or less radially symmetrical (Figs. 1d and 2d) and are overlapped on the cell membrane in a somewhat unorganized manner. With a few exceptions

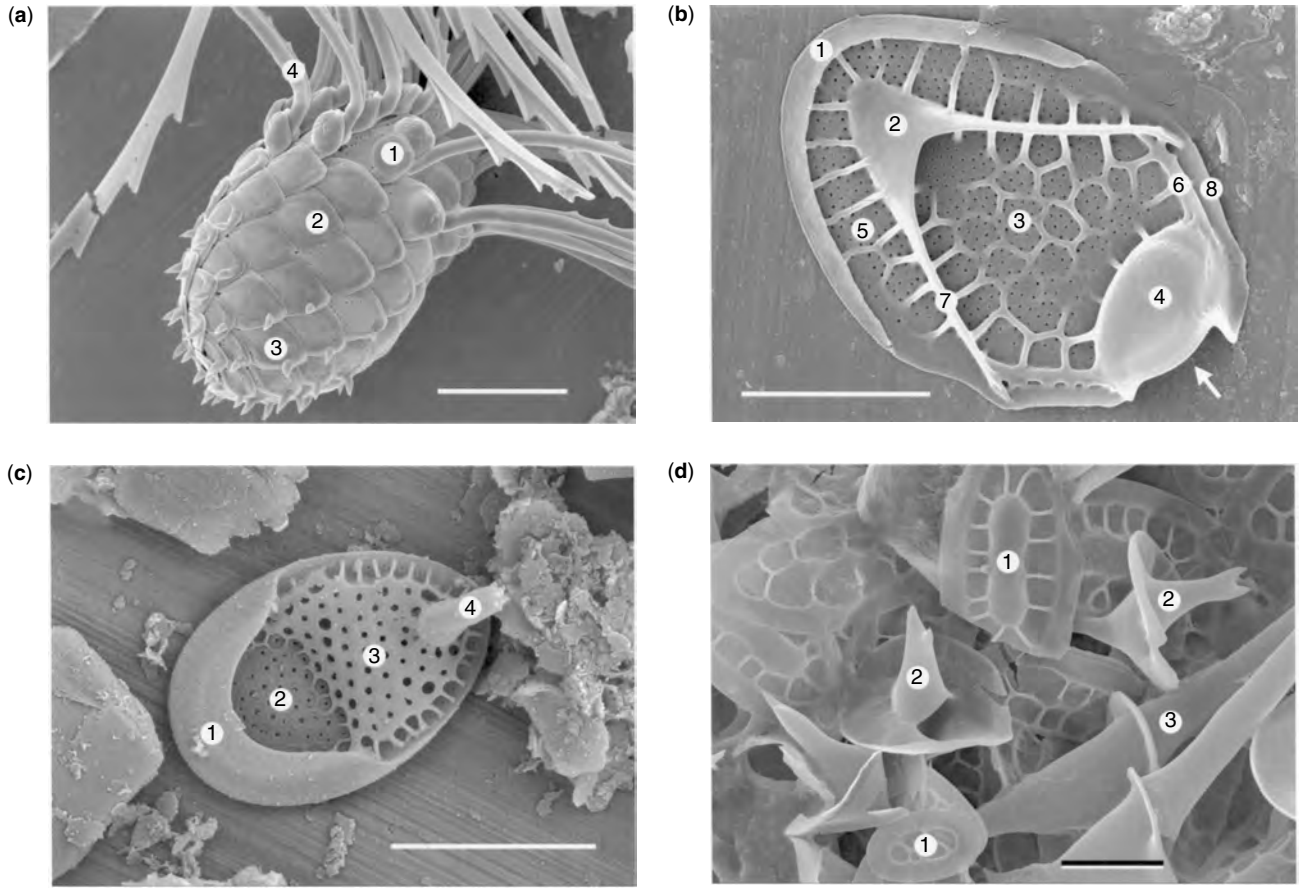

Figure 1. Cell and scale remains from scaled chrysophyte algae. (**a**) Whole cell of *Mallomonas tonsurata*. Note the arrangement of (1) domed, (2) domeless, (3) spined posterior scales, and (4) bristles. Scale bar = 5 μm. (**b**) A single domed scale of *Mallomonas crassisquama* denoting the (1) posterior rim, (2) base of the V-rib, (3) shield, (4) dome, (5) posterior flange, (6) anterior submarginal rib, (7) V-rib arm, and (8) anterior flange. Scale bar = 2 μm. (**c**) A spined scale of *Synura spinosa* denoting (1) posterior rim, (2) area of the scale lacking a secondary layer, (3) area of the scale with a secondary covering, and (4) the spine. Scale bar = 2 μm. (**d**) Plate and spine-scales of *Chrysosphaerella longispina*. Note (1) plate scales, (2) short spine scale, and (3) long spine scale. Scale bar = 2 μm.

the scales of synurophytes are bilaterally symmetrical and arranged on the cell surface in a highly organized manner (Fig. 1a) (16,17).

Scales of synurophyte taxa are overlapped in spiral rows. Each row starts with a scale that is part of a ring of scales surrounding the flagellar opening, includes a number of body scales, and ends with posterior or caudal scales. The shift in scale type along a given spiral row may be gradual or very abrupt (17,18). As a result, although the basic design or pattern of all scales of the same species remains similar, the shape and morphology of the scales can vary significantly. Within a given row scales are orientated with their distal ends pointed toward the anterior of the scale, perpendicular to the longitudinal axis of the cell, or in between these two orientations (16,19). The patterns that the scales are overlapped within a row, as well as the overlapping of neighboring rows, are discussed in detail in Siver and Glew (16) and Siver (17). The most notable exceptions to the patterns of scale design and position on the cell covering are two colonial taxa, *Synura lapponica* and *Tesselaria* (known only in Australia), whose scales are radially symmetrical and positioned in a layer around the colony and not around individual cells (20,21).

Regardless of the position and orientation of the scales on the cell, when the organism dies the cell covering disarticulates and the resultant siliceous pieces become archived in the sediments. Thus, the disarticulated components, primarily the scales, are used in paleolimnological studies (8). Despite the fact that paleolimnologists utilize scale remains, a basic appreciation of the morphology of the whole living cell is necessary to understand the range of scale morphologies possible for each species.

Taxa in the family Paraphysomonadaceae, such as *Chrysosphaerella*, *Spiniferomonas*, and *Paraphysomonas*, possess scales ranging from round or oval platelike to basketlike to ones with long projections known as spines. Most scales of taxa in this family have a relatively unpatterned under surface (the surface in association

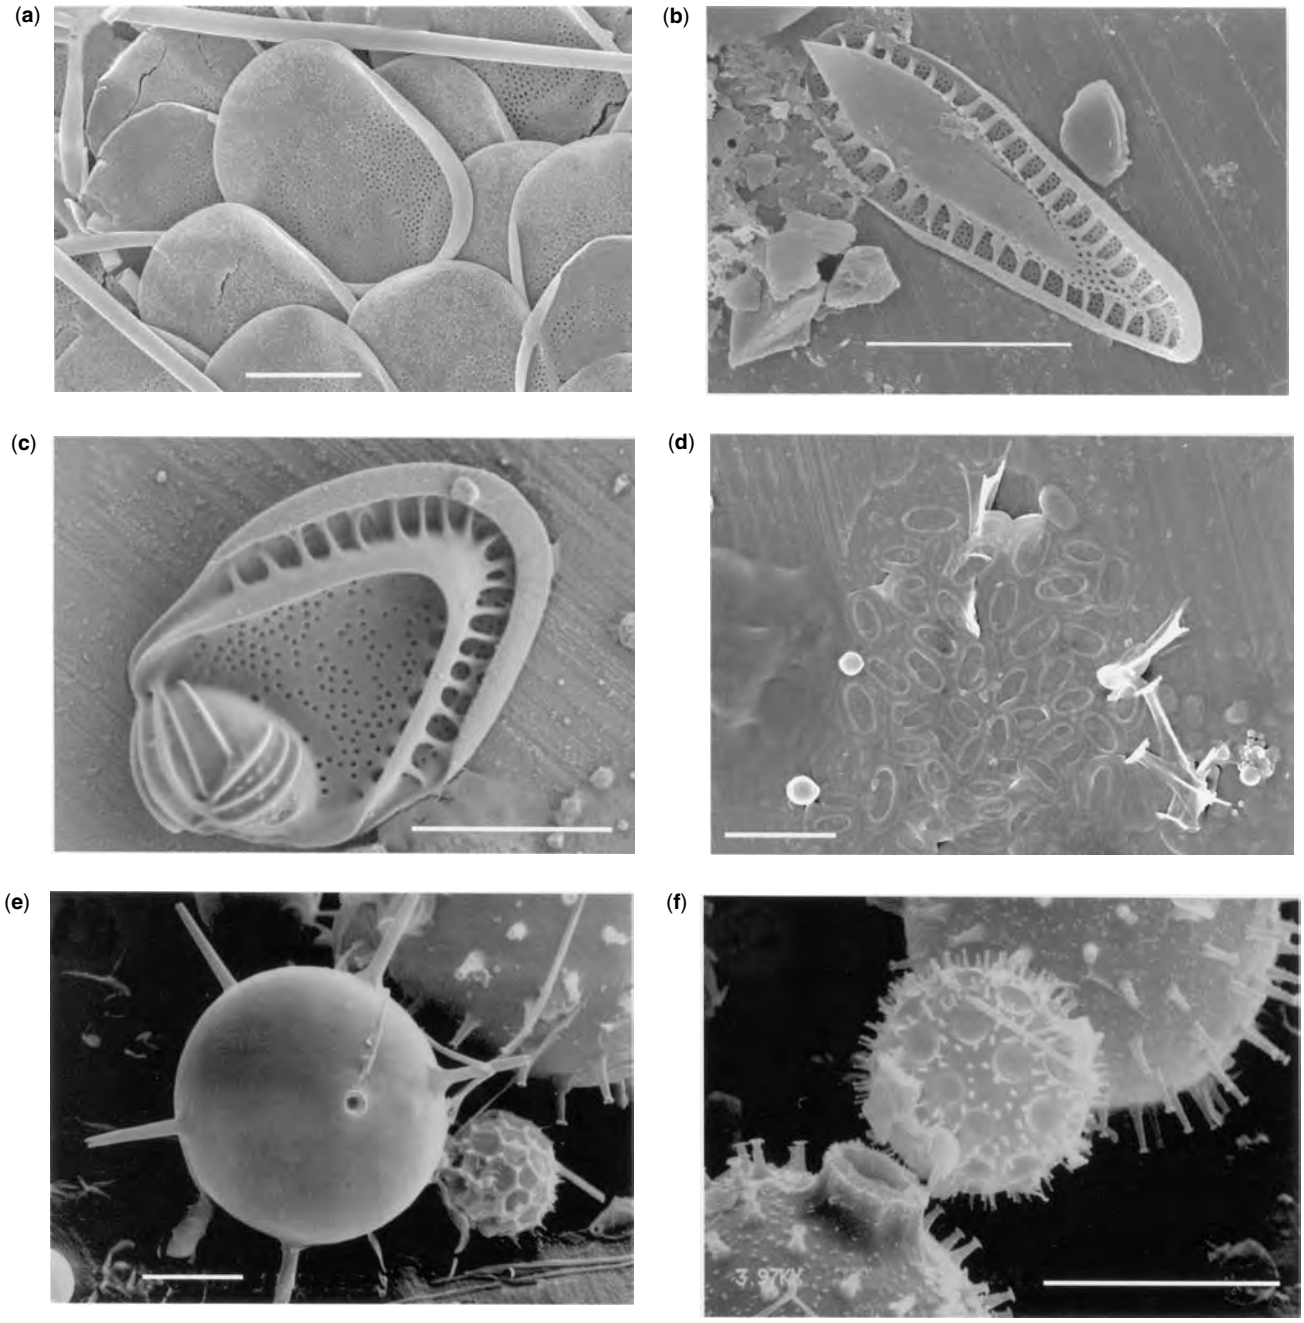

Figure 2. Scale and cyst remains of chrysophycean algae. (**a**) Scales of *Mallomonas caudata*. Note the simple nature of the scales. Scale bar = 2 μm. (**b**) Scale of *Synura petersenii* denoting the keellike spine positioned on top of the scale. Scale bar = 2 μm. (**c**) Domed scale of *Mallomonas acaroides* var. *muskokana*. Scale bar = 2 μm. (**d**) Scale remains of a cell of *Spiniferomonas takahashi*. Note the plate scales with a single lacuna and spine scales with short flared tips. Scale bar = 2 μm. (**e**) Chrysophycean cysts. Note the pore and surrounding collar on the centrally positioned cyst. Scale bar = 5 μm. (**f**) Chrysophycean cysts with surface ornamentation consisting of papillae, dimples, and spines. Scale bar = 5 μm.

with the cell membrane) and a slightly more patterned and sculptured exterior surface (13,22–24). Regardless, except for some species of *Paraphysomonas*, scales of taxa in the Paraphysomonadaceae are not as complex as those on taxa of Synurophyceae.

Platelike scales of *Chrysosphaerella* are oval in outline and range mostly from 2 to 4 μm in length (24). The two most important species, *Chrysosphaerella longispina* and *Chrysosphaerella brevispina*, differ in their scale morphology. The exterior surface of scales of *C. longispina* consists of a flat and smooth marginal rim, a raised elliptical-shaped smooth dome, called a *cupola*, and a series of radial ridges that connect the cupola to the marginal rim (Fig. 1d). The exterior design of scales of

C. brevispina is even simpler, consisting of a thickened oval-shaped and raised ring of silica that is positioned about 0.25 μm in from the scale margin. Except for the thickened ring that encircles a central lacuna, the external surface is unpatterned. Spine scales of *Chrysosphaerella* consist of two circular plates connected by a flared shaft (24). A long and hollow spine extends out from the surface of the second plate (Fig. 1d). The range in length of the spine varies between species.

Like *Chrysosphaerella*, scales of *Spiniferomonas* are of two primary types, oval platelike scales and spine scales originating from more circular-shaped plates (Fig. 2d) (22,23). All platelike scales of *Spiniferomonas* have either a single or two large depressions referred to as lacunae (Fig. 2d). With one known exception (25), scales with a single lacuna are larger than those with two lacunae. Other than the lacunae and the possible presence of one, two, or four rods, additional ornamentation is lacking on plate scales. The spined scales of *Spiniferomonas* taxa consist of a shaft that extends from either a flat or cone-shaped base. The shaft of the spine may be ribbed or smooth and the tip flared or tapered in design. Compared to other taxa of scaled chrysophytes most isolated scales of *Spiniferomonas* cannot always be identified to species. *Paraphysomonas* is a strictly heterotrophic genus whose members possess scales that range from being flat and quite simple to ones that are complex and highly three-dimensional in design (13,14). For most species of *Paraphysomonas* electron microscopy is needed for proper identification.

The basic design of synurophyte scales differs from silica-scale–bearing Chrysophyceae in having bilateral symmetry and in being typically more complex. All scales of synurophyte taxa consist of a base plate and an upturned rim (Fig. 2a). The base plate most often is perforated with small pores, and the upturned rim often encircles half of the scale and is referred to as the posterior rim. The end of the scale with the posterior rim is referred to as the proximal end, and the end that is typically aligned toward the flagellar portion of the cell the distal end.

The vast majority of synurophytes have additional siliceous structures, termed *secondary structures*, on the base plate (Figs. 1b, 1c, 2b, and 2c). The secondary layer on scales of *Synura* species usually consists of an additional layer of silica with pores and a series of ribs (26,27). In addition, scales, especially those on the anterior end of the cell, possess spines. For species within the Spinosae group of the genus *Synura*, the spine originates on the distal end of the scale and extends forward away from the base plate (Fig. 1c). For taxa within the section Peterseniae, the spine, also known as a keel or thorn, is positioned further back on the scale (Fig. 2b). In general, spines become reduced or are lacking on scales positioned on the posterior portion of the cell.

The most complicated types of scales are found in the genus *Mallomonas*, the largest genus within the scaled chrysophytes. Some species have highly ornate scales with specialized structures known as V-ribs, submarginal ribs, domes, and spines (17). A V-rib is a V-shaped to U-shaped ridge situated on the surface of the scale such that the base of the V or U lies near the posterior rim (Figs. 1b and 2c). The sides or arms of the V-rib extend toward the distal end of the scale and terminate at different areas of the scale, depending on the species. Many species have additional siliceous ridges known as anterior submarginal ribs (Fig. 1b). The anterior submarginal ribs are typically aligned parallel to the distal margins of the scale and extend from the ends of the V-rib arms to the distal end of the scale. A dome is a raised region of the distal end of the base plate that forms a cavity (Figs. 1b and 2c) from which one or more bristles emerge (see later). In some species domes are smooth and unornamented, whereas in others they are highly ornate. The overall structure of the dome is of taxonomic importance. Spines are siliceous structures that extend from the distal end of the scale. In species of *Mallomonas*, scales with spines, known as spined scales, are found exclusively on the posterior of the cell and are positioned such that the spines radiate out from the back of the cell.

The V-rib and anterior submarginal ribs, often referred to collectively as the submarginal rib, divide the scale into areas called the *shield* and *flanges*. The shield is that area of the scale bound by the submarginal rib, whereas the flanges are regions of the scale outside of the submarginal rib (Fig. 1b). The posterior flange is the portion of the scale situated between the posterior rim and the V-rib. The anterior flange is the region between the anterior submarginal ribs and the margin of the scale. The ornamentation of the flanges and shield may be very similar in nature or quite distinct from each other.

Bristles are elongated siliceous structures that are distinctly separate from scales and unique to the genus *Mallomonas* (Fig. 1a). Bristles are divided into a foot (proximal end) and a shaft (17). The foot of the bristle is tucked under the distal end of the scale within the cavity of the dome and the shaft radiates out from the cell. Because bristles are not physically fused with scales, their orientation changes with the swimming motion of the cell. Species often have two distinctly different types of bristles that are typically positioned on different parts of the cell. A wide degree of variation in the structure of the shaft and distal tip of the bristle is found between species. As with scale structure, because bristle morphology is distinct at the species level it is also of taxonomic significance. A wide degree of variation in the structure of the shaft and distal tip of the bristle is found between species.

CYST STRUCTURE AND MORPHOLOGY

All chrysophytes and synurophytes are capable of forming a siliceous resting stage known as a cyst, stomatocyst, or a statospore. Cysts are formed endogenously within a specialized vesicle called a *silica deposition vesicle* (SDV) as a result of either sexual or asexual reproduction (28). The formation of the cyst is a continuous process that, in most species, is believed to occur in two steps (29). The first step involves the formation of a primary or inner wall that usually results in a smooth unornamented structure that is presumably similar for many species (30). The second step results in the deposition of additional siliceous layers on the outside of the primary wall, including wall ornamentation, and eventually yields a mature cyst. The

mature cyst is often quite different and distinct from their immature counterparts (reviewed in 30).

Duff and coworkers (30) provided an excellent summary of cyst terminology and structure. A brief overview is provided here. Cysts are hollow, globose structures with a small opening referred to as the pore from which the protoplast will eventually emerge (Fig. 2e and 2f). The majority of cyst types range in diameter from 2 μm to just over 30 μm and come in a variety of shapes, including spherical, oval, pyramidal, and compressed or flattened (5,30). The outer surface of the cyst wall can range from being smooth (Fig. 2e) to highly ornamented with spines, papillae, nodules, and ridges (e.g., Fig. 2f). The pore is usually circular in shape and often surrounded by a siliceous ridge called a *collar*. Collars can be very simple or highly complex structures consisting of multiple concentric ridges surrounding the pore opening.

The shape, size, and ornamentation of the outer wall and collar form the basis for separating cysts into different morphotypes. Because each species is believed to produce a single type of fully mature cyst, shifts in the composition of cysts are believed to reflect species-level changes, making them especially attractive as paleolimnological indicators. The taxonomic identities are known for a relatively small percentage of the large number of cyst morphotypes that have been described (30). It is also inevitable that some cyst types are simply immature stages of more fully developed types, or perhaps represent different ends of the full range of cyst types possible for a given species. Despite these drawbacks cysts have been and will continue to be important bioindicators, especially in paleolimnological studies.

DISTRIBUTION OF CHRYSOPHYTES ALONG ENVIRONMENTAL GRADIENTS AND THEIR USE AS PALEOLIMNOLOGICAL INDICATORS

The remains of chrysophyte algae have been utilized successfully to study historical shifts in many different types of lake ecosystems, especially ones from North America and Europe. The increased use of chrysophytes to infer historical conditions over the past two decades is correlated closely with the rise in importance of paleolimnological studies as a tool for understanding environmental changes, especially anthropogenic-related ones (8). The remains of chrysophytes have now been used to examine changes in variables such as pH (31), specific conductivity (32), trophic status (33), salinity (34), and climate-related variables (35).

Many recent paleolimnological studies, including those incorporating chrysophytes, have used multivariate statistical methods to yield models that, in turn, are used to infer quantifiable changes in specific chemical variables. The statistical methods used to develop inference models are well established, and the reader is referred to Birks (36,37) and Birks and coworkers (38) and references therein, for details. Briefly, the following steps are used to develop and use an inference model. First, surface sediments (e.g., from the top 1 cm) are taken from a group of waterbodies in a given region. The suite of lakes, called the *calibration* or *training set*, is selected such that the individual lakes span the environmental gradient of interest. Present-day limnological data, most importantly for the parameter being inferred, is estimated for each lake in the calibration set and used to produce an environmental parameter-lake data matrix. The relative abundances of the inference organisms, in this case chrysophytes, are estimated from the surface sediments for each calibration lake and used to establish a species-lake data matrix. The environmental parameter-lake matrix is regressed on the species-lake matrix to estimate optima and tolerances for each species for the limnological variable of interest (Fig. 3). Once estimates of the species optima and tolerances are made, they can be used to infer the value of the environmental variable in a down core sample; this can be done using, for example, weighted averaging methods (36,37).

In addition to their utility in developing inference models, the species and environmental parameter data matrices can also be used to explore similarities and differences between taxa or sites (lakes), and to determine the relative importance of each limnological variable in controlling the distributions of the organisms in the suite of lakes. The most widely used statistical methods for these analyses include indirect and direct ordination techniques (39). Correspondence analysis (CA) and principal component analysis (PCA) are indirect ordination techniques that effectively arrange both species and sample scores in low-dimensional space along extracted (principal) axes. The axes are extracted such that they maximize the variance in the data, and scores can be correlated subsequently with environmental data (in an indirect manner). CA and PCA are effective methods for estimating the similarity (or dissimilarity) of samples in a quantitative manner on the basis of their floristic characteristics. Canonical correspondence analysis (CCA) and redundancy analysis, the canonical equivalents of CA and PCA, are direct ordination methods where the derived axes are constrained during the analysis to be linear combinations of the environmental variables. The reader is referred to Jongman and coworkers (39) for a discussion on ordination techniques. Ordination methods have been invaluable in our understanding of the distribution of chrysophytes along environmental gradients, including many of the studies referred to subsequently.

Acidic Deposition and Related Studies

Lakewater pH has been shown in many studies to be one of the main factors controlling the distribution of scaled chrysophytes (4,5,8). The importance of pH has been observed in floristic-based studies (22) as well as in ones using multivariate statistical analyses (40–42). In addition, pH has also been shown to be a primary factor responsible for the distribution of chrysophyte cysts (43–45). Most of the studies documenting the importance of pH have been from localities in North America, including Connecticut (40,46,47), the Adirondacks (41,44), Florida (48), Cape Cod (49), Iowa (50), Ontario, Canada, (43,51), and the northeastern United States (42).

Siver and Hamer (40) reported that the species diversity of scaled chrysophytes in Connecticut lakes and ponds was generally highest in slightly acidic waters,

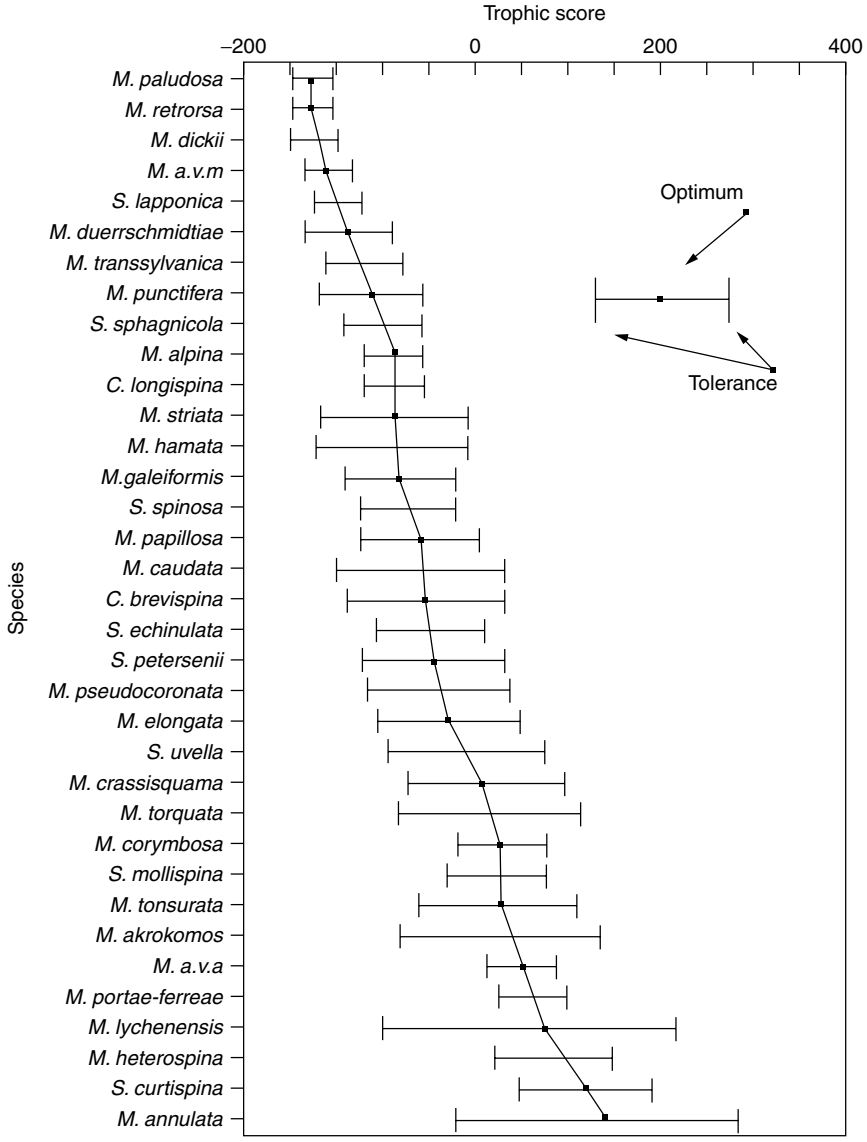

Figure 3. Optima and tolerances of 35 scaled chrysophyte taxa for trophic score. Lower and higher trophic scores are correlated with oligotrophic and eutrophic conditions, respectively. *Source:* P. A. Siver and L. J. Marsicano, *Beih. Nova Hedwigia* **114**, 233–246 (1996).

usually between pH 5.5 and 6.5, and decreased above and below this range. Nielson (52) observed a similar pattern in Danish lakes, and Siver and Smol (53) also reported a similar pattern based on the literature records suggesting that the effect of pH on species diversity was similar in many regions of the world. Although Dixit and coworkers (42) also reported the same general pattern for a large region of the northeastern United States, the maximum diversity was reported to be between pH 7 and 7.5.

Many species of scaled chrysophytes have well-defined distributions along a pH continuum (4,8,17,54) that often are similar in widely separated geographic regions (54). Specific distributions for many taxa are given elsewhere (17,22,41,53,54). It is clear that groups of species are consistently found at specific points along a pH gradient. For example, *Mallomonas canina*, *M. pugio*, *M. paludosa*, *S. sphagnicola*, and *Chrysodidymus synuroideus* are all taxa most often found below pH 6 and that have very low pH optima (4). At the other end of the pH gradient taxa, such as *Mallomonas acaroides* var. *acaroides*, *M. tonsurata*, *M. alpina*, and *M. portae-ferreae*, are more likely to be found. In addition, many cyst types are also differentially distributed along a pH gradient (44,55, and references therein). As a result of the rather narrow distributions of many taxa along the pH continuum, siliceous chrysophytes have been useful indicators of pH and have been instrumental in our understanding of how lake systems have responded to acidic deposition.

Scaled chrysophytes and cysts have been used to examine lake acidification in many regions of the world, especially lakes in the Adirondacks of New York, Connecticut, and the Sudbury, Ontario, region. Smol and coworkers (56) first suggested a strong relationship between scaled chrysophyte remains and pH in the Adirondacks, and quantitative inference work followed by Cumming and coworkers (41). In that work Cumming and coworkers (41) estimated that about 80% of waterbodies with a present-day pH of less than 6.5 had acidified

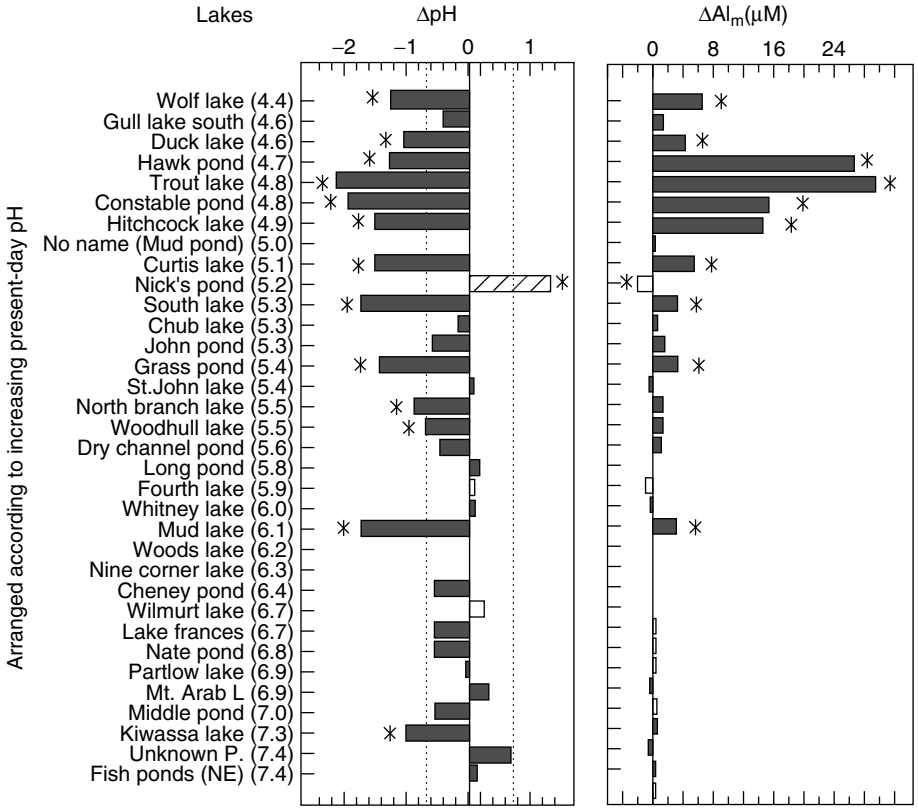

Figure 4. Chrysophyte-based estimates of historical changes (preindustrial to the present) in pH and total monomeric aluminum (Al_m) from 37 Adirondack study lakes. Values are presented as the differences in inferred water chemistry between the top (0 to 1 cm) and bottom (usually >25 cm) intervals of sediment cores. The dotted line represents $\pm RMSE_{boot}$ of prediction for pH. Asteriks denote significant changes. *Source:* B. F. Cumming, J. P. Smol, and H. J. B. Birks, *J. Phycol.* **28**, 162–178 (1992).

since the preindustrial period. Many of the waterbodies that had declined in pH had inferred increases in total monomeric aluminum concentrations (Fig. 4). In a subsequent study, Cumming and coworkers (57) reported that the Adirondack lakes with preindustrial pH values between 5 and 6 acidified first, starting at ca. 1900, whereas those that were slightly better buffered did not commence to acidify until about 1930 to 1950. On an average, the Adirondack lakes declined by 0.96 pH units since preindustrial times and many have not yet significantly begun to recover. Acidification of the Adirondack lakes was confirmed using cyst remains (44).

Using a similar approach Marsicano and Siver (31) began to explore acidification patterns of lakes in Connecticut that were situated in watersheds with thin and poorly buffered soils and on crystalline bedrock. They also reported that, despite the region being impacted by very acidic deposition, none of the lakes included in the study had acidified. In fact, several of the lakes appeared to have actually increased in pH. In a subsequent study of Connecticut lakes, Siver and coworkers (47) reported that none of the 23 lakes in the study had declined in pH, but that 20% had significantly increased in pH over the last century. Siver and coworkers (47) further concluded that despite receiving acidic deposition with pH values near 4.5, the Connecticut lakes were most likely being buffered via sources associated with increased residential development and through enhanced in-lake alkalinity production.

Scaled chrysophytes have also been used effectively to document changes in the pH, as well as other variables, in waterbodies near Sudbury, Ontario (51). Like lakes in the Adirondack region, lakes near Sudbury also dropped in pH by a mean of 0.9 units; however, some lakes had declined over 2 pH units (58). Scaled chrysophytes, along with diatoms, were also used to examine recovery of Sudbury lakes (51). Unlike the Adirondack lakes, Smol and coworkers (58) estimated that 40% of the waterbodies in the Sudbury region have increased in pH as emissions have declined, indicating that some recovery has occurred.

Inferring Dissolved Salt Conditions

Scaled chrysophytes are usually found in greater abundances and at higher species diversities in waterbodies with low specific conductance values (5,40,59), and are essentially absent in more saline lakes (60). Siver and Hamer (40) found that specific conductance was an important variable controlling the distribution of scaled chrysophytes, and further observed that species richness was also related to the dissolved salt content of the water. Both scale (41) and cyst (44) remains in lakes from the Adirondacks (New York) were found to be correlated significantly with specific conductance, and in a study of lakes from the northeastern United States (including the Adirondacks) Dixit and coworkers (42) reported this variable to significantly load onto the first axis of a CCA analysis. Zeeb and Smol (61) successfully used scaled chrysophyte remains to examine the effects of road salt on a waterbody in Michigan.

Siver (32) developed a scaled chrysophyte-based inference model for specific conductance that was subsequently used to trace changes related to deforestation (62) and

residential land use development (47). Siver and coworkers (47) found that 25% of lakes examined in Connecticut had significantly increased in specific conductance, some by more than 100%, over the last century, and that these waterbodies were primarily situated in watersheds that had become highly residential in nature.

Trophic Gradient Studies

Even though relatively high numbers of species can be found in eutrophic habitats (17,40,63–65), scaled chrysophytes have historically been shown to account for a larger percentage of the total phytoplankton biomass in oligotrophic and early mesotrophic lakes as opposed to more eutrophic waterbodies (4,5,7,66). As reviewed by Siver (4,5) chrysophytes have been reported as a dominant component of phytoplankton communities in oligotrophic lakes from many regions of the world, and Sandgren (59) reported that it was not uncommon for this algal group to account for between 10 and 75% of the biomass in these lake systems. The contribution of chrysophytes declined generally to less than 5%, with increased trophic status (59), and typically scaled chrysophyte taxa were less important in highly eutrophic habitats (17,63).

Despite their decreased importance in total biomass at more eutrophic conditions, nutrient-rich habitats can contain high numbers of species (67–69). For example, between 23 and 40 taxa have been reported from nutrient-enriched waters in China (70), Denmark (71), and Germany (64,72). Siver and Hamer (40) found no difference in species richness (number of species) in collections made over a total phosphorus gradient ranging from ca. 4 to 60 $\mu g\,L^{-1}$, supporting the hypothesis that large numbers of scaled chrysophytes can be found in oligotrophic as well as eutrophic sites (5). Dixit and coworkers (42) also reported little difference in species richness of scaled chrysophytes relative to nutrient gradients.

In addition to differences in biomass of scaled chrysophytes along a trophic gradient, there are also clear differences in how individual species are distributed along a trophic gradient (17,33). For example, in a study of waterbodies in Connecticut, Siver and Marsicano (33) reported *M. paludosa*, *M. retrorsa*, *M. dickii*, *M. acaroides* var. *muskokana*, and *Synura lapponica* as being almost exclusively found in very oligotrophic habitats, whereas other taxa such as *M. heterospina*, *M. portae-ferreae*, *M. acaroides* var. *acaroides*, and *Synura curtispina* were encountered in mostly eutrophic localities. Other taxa, such as *M. tonsurata* and *M. corymbosa*, may be found under slightly less eutrophic conditions, but hardly ever in oligotrophic lakes, whereas still other species, such as *M. elongata*, *M. pseudocoronata*, and *S. uvella* are more often observed in slightly eutrophic sites, but can also be found in oligotrophic habitats (17). Other studies by, for example, Siver and Vigna (73), Saha and Wujek (74), Santos and Leedale (75), and Gutowski (64,65) confirmed the fact that species are differentially distributed along trophic gradients. In addition, a number of studies (55,76) have reported that many chrysophyte cyst types are also related to trophic gradients. Because many species and cyst types are differentially distributed along trophic gradients they can be used to infer changes in trophic conditions.

Although qualitative in nature, the use of species-level changes to detect changes in lake eutrophication was initially reported by Munch (77), Battarbee and coworkers (78), and Smol (79). Munch (77,80) observed significant changes in scaled chrysophytes in Hall Lake, Washington, before and after the arrival of European settlement, and attributed the shifts to increased nutrient levels. Likewise, Battarbee and coworkers (78) noted distinct differences in the species diversity as related to different nutrient conditions in laminated sediments from a lake in Finland. Smol (79) also reported on the sensitivity of the scaled chrysophyte flora as a result of eutrophication of three lakes from Algonquin Park, Canada. In subsequent studies Haworth (81,82), Smol and Boucherle (83), Gutowski (65), and Zeeb and coworkers (76,84) related changes in chrysophytes to changes in trophic status. The use of scaled chrysophytes as bioindicators of trophic status is further discussed by Kristiansen (63).

Smol (85) proposed the use of the ratio of the number of cysts to the number of diatom frustules as an indicator of trophic status. The hypothesis was that the ratio of cysts to frustules would be high under oligotrophic conditions and decline as the water became more eutrophic. Although this ratio was later used to examine historical changes in the Great Lakes (86) and lakes in Yellowstone National Park (87), lumping all cyst types into a single group underutilizes their full potential use as bioindicators (8).

Because of the differential distribution of scaled chrysophyte species along a trophic gradient, Siver and Marsicano (33) were able to construct a paleolimnological model based on scaled chrysophytes to infer trophic condition of lakes in Connecticut. They reported a wide variability in the distribution of species along a trophic gradient (Fig. 3) and the resultant inference model, based on weighted averaging with tolerance downweighting, yielded an $r^2 = 0.74$ (Fig. 5). The model was subsequently used to evaluate changes in trophic status relative to alterations in land use over the last century and to make lake management recommendations (47). In a similar fashion, chrysophyte cysts have been used to quantify changes in the trophic status of lakes (55,76,84).

Studies Relating to Climate Change

Although chrysophytes have not been utilized as extensively as other indicator groups in paleoclimate work, the studies that have been undertaken indicate that they will certainly aid in our understanding of climate change (88). The value of the chrysophytes in understanding long-term climate change will most likely be related to the responses of species to temperature and dissolved salt concentrations (see earlier). Studies have related changes in species composition directly to lake water temperature (89), summer surface water temperature (90), and mean annual air temperature (35). Thus, as the temperature regime in a region shifts causing changes in lake water temperature and stratification characteristics, chrysophyte species composition would also be expected to change. As noted earlier, the composition of chrysophytes changes along a

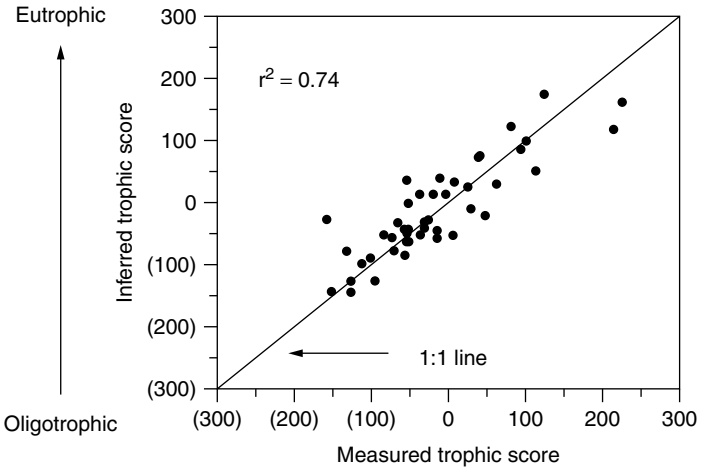

Figure 5. Relationship between the measured trophic score of 45 lakes in Connecticut, and values inferred from scaled chrysophytes. Lower and higher trophic scores are correlated with oligotrophic and eutrophic conditions, respectively. A 1 : 1 line is denoted. *Source:* P. A. Siver and L. J. Marsicano, *Beih. Nova Hedwigia* **114**, 233–246 (1996).

dissolved salt gradient (32). Thus, the hypothesis is as the ratio of precipitation to evaporation shifts in response to climate change the concentrations of dissolved salts in lake basins would also change resulting in shifts in chrysophyte species compositions and abundances.

Both Roijackers and Kessels (91) and Siver and Hamer (40) concluded that, although of lesser importance than other variables such as pH and specific conductance, water temperature was involved in determining how abundant and at what time of year populations of specific taxa would develop. Further work by Gutowski (64) and Siver and Hamer (89) showed that water temperature was an important variable controlling the seasonal succession of species and, as summarized by Siver (4), many taxa are clearly found to develop at different points along a temperature gradient. In addition to the fact that species are differentially distributed along a temperature gradient (17), absolute abundances are also known to be related, in part, to water temperature. In an excellent analysis of the literature, Sandgren (59) observed that the largest biomass of chrysophytes was between 10 and 20 °C, and that concentrations significantly declined at higher temperatures. Other studies collaborate the findings of Sandgren (59) and further indicate that maximal biomass levels of chrysophytes are often reported in temperate regions during spring mixing (5). As a result of these findings shifts in both species composition and total abundance may provide indirect evidence of climate change.

The use of algal remains, including studies based on chrysophytes, in tracking climate changes was recently reviewed by Smol and Cumming (88). Based on a 5-year study of scaled chrysophytes in a small pond in southern New England, Siver and Hamer (89) were able to develop a highly significant inference model for water temperature. Pla (35) was able to use sediment traps to determine differences in the seasonal occurrences of cyst morphotypes in the Pyrenees of Spain. Based on these studies, further development of models that directly infer water temperature may prove valuable in understanding climate change.

Other climate-related studies have incorporated the use chrysophyte cysts over both long and short time periods. For example, as part of a large-scale study of Elk Lake in Minnesota, Zeeb and Smol (92) noted a significant shift in the composition of cyst types at about 8,500 years ago when the region is believed to have shifted to prairie vegetation. Pla (35) reported that the proportion of warmer water cyst types had increased in a lake in the Spanish Pyrenees over the last several decades. Brown and coworkers (90) studied changes in the cyst morphotypes in lake basins that spanned treeline latitudes. Cumming and coworkers (34) and Zeeb and Smol (60) both discussed the use of cysts in inferring dissolved salt concentrations, especially as a potential indirect means of examining climate change (88). Based on these initial studies, chrysophycean algal remains will be useful in climate change studies.

CONCLUSION

Chrysophycean algae are a diverse group of organisms that exist in many different aquatic habitats. Three different types of siliceous structures, known as scales, cysts, and bristles, can be produced by chrysophyte algae and eventually become part of the sediment record. Because the siliceous structures are largely species specific their remains can be used to reconstruct effectively historical changes in the flora. This fact, coupled with the reality that many taxa are found to be rather restricted along different environmental gradients, make the chrysophytes an effective bioindicator group of organisms, especially from a paleolimnological point of view. Studies utilizing chrysophycean algal remains have been instrumental in understanding how waterbodies have responded to such anthropogenic disturbances as acidic deposition, cultural eutrophication, dissolved salt pollution, and land use changes. Undoubtedly, these organisms will play a role in understanding climate change in the years to come.

PARASITIC PROTOZOA: FATE IN WASTEWATER TREATMENT PLANTS

J. SCHWARTZBROD
M. MAUX
T. CHESNOT
UMR Université–CNRS 7564
Nancy, France

Wastewater issue harbors large quantities of organic and mineral matter and is also loaded with many pathogenic microorganisms. Infected individuals (whether symptomatic or not) and certain water sources, such as those released from slaughterhouses, are major sources of microorganisms (viruses, bacteria, and parasites) with pathogenic potential for humans and animals. Parasites are found in the environment in their resistant forms: eggs for helminths and cysts or spores for protozoa.

WASTEWATER TREATMENT

Wastewater treatment leads to the production of treated wastewater and sludge (biosolids) resulting from the separation of the solid matter from the aqueous phase (Fig. 1).

The treated wastewater is generally released into surface waters, into soils, or directly into the sea. Whatever the final destination, this effluent must meet health standards because surface water is increasingly used as a source of potable water. Similarly, contaminated effluents released into the sea may have an impact on the health of swimmers and may affect the sanitary quality of seafood and fish. Finally, the search for improved water resource management has led to the reuse of treated wastewater for irrigation (irrigation of crops destined for human consumption or recreational areas). To avoid transferring pollution from wastewater to agricultural crops or recreational areas, wastewater effluents must comply with health standards.

Wastewater treatment involves three steps:

1. Pretreatment operations include screening, settling, and decanting procedures to remove coarse material and heavy (e.g., sand) or light (e.g., oil) matter.

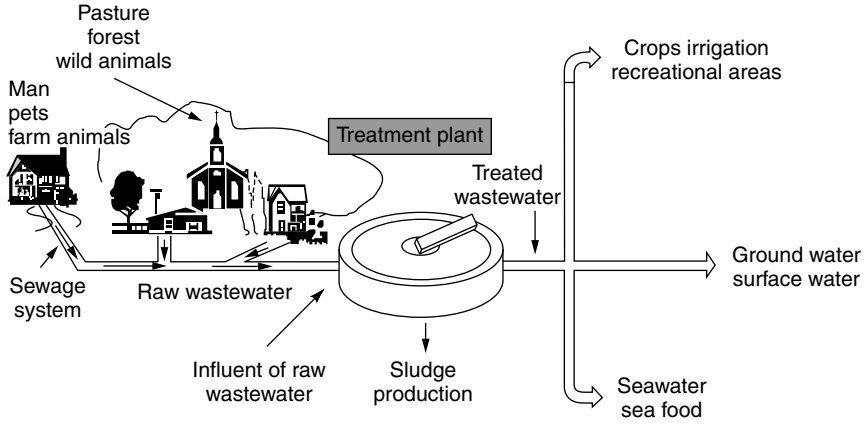

Figure 1. General outline of the wastewater circuit.

Table 1. Overview of Unit Processes and Operations Used in Wastewater Reclamation (1)

Process	Description	Application
	Solid/liquid separation	
Coagulation	Addition of chemicals to destabilize suspended and colloidal matter	Promote particle destabilization to improve flocculation and solids separation
Flocculation	Particle aggregation	Particle agglomeration upstream of liquid/solid separation processes
Sedimentation	Gravity sedimentation of particulate matter, chemical floc, and precipitates from suspension by gravity settling	Settleable solids removal
	Biological treatment	
Aerobic biological treatment	Biological metabolism of waste solids by bacteria in an aeration basin	Removal of organic matter from solution by synthesis into microbial cells
Oxidation pond	Ponds with 2–3 ft of water depth for aerated lagoons and sunlight penetration	Reduction of suspended solids, biochemical oxygen demand (BOD), fecal bacteria, parasites, and ammonia
Disinfection	The inactivation of pathogenic organisms using oxidizing chemicals, ultraviolet light, caustic chemicals, heat, or physical separation processes	Protection of public health coagulation enhancement
	Advanced treatment	
Activated carbon	Process by which contaminants are physically adsorbed onto the carbon surface	Removal of hydrophobic organic compounds
Reverse osmosis	Pressure membrane to separate ions from solution based on reversing osmotic pressure differentials	Removal of dissolved salts from solution and pathogens

2. Secondary treatment can be either biological (e.g., activated sludge, trickling filter, and oxidation pond) in which organic matter is digested by microorganisms or physicochemical in which chemical reagents (flocculants or coagulants) agglomerate solid particles that form decantable flocs. Sludge results from the sedimentation occurring during the preceding operations. These steps can be completed by a disinfection operation (e.g., chlorine and ozone).
3. An advanced treatment phase (e.g., activated carbon) aimed at improving the elimination of contaminants.

Table 1 presents some unit processes and operations used in wastewater treatment.

PROTOZOA FOUND IN WASTEWATER

Qualitative Aspects

Wastewater, surface water, and recreational water can carry a large quantity of protozoa released by infected or healthy carrier individuals and/or animals. The protozoa eliminated in fecal matter or urine are in the form of resistant cysts or oocysts (Table 2).

Table 2. Types of Protozoa found in Water: Qualitative Data

Protozoa Type	Protozoa Species	Presence in Waste Water	Surface Water	Recreational Water	Drinking Water	Reference
Flagellates	*Giardia intestinalis* or *lamblia*	+	+	+	+	(2–4)
	Naegleria fowleri		+	+		(5)
Amoebae	*Entamoeba histolytica*	+	+		+	(6,7)
	Acanthamoeba spp.	+[a]	+	+		(8–10)
Coccidia	*Cryptosporidium parvum*	+	+	+	+	(11–14)
	Cyclospora cayetenensis	+	+		+	(15–18)
	Isospora belli	+				(19,20)
Microsporidia	*Enterocytozoon bieneusi*	+[b]	+[c]			(21–23)
	Encephalitozoon intestinalis	+	+			(21–23)
	Vittaformae corneae	+[b]				(21,22)

Note: [a]Presence in sediment and soil contaminated by sewage.
[b]Detection by PCR in tertiary effluent.
[c]Detection by PCR in surface water and ground water.

Table 3. Parameters Influencing the Contamination Level of Water

	Entamoeba histolytica	*Giardia intestinalis*	*Cryptosporidium parvum*	Reference
Prevalence	10% World 20–80% Developing countries	7% World 2–15% Developed countries 20–30% Developing countries	1–16% Developed countries 5–40% Developing countries	(7,24,25)
Concentration in fecal matter	1.5×10^7 cysts/day	9×10^8 cysts/day	10^8–10^{10} oocysts/day	(26,27)
Animal reservoir	No	Yes	Yes	
Cross-infectivity between animals and humans	No cross-transmission has not been documented	Yes for instance, beavers implicated in water outbreaks	Yes associated with cattle and possibly other domestic and wild animal wastes	(28)
Resistance or survival in environment	Feces: 1 month Wastewater: 15–30 days Sludge: 15–30 days Surface water: 1 month	Surface water: 1–3 months Wastewater: 1 month Sludge: 3 months Soil: 2 months (−4° at 4 °C)	Feces: 4 months Surface water: 1–6 months Soil: 3 months (−4° at 4 °C)	(29)

Except for microsporidiae that have been demonstrated only by polymerase chain reaction (PCR), resistant forms (cysts and oocysts) of all the protozoa presented in Table 2 have been observed under the microscope.

Quantitative Aspects

Factors with a Possible Influence on Environmental Parasite Contamination. The concentration of the observed protozoa (*Entamoeba histolytica*, *Giardia intestinalis*, and *Cryptosporidium parvum*) depends on:

1. the prevalence in the environment,
2. the presence of an animal reservoir,
3. the quantity of cysts excreted and their resistance in the environment,
4. the social and economical conditions, and
5. the presence of effluents from slaughterhouse (Table 3).

Level of Contamination in Raw Wastewater. Various levels are reported in the literature; hence, mean concentrations cannot be given. Table 4 presents a few examples of data selected on the basis of geographic criteria.

It is important to emphasize the large variations observed in concentration levels. This could be explained, at least in part, by the wide range of methods used and their respective performances. Nevertheless, mean concentrations of *Giardia* cysts in raw wastewater are always higher than *Cryptosporidium* oocyst concentrations (59).

Globally, the concentration of protozoan cysts detected in raw wastewater is affected by

1. the number of contributors (i.e., number of infected humans and animals in the community served by the sewage treatment works),
2. the quality of the cysts excreted and their resistance in the environment, and
3. the dilution by other waste discharging into the sewage treatment works.

Giardia cysts can thus account for up to 23% of all parasites in sewage (58). This high percentage of *Giardia* cysts in wastewater can be explained by the number of contributors (infected and/or healthy human carriers) and the large number of animals infected with *Giardia* (both *duodenalis* and other species), with both symptomatic and asymptomatic infections. Seasonal variations in cosmopolitan parasitic diseases have been described during the autumn and winter for *Giardia* (40) and during calving periods in feedlots for *Cryptosporidium*.

Entamoeba histolytica is found in geographical areas with a tropical (warm and humid) climate and poor sanitary conditions.

INFLUENCE OF WASTEWATER TREATMENT ON PROTOZOA CONCENTRATIONS

The treatment procedure varies from one station to another, but in general, wastewater treatment stations use biological and physicochemical processes. Each of these processes can be more or less effective with regard to the removal of protozoan parasites.

The capacity of treatment stations to remove and/or inactivate the largest possible percentage of protozoan cysts depends on the capacity of the different procedures to affect resistant forms.

Before reviewing the different procedures used, it is important to point out that data in the literature demonstrated the considerable variations observed both within and between sewage treatment works. It is also quite difficult to compare the different studies published because of variations in sampling and processing. Under these conditions, interpretations must be made with caution.

Removal of Protozoa by Sedimentation

Sedimentation is the fundamental operation for primary treatment, but is also involved in secondary and sometimes tertiary treatment. Primary and secondary sedimentation remove only a small proportion of cysts because cysts are small and have low density. The theoretical data in Table 5 summarizes density and settling velocities of freely suspended cysts as described by Stokes' law.

The main objective of primary treatment is to retain large particles that have much higher sedimentation velocities ranging from 500 to 150 cm/h.

The theoretical sedimentation velocity is given for isolated cysts, but when cysts are in contact with sewage particles, the sedimentation velocity increases with the size of the particle. The percentage of attachment of cysts and oocysts to wastewater particles appears to reach a maximum (75%) after approximately 24 hours, and prolonged incubation (48 hours) does not result in a higher percentage of attached cysts. This may be due to detachment of attached cysts caused by shear forces related to fluid movement (61).

Table 6 displays the percentage of cyst removal or reduction after primary treatment expressed in logarithm units.

Primary treatment is not very effective in removing protozoan cysts. Most rates are below 50%, with a maximum reduction of 90%. Studies aimed at determining the relationship between cyst removal and suspended solids removal during primary clarification have not been able to demonstrate any correlation (13).

Table 5. Theoretical Sedimentation Velocities of Cysts (7,60)

Parasite	Size	Density (gram per cubic centimeter)	Sedimentation Velocity (meters per hour)
Entamoeba histolytica	10–15 μm	1.06	0.11
Giardia intestinalis	9–15 μm	1.11	0.005
Cryptosporidium parvum	4–6 μm	1.05	0.001

Table 6. Calculated Removal Efficiencies of Primary Sewage Treatment for Protozoan Cysts

Parasite	Removal (% or reduction log 10 unit)	References
Cryptosporidium	44–90%	(61)
	80–84%	(62)
	52%	(63)
	4–30%	(13)
	No reduction	(31)
Giardia	18–80%	(32)
	0.1 log	(31)
	24–47%	(13)
	62–71%	(36)
E. histolytica	27–64%	(64)
	49%	(7)
	68–80%	(36)

Removal of Protozoa by Trickling Filters

Trickling filters alone do not appear to be efficient in removing protozoa from sewage. Reductions reported in the literature vary from 10 to 99%, with most results indicating 20 to 40% removal (Table 7). Many protozoan cysts will pass through trickling filters.

Casson and coworkers (32) and Robertson and coworkers (13) compared efficiency of trickling filters and activated sludge treatment at removing *Giardia* cysts. The trickling filters were found to be less efficient in removing cysts than activated sludge, but the difference was small (<5%).

Several studies on trickling filters have shown that a secondary sedimentation improves the system performance. The rotating biological contactors (RBC) treatment system may have a performance level equivalent to that of trickling filters.

Removal of Protozoa by Activated Sludge

The activated sludge treatment process has been studied in different countries, but the results are difficult to compare because of the differences in sampling (continuous or grab samples), identification methods, and the lack of simultaneous analysis of influent and effluent. Globally, the activated sludge process has little effect on protozoan cysts because the environment is wet and not hostile, temperatures are ambient, and retention times are short (6–12 hours). Cysts may become entrapped in the flocs, in which case they will be removed during secondary sedimentation.

Table 7. Calculated Removal Efficiencies of Protozoan Cysts by Trickling Filters

Parasite	Removal (%)	References
E. histolytica	25–74%	(7)
Giardia	10–99%	(40)
	30–80%	(32)
	74–85%	(13)
Cryptosporidium	5–38%	(13)
	93%	(38)

For *E. histolytica* cysts, removal rates of about 80% have been described (64). For *Giardia* cysts, Battigelli and coworkers report a 0.7 log reduction, whereas other authors have found higher levels of about 3 log (65). Robertson and coworkers (13) conducted a field study in which three sewage treatment works (two with primary treatment and one without primary treatment) were monitored over three years for concentrations of *Giardia* cysts and *Cryptosporidium* oocysts. At both sewage treatment works, calculated removal efficiency was significantly higher for *Giardia* cysts than for *Cryptosporidium* oocysts. Removal of *Giardia* cysts can be estimated to be 60 to 90% in sewage treatment works incorporating a primary process and a secondary process. Data analysis indicates that primary settlement alone is relatively inefficient at removing both parasites and that removal occurs during the secondary treatment stage.

For *Cryptosporidium* oocysts, the removal efficiency varies greatly from 15 to 98%, depending on the study. Robertson and coworkers (13) did, however, emphasize that variations in calculated removal efficiency were considerably greater for *Cryptosporidium* oocysts than for *Giardia* cysts in all the sewage treatment works studied.

The efficiency of activated sludge treatments would result from the large quantity of particles suspended during the aeration process. During the sedimentation stage, these particles flocculate and form a layer that acts like a filter; this layer would entrap the oocysts, holding them in the sludge (61). Laboratory studies have demonstrated that oocyst attachment to particles found in effluents of activated sludge is a rapid and widespread phenomenon (60). These data have not been investigated in the field, but they support the hypothesis that the presence of a large quantity of particles after activated sludge treatment favors oocysts removal during the secondary sedimentation stage.

Aerated lagoons and oxidative ditches can be considered as variants of the activated sludge process and have shown very similar removal rates for protozoan cysts. The removal efficiency of protozoan cysts and oocysts by the activated sludge process is summarized in Table 8.

Giardia	88.5–93.8%	(38)
	60–90%	(13)
	97%	(32)
	98–99%	(67)
	80–84%	(62)
Cryptosporidium	90–98%	(61)
	84.5–98%	(66)
	79%	(48)
	46–54%	(38)
	15–91%	(13)

Removal of Protozoa by Waste Stabilization Ponds

Waste stabilization ponds can be used either as the principal treatment, which implies many successive ponds for sedimentation or as a secondary treatment of wastewater (40,51,68). Anaerobic and facultative ponds are theoretically designed for the removal of biochemical oxygen demand, whereas the function of maturation ponds is the removal of excreted pathogens. The efficiency of this treatment depends on the total theoretical retention time in the ponds to allow a good sedimentation of particles, although this is not the only parameter involved (39). Temperature, pH, and solar radiation also have an important effect. Table 9 summarizes the efficiency of stabilization ponds in removing protozoan parasites.

The results presented in Table 9 show that stabilization ponds are an efficient means of removing protozoan cysts if a certain number of conditions are met:

1. sufficient retention time (20 days to more than 30 days) (7,39,51) and
2. sufficient temperature and solar radiation (low radiation levels can occur depending on the season) (39).

The principal mechanism involved in protozoa removal probably is due to the adsorption of cysts and oocysts to suspended matter. Predation phenomena described for bacteria have not been reported with protozoa.

The occurrence and concentration of cysts and oocysts detected in pond effluent in series decreased sequentially, indicating that the removal of oocysts and cysts is also related to the cumulative effect of retention time.

Impact of Tertiary Treatments

Tertiary treatments are routinely used in many countries to improve the quality of effluents produced by conventional biological treatment.

Sand Filtration. Rapid filtration (5–15 m/h flow rate) and slow filtration (10–30 cm/h) on sand have been found to be the two effective tertiary treatment methods with different efficiencies for the removal of protozoa. Slow filtration provides complete cyst removal from secondary effluents (>3 log removal) (72,73), whereas rapid filtration can remove 70 to 80% of *Giardia* and *E. histolytica* cysts and 50% of *Cryptosporidium* oocysts (38,48,74).

Infiltration Percolation. There are few data on the performance of infiltration percolation on cysts removal from wastewater. Castillo and coworkers (75) reported that in Chile soils (sandy-lime and lime-gravel) can provide a total cyst removal with an infiltration rate of 20 to 30 cm/day.

Tertiary Lagoons. Conventional effluents can be further polished in tertiary lagoons. The mechanisms involved are similar to those described for waste stabilization ponds (76). A study conducted in the United Kingdom indicated a mean 0.6 log reduction of *Giardia* cysts (77).

Artificial Wetlands. Artificial wetlands are being increasingly used for the tertiary treatment of secondarily treated wastewater (activated sludge). Enhancement of water quality occurs due to the wetland's ability to remove nutrients, various chemical contaminants, and wastewater microorganisms. There are several types of wetlands: aquatic pond, subsurface flow, and surface flow.

Figure 2 shows a comparison of the mean efficiencies observed for *Giardia* cysts and *Cryptosporidium* oocysts removal in different types of wetland (78).

In all the wetland systems studied, the concentration of protozoan cysts decreased from the influent to the effluent. The aquatic pond system is the most efficient for removing protozoa. The primary mechanism of removal within the pond system is likely to be sedimentation, although other factors such as natural die-off and adsorption to detritus may also be involved to some degree (78).

High Rate Algae Ponds. This type of system has been efficiently used to remove *Cryptosporidium* oocysts (79) provided the retention time is sufficient. After three days retention, efficiency reaches 97% removal; 99.9% is reached after 10 days, and 100% after 12 days.

Disinfection

Chlorination. Chlorine is the most widely used disinfectant for municipal wastewater because it destroys target organisms by oxidizing cellular material. Chlorine can

Table 10. Inactivation of Protozoan Cysts by Chlorination of Wastewater

Parasite	Chlorine Dose	Experimental Conditions	Inactivation Efficiency	References
Giardia	10 mg/L	pH 6.7 T° 22 °C T 3–4 h	82%	(80)
Entamoeba histolytica	12 mg/L	pH 6.7 T° 22 °C T 24 h	84%	(80)
		pH 6.8 T° 22 °C T 48 h	92%	(80)

be supplied in many forms, which include chlorine gas, hypochlorite solutions, and other chlorine compounds in solid or liquid form. It is a complex operation because of the difficulty in maintaining a constant chlorine residual level for effective disinfection. Cysts and oocysts resist quite well even at high chlorine concentrations (Table 10).

Table 11 describes some of the more common wastewater characteristics and their impact on chlorine.

Ozonation. Ozone is a very strong oxidant. The mechanisms of disinfection using ozone include direct oxidation/destruction of the cell wall, reactions with radical by-products of ozone decomposition, and damage to the constituents of the nucleic acids (purine and pyrimidine). Ozone is more effective than chlorine in destroying protozoan cysts, but low dosage may not effectively inactivate cysts (Table 12).

Ultraviolet (UV) Radiation. It is well known that UV radiation damages microbial RNA and DNA. For protozoan cysts, the exact target of UV radiation is not well known. The doses required to inactivate protozoan cysts are much higher than those currently used (Table 13).

UV radiation is a relatively simple method but is highly dependent on wastewater characteristics: turbidity, total suspended solids (TSS), and colloidal matter (83). For instance, UV disinfection with low presence lamps is not as effective for secondary effluent with TSS levels above 30 mg/L (81).

Table 11. Wastewater Characteristics affecting Chlorination Performance (81)

Wastewater Characteristic	Effects on Chlorine Disinfection
Ammonia	Forms chloramines when combined with chlorine
Biochemical oxygen demand (BOD)	The degree of interference depends on their functional groups and chemical structures
Hardness, iron, and nitrate	Minor effect, if any
Nitrite	Reduces effectiveness of chlorine and results in THMs
pH	Affects distribution between hypochlorous acid and hypochlorite ions and among the various chloramine species
Total suspended solids (TSS)	Shielding of embedded microorganisms and chlorine demand

Other Tertiary Treatment Processes. Several other treatment processes are in use or under experimentation, including membrane microfiltration or ultrafiltration. These systems provide excellent barriers against protozoan cysts and oocysts (84,85).

Table 12. Inactivation of Protozoan Cysts by Ozonation of Wastewater

Parasite	Ozone Residual Dose	Contact Time	Inactivation Efficiency	References
Giardia	0.4 mg/L	8–12 min	99%	(82)
Cryptosporidium	15 ppm	10 min	90%	(82)

Table 13. Inactivation of Protozoan Cysts by UV Radiation of Wastewater

Giardia	100–160 mW s cm^2	80%	(82)
Cryptosporidium	100–160 mW s cm^2	80%	(82)

PROTOZOA FOUND IN SLUDGE AND THE IMPACT OF TREATMENTS

Treatment of wastewater leads to the production of large quantities of sludge where protozoa are concentrated. Quantitative data on *Giardia* cysts are given in Table 14.

The quantity of cysts removed is quite variable, and no correlation exists between *Giardia* cyst concentration in raw sludge and the size and/or geographic localization of the treatment station. The impact of sludge treatments on these cysts is difficult to assess.

Mesophilic anaerobic digestion would be moderately, or poorly efficient at cyst removal. Thermophilic aerobic digestion (55 °C) provides 100% inactivation. Storage techniques (>24 weeks) can remove protozoan cysts.

There are very few data concerning *Cryptosporidium* oocysts in sludge. Chauret and coworkers found in mixed sludge 5.3×10^2 oocysts/100 g wet sludge and indicated 0.3 log 10 reduction during the anaerobic sludge digestion (31).

CONCLUSION

Wastewater carries large quantities of protozoan cysts (*Giardia*, *Cryptosporidium*, *E. histolytica*, etc.). The concentrations observed depend on a certain number of parameters including the number of contributors (infected individuals and/or healthy carriers) excreting large quantities of cysts capable of surviving in the environment. Wastewater treatment leads to the production of treated wastewater, which flows into the receiving environment (surface water, sea, and soil), and which must meet sanitary standards.

Table 14. Occurrence of *Giardia* Cysts in Wastewater Sludge

Sludge Type	Initial Cysts Concentration	Treatment	Final Cysts Concentration	Removal	References
Raw sludge	7.7×10^4–3.3×10^6/Kg*	Mesophilic anaerobic digestion	1.0×10^5–4.1×10^6/Kg*	0–86.4%	(86)

*Dry Weight
**Wet Weight
ND: Not Detected

Protozoan cysts resist the different stages of conventional wastewater treatment quite well. They can be removed by adsorption to sewage particles and slow sedimentation, two operations that present a certain degree of efficiency in cyst removal.

For disinfection procedures, chemical compounds such as chlorine have little effect at commonly used doses. For other tertiary treatments, certain new techniques using different membranes capable of removing cysts are noteworthy.

Sludge also contains considerable quantities of cysts. If the sludge is reused, these cysts have to be eliminated. It would appear that radiation and/or destructive treatment of the cysts could be achieved by different methods using temperatures above 65 to 70 °C, long-term storage, and so forth.

Sanitary treatment of sludges opens a vast and emerging field of technological development.

PATHOGENIC *ESCHERICHIA COLI*

E. W. RICE
U.S. Environmental Protection Agency
Cincinnati, Ohio

Escherichia coli is a bacterial species that inhabits the gastrointestinal tract of humans and warm-blooded animals. Because of the ubiquity of this bacterium in the intestinal flora, it serves as an important indicator organism of fecal contamination (1). *Escherichia coli*, aside from serving as a sanitary indicator, has played an important role in the science of microbiology. It has been extensively utilized as a model organism in a variety of physiological and genetic research studies. The recent sequencing of the *E. coli* genome bears witness to the continued importance of this microorganism in scientific research.

Originally referred to as *Bacterium coli*, the initial isolation of this organism from feces was first reported in 1885 and was for many years considered a harmless commensal organism of the gut. It was not until the mid-1940s that it was determined that certain strains of this bacterial species could indeed serve as etiological agents of diarrheal illness (2). This finding was first associated only with illness in children in what was referred to as "summer diarrhea." At a later date, it was found that adults could also become infected. Today it has been well established that although generic strains of *E. coli* are nonpathogenic, many *E. coli* strains are capable of causing gastrointestinal disease. The disease-causing strains in general are very similar to the generic strains; however, some pathogenic strains differ in certain phenotypic traits such as carbohydrate fermentation and growth temperatures. The disease-causing strains have been categorized into pathogenic groups, on the basis of virulence characteristics, clinical manifestations, and epidemiological patterns. Individual serotypes have been found to be associated with specific pathogenic groups. Adhesion and attachment traits, as well as toxin and hemolysin production are the primary virulence factors used for distinguishing individual pathogenic groups. Virulence characteristics may be mediated by various genetic elements, such as plasmids (extra chromosomal genetic material) or bacteriophages (bacterial viruses). Molecular techniques have proven most useful for the detection of many of these traits. The primary pathogenic groups of interest in environmental microbiology are enterohemorrhagic *E. coli* (EHEC), enteropathogenic *E. coli* (EPEC), enterotoxigenic *E. coli* (ETEC), and enteroinvasive *E. coli* (EIEC) (3). Other pathogenic groups such as enteroaggregative *E. coli* (EAEC) also exist but to date have not been definitely linked with transmission via an environmental source. Dissemination for all groups is by the fecal-oral route, with person-to-person or animal to person, as well as food and water being the primary means of transmission. Research studies on survival in aquatic environments have found that, under similar conditions of temperature and other water-quality parameters, pathogenic *E. coli* do not appear to persist longer than generic *E. coli*. The detection of pathogenic *E. coli* in the environment requires specialized techniques not normally employed in routine sanitary analysis; however, the presence of generic *E. coli* in a sample serves as an indication that pathogenic strains of *E. coli* and other enteric pathogens may be present (1).

The adherence to and invasion of the cells of the intestinal mucosa are important characteristics of the pathogenic groups. Adhesion is mediated by structures that project from the bacterial cell and are referred to as fimbrae or pili. Adherence patterns are determined by observation of strains in vitro on tissue culture cells.

Strains may adhere in a uniform manner or they may adhere in clumps or aggregates. Invasive strains are capable of penetrating the mucosal cells, and some strains have the ability to spread to adjacent cells after invasion. Certain strains also have the ability to efface the cells of the intestine. Microvilli, the small fingerlike projections of the intestinal cells, increase in length and eventually are destroyed during the process of effacement.

Toxin production is another major virulence factor used to characterize pathogenic *E. coli*. Not all pathogenic groups possess toxins and some toxins may be present in more than one specific group. Toxins are classified into two major types based on their response to heating. Heat-stable toxins can withstand heating for 30 minutes at 100 °C without losing their activity. Heat-labile toxins lose their activity under these conditions. Some *E. coli* strains produce potent toxins known as a verocytotoxins or shiga-like toxins, which are similar to the toxin produced by *Shigella*, the causative organism of bacterial dysentery.

Serological techniques are used to classify *E. coli* within pathogenic groups in reference to their antigenic structure. The O and H antigens are the primary phenotypic characters used in serotyping *E. coli*. The O antigens, referred to as somatic antigens, are thermostable and are the polysaccharide portion of the lipopolysaccharide complex attached to the bacterial cell membrane. Strains that are motile because of the presence of flagella contain H antigens. These antigens are derived from the flagellar structure.

ENTEROHEMORRHAGIC *E. COLI* (EHEC)

Escherichia coli O157 : H7 is one of the most frequently occurring serotypes in the EHEC group of pathogenic *E. coli*. Other serotypes such as O26 and O111 have also been associated with the EHEC group. *Escherichia coli* O157 : H7 attaches, invades, and effaces the intestinal mucosal cells. Strains of this group produce the toxins referred to as verocytotoxins or Shiga-like toxins. These toxins are mediated by the presence of bacteriophages. Strains may possess both a type I or type II toxin or may produce only one toxin type. The clinical symptoms of infection vary from nonbloody diarrhea to bloody diarrhea, which is generally referred to as hemorrhagic colitis. A life-threatening condition known as *hemolytic uremic syndrome* may develop from these infections and cause renal failure. This condition is often of greater risk in young children. *Escherichia coli* O157 : H7 is one of the serotypes of pathogenic *E. coli* that exhibit variations from the phenotypic characteristics associated with generic strains. Unlike generic *E. coli*, most strains of *E. coli* O157 : H7 do not readily ferment the carbohydrate sorbitol and also do not grow well at the elevated temperature (44.5–45 °C), which is used to detect the fecal indicator group of thermotolerant coliform bacteria. The infective dose for this organism is quite low, thus the ingestion of small numbers of the bacteria may be sufficient to cause disease. Other serotypes of EHEC include O26 : H11, O111 : H8 and O104 : H21. These serotypes may exhibit different virulence characteristics in terms of their attachment-effacement capabilities.

Escherichia coli O157 : H7 is widely known as a food-borne pathogen, but it has become increasingly recognized as the etiological agent in several waterborne outbreaks. Unlike other pathogenic *E. coli* groups, cattle and humans may serve as a reservoir for this organism. Thus, sources of contamination include runoff from cattle operations and human sewage. It has been reported that *E. coli* O157 : H7 can survive both in water (4,5) and manure (6). Several waterborne outbreaks have been reported relating to both drinking water and recreational water exposure (7). EHEC, and generic *E. coli* are sensitive to chlorination, and therefore proper chlorination of drinking water supplies should be sufficient for controlling these organisms (8). Many of the reported drinking water outbreaks have been linked to unchlorinated groundwater supplies. Contamination of wells via runoff and distribution system disturbances have been implicated in these outbreaks. One such outbreak in Cabool, Missouri in 1989 resulted in several deaths (9) as was also the case in a more recent outbreak in 2000 in Walkerton, Ontario. Lakes used for recreational water may also serve as a source of contamination and would not be subject to chlorination. Outbreaks have occurred in chlorinated swimming pools and water parks, where chlorine levels would not be sufficient to counteract an overt fecal accident.

ENTEROPATHOGENIC *E. COLI* (EPEC)

The EPEC was the first group of *E. coli* to be recognized as a cause of diarrheal illness and was initially reported as an etiological agent of infant diarrhea. Like EHEC, this group attaches, effaces, and invades the intestinal mucosa, but unlike EHEC does not produce toxins. Watery diarrhea, fever, and dehydration are the primary symptoms. In infants, these symptoms may be prolonged over an extended period (>14 days). In recent years, there has been a low incidence of EPEC infections in most industrialized nations, but this group remains an important cause of childhood diarrheal illness in developing countries. Although primarily a disease of children, adults can also become infected. The low occurrence rate in adults is thought to be due to the acquisition of immunity at an early age. The serotypes 018, 044, 055, 086, 0119, 0125, 0126, 0127 are several of the serotypes associated with EPEC. Serotype O111 has been implicated with this group (EPEC) and also with the EHEC group.

Person-to-person contact is a major source of contamination for EPEC, but water also serves as a means of transmission especially in areas with poor hygienic standards. A large waterborne outbreak occurred in 1971 at a conference center in Washington, D.C. The pathogen (serotype O111) was isolated both from fecal specimens and the unchlorinated drinking water supply (10). In 1969, an outbreak of gastroenteritis caused by serotype O126 was reported in a logging camp where the inhabitants had ingested sewage-contaminated water (11).

ENTEROTOXIGENIC *E. COLI* (ETEC)

The condition known as travelers' diarrhea is associated with the ETEC group. Travelers' diarrhea is most often seen in individuals traveling from industrialized countries to countries with poorer hygienic standards. Like EPEC, the ETEC group is also an important cause of infant diarrhea in less-developed countries. Adherence to intestinal mucosal cells in a uniform pattern is characteristic for the ETEC group; however, invasion does not occur. Toxin production does occur, and strains may produce a heat-labile toxin, a heat-stable toxin, or both types simultaneously. The heat-labile toxin is very similar to the toxin produced by toxigenic strains of *Vibrio cholerae*, the etiological agent of cholera. Infection often results in cholera-like watery diarrhea symptoms without blood or mucus and is accompanied by fever and vomiting. Serotypes in the ETEC group include O6, O8, O15, O20, O25, O27, O63, O78, O80, O114, O115, O128ac, O148, O153, O159, and O167.

ETEC was responsible for one of the largest waterborne outbreaks of pathogenic *E. coli* in the United States (12). In 1975 more than 2,000 individuals who had visited Crater Lake National Park in southwestern Oregon experienced gastroenteritis. ETEC serotype O6 was isolated from both fecal specimens and the park's water supply. Direct sewage contamination of the water supply coupled with inadequate chlorination procedures were cited as causative factors in this outbreak.

ENTEROINVASIVE *E. COLI* (EIEC)

EIEC cause an inflammatory disease of the gastrointestinal tract. These bacteria invade the intestinal mucosa, multiply within the epithelial cells, and may spread laterally to adjacent cells. While the disease process closely resembles that seen with *Shigella*, there have been no reports of toxin production from EIEC strains. Typical serotypes of EIEC include O28ac, O29, O124, O136, O143, O144, O152, O164, and O167. Endemic infections of EIEC appear to be limited to developing countries; however, outbreaks have been reported in industrialized nations. Strains of EIEC differ from generic *E. coli* in their inability to readily ferment the carbohydrate lactose.

Person-to-person spread appears to be the predominant mode of transmission. A waterborne outbreak of serotype O124 has been reported in a children's camp in Hungary. Drinking water contaminated from a leaking sewer was implicated and the organism was isolated from fecal specimens and a reservoir supplied by a spring water source (13).

PATHOGENS IN ENVIRONMENTAL BIOFILMS

C. WILLIAM KEEVIL
University of Southampton
Southampton, United Kingdom

The attachment of prokaryotic microorganisms to air–liquid, liquid–liquid, and solid–liquid interfaces in the aquatic environment (1), and their subsequent maturation into heterogeneous but highly ordered communities of biofilms predated by eukaryotic microorganisms, has represented an important step in the evolution of life on earth (2). Biofilms are ubiquitous in both the natural and built environments and exist despite, and frequently in response to, extremes of temperature, pH, redox potential, nutrients, and toxic molecules such as heavy metals, industrial organic pollutants, and biocides (3,4). Unlike the more commonly encountered monospecies cultures in vivo, environmental biofilms are usually comprised of complex consortia of microorganisms and can contain a high species diversity of aerobic and anaerobic bacteria, archaea, fungi, amoebae, protozoa, and nematodes (5). Of concern to modern society is the threat that microorganisms pathogenic to animals and/or man can survive and even flourish in such ecosystems. This is related to the sharp rise in the world population, itself causing bacterial, protozoal, and viral pathogen dissemination and amplification through person to person infective transmission, and the requirement of intensive agricultural practices to provide sufficient food, exacerbating propagation and transmission of zoonotic pathogens. The need

to dispose of increasing quantities of waste and wastewater from homes, industries, and intensive animal rearing facilities has strained the resources of farmers and many sewage treatment utilities worldwide. Poor sewage and animal waste disposal, and intensive stocking of animals in fields near abstraction points built for supplying potable water, has increased the transmission of microbial pathogens back into the natural environment and in water supplying agricultural, industrial, and domestic premises (Table 1). Consequently, the normal water cycle has been perturbed by the introduction of toxic organic compounds and heavy metals from disposal of waste to land and leaching into watercourses. Eutrophication of rivers and lakes has occurred owing to ingress of nitrogen and phosphorus resulting from excessive use of detergents, promoting biofilm formation, and production of toxic by-products from cyanobacterial biofilm blooms, such as microcystin hepatotoxins and anatoxin neurotoxins (6). According to World Health Organization statistics (7), developing countries no longer have a monopoly of waterborne diseases. Some 20 million people die each year from waterborne diseases, over one million of them in Europe. In addition to "traditional" microorganisms, new pathogens have emerged and are currently major concerns for industrialized countries. Their prevalence and relationship to persistence in aquatic biofilms will be featured in this article.

The complex physical and physiological interactions of the biofilm consortia, and survival of pathogens therein, has made their study difficult and several model systems have been advocated to reproducibly generate high species diversity biofilms in defined environments. Advances in microscopy, immunology, and molecular biology have also allowed the development of various light and epifluorescence (EF) techniques, utilizing antibody and molecular probes, to study biofilm physicochemistry and track individual species in situ. This article will focus, in particular, on the use of episcopic differential interference contrast (EDIC) and EF microscopies (8,9) to observe biofilms generated in a continuous culture ecological system in the laboratory to model biofilms in the environment. The development and use of chemostat models to study environmental biofilms and colonization by pathogens has been reviewed elsewhere (10) and, therefore, will only briefly be considered here. A primary seed vessel ensures the reproducible maintenance of complex microbial consortia and supplies subsequent growth vessels, each also receiving their own nutrient feed, in an open flow system for biofilm experimentation in defined environments. The chemostat vessels are constructed of nonferrous materials, typically titanium top plates with glass bodies and Teflon stirrers, to avoid leaching of iron, chromium, and manganese from the more conventional stainless steel fabrications which would perturb the chemistry of the nutrient supply (Fig. 1). Tiles or coupons of known physicochemistry can be inserted and removed aseptically after hours or months for microbiological and microscopic image-analysis. In contrast to field studies, the model is cheap, reproducible, and easily manipulated. It can be used to model natural water systems and potable water mains distribution and plumbing systems in buildings, and the effects

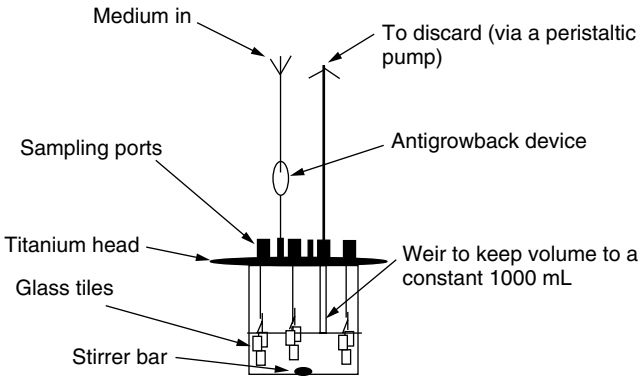

Figure 1. Diagram of the second stage model biofilm system with multiple assemblages of coupons suspended from rigid titanium wire inserted through silicone rubber bungs in the top ports. The weir system was used to maintain the volume at the required level. Temperature, oxygen and pH probes are not shown. *Source:* From Surman and coworkers (25).

of different growth rates, temperatures, environmental chemistry, and disinfectant concentration. The shear rate imposed on surfaces by water velocity can be determined by manipulation of the stirrer speed: typical water velocities of 0.2 to 3.0 m second^{-1} have been investigated. Importantly, the model has few working parts and can be assembled in Class III containment cabinets for the study of more infectious pathogens.

To date, this model and others have shown that biofilms consisting of aerobic heterotrophs and autotrophs provide an environmental reservoir or safe haven for the fecal indicator bacteria *Escherichia coli* (including verocytotoxigenic *E. coli* 0157), *Klebsiella oxytoca*, and *Klebsiella pneumoniae*, the opportunistic pathogens *Aeromonas hydrophila* and *Pseudomonas aeruginosa*, microaerophilic bacteria including *Legionella pneumophila*, *Campylobacter jejuni*, *Helicobacter pylori*, and *Mycobacterium avium*, pathogenic acanthamoebae and *Cryptosporidium parvum*, and possibly viruses such as Poliovirus-1.

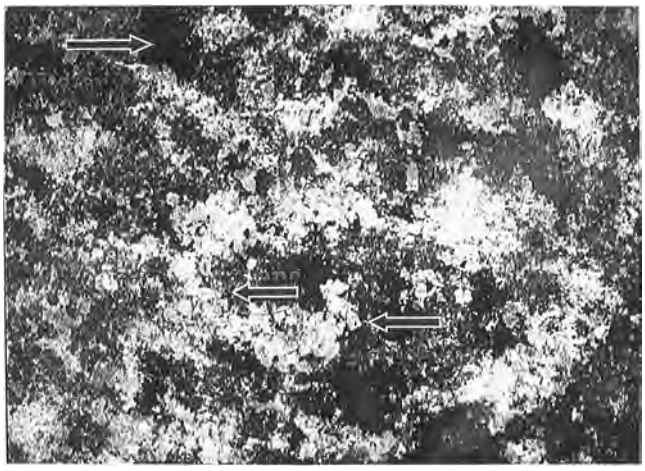

Figure 2. Heterogeneous biofilm showing stacks of microcolonies rising from the substratum and water channels. *Source:* From Keevil and coworkers (13). See color insert.

BIOFILM STRUCTURE

Biofilm formation comprises a dynamic flux of processes involving attachment, colonization and maturation, active detachment or passive sloughing, and predator grazing (1,3). A pseudo-steady state is reached for biofilms in potable and natural waters in which the numbers of recoverable, viable bacteria varies between 10^5 and 10^7 per cm^2, dependent on the nutrient availability, shear force, and physicochemistry of the substratum (5). By contrast, the numbers of viable bacteria recovered from the planktonic phase are typically only 10 to 10^3 per milliliter. Thus, considering the many kilometers of distribution main and plumbing pipe used to supply potable water from the treatment works to the tap, the biofilm represents a much more significant environmental reservoir of microorganisms than the water phase.

The chemostat biofilm model has facilitated important breakthroughs in our knowledge of biofilm structure, function, and ecology. The majority of the so-called *biofilms* are actually *extremely heterogeneous but highly ordered* in structure with many water channels penetrating to the substratum; these permit partial, convective ingress of nutrients and, presumably, antibiotics or disinfectants (11,12). The "biofilm" consists of a patchy basal layer, 5- to 10-μm thick, covered with stacks or fronds of microcolonies rising typically 100 to 200 μm above the substratum surface (Figs. 2 and 3). Variations in cell morphology and color within the microcolonies of the stacks suggest close physiological associations of consorting species (13). There are inevitably many water channels but the apparent spaces between the stacks is dependent on the physicochemistry of the substratum and its conditioning pellicle layer, the availability of nutrients, and the activity of grazing predators. Indeed, we have demonstrated that motile bacteria, protozoa, and nematodes can be seen passing through the channels. The convective flow of microscopic fluorescent beads through the channels has also been described (14,15). In nutrient-rich environments the biofilm may thicken and consolidate, with the water channels narrowing to

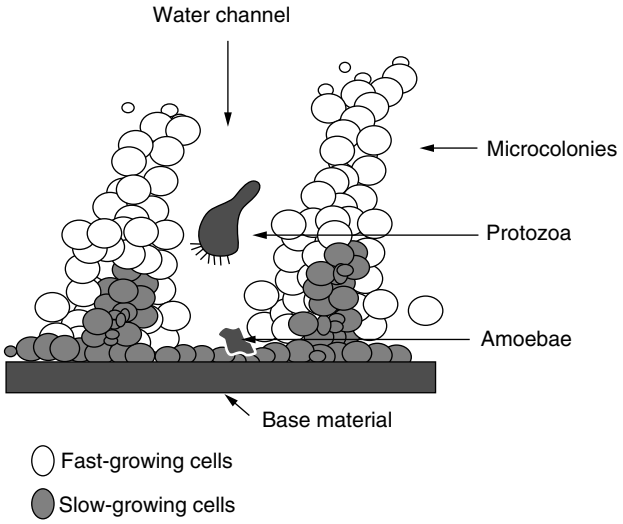

Figure 3. Open architecture structure of biofilm with fronds, water channels, and grazing eukaryotic predators. *Source:* From Keevil (157).

resemble a sponge. The structure can also appear confluent owing to the production of copious exopolysaccharide (EPS) gel within the channels. Any observation technique that requires even partial dehydration will result in shrinkage phenomena, generating artifacts. The structures described are still *largely microscopic* in scale. In the presence of sunlight, however, photosynthetic species can proliferate, producing secondary metabolites, EPS, and intracellular storage polymers to subsequently enrich the other members of the adherent consortium. This photosynthetic stimulation of biofilm metabolism can result in the proliferation of green macroblooms, obvious to the naked eye (13).

The surface of the so-called *biofilm* may scavenge reactive biocides such as chlorine, acting sacrificially to protect autochthonous and pathogen cells within. However, diffusion may not be rate limiting owing to

accessibility through the water channels that penetrate to the substratum. This penetrability might explain how less-reactive monochloramine appears to be a better residual disinfectant than chlorine to control biofilm microorganisms (16,17).

AUTOCHTHONOUS BIOFILM MICROFLORA

A diverse range of microorganisms are found in the planktonic phase of environmental waters and frequently also in sessile biofilm communities. These include autotrophic and heterotrophic gram-positive and gram-negative bacteria, yeasts, fungi, amoebae, ciliates, and rotifers (Table 2). Potable waters are treated to European Union and World Health Organization standards to prevent the spread of pathogens and indicator bacteria; however, this water is not intended to be sterile and, consequently, also contains a diverse range of microorganisms (18). Biofilms exist in all water distribution and plumbing systems at temperatures below 60 °C (19,20).

Very little is known about the presence of viruses in natural or potable waters, owing to lack of study, but it is presumed that bacteriophages are commonly present. It was widely believed that bacteriophages cannot infect surface-attached bacteria (biofilms) because such bacteria are protected by an exopolymeric matrix that binds macromolecules and prevents their diffusion into the biofilm. However, Doolittle and coworkers (21) were able to show that bacteriophage T4D+ can infect and multiply within *E. coli* cells growing as a biofilm. Subsequently, Hughes and coworkers (22) found that bacteriophages for three representative strains of gram-negative biofilm bacteria were of widespread occurrence. Lytic bacteriophage was isolated from local sewage for the bacterium 1.15, an EPS-producing pseudomonad found originally as a component of biofilms in a local river, and for two *Enterobacter agglomerans* strains from industrial biofilms. These bacteriophages are similar to other viruses for EPS-producing bacteria in inducing the synthesis of enzymes degrading the polymers that occlude the bacterial cell surface. The soluble phage enzymes each degrade their substrate by acting as endo-glycanohydrolases, and may serve as a detachment mechanism for nearby cells in biofilms. McLean and coworkers (23) have recently begun studies of bacterial biofilm–phage interactions. These authors anticipate that some phage are better adapted to growth in biofilms, some are adept to growing in mixed culture biofilms, and others are better adapted to infecting planktonic organisms. Whereas biofilms are now widely accepted as a fundamental aspect of microbial growth in nature, the field of phage ecology is quite new and an exciting challenge for the future.

Table 2. Microbiology of Water and Biofilms

Heterotrophic Organisms/ Genera	Other Organisms
Acinetobacter	*Nitrosomonas*, *Nitrobacter*
Aeromonas	Iron oxidizing bacteria
Alcaligenes	Sulfate reducing bacteria
Flavobacterium	
Methylobacterium	
Pseudomonas	Yeasts, *Actinomycetes*
Legionella	*Chladysporium, Aspergillus*
Enterobacter, *Klebsiella*, *Proteus*, etc.	
Micrococcus	*Acanthamoeba*, *Hartmanella*
Staphylococcus	*Paramecium*, *Tetrahymena*
Bacillus	*Lachrymaria*, *Vorticella*
Corynebacterium

The significance of actinomycetes and filamentous fungi in biofilms is currently being investigated. Previous work found *Aspergillus* spp. in biofilms of large institutional buildings in Scotland (20). Wuertz and coworkers (24) investigated zinc uptake by activated sludge biofilm in a rotating biofilm annular reactor, which consisted of an external cylinder with removable slides and an internal solid drum. This work revealed a gradual change in zinc concentration associated with EPS, although the total zinc concentration in the biomass remained constant. Concurrently, the amount of extractable EPS decreased. This was a consequence of a microbial population shift, with bacterial counts decreasing and algal and fungal biomass increasing. This showed the adaptive response of fungal enrichment in biofilms for important processes such as heavy metal sorption: this may be important, for example, in biofilms on galvanized steel pipework. Importantly for public health, Surman and coworkers (25) reported the presence of *A. flavus* and *Acremonium strictum* in potable water biofilms generated in the two-stage chemostat model at 30 °C. These findings for the presence of fungi such as *A. flavus* in biofilms are disconcerting because Kelly and coworkers (2) not only found this species but also its associated carcinogenic toxic secondary metabolite, aflatoxin B2, at a concentration of 0.2 to 1.6 $\mu g\,L^{-1}$ from a cold-water storage tank. Therefore, we should not concentrate solely on the presence of bacteria in biofilms but be more aware of the potential for toxicants to be produced by autochthonous biofilms.

The predatory eukaryotes have evolved to graze environments in which there is a plentiful supply of food, that is, bacterial, yeast, and algal biofilm communities on marine and freshwater surfaces. This can be seen even using scanning electron microscopy in which amoebae sit on the substratum and sweep over and engulf the biofilm present (Figs. 3 and 4). Video microscopy has demonstrated how they swim or glide through the water channels in heterogeneous biofilm to find appropriate stacks or fronds of biofilm microcolonies on which to feed (Fig. 3). This feeding can be highly specific, perhaps involving chemotactic mechanisms sensing secondary metabolites excreted by desirable prey in the mosaic of microenvironments of the biofilm. Of importance, some of the grazing amoebae are opportunistic pathogens of man. Free-living amoebae cause three well-defined disease entities: a rapidly fatal primary meningoencephalitis, a chronic granulomatous amoebic encephalitis, and a chronic amoebic keratitis. For example, *Acanthamoeba* and *Hartmanella* spp. can cause keratitis of the cornea

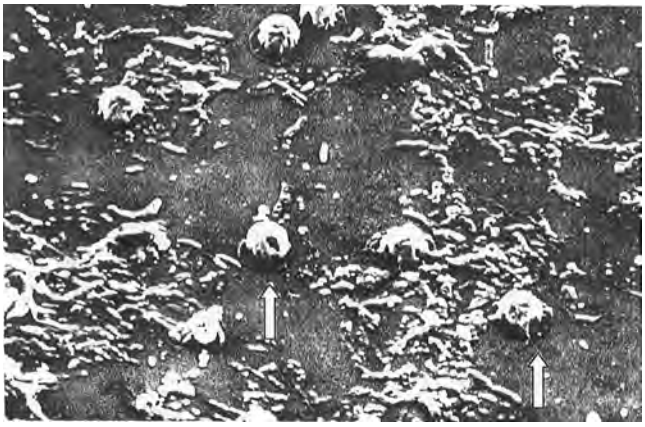

Figure 4. Scanning electron micrograph showing grazing of biofilm by *Acanthamoeba* sp. *Source:* From Rogers and coworkers (34). See color insert.

and subsequent blindness (26), whereas *Naegleria* spp. can invade the olfactory neuroepithelium and consequently migrate through olfactory lobes into the cerebrum and cause primary amoebic meningoencephalitis which is invariably fatal (27). The role of biofilm amoebae as carriers of bacterial pathogens will be discussed later.

AUTOCHTHONOUS BIOFILM PATHOGENS

Several studies have been undertaken to examine quantitatively the risks to human health posed by heterotrophic plate count (HPC) bacteria found naturally in ambient and potable waters (28–30). There was no convincing evidence that the HPC bacteria as a whole pose a public health risk. Only certain members are opportunistic pathogens. Using the four-tiered approach for risk assessment from the National Academy of Sciences, hazard identification, dose–response modeling, and exposure through ingestion of drinking water were evaluated to develop a risk characterization, which estimates the probability of infection for individuals consuming various levels of specific HPC bacteria (30). HPC bacteria in drinking water often include isolates from the genera *Pseudomonas*, *Acinetobacter*, *Moraxella*, *Aeromonas*, and *Xanthomonas*. Other bacteria that are commonly found are *Legionella* and *Mycobacterium* spp. All of these genera contain species that are opportunistic pathogens and may cause serious diseases. For example, the three nonfermentative gram-negative rods most frequently isolated in the clinical laboratory are (*1*) *P. aeruginosa*, (*2*) *Acinetobacter* spp., and (*3*) *Xanthamonas maltophilia*. Some of these species will now be reviewed further.

Pseudomonads

Pseudomonas aeruginosa is a major cause of hospital-acquired infections with a high mortality rate. It is also associated with otitis externa or folliculitis in people who have used swimming pools and spa pools (31), suggesting a possible link with aquatic biofilms. In addition, and of particular importance, *P. aeruginosa* biofilms occur in the lungs of chronically infected cystic fibrosis patients, in which they protect the bacteria against antibiotics and the immune response. The lung tissue damage is because of immune complex mediated chronic inflammation dominated by polymorphonuclear leukocytes releasing proteases and oxygen radicals (32). Accordingly, the majority of biofilm studies with this opportunistic pathogen have concentrated on its significant role in cystic fibrosis. Laboratory studies have modeled single strain cultures forming biofilm in rich nutrient media to ascertain the role of exopolymeric alginate formation, other attachment factors, expression of virulence determinants such as elastase and iron sequestering siderophores, and the influence of quorum-sensing *N*-acyl homoserine lactones (AHLs) on physiology and pathogenicity (discussed later). Little has been studied concerning its niche in the natural environment. One study showed that *P. aeruginosa* could form a biofilm in a PVC pipe containing sterile water and that viable bacteria could still be recovered after 7 days of exposure to 10 to 15 ppm chlorine (33). In another study, Rogers and coworkers (34,35) grew an aquatic biofilm consortium in drinking water and followed the initial attachment of pioneer organisms and the subsequent maturation of biofilm consortia on various metal and plastic substrata. Of note, *P. aeruginosa* was present in very low numbers in the original inoculum but was enriched in immature biofilms developing on polypropylene and polyethylene surfaces after one day (Table 3), and in more mature biofilms developing on stainless steel after 21 days (Table 4).

This study also showed that a range of HPC microorganisms could be isolated and cultured from the biofilms, including pseudomonads such as *P. acidovorans*, *P. diminuta*, *P. fluorescens*, *P. maltophila*, *P. mendocina*, *P. stutzeri*, *P. testosteroni*, *P. vesicularis*, *P. xylosoxidans*, and the related *Sphingomonas paucimobilis*.

Until recently, *Burkholderia cepacia* was classified as *Pseudomonas cepacia* because of phenotypic and morphological similarities to the *Pseudomonaceae*. It also is an opportunistic pathogen, similar to *P. aeruginosa*, and can cause biofilm-like infections in cystic fibrosis patients and in catheterized patients (36). It is commonly isolated from soil but is little studied in the aquatic environment. *Burkholderia cepacia* can be isolated from drinking water (37) and a survey of 85 public and private buildings in the province of Bologna (Italy) recovered it in low numbers from 3.5% (mean value = 1 cfu/100 mL) of the samples (38). Interestingly, *B. pseudomallei*, another opportunistic pathogen of man, which causes the fatal melioidosis in endemic areas of Southeast Asia and northern Australia (39), was recovered in high numbers (mean value = 578 cfu/100 mL) in about 7% of samples. *Burkholderia cepacia* has been isolated from the biofilm slime produced in paper mills, running typically at a temperature of 45 to 50 °C and at pH 4.5 to 5 (40), and in a subsequent study it was shown to form slime-producing biofilms on glass and stainless steel coupons (41). When inoculated into sterile water in a PVC pipe, it quickly formed a biofilm and viable bacteria could still be recovered after seven days of exposure to 10 to 15 ppm chlorine. These data suggest that the opportunistic *Burkholderia* spp. may therefore pose a waterborne risk to humans, possibly associated with the biofilm reservoir.

Legionellae

Legionella pneumophila was first recognized, and named accordingly, following an outbreak of a mysterious and deadly pneumonia that affected attendees of an American Legion convention in Philadelphia in 1976 (42,43). The source of the outbreak was *Legionella* bacteria in aerosolized water droplets originating from an air-conditioning system. Legionellosis is actually a group of respiratory diseases caused by legionellae, comprising: Legionnaires disease, an acute fulminating pneumonia with a low attack rate but causing approximately 12% fatalities; Pontiac fever, a mild, nonpneumonic fever with a high attack rate which was first recognized to have occurred at the County Health Department, Pontiac, in 1968 (44); and Lochgoilhead fever, a mild nonpneumonic,

atypical infection causing breathlessness and a long fever which was caused by *L. micdadei* at the Lochgoilhead leisure complex in Scotland in 1987 (45).

The *Legionella* genus includes 43 valid species, about half of which are linked to human illness. *Legionella pneumophila*, the principal etiological agent of Legionnaires' disease, causes 4 to 20% of cases of community-acquired pneumonia and has been ranked as the second or third most frequent cause of pneumonia requiring hospitalization. However, because of difficulties isolating this bacterium from infected individuals and of treatments that eradicate it before its presence can be verified, this figure may underestimate the pathogen's prevalence. The *L. pneumophila* species includes 16 serogroups, all of which are associated with disease, but serogroup 1 appears to be the most important, causing 50% of all *L. pneumophila* infections. *Legionella pneumophila* is a facultative intracellular parasite of both protozoa and human alveolar macrophages and is ubiquitous in aquatic environments. It typically infects man following inhalation of aerosols generated by devices such as air-conditioning systems, cooling towers, spas, showerheads, and grocery mist machines (46). *Legionella* does not transmit laterally in the human population, and is therefore considered to be an accidental or opportunistic pathogen of man and may be an occasional pathogen of other mammals, such as calves. Thus, legionellae may not have caused appreciable disease until after modern society invented such devices to provide the means for transmitting this natural parasite of amoebae into humans.

In terms of its ecophysiology, *L. pneumophila* is found in natural, industrial, domestic water systems and can survive high temperatures and low pH. It can be isolated from natural waters between 5 and 63 °C and multiplies between 20 and 45 °C (47). It is incapable of growth in sterile water and obtains its nutrient source from sludge and rust deposits, algae, amoebae, and bacteria in biofilms (9,48–50). Without question, legionellae are biofilm species. The engineering practices that have encouraged its dissemination include poor design and operation of calorifiers and water supplies with long runs and dead legs, inappropriate use of disinfectants such as chlorine, poor control of aerosol generation by cooling towers, showers, taps, recirculating spas, and humidifiers, and inappropriate selection of construction materials. The involvement of many of these parameters in proliferation of legionellae becomes clear from experiments using the chemostat biofilm model. It was demonstrated that biofilms of high species diversity could be generated reproducibly for many months on a range of plastic and metal materials immersed in medium hard potable water at 30 °C (Tables 3–5) (34,35). *Legionella pneumophila* was able to colonize these materials which are commonly used in cold or warm potable water supplies, including mild steel, stainless steel, polypropylene, polyethylene, unpolymerized polyvinyl chloride (uPVC), chlorinated polyvinyl chloride (cPVC), and the jointing compounds, latex and ethylene–propylene copolymer. The use of in situ immunogold labeling and EDIC microscopy clearly identified the presence and location of the legionellae in the biofilm (Fig. 5; 9). It is noticeable that they grow as distinct microcolonies within specific zones of the heterogeneous biofilm, the stacks or fonds, in which there are large numbers of respiring heterotrophs present. There is no evidence of amoebae having been present, again supporting several lines of data that indicate that legionellae can grow freely in biofilms. In the image shown, the biofilm was grown in a hard potable water with a high calcium carbonate content. The biofilm physicochemistry catalyzed the deposition of scale within the biofilm, thereby affecting its structure and probably resistance to heat and disinfection.

This colonization of a range of plumbing materials may be partly related to the fact that plastic and rubber materials can actively encourage the growth of microorganisms (51,52). Such materials can contain alkyl phthalates as plasticizers, butylated hydroxytoluene as antioxidant, stearates as lubricants, and thioethers as heat stabilizers. Indeed, *L. pneumophila* was also able to colonize the biofilm formed on bitumen-painted iron pipe used for distribution supplies at 25 °C, which may have provided a useful supply of organic nutrients

Table 5. Comparison of Plumbing Materials to Support Biofilm Formation and Colonization of *Legionella pneumophila* in Medium Hard Water at 30 °C

	Maximal Colonization[a]		Colonization Ratio	
Materials	Non-legionellae	*L. pneumophila*	Non-legionellae	*L. pneumophila*
Copper (aged)	70	0.7	1	1
Glass	150	1.5 (1%)	2.1	2.1
Polybutylene	180	2.0	2.6	2.9
Stainless steel	210	10 (5%)	3.0	14.3
Polyethylene	960	23	13.7	33
uPVC	1,070	11	15.3	15.7
cPVC	1,700	78.5 (5%)	24.3	112.1
Steel	4,900	450 (9%)	70	642
Ethylene–propylene	27,000	500 (2%)	386	714
Latex	89,000	550	1,271	785

[a]Colonization units are 10^3 cfu cm^{-2}. The colonization ratio is the cfu of the total microbial flora or legionellae recovered from each material referred to the copper data.

Note: Figures in parentheses represent the percentage of the total culturable microflora identified as *L. pneumophila*.

Source: Data compiled from Rogers and coworkers (34,35).

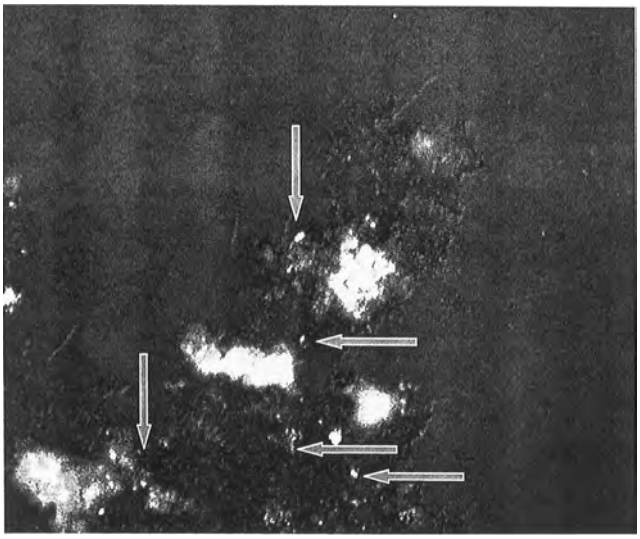

Figure 5. Episcopic differential interference contrast image of immunogold-labeled *L. pneumophila* in an autochthonous biofilm stack developed in hard potable water. The arrows mark microcolonies of cells. Large areas of lighter colored material are deposited calcium carbonate scale. *Source:* From Rogers and Keevil (9). See color insert.

Table 6. Colonization of Plumbing Materials by Aquatic Flora and *Legionella pneumophila*

Temperature	Material	Microflora	*L. pneumophila*
20 °C	Copper	2.2×10^5	0
	Polybutylene	5.7×10^5	665
	PVC	1.8×10^5	2,130 (2%)
40 °C	Copper	8.1×10^4	2,000 (2%)
	Polybutylene	1.2×10^6	112,000 (10%)
	cPVC	3.7×10^5	68,000 (18%)
50 °C	Copper	2.3×10^4	0
	Polybutylene	3.2×10^6	890
	cPVC	1.2×10^5	60
60 °C	Copper	4.5×10^2	0
	Polybutylene	4.3×10^4	0
	cPVC	5.2×10^3	0

Note: Figures in parentheses represent the percentage of the total culturable microflora identified as *L. pneumophila*.
Source: From Rogers and coworkers (35).

either directly to the legionellae or indirectly to the biofilm consortium which then produced secondary metabolites (2,53). Mild and stainless steels probably encourage proliferation of *L. pneumophila* in aquatic biofilms, in which its proportion of the total culturable flora increased from typically 1 to 9%, because the pathogen has a high requirement for iron (54,55). Fortunately, however, *L. pneumophila* is sensitive to copper and can only colonize biofilms on aged copper surfaces in low numbers (Table 6) (34,35). Although the total heterotrophic biofilm microflora on copper decreased by 70-fold compared to mild steel, the legionellae decreased over 600-fold. This effect of copper was also noticeable at different growth temperatures. Thus, there were no legionellae detected in biofilms on copper at 20 °C, whereas significant numbers were present on polybutylene and cPVC. Maximum colonization occurred at 40 °C when low numbers of legionellae were detected in biofilms on copper but very high numbers occurred on the two plastic materials. The proportion of the total culturable flora recovered as legionellae increased from less than 2% on copper to 18% on cPVC, a significant enrichment. Nevertheless, higher numbers of legionellae were recovered in biofilm on polybutylene because this material also supported threefold more biofilm than cPVC. Some codes of practice recommend that hot-water systems be maintained at temperatures greater than 50 °C to suppress survival of legionellae. This practice would seem to be acceptable where copper materials have been installed but significant numbers of legionellae were still recovered from biofilms on polybutylene and, to a lesser extent, cPVC. Consequently, it would seem more appropriate to operate hot-water systems at higher temperatures. In support of this conclusion, no legionellae were detectable in the scant biofilms grown on any of the three materials at 60 °C. These laboratory studies were subsequently supported by direct observations of plumbing pipework supplying water in German hospitals: only 2% of the copper surfaces recovered were found to contain any *L. pneumophila*, whereas 65 and 90% of polyethylene and iron surfaces, respectively, were positive for the pathogen (56). This again confirms the association of legionellae with iron surfaces and the inhibitory effects of copper surfaces, which would appear to be of benefit to the public health. The use of copper would be especially beneficial in the hospital environment in which many of the patients are immunocompromised and therefore more susceptible to infection by opportunistic pathogens.

Mycobacteria

Nosocomial outbreaks and pseudo-outbreaks caused by the nontuberculous mycobacteria (NTM), such as the *M. avium* complex, have been recognized for more than 20 years and continue to be a problem (57). The number of cases of pulmonary disease associated with *M. avium* is rapidly increasing and is approaching the incidence of *M. tuberculosis* in some areas. *Mycobacterium avium* is an environmental microorganism that is adapted to live both in the environment (mainly in water and soil) and in birds, fish, and mammal hosts. In humans, *M. avium* infection is seen in immunosuppressed patients, such as those with chronic lung disease and acquired immunodeficiency syndrome. For the latter, *M. avium* infection is a major cause of death (58,59). More recently, other populations were shown to be at risk of developing *M. avium* disease. For the majority of time, humans acquire *M. avium* through the intestinal tract in which the bacterium comes in contact with and translocates across the intestinal mucosa (60). However, some mycobacteria are easily aerosolized from water (61) and inhalation of aerosolized particles is also an important cause of pulmonary disease (62). Recently, five healthy people developed respiratory illnesses characterized by bronchitis, fever, and "flulike" symptoms after using a hot tub with water containing *M. avium* (63). The symptoms

and the results of investigations were more suggestive of a hypersensitivity pneumonitis than of an infection.

The reservoir for *M. avium* outbreaks is generally municipal and (often separate) hospital water supplies. For example, NTM were recovered from 12 (92%) of 13 reservoirs, 45 (82%) of 55 homes, 31 (100%) of 31 commercial buildings, and 15 (100%) of 15 hospitals in Los Angeles (64). The mycobacterial species involved are very hardy, able to grow in municipal and distilled water, thrive at temperatures of 45 °C or above, and resist the activity of organomercurials, chlorine, 2% concentrations of formaldehyde, and alkaline glutaraldehyde, and other commonly used disinfectants (57). The high number of *M. avium* isolates recovered from hospital water and their close relationship with clinical isolates suggests the potential threat of nosocomial spread. Indeed, it was concluded that potable water is an important source for the acquisition of *M. avium* infections (64). This has since been supported by research which showed that environmental and patient isolates of *M. avium* were resistant to chlorine, monochloramine, chlorine dioxide, and ozone in potable water (65). For chlorine, the product of the disinfectant concentration (in parts per million) and the time (in minutes) to 99.9% inactivation for five *M. avium* strains ranged from 51 to 204. Indeed, water-grown cells were 10-fold more resistant than nutrient-medium-grown cells.

Mycobacterium avium subspecies *paratuberculosis* (Map) is the causative organism of Johne's disease, a chronic enteritis of cattle that can also affect many animals, including rabbits, mice, rats, deer, antelope, mountain goats, camels, alpaca, and bison (66). Map has also been suggested as an etiological agent of Crohn's disease, a chronic inflammatory disease of the gastrointestinal tract of humans. Concern is growing that Crohn's disease may be associated with infection by Map ingested through not only improperly heat-treated milk but also contaminated water (67). However, the isolation of this pathogen is complex and time consuming, taking several months for culture, and there are little data about its distribution in the aquatic environment, treated water systems, or ability to colonize biofilms. In one study, the organism was believed to have been spread by standing water that was used by elk calves as a wallow and a source of drinking water (68). The water was believed to have been contaminated by an infected adult female elk introduced to the herd just before calving season.

There is scant evidence that nontuberculous bacteria form biofilms, but laboratory studies with the opportunistic pathogens, *M. fortuitum* and *M. chelonae* have shown that this is possible in high density polyethylene tubes used for water distribution (69). In a survey of water treatment plants and domestic water systems in Germany and France, mycobacterial species were found in 90% of the 50 biofilm samples taken (70). Their densities usually ranged between 10^3 and 10^4 cfu cm^{-2} (maximum density 5.6×10^6 cfu cm^{-2}). Organic substances such as plastics and rubber were usually colonized by larger numbers of mycobacteria than inorganic substances such as copper and glass. The authors suggested that mycobacteria are ubiquitous in biofilms and that solid–liquid interfaces, particularly plastic surfaces, may select for mycobacteria. In another study, *M. chelonae* was inoculated into PVC pipes containing sterile water and found to form biofilms after eight weeks (33). Of concern, viable organisms could still be recovered after seven days of treatment with 10 to 15 ppm chlorine. Fortunately, some mycobacteria are susceptible to dissolved copper salts (71), which might suggest that they will also be inhibited in biofilms on copper tube. Given the increasing threat of mycobacteria to public health, this possibility should now be investigated urgently.

ALLOCHTHONOUS BIOFILM PATHOGENS

Aeromonads and Indicators of Fecal Pollution

The presence in potable water of coliform bacteria in general, and *E. coli*, in particular, is a public health concern because it is assumed that these organisms are there as a result of fecal contamination of human or animal origin. Their presence is believed to be owing to (*1*) a loss of residual disinfectant (e.g., chlorine); (*2*) backsiphonage, cross-connections, line breaks, and/or repair of the distribution main; (*3*) survival and recovery of injured organisms; or (*4*) failure of the treatment plant (53). The presence of coliforms in drinking water, when there are no known breaches in treatment barriers, and the presence of these organisms in the absence of any evidence of fecal contamination, continues to be a major problem for the water industry, and has emerged as a critical regulatory issue. The chronic presence of coliform bacteria in drinking water supplies is characterized by: the absence of coliforms from water that leaves the treatment plant; the routine presence of coliforms in distribution supply samples at various points; the persistence of coliforms in the system despite the maintenance of a disinfectant residual that is assumed to be effective; and the persistence of the problem over a long time. *Escherichia coli* has attracted the greatest interest as an indicator of the microbiological quality of water, but other bacteria have recently been considered as waterborne pathogens. For example, aeromonads are ubiquitous in freshwater environments and *A. hydrophila* is being increasingly recognized as an etiological agent of gastrointestinal disease associated with chlorinated water supplies (72). Aeromonads are sometimes also associated with wound infections.

The possibility that coliforms and aeromonads can become part of the biofilm community, and show regrowth or aftergrowth, was investigated using the continuous culture model (53). Bitumen-painted mild steel is a material used for the construction of many potable water distribution supplies in the United Kingdom. Heterotrophic biofilms were developed on tiles of this material in potable water at 5, 15, and 25 °C and dilution rates of 0.1 and 0.2 $hour^{-1}$; these were challenged with *E. coli* and *A. hydrophila* isolated from distribution supplies. These organisms established in the planktonic population, become rapidly incorporated into the biofilms and survived many weeks at approximately 1% of the population (Table 7). Monochloramine has been advocated as a superior disinfectant for potable water systems rather than chlorine, owing to greater longevity in long distribution supplies with a high chlorine demand and

Table 7. Effect of Monochloramine on Colonization of a Heterotrophic Biofilm on Bitumen-Painted Mild Steel by *Aeromonas hydrophila* and *Escherichia coli*

Time (days)	Heterotrophs	*A. hydrophila*	*E. coli*
1	6.1 (4.9)	4.8 (3.3)	5.6 (2.8)
4	5.8 (5.9)	3.3 (3.0)	5.0 (5.1)
7	4.9 (5.3)	3.7 (4.3)	3.4 (4.6)
14	5.8 (5.6)	3.8 (4.2)	3.3 (4.2)
21	5.6 (5.3)	3.8 (4.5)	3.1 (4.3)

Note: The biofilm viable counts are expressed as $\log_{10}$ cfu cm^{-2}. Cultures were grown aerobically at 25 °C at a dilution rate of 0.2 h^{-1}. Values in parentheses indicate viable counts after addition of monochloramine to the culture medium at a concentration of 0.3 mg L^{-1}.
Source: From Mackerness and coworkers (53).

suggested ability to penetrate biofilms (16,17). When monochloramine was added to the model system at 0.3 mg L^{-1} (a concentration regularly used by water suppliers), there was no decrease in the biofilm viable counts although *E. coli* was eliminated from the aqueous planktonic phase. Rather, the numbers of *E. coli* and *A. hydrophila* recovered from the biofilms rose slightly. Higher concentrations of monochloramine were required for their eradication. Thus, *E. coli* and *A. hydrophila* can become part of the autochthonous heterotrophic biofilm and resist chemical disinfection. Subsequently, Block and coworkers (73) were able to show that their isolate of *E. coli* could grow slowly in an autochthonous biofilm on the pipework of a large-scale model distribution water supply operating at 20 °C and a residence time of 24 hours, producing an erratic transient colonization. The variable growth rate, initially 14 days but then decreasing, was related to the availability of biodegradable organic matter in the water and that provided by the biofilm.

Attempts to control dissemination and regrowth of pathogens and indicator bacteria in potable water through the use of oxidative disinfectants such as chlorine or ozone have led to subsequent biofilm problems. This is because these disinfectants oxidize refractory carbon to assimilable organic carbon (AOC), which fuels biofilm growth. Van der Kooij (74) has suggested that AOC concentrations of greater than 10 μg L^{-1} enable growth and biofilm formation in potable water systems. The implication of these findings is that it is essential to maintain low AOC concentrations for water in distribution to prevent regrowth and the multiplication of indicator bacteria and potential pathogens such as *Legionella*, *Aeromonas*, and *Pseudomonas* spp. With ozonation treatment of potable water becoming widespread, oxidizing refractory dissolved organic carbon to AOC, it is essential to install something like granular activated carbon and/or sand filtration to reduce the AOC postozonation.

Van der Kooij (75) demonstrated that aeromonads can utilize a wide range of low molecular weight compounds, including amino acids, carbohydrates, and long-chain fatty acids at a concentration of a few micrograms per liter. The concentration of substrates available in drinking water was usually below 10 μg Cl^{-1} and the autochthonous bacteria utilized these substrates more rapidly than the aeromonads. The multiplication of aeromonads in drinking water during distribution was therefore explained by their growth on biomass components in the biofilm and in sediments in the pipes.

Studies by Packer and coworkers (76) showed that *K. oxytoca* can also persist in the biofilm model of water distribution systems for several weeks at a temperature of 20 °C, irrespective of the chemistry of the source waters used for growth. Although there was a gradual decline in the numbers of klebsiellae which could be recovered from the model by culture, the decline was much less than that predicted by the theoretical wash-out rate of the chemostat system (for a review, see Keevil (10)). Thus, slow growth must have occurred. Similarly, a *Klebsiella* sp. was enriched in an autochthonous biofilm formed on latex substrata in potable water at 30 °C: yet this coliform was only present in very low numbers in the inoculum (34). Camper and coworkers (77) used staining with fluorescent antibody conjugates to show that *K. pneumoniae* could also exist as discrete microcolonies on the surface of biofilms generated in potable water. The inoculum growth rate had a dramatic effect on the ability of coliforms to remain on surfaces. The most slowly grown coliforms ($\mu = 0.05$ $hour^{-1}$) survived in the highest concentrations. Both coliforms and HPC bacteria were supported in larger numbers on a reactive substratum, mild steel, than on polycarbonate. Consequently, the occurrence of coliforms in a distribution supply or building plumbing system which has no fecal contamination might be because of the detachment of these organisms from the biofilm, from where they can be transported around the system and colonize new sites. The only course available for their control by the supplier is to use a residual disinfectant that persists and is nontoxic to man. The biofilm model system is ideal for deciding which disinfectant is the most appropriate under the conditions of use. For example, *A. hydrophila* is more susceptible to eradication with a low dose of monochloramine at 5 or 15 °C rather than warmer temperatures.

The ability of opportunistic pathogens such as *A. hydrophila* or *P. aeruginosa* to colonize and persist in high species diversity autochthonous biofilms may be related to the production of quorum-sensing AHLs (78–80). This population-dependent cell-to-cell communication was classically shown in the marine endosymbiont, *Vibrio fischeri*, to involve the LuxR/LuxI family of proteins, which are responsible for diffusible 3-oxohexanoyl-L-homoserine lactone signal response and synthesis for controlling light production in response to high cell density (81). In *P. aeruginosa*, two quorum-sensing regulons have been identified in which the LuxR homologs LasR and RhlR are activated by diffusible *N*-(3-oxododecanoyl)-L-homoserine lactone (3-oxo-C_{12}-HSL) and *N*-butanoyl-L-homoserine lactone (C_4-HSL), respectively. The *lasR* and *rhlR* genes are linked to the *luxl* homologs *lasl* and *rhll*, which are responsible for synthesis of 3-oxo-C_{12}-HSL and C_4-HSL, respectively; *lasRl* and *rhlRl* are both involved in regulating the expression of several virulence factors, including elastase and rhamnolipid (82). In *A. Hydrophila*, the Lux homologs are AhyR/AhyI (80). The key signal is C_4-HSL, whereas *N*-hexanoyl-L-homoserine

lactone (C_6-HSL) plays a minor role. For coordinate gene expression at high cell density *ahyI* transcription requires AhyR and C_4-HSL (i.e., a positive feedback loop). Indeed, putative virulence determinants such as extracellular protease are regulated by C_4-HSL quorum sensing (83). The roles of AhyR, AhyI, C_4-HSL, and C_6-HSL in biofilm formation were defined in a study by Lynch and coworkers (80), which showed that wild type *A. hydrophila* formed normal biofilms on stainless steel substrata. However, an *ahyI* mutant was impaired in its ability to form biofilms but this ability was restored upon addition of exogenous C_4-HSL. Long-chain analogs, such as *N*-(3-oxodecanoyl)-L-homoserine lactone (3-oxo-C_{10}-HSL), induced the sloughing off of established biofilms. Therefore, *A. hydrophila* may respond to quorum-sensing cross-talk between different species by preferentially colonizing biofilm microenvironments in which there are appropriate concentrations of C_4-HSL but not 3-oxo-C_{10}-HSL.

Similarly, another marine *Vibrio*, *V. harveyi* possesses two parallel quorum-sensing systems, and each is composed of a sensor-autoinducer pair (81). *V. harveyi* reporter strains capable of detecting only autoinducer 1 (AI-1) (β-hydroxybutyl homoserine lactone) or autoinducer 2 (AI-2) have been constructed and used to show that many species of bacteria, including *E. coli* MG1655, *E. coli* 0157 : H7, *Salmonella typhimurium* 14028, and *S. typhimurium* LT2 produce autoinducers similar or identical to the *V. harveyi* system 2 autoinducer AI-2 (84). The genes responsible for AI-2 production in *V. harveyi*, *S. typhimurium*, and *E. coli*, called *luxSV.h.*, *luxSS.t.*, and *luxSE.c.*, respectively, are highly homologous to one another but not to any other identified gene. The *luxS* genes define a new family of autoinducer-production genes and that AI-2 is probably a furanone arising from secondary metabolism of *S*-adenosyl methionine. This again suggests that colonization of biofilms by a coliform is influenced by both its own physiological state and its response to that of the cell density controlled autochthonous microflora in a particular biofilm microenvironment, involving intraspecies and interspecies communication (81).

One approach to studying the physiology of *E. coli* in biofilms in situ utilized a strain containing a *lacZ* reporter linked to the *nirB* promoter (85). This promoter is susceptible to low oxygen concentrations and it was possible to see β-galactosidase expression identifying a mosaic of microenvironmental niches of low oxygen concentration in the biofilm in which the *E. coli* colonized (Fig. 6). The location of all of the *E. coli* bacteria was identified by measuring the glucuronidase activity, expressed by the *gusA* gene, with a fluorogenic substrate. The work confirmed the ability of *E. coli* to persist in waters of different chemistries and that the regions of lowest oxygen concentration and redox potential are in and closely adjacent to the biofilm stacks. This is presumably because of the concerted respiratory activity of the heterotrophic autochthonous microflora. It will be intriguing to ascertain the effects of lox oxygen concentration on the production by nontoxigenic and toxigenic *E. coli*, or possibly members of the autochthonous biofilm flora, of the important secondary metabolite involved in quorum sensing, AI-2, discussed earlier.

Verocytotoxigenic *E. coli* 0157

Verocytotoxic *E. coli* (VTEC), most significantly serogroup 0157, is a particularly *nasty organism* (86). The bacterium is present as part of the normal flora of domesticated animals but is able to attach to enterocytes in the large intestine of man, colonize and efface the microvilli, and produce verocytotoxins (VT1 and/or VT2 and its variants) (87). In many patients it may cause hemorrhagic colitis, with a characteristic bloody diarrhea, and the toxins enter the bloodstream to target the kidneys. In 10% of cases, infection can lead to hemolytic uremic syndrome (HUS) or thrombotic thrombocytopenic purpura. These conditions may result in kidney failure in the young or stroke in the elderly. Indeed, the majority of cases of all renal failure in children are the result of HUS (88). The mortality rate is less than 10% in young children, but as high as 50% in elderly patients. Many patients require long-term kidney dialysis.

Outbreaks of have been associated with consumption of inadequately cooked minced beef, milk, yoghurt, cheese, cooked meats, meat pies, dry cured salami, raw vegetables, unpasteurized apple juice, and water (89). The waterborne outbreaks of *E. coli* 0157 include 20,000 cases in Swaziland in 1992 and 243 cases (four deaths) in Cabool, Missouri, in 1989 (90), 1,000 cases (two deaths) near Albany, New York,

in 1999 (91), and 2,000 cases (seven deaths) in Walkerton, Canada, in 2000 (92). This raises concern that the pathogen may survive long enough in feces-contaminated soil to wash into surface waters in which it could pollute potable water supplies, recreational waters, or water used for crop irrigation. Indeed, VTEC have been found to occur in significant numbers in rivers (93) and outbreaks have been described involving swimming in recreational lakes or pools in Europe and the United States (94,95). Recently, it has become clear from European and American studies that private and/or untreated drinking water supplies represent a significant risk for transmission of *E. coli* 0157 from fecal ingress, and several outbreaks have been described in Scotland and the United States (96–98).

Studies similar to the work described earlier with nontoxigenic coliforms have shown that *E. coli* 0157 : H7 is able to persist for many weeks in chemostat model systems receiving a continuous flow of a soft potable water at 10, 20, or 40 °C (99). This water type is typical of an upland catchment supply. The lower temperatures are representative of water supplied to buildings in moderate or hot seasons, the higher temperature reflecting poorly heated hot water supplies or those with poorly insulated pipes. Of note, *E. coli* 0157 was able to colonize biofilms of high species diversity and persist for several weeks at the lower temperatures (Table 8). Significantly higher numbers were detected in the biofilms on plastic pipework compared to copper or stainless steel. Similar results have now been obtained using moderately hard and hard potable waters. This suggests that the type of plumbing material used for supplying poorly treated water to the home or factory is important, and that use of copper pipe might confer some public health benefit by reducing pathogen persistence in biofilms. Another study has shown that *E. coli* 0157 will form a biofilm and grow on the walls of bottled water (100). These studies support the available epidemiological evidence that private water supplies with inadequate disinfection treatment, supplying tap or bottled water, may be at particular risk of harboring and transmitting *E. coli* 0157 (98).

Campylobacters

Current epidemiological evidence suggests that *C. jejuni* is the major cause of human gastroenteritis worldwide, responsible for 400 to 500 million cases of diarrhea each year (101). Of great significance, *Campylobacter* can also cause reactive arthritis and Guillain-Barre syndrome, which can result in paralysis and death. This important zoonosis is spread through contact with pets or consumption of raw milk and contaminated meat, particularly poultry. However, it also survives sufficiently well in untreated and inadequately treated aquatic environments to cause human disease. Survival in the water systems of animal husbandry facilities and animal processing units has also been suggested to promote infection in animals and cross-contamination of animal carcasses (102). Using the two-stage continuous culture biofilm model supplied with potable water, Buswell and coworkers (103) were able to show that several different isolates of the pathogen colonized the autochthonous high species diversity biofilm. These strains persisted, as measured by culture, for up to 4 weeks at 4 °C. Increasing the temperature to 30 °C reduced their persistence to less than 10 days, but this was considerably in excess of the 1 to 2 days observed in the absence of an autochthonous biofilm flora in preliminary sterile batch microcosm studies. Reducing the oxygen concentration generally improved the culturability of the strains. The influence of carbon concentration on the persistence of *C. jejuni* in biofilms was investigated by adding a low concentration of serine typical of reported lower and upper limits of carbon and amino acid load reported in surface water (5 nM and 5 μM). The addition of increasing concentrations of serine progressively reduced the persistence of the isolate by up to 50%. Conversely, the biomass of the autochthonous biofilm flora increased, indicating that the population had previously been carbon or possibly nitrogen limited. Buswell and coworkers (103) speculated that the balance of nutrients is likely to change the competitive interactions between the autochthonous flora, and intensify competition for other limiting nutrients that may be detrimental to the persistence of nutritionally fastidious campylobacters.

Initial surface colonization and structural development of either environmental or clinical biofilms is partly dependent on several types of cell–cell interaction between different pairs and groups of bacteria. For example, strong parallels exist between the early work of Kolenbrander (104) on coaggregation between dental plaque species and the autochthonous members of aquatic biofilms. Pairs of water isolates coaggregated to form visible flocs of various sizes (105). One strain coaggregated with every other strain tested, suggesting the possibility of it forming multigeneric coaggregates, and a role for this strain as a bridging organism, similar to that proposed for *Fusobacterium* and *Prevotella* in dental plaque. Indeed, Buswell and coworkers (105) were able to show varying degrees of coaggregation between *C. jejuni* and members of the autochthonous biofilm flora. Coaggregation scores were generally low with the pathogen but this is unlikely to reflect the strength of the interaction, just the size and density of the aggregates formed.

The potential for *C. jejuni* to coaggregate with members of the autochthonous biofilm flora was visualized directly using 16S rRNA probes. These have been used successfully to study biofilm structures, including cell–cell associations, and the detection of pathogens therein (106–108). Similarly, *C. jejuni* was tracked in the biofilm stacks using

Table 8. Colonization of *Escherichia coli* 0157 (Human Isolate PS 14) Survival in Potable Water Biofilms Formed on Different Materials at Temperatures Typical of Cold and Warm Water Supplies

Temperature (°C)	Glass	Copper	Stainless Steel	Polybutylene
10	+	+	++	+++
20	+	+	++	+++
40	+	+/–	+	+++

Note: +/– denotes little or no colonization; + denotes light colonization; ++ denotes good colonization; +++ denotes heavy colonization.

a fluorescently labeled *Campylobacter*-specific 16S rRNA probe in conjunction with a differently labeled eubacterial probe to simultaneously visualize the rest of the biofilm flora. Use of fluorescence in situ hybridization with the 16S rRNA oligonucleotide probes demonstrated an extended association of the pathogen with the biofilm up to the time when the experiments were terminated, that is, 28 days at 30 °C and 42 days at 4 °C (103). This was long after the *C. jejuni* had ceased to be culturable. It was clearly associated with the microcolonies of the biofilm stacks, suggesting that it was incorporated within the biofilm matrix (Fig. 7). This location was probably preferred to obtain secondary metabolites from the biofilm consortium and also seek a lower oxygen, lower redox environments to suit its microaerophilic physiology. At 4 °C the *C. jejuni* were predominantly spiral shaped and contained an higher 16S rRNA content than the predominantly coccoid cells found at 30 °C. This may indicate that they became viable but nonculturable (VBNC) at the lower temperatures and persisted for many weeks in the biofilm.

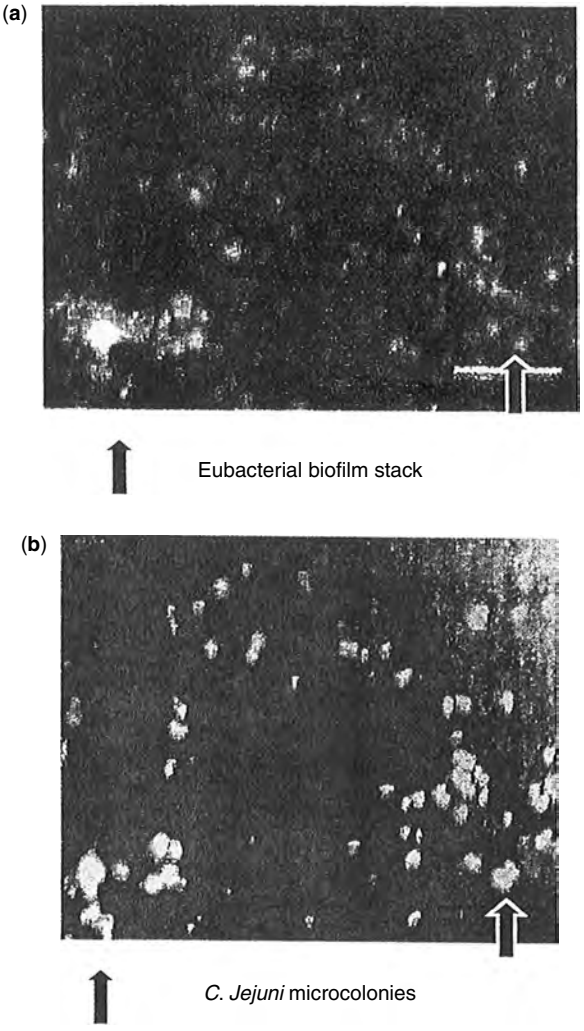

Figure 7. Detection of eubacteria (**a**) and *C. jejuni* (**b**) in biofilm stacks using fluorescence in situ hybridization with 16S rRNA oligonucleotide probes. *Source:* From Buswell and coworkers (103). See color insert.

Therefore, despite the sensitivity of *C. jejuni* to environmental stress, its persistence in a culturable form in aquatic biofilms can be sufficiently long for this to provide an important reservoir for transmission of the pathogen. The significance of a more extended persistence in a nonculturable form, with the possibility of an infectious VBNC state (109), has further consequences for long-term persistence, pathogenicity, and our ability to detect and control it easily.

Helicobacters

Campylobacter jejuni is closely related, both phylogenetically and physiologically, to the emerging pathogen, *H. pylori*, the causative agent of stomach ulcers. This microaerophilic pathogen is also involved with several gastrointestinal diseases including type B gastritis (110), gastric ulcer and mucosa-associated lymphoid tissue lymphoma, and gastric adenocarcinoma (111). In Western countries, rates of infection are as high as 60% by age 65, whereas in developing countries the prevalence of infection can be as high as 90% by 20 years of age (112). However, although the presence of *H. pylori* in the natural environment has also been demonstrated in a number of studies, similar to *C. jejuni*, its route of infection into humans is unknown. Recent research has found *H. pylori* in Peruvian drinking water (113) and the U.S. EPA have shown this pathogen to have a threefold greater resistance to chlorine than *E. Coli* (114). In a region of Japan with a high infection rate, *H. pylori*-specific DNA was detected in tap and well water, field soil, flies, and cow feces by nested polymerase chain reaction, and the *ureA* gene alignments were closely homologous to those of established clinical isolates (115). The detection of *H. pylori* in local water supplies in Canada may indicate a natural reservoir for the organism or possible contamination from human sewage (116). As *H. pylori* is an emerging pathogen associated not only with peptic ulcers but also gastric cancer (117), there is an urgency to understand its possible dissemination and methods of control in drinking water. Pure cultures of *H. pylori* appear able to form biofilms, particularly hydrophobic biofilms at the air–liquid interface of nutritious culture media (118) but little is known about colonization of aquatic biofilms. In one study, Mackay and coworkers (119) adapted a method originally described by Mackerness and coworkers (53) to study fecal pathogens in water and biofilms. This consisted of a single-stage chemostat, growing an autochthonous flora obtained from a water treatment works prechlorination, which supplied a modified Robbins device containing stainless steel stud substrata. When this model was inoculated with a culture of *H. pylori*, the pathogen could subsequently be detected in the biofilms for up to 192 hours using polymerase chain reaction (PCR) analysis of the 16S rDNA and specific primers to amplify a 500 bp product. If the cells were first heat-inactivated, then *H. pylori* could not be detected in the biofilm, suggesting that incorporation into autochthonous biofilms requires the organism to be in a viable state. The authors did not report isolating the pathogen from the biofilms using conventional agar culture. Clearly, more work is required to determine if it can actually persist in a viable state capable of subsequent

sloughing into raw or improperly treated water to cause waterborne disease.

In support of these preliminary studies, Park and coworkers (120) have analyzed a section of cast iron mains distribution pipe removed from an urban environment in the north-east of Scotland during routine maintenance work. Immediately upon removal of the pipe section, the interior lumen was swabbed to remove the biofilm layer. Subsequent analysis for the presence of *Helicobacter* DNA using a nested PCR approach produced a positive result. These authors claim that these data provide the first evidence for the existence of *Helicobacter* in biofilms found in water distribution systems anywhere in the world.

Cryptosporidia

Ten valid species of the coccidian protozoan parasites, *Cryptosporidium*, are currently recognized, and capable of causing infection in animals and/or man (121). Awareness of the importance of the human parasite, *C. parvum*, has increased since it was first identified as a cause of human enteritis in 1976. Molecular studies show that there are at least two genetic subgroups of *C. parvum*, one found almost exclusively in man (genotype 1) and the other present in man, cattle, and a range of small mammals (genotype 2). Cryptosporidiosis is particularly severe and protracted in people with impaired immunity, but can cause several weeks of debility and watery diarrhea in immunocompetent people, including abdominal pain, sometimes with anorexia, vomiting, and fever (122). Surveys of stools carried out in developed countries have shown the prevalence of infection to be between less than 1 and 4.5%, and many infections are subclinical. Children under two years of age (and their carers), animal handlers, travelers, and homosexual men are particularly likely to be infected. Outbreaks have been associated with contact with animals, consumption of inadequately pasteurized milk, use of swimming pools, and contaminated water supplies. Indeed, 400,000 people were affected in a single outbreak in Milwaukee, Wisconsin, in 1993 because of contaminated drinking water (123). However, only 6.7 to 13.2 oocysts per 100 L of water could be detected, suggesting a low infectious dose and the need for vigilance and rigorous water treatment. The low infectivity was confirmed for three *C. parvum* isolates (Iowa [calf], UCP [calf], and TAMU [horse]) of the genotype 2 subgroup ingested by healthy adults. The 50% infectious dose (ID_{50}) was found to differ among the isolates chosen: Iowa, 87; UCP, 1,042, and TAMU, 9 oocysts (124). *Cryptosporidium parvum* is an obligate parasite and has a complex life cycle that is completed in one host (122). The transmissible stage is the 5-μm diameter round oocyst (spore). After ingestion each oocyst releases four motile sporozoites into the gut, primarily in the small bowel. The sporozoites attach to the gut wall and develop by two asexual stages, producing merozoites and a sexual stage producing zygotes, which sporulate to produce two types of oocysts. These stages develop just inside the outer walls of the cells lining the gut; the infection is intracellular but it is extracytoplasmic, that is, the protozoa do not penetrate deeply into the host's cells. Oocysts mostly sporulate within the gut and two types are produced. The thin-walled type releases more sporozoites in the gut (auto-infection) and the thick-walled types are excreted in feces in a fully infective form. They do not need any further maturation, unlike many other coccidian protozoa. Oocysts can remain viable for about 18 months in a cool, damp, or wet environment. They are quite common in rivers and lakes, especially where there has been sewage or animal contamination. Consequently, the source of oocysts is usually either insufficiently treated surface water or contamination of drinking water with surface water. The complete removal of *C. parvum* from water supplies is difficult, even for modern water treatment plants. The pathogen's oocyst appears resistant to high concentrations of chlorine-based disinfectants but more susceptible to ozone (125). The oocysts' small size means that they may pass through the filtration systems. Control measures include not using water sources polluted by runoff from land contaminated by animals or otherwise contaminated with manure or sewage; good maintenance and design of the filtration systems (flocculation and slow sand filtration appear the most useful technologies), and careful control of the treatment facility and processes.

The chemostat model has been used to show that the 5-μm diameter oocysts can survive in potable water biofilms for many weeks at 20 °C in an infectious state (13,126). The *C. parvum* oocysts were labeled with FITC-conjugated antibody and observed by EF microscopy to attach to 16–day-old potable water biofilm stacks that were visualized with the nucleic acid fluorophore, propidium iodide (Fig. 8). After 24 hours contact with the biofilms, oocysts adhered at a concentration of 14,000 oocysts cm^{-2} and maintained a high concentration in the biofilms over several months. When the oocysts were recovered from the biofilms after several months they were found to be still capable of excystation, indicative of viability, and could cause an infection in an animal model. Similar attachment data were obtained by White and coworkers (127) using a tri-species biofilm (*P. aeruginosa*, a *Bacillus* sp., and an *Acidovorax* sp.) developed on stainless steel surfaces in a flow cell supplied with

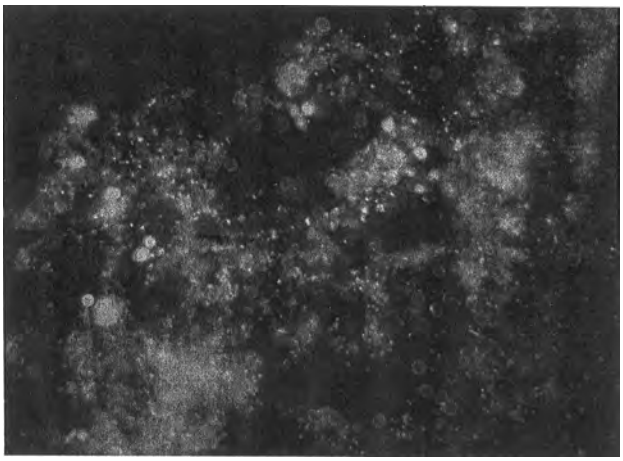

Figure 8. FITC-antibody-labeled *Cryptosporidium parvum* oocysts attached to potable water biofilm stacks stained with propidium iodide. *Source:* From Keevil and coworkers (13). See color insert.

potable water. When the system was challenged with *C. parvum*, the oocysts attached to the biofilm at twice the concentration compared to the bare surface without biofilm. The work of Rogers and Keevil (126) indicated that higher shear rates are required for removal of oocysts from the autochthonous biofilm and transient sloughing might explain the many sporadic cases of unknown origin, even long after previously contaminated source waters are considered safe. It was notable that biofilm-associated oocysts occurred in clusters; this would suggest that biofilm sloughing may release a small but effective dose of oocysts into the water system, which would also be difficult to detect by routine monitoring. The persistence of chlorine-resistant viable oocysts in the biofilm safe haven, therefore, presents an interesting challenge for the disinfectant industry and the safeguarding of the public health.

Enteroviruses

As discussed earlier, there has been little research on virus survival in biofilms. However, in one notable study, Quignon and coworkers (128) followed the survival of Poliovirus-1 pulsed into a 90-m-long pilot distribution system operating at a flow of 500 L hour^{-1}. Greater numbers of virus were recovered from the biofilm on the walls of the pipe than from the water flow; this was by a factor of 2 or 10 in the absence or presence of chlorine disinfectant, respectively. Consequently, this would suggest a tendency for virus accumulation within biofilms and protection of viral pathogens from disinfectants such as chlorine.

BIOFILM SAFE HAVEN

Extracellular Survival

It is now abundantly clear that biofilms provide an environment for autotrophic and heterotrophic microorganisms, to consort together, and grow in ordered communities. This is especially important in low nutrient aquatic environments and where carbon and nitrogen sources may be tied up in complex macromolecules such as humic and fulvic acids. Concerted metabolism provides an efficient breakdown of such complex, high molecular weight compounds and also releases secondary metabolites, which more fastidious species require (4,129,130). Indeed, we are still incapable of culturing many of the fastidious, unidentified species in biofilms now starting to be recognized through 16S rRNA analysis (131,132). Presumably, their nutritional and physiological requirements have evolved for life in the biofilm and we cannot yet provide these conditions for their growth as monocultures in the laboratory. For now they are considered viable but not culturable, but this should not be confused with the viable but unculturable state which describes a physiological transition to dormancy, perhaps akin to spore formation (109,133). Moreover, the heterogeneous mosaic structure of biofilms provides a safe haven, not only for essential nutrients but also to protect from extremes of physicochemistry, such as temperature, pH, and oxygen concentration, and antimicrobial substances such as heavy metals, disinfectants, and antibiotics. As discussed previously, this is not merely a physical protection but includes important physiological adaptations involving quorum sensing, oxidative stress OxyR and SoxR (134), and antimicrobial efflux MarA (135). Also of great importance is the general stress response with DNA supercoiling (136) and alternative RNA polymerase sigma factors coming into play (137) for upregulation of essential genes such as the heat shock molecular chaperones, DnaK, DnaJ and GrpE, and GroEL and GroES (138), the oxidative stress catalase, KatE, and osmotic shock, OsmY (139). The challenge will be to understand the complex interplay of all of these important regulators on biofilm physiology, which aids pathogen survival.

Intracellular Survival

It has been known for almost 20 years that *L. pneumophila*, the principal etiological agent of Legionnaires' disease, can survive intracellularly within cyanobacteria and a range of amoebae and other protozoa, including *Acanthamoeba*, *Naegleria*, *Hartmanella*, *Vahlkampfia*, and *Tetrahymena* spp. and *Dictyostelium discoideum* (49,140,141). Consequently, this provides another important mechanism which links survival of legionellae in the environment to biofilms through survival inside biofilm protozoal grazers. In some circumstances this endosymbiotic relationship not only affords protection against desiccation and disinfection, permitting widespread dissemination, but may also make the pathogen more virulent when inhaled by man (142,143). Following phagocytosis by amoebae, legionellae are able to multiply within the cytoplasm by evading the host lysosomal attack. After one or two days a single membrane vesicle of motile legionellae fills most of the trophozoite. The vacuole then lyses, liberating the pathogen back into the environment. Larger *Acanthamoeba* spp. can contain hundreds of legionellae in the infected vesicle before the lytic phase. The ability of *L. pneumophila* to grow in amoebae, other microorganisms, and lung macrophages, coupled with the early difficulties of first being able to isolate and grow this apparently fastidious pathogen, has led many to speculate that it is an obligate intracellular parasite. However, we have shown that this is not so: it is able to exploit the biofilm physicochemical heterogeneity to proliferate in the microaerophilic niches of the biofilm (85). In the absence of environmental hosts, it utilizes its considerable metabolic versatility (144) to grow on the consortium's secondary metabolites (9,34,35,145). This was finally confirmed by Surman and coworkers (25) who conclusively demonstrated that it is a facultative intracellular parasite when they grew the aquatic flora in the biofilm model in the presence of cycloheximide to eradicate all eukaryotic species. In these conditions, the numbers of legionellae actually increased by greater than 50-fold in the biofilms, indicating that classical predator/prey relationships might actually keep legionellae under control in a biofilm. Nevertheless, intracellular survival in amoebae is a useful evolutionary adaptation because it promotes extracellular survival by inducing a stress-resistant phenotype, characterized by altered morphology and envelope composition, increased resistance to antimicrobial agents, and induction of polyhydroxybutyrate as a carbon and

energy store for low nutrient environments (146,147). It may be no coincidence that in a survey of ground water, potable water, and whirlpools, 65% of the samples that contained legionellae also contained amoebae (148).

Mycobacterium avium is able to grow saprozoically on products secreted by the amoebae whereas *L. pneumophila* multiplied only in coculture (149). A comparison of amoebae infected with *L. pneumophila* and amoebae infected with *M. avium*, observed by electron microscopy, demonstrated that there were striking differences in the locations of the bacteria within amoebal cysts. Whereas *L. pneumophila* resided within the cysts, *M. avium* was found within the outer walls of the double-walled cysts of *Acanthamoeba polyphaga*. These locations may provide a reservoir for the bacteria when environmental conditions become unfavorable. Intra-amoebal survival and multiplication has been confirmed for ingested *P. aeruginosa*, *Burkholderia cepacea*, *Listeria monocytogenes*, *Vibrio cholerae*, *Edwardsiella tarda*, *Sarcobium lyticum*, and *Chlamydia* spp. (150–153). Intracellular survival, not necessarily with multiplication, has been shown with *Pseudomonas*, *Alcaligenes*, and *Bacillus* spp., *Aeromonas salmonicida*, *Yersinia enterolitica*, and *C. jejuini*, and coliforms including *E. coli*, *Citrobacter freundii*, *E. agglomerans*, *Enterobacter cloacae*, *K. pneumoniae*, *K. oxytoca*, *Shigella sonnei*, and *S. typhimurium* (149,154,155). Recently, Barker and coworkers have reported that *E. coli* 0157 is also capable of surviving ingestion by *Acanthamoeba* and will survive many weeks in intracellular vacuoles (156). As these amoebae are plentiful in the environment, both in soil and aquatic biofilms, this might therefore suggest that intracellular survival could provide another important mechanism for persistence of *E. coli* 0157 and other dangerous pathogens in the soil and aquatic environments.

In conclusion, the earlier description of quorum sensing showed how this is a powerful mechanism to rapidly switch the physiology and virulence of a pathogen when adapting to new environments. Endosymbiotic survival in amoebal cysts, particularly for pathogens capable of extensive intracellular multiplication such as legionellae, affords a microenvironment in which accumulation of autoinducing pheromone molecules such as AHLs, furanones, or peptides could readily occur. This will clearly merit further investigation.

PERIPHYTON

ANTONELLA CATTANEO
Université de Montréal
Montréal, Quebec

Periphyton is the algal community growing attached to all objects submerged in water. Growth on a substratum confers to periphyton peculiarities that distinguish it from phytoplankton, which is suspended in the water column, and make its sampling and measurement particularly challenging. Probably, because of these methodological difficulties, periphyton has been studied much less than other aquatic communities, despite mounting evidence of its crucial contribution to aquatic metabolism and food webs. Its distribution in rivers, lakes, and wetlands is regulated both by the availability and type of colonizable substratum and a balance between light, nutrients, current, and grazing. Periphyton responds to several anthropogenic disturbances and therefore can be used to monitor water quality.

DEFINITION, CHARACTERISTICS, AND DEVELOPMENT

The term periphyton, in the broadest sense, applies to all microflora (algae, bacteria, and fungi) growing attached to any underwater substratum. However, usually periphyton studies predominately address the algal component. Several synonyms for periphyton are used in the literature including Auwfuchs, biofilm, and benthic algae. Depending on the substratum on which the algae are growing, periphyton can be subdivided further into epiphyton (aquatic plants or filamentous algae), epilithon (rocks), epipsamnon (sand), epipelon (fine sediments), epidendron or epixilon (wood), and epizoon (aquatic animals). Finally, masses of algae floating among the substrata are called *metaphyton*.

On all substrata and environments, diatoms usually comprise the majority of species and often are numerically dominant. Cyanobacteria and Chlorophytes are always well represented and may also at times become dominant. Filamentous Xanthophyceans and Rhodophytes are less widespread, but they can occasionally be important. Other algal groups (Crysophyceans, Cryptophytes, and Dinophytes) that are prevalently planktonic can also be present but usually as minor components. In addition to taxonomic considerations, it is important to classify periphytic algae relative to growth-form or the degree of attachment to the substratum. Prostrate or adnate algae adhere their entire surface to the substratum. Other algae are attached only through a short mucilaginous pad or long stalk. Filamentous forms anchor through a holdfast cell or are freely floating. Some species are motile (especially pennate diatoms), and others are planktonic forms trapped within the periphyton matrix. Mucilaginous compounds secreted by algae and bacteria bond this matrix together. Algal sizes span several orders of magnitude from small blue-green Chroococcales and minute diatoms (e.g., *Achnanthes minutissima*), which are less than 10 μm in length, to macroscopic algae such as *Cladophora*, whose filaments can be few centimeters long.

Because of growth on a substratum, periphytic algae experience different challenges and advantages than that experienced by phytoplankton suspended in the water column. Self-shading and reduced water exchanges are a consequence of the vertical growth of the community on a horizontally limited substratum. At the same time, some refuge from grazing is offered by close proximity to a substratum. Although phytoplankton relies solely on the water column for nutrients, some attached communities such as epipelon (1) and epiphyton (2) can at least partially exploit elements released from their substratum. Nutrient retention and recycling is more effective in periphyton than in phytoplankton because of the closer aggregation of algae and bacteria within the complex matrix (3).

Because of its vertical stratification, periphyton resembles a forest where organisms compete for light and nutrients. Complex strategies related to growth-forms and sizes, like those observed in marine benthic communities, are encountered in periphyton (4). Small algae are fast-growing and apt to colonize any new empty substratum quickly. Their propensity to be easily grazed is partly counterbalanced by their proximity to the substratum. They must adapt to reduced light and water exchanges when the community becomes thick. Large algae are more often found in the overstory where resources are abundant but losses by grazing and sloughing are increased. They usually dominate mature communities. Operationally, periphyton is often separated in two fractions of loosely and tightly attached algae. The loose fraction, which is easily collected by shaking or brushing the substratum (see methods), is probably more metabolically active and readily available to grazers than the tight fraction, which is left relatively intact on the substratum by most sampling methods.

Consideration of the vertical structure of periphyton is crucial for understanding its dynamics, which are controlled principally by density-dependent factors. One other implication of periphyton structure is that it is generally less productive per unit of chlorophyll than phytoplankton. In fact, there is a systematic decline in the primary production of periphyton per unit of chlorophyll with increasing standing stock, whereas phytoplankton production and standing stock remain approximately proportional over a broad range of values (5).

Several studies have documented the typical development of periphyton from colonization of a bare substratum to establishment of a mature community and have delineated temporal changes in biomass and the importance of different growth-forms (Fig. 1). After a lag phase, biomass usually increases rapidly to reach the maximum value that can be supported by the substratum under given ecological conditions. At this point, self-shading and increasingly reduced water renewal at the base of the community leads to senescence of the basal layer. This weakens the

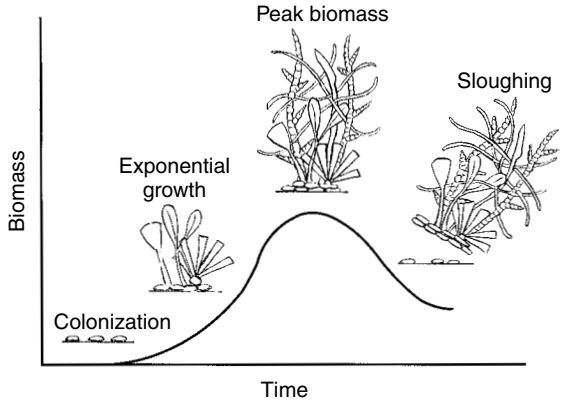

Figure 1. Changes in biomass and algal growth-forms during succession in a periphyton community.

attachment to the substratum and renders the entire mat vulnerable to sloughing. The speed with which peak biomass is reached varies from less than two weeks to around 100 days and largely depends on nutrient enrichment (6). Peak biomass increases relative to increasing nutrients, which result in better diffusion gradients across the mats and therefore development of thicker communities (7). Community composition also influences the peak biomass that can be supported by substratum. Diatom and cyanobacteria mats do not exceed chlorophyll concentrations of 400 mg/m^2 (8), whereas filamentous chlorophytes can reach 1,200 mg/m^2 of chlorophyll (9). The succession sequence of different taxa and growth-forms during periphyton development has been documented with scanning electron microscopy (10,11). A new substratum is first coated with an organic matrix and bacteria flora that form a favorable attachment site for early algal colonizers, usually small adnate diatoms. Afterwards, apically attached diatoms (rosette or stalked) appear, followed by filamentous forms.

METHODS USED TO STUDY PERIPHYTON

Sampling

Quantitative sampling of periphyton is difficult because of problems associated with detaching algae from the substratum and correctly estimating the area sampled. Different methods have been proposed relative to the substratum on which the periphyton grows. For epilithon, algae are detached from individual stones removed from the water by scraping with a scalpel (on smooth surfaces) or by brushing a known area of the substratum. When the substrata are too large or too deep to be lifted from the water, some form of enclosing device is used. The simplest is the sampler first devised by Stockner and Armstrong (12) consisting of a toothbrush connected to a syringe that can remove periphyton from a known surface underwater. This technique has been improved by adding another syringe to collect the scrapings, thereby improving sampling efficiency (13). Various modifications of this technique followed (14). Epipelon growing on fine sediments is mostly sampled with a small handheld core (15). Surface sediments of a few centimeters in depth from the top are retained for analysis. Separation of algae from the sediment remains a problem. One method based on algal phototrophism has been proposed in which algae are collected on lens paper or cover glasses placed over illuminated sediment (16). This technique is, however, selective for motile algae. Other methods take advantage of the differences in sedimentation between algae and sediments to separate epipelon (15). For epiphyton, detachment from the substratum is even more of a problem. Usually, the plant with its epiphytes is agitated vigorously in a jar filled partially with water. This procedure can last from 30 seconds to several minutes and be repeated several times. Effectiveness of the detachment is rarely complete (17). Sometimes, addition of chemicals that are able to solubilize the mucopolysaccharide matrix can lead to more complete sampling, but this is not suitable when epiphytes are used in analysis of photosynthetic pigments or primary production. Removal of epiphytes by a scalpel can contaminate the sample with macrophyte tissue.

A correct estimation of the sampled area is crucial to report quantitatively periphyton data, which are expressed per unit of surface. Rock surface area can be estimated by the weight of the aluminum foil necessary to wrap it (18) or alternatively by measuring the rock's three main diameters (19). Because plant surface measurements are laborious (20), epiphyton data are usually expressed per unit of dry weight of the host plant.

Artificial Substrata

To overcome problems of detachment from the substratum and determination of the sampled area, artificial substrata are being increasingly used. Since glass slides were first suspended in a lake in 1916, periphyton workers have experimented with many different anchoring devices and materials as varied as glass, tiles, styrofoam, nylon lines, plastic aquarium plants, and nutrient diffusing substrata (14). The U.S. Environmental Protection Agency suggests the use of frames anchored with rebars to the stream bottom and holding glass microslides or other suitable substratum (21). Artificial substrata are supposed to both decrease variability among replicates and to facilitate comparisons among sites by providing a uniform and standardized colonization substratum. However, there is still a controversy as to how well these substrata mimic natural communities. On the basis of a survey of the extensive literature on the subject, Cattaneo and Amireault (22) found that, in general, epilithon biomass was underestimated using artificial substrata, whereas epiphyton was somewhat overestimated. On stones, differences between natural and artificial substrata were smaller in warmer, richer sites and everywhere tended to decrease with longer colonization times (>30 days). For taxonomic comparisons, there was generally good agreement between diatom assemblages on natural and artificial substrata, whereas green and blue-green algae tended to be underestimated using artificial substrata. A careful evaluation of the goals of the study should precede the decision to use artificial substrata.

Biomass

The fastest method to estimate periphyton biomass is to measure it as a chlorophyll concentration. Various extractants, most commonly acetone and ethanol, have been used to extract pigments from the algae. Because periphyton can be associated with a significant amount of detritus and dead cells, correction for the presence of pheophytin (degraded chlorophyll) is advisable in order to correctly estimate living algae (23). The drawback of chlorophyll measurements is that pigment content is variable among different groups of algae and is influenced by light conditions. Values tend to be higher in algae growing in shade than under full light (24).

Measures of periphyton dry mass are unreliable because of the presence of inorganic sediments, but ash-free dry mass (after incineration at 550 °C) is a simple method to estimate periphyton total organic material. Alternatively, organic material can be estimated by carbon and nitrogen measurements with an elemental analyzer. All these measurements are not selective of the algal fraction but also include detritus, bacteria, and meiofauna.

Periphyton can also be quantified directly as algal biovolume by first counting and measuring algae under a microscope, and then calculating their volume by approximation to geometric solids. This method is time consuming but contemporaneously provides information on the taxonomic composition. There are some difficulties in estimating algal volume consistently because mucilage, vacuoles, and spines are sometimes present and are included or excluded from the volume calculation depending on the bias of the researcher or the goal of the study.

Composition

Taxonomic composition can be determined through microscopic examination of a periphyton subsample using a nanoplankton counting chamber or semipermanent glucose mounts (25). The number of cells to be counted depends on the goal of the study and the statistical analyses to be used. Most investigators enumerate from 300 to 500 organisms (26). Automated methods that use a computer interface to enter data can expedite enumeration and increase accuracy (27). Species composition is sometimes summarized in diversity indices that account for the number of species (richness) in the assemblage and the evenness of their abundance distribution among species (28).

A coarse assessment description of the taxonomic composition of the community can also be achieved by studying pigment composition using high-performance liquid chromatography (HPLC). This technique analyzes with great sensitivity individual chlorophylls and carotenoids allowing identification of different algal groups on the basis of their distinctive pigment composition. At the class level, good agreement exists between traditional taxonomical analyses based on microscopy and the faster delineation based on pigment composition (29).

Besides taxonomic composition, community structure can be described as size distribution by grouping algae in logarithmic size classes. Because metabolic rates are a function of body size (30), size distribution can be used to estimate community processes (31). Unlike phytoplankton in which size analysis can be automated with electronic particle counters, in periphyton, it must be done microscopically assisted by computer-based image analysis systems (32) because of contamination from inorganic and other biological particles.

Community composition also can be based on the concentration of different chemical constituents. Lipid and fatty acid compositions have been used to characterize algal communities with different taxonomic composition and to trace their usage in food webs (33). Cellular nutrient (carbon, nitrogen, phosphorus) ratios can serve as indicators of nutrient status for periphyton (34). Stoichiometry, as demonstrated in planktonic communities, might have important implications for periphyton usage by higher trophic levels (35).

Metabolic Rates: Production, Respiration, Grazing

Production and respiration of periphytic communities are usually measured by enclosing the periphyton on its substratum in test chambers (36) and measuring changes in oxygen or incorporation of ^{14}C during an incubation period. Measurements using chambers are relatively easy but suffer from several enclosure artifacts such as nonrepresentative sampling of heterogeneous stream vegetation and altered environmental conditions. The scaling-up of such results to an entire stream reach is particularly difficult when vegetation is not uniformly distributed. Measurement of gas exchange, oxygen or carbon dioxide, over an entire reach has the advantage of integrating metabolism over the whole heterogeneous community. This method, first proposed by Odum (37), requires accurate estimates of gas diffusion between air and water (38).

Estimates of periphyton grazing rates are usually obtained by excluding or adding grazers to periphyton communities and measuring, after a certain period, differences in biomass between treatments and controls (35). More rarely, grazing has been estimated by incorporation by the grazers of radioisotopically labeled periphyton (39).

DISTRIBUTION IN DIFFERENT HABITATS

Streams and Rivers

Periphyton is the most successful primary producer in streams. Along a longitudinal profile from the headwaters to large rivers, there are some general predictable patterns in periphyton distribution (40). Headwaters, at least in temperate North America, are usually heavily shaded by riparian vegetation, thus preventing significant development of periphyton. As the streams become larger (third, fourth order), more light can reach the bottom favoring algal growth. Periphyton importance is maximal in this midportion of the continuum. Further downstream, depth increases and light once again becomes limiting because of phytoplankton development and turbidity in the water column. Available substratum also changes longitudinally. Rocks and wooden debris are important in the upper reaches, whereas fine sediments and aquatic plants are the main substrata in the

downstream sections. Besides these large longitudinal changes, there are spatial differences also at a smaller scale between riffles that are shallow and with fast current and pools that are depressions in the stream bed with fine sediments and reduced current (41).

In running water, hydrology has an overwhelming effect in controlling the temporal distribution of periphyton. The time elapsed since the last flood is a good predictor of biomass, at least in disturbance-prone systems (42). Pronounced seasonality with spring and fall maxima, similar to those observed in lakes (see next section), is encountered only in streams with relatively stable water flow. The relative importance of biotic and abiotic control of periphyton is also dependent on the hydrologic regime because grazing effects are only detected during periods of stable flow (7).

Lakes

Lake morphometry dictates the extent of the littoral zone where periphyton can develop. Vertical profiles of epipelon biomass tend to show a maximum at intermediate water depths suggesting a balance between the effects of light and disturbance by wind and waves (15). Substrata available for periphyton change with depth. Rocks and macrophytes, especially in lakes with gentle slopes, prevail in the shallow littoral zone (eulittoral), whereas only fine sediments are found in deeper water. Diatoms and filamentous greens *(Cladophora*, *Ulothrix*, *and Oedogonium* in hard water and Zygnemataceae in soft water) are the dominant algae in the eulittoral. Epipelon of the deep littoral zone is usually dominated by mobile diatoms and blue greens (43) along with a significant presence of sedimented planktonic algae (15).

Temporal trends are less affected by meteorologic events in lakes than in streams. Typical patterns in temperate oligo and mesotrophic lakes resemble those observed for phytoplankton with spring and fall peaks in biomass, dominated by diatoms, and lower biomass in midsummer dominated by green and blue green algae (44,45). These trends could be related to higher nutrient availability and lower grazing at the beginning of the growing season. Higher grazing pressure in midsummer could lead to the predominance of larger, less palatable algae such as greens and blue greens. An alternative hypothesis for the wane of diatoms in midsummer could be silica limitation. Summer periphyton maxima are encountered in eutrophic sites following large growth of filamentous green algae (44).

Wetlands

Wetlands provide abundant colonizable substrata to periphyton because they are shallow with abundant macrophytes. The relative importance of the three main benthic communities (epipelon, epiphyton, and metaphyton) is regulated by hydrodynamics, stability of the water column, and nutrient supply. Macrophytes play a major role in these ecosystems by providing substratum for epiphytes and conversely reducing epipelon through shade and competition for sediment nutrients. Wind action can affect water turbidity and therefore the light regime. However, fluctuation in water levels is the overwhelming factor controlling algal distribution. On the basis of several years of research in Manitoba wetlands, Goldsborough and coworkers (46) generalized patterns generated by hydrodynamics. A dry state with epipelon dominance follows a period of drought. With increasing water level, an open state is reached in which development of emergent and submerged vegetation is important and accompanied by significant epiphyton growth. This state is the most typical in wetlands. Further increase in water level leads to the lake state in which macrophytes and epiphytes are reduced, whereas phytoplankton becomes prevalent. Nutrient supply also affects this succession by stimulating the massive development of metaphyton. The shading produced by these floating algae brings about the demise of plants and their epiphytes. At this stage, a switch between metaphyton or phytoplankton dominance is dictated by exposure to winds because turbulence reduces the persistence of floating algal masses.

IMPORTANCE OF PERIPHYTON IN THE METABOLISM AND FOOD WEB OF AQUATIC ECOSYSTEMS

To evaluate the importance of periphyton in the metabolism of aquatic ecosystems, it is necessary to compare its production with inputs of other sources of organic material. In streams, the importance of periphyton production (autochthonous carbon) has long been underestimated because early studies (47) in small, shaded reaches pointed out the overwhelming importance of organic material contributed by the surrounding riparian zone (allochthonous carbon). Later studies demonstrated that autotrophy can contribute a significant amount to the carbon budgets of stream ecosystems. Longitudinal trends in ecosystem processes were examined along a sub-Arctic river system (48). The importance of periphyton production was low in a first order station (4% of total) but increased with stream size to reach 29% in a fifth order reach. Biome type also affects the importance of autochthonous versus allochthonous contributions to river metabolism. Autotrophy is higher in arid regions where riparian vegetation is reduced relative to woodlands; deciduous forests promote more in-stream production than coniferous areas (49). A study of a New Zealand grassland river stressed the importance, besides longitudinal patterns, of hydrologic interannual variations. Autotrophy was prevalent at all stations during a year when water level was low and turbidity reduced, whereas respiration prevailed in the downstream stations during a year of high discharge (50).

Periphyton production can account for a significant portion of total lake production. The relative importance of periphyton compared with phytoplankton and macrophytes varies relative to basin morphology, shoreline development, depth of the euphotic zone, and nutrient loading. (51) Among the data summarized by Wetzel (52), the lowest percentage (1%) of the total production was measured in Canadian Shield lakes with an extremely reduced littoral zone, whereas up to a 70% contribution was noted in Lawrence Lake (Michigan) where epiphyton is highly developed on emergent and submersed vegetation. In a detailed study of primary production in a

Manitoba wetland (53), metaphyton was usually the dominant algal producer (mean 69.5%); the importance of epiphyton was maximal (25%) when the water level was low (7–28 cm), whereas the percentage of phytoplankton production peaked (12%) at high water level (67–88 cm).

Periphyton competes for available resources with other primary producers. Dense growth of epiphytes can limit production of host macrophytes by reducing carbon uptake and light intensity (54), whereas high phytoplankton biomass can similarly decrease light available to periphyton. Nutrients released from sediments can be incorporated by epipelon and prevent their utilization by phytoplankton (1). These interactions can explain patterns observed in several aquatic ecosystems consequent to enrichment. In shallow English lakes, it is likely that shading triggered a macrophyte decline by increasing epiphyton biomass during progressive enrichment leading to excessive development of phytoplankton and the demise of benthic communities (55). Along a productivity gradient of Antarctic and temperate and sub-Arctic Swedish lakes (Fig. 2), periphyton algal biomass was negatively correlated with phytoplankton biomass (measured as light extinction in the water column) when light extinction coefficient was greater than 1.5/m. Maximum periphyton biomass was reached at intermediate light extinction in which neither light nor nutrients were probably limiting. At low light extinction (<0.5/m) typical of oligotrophic lakes, periphyton and phytoplankton were probably limited by nutrients (56). Enrichment in oligotrophic lakes seems initially to favor periphyton over phytoplankton. Phosphorus enrichment following forest harvesting and wildfires stimulated periphyton biomass more than phytoplankton in oligotrophic Canadian Shield lakes (57).

The balance between primary producers can be changed by disturbances other than eutrophication. In an alpine lake, increased UV affected epilithon more than epipelon and phytoplankton. The differential response between epipelon and epiphyton was possibly related to the capacity of epipelic motile cells to find refuge in sediments (29).

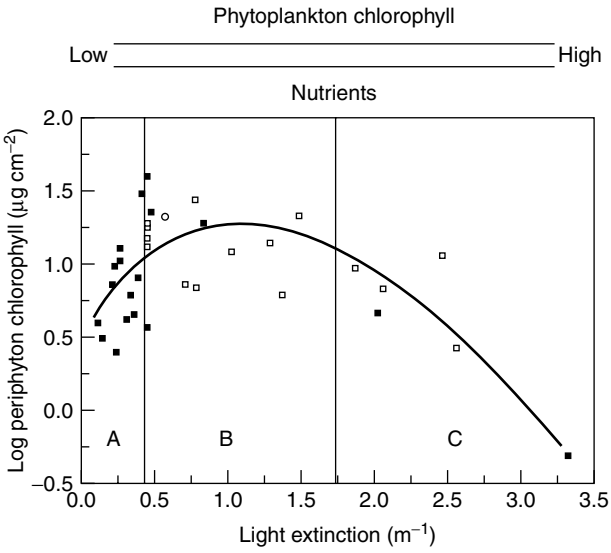

Figure 2. Variation in periphyton biomass along a productivity gradient expressed as light extinction in the water column. Samples are from Antarctic (closed symbols, n = 18) and Swedish lakes (open symbols, n = 16). Modified from L.-A. Hansson, *Limnol. Oceanogr.* **37**, 322–328 (1992) with permission.

Several studies suggest that periphyton is used by consumers in a disproportionate manner relative to its contribution to biomass and production of aquatic ecosystems. In Bear Brook (New Hampshire), where 99% of the energy input is allochthonous, an abundant caddisfly depended on periphyton for most of its growth (58). On the basis of analyses of diets of invertebrate (59), it has been traditionally thought that epiphyton was more available to consumers than the plant on which it grows. This hypothesis, sometimes challenged (60), has now been confirmed by a compilation of literature data on stable isotope ratios for several aquatic ecosystems. The consumer ratio more closely approximates epiphyte values than those of vascular plants (61). Similarly, a study of stable isotopes in fish in several tropical, temperate, and subarctic lakes indicated that the contribution of benthic algal productivity to food webs was substantial even in lakes where phytoplankton clearly dominated total carbon production. This discrepancy between the relative importance of periphyton and phytoplankton in production and food web contribution could be related to consistent methodological underestimation of benthic production. Possibly, the mismatch could indicate that periphyton concentrated on a substratum offers a more energy-efficient diet than dilute phytoplankton (62).

Not all periphyton production is directly used by grazers. Upon sloughing, a part of the detached algae can contribute to detritus or sometimes can remain in the water column and be used by filter feeders. Export rates have been rarely quantified and mostly in laboratory streams. In these systems, it has been demonstrated that grazers, by their somewhat wasteful feeding activity, dislodge algae and increase their export downstream compared with ungrazed controls (35).

CONTROL OF PERIPHYTON COMMUNITIES

Periphyton biomass present at any given time is the result of accrual through immigration and growth minus loss due to grazing and sloughing. Various variables are crucial in controlling these processes, with their importance changing according to environmental conditions. Geomorphology (i.e., stream order, lake morphometry) sets the primary control on periphyton, dictating the colonizable substratum and setting the context in which all other variables interact.

Temperature

Despite the importance that temperature exerts on all biological processes, its effect on periphyton communities has received less attention than that of other variables. Seasonal changes in biomass and composition cannot easily be ascribed directly to temperature because of the interactions with other factors such as nutrients, light, and grazing.

In an analysis of published studies of stream epilithon in situ and in the laboratory, maximum areal primary

production was a function of temperature up to 30 °C (63). Temperature sets the upper limit of production when other factors are not limiting.

Light

Because periphyton consists mainly of primary producers, light is a fundamental variable controlling its distribution and abundance. Relationships between available light and algal production are studied through the irradiance-photosynthesis curve (I/P). In most studies, photosaturation, or the light intensity at which photosynthesis is maximal, is encountered over a rather narrow range from 100 to 400 μ mol/m^2/s (64). Photoinhibition at high light intensity is more likely to be encountered in periphyton communities from shaded sites. These communities show shade adaptation and outperform communities from open sites at low irradiance (65). Photosynthesis-irradiance responses change with the thickness of the periphytic mat. The onset of photosynthetic saturation and photoinhibition occur at higher irradiance as periphytic mat thickness increases. With light microsensors, it is possible to demonstrate light attenuation across the mat, which varies not only with mat thickness but also with its composition (66).

In streams and small rivers, light availability is regulated by riparian canopy and, at least for streams flowing through deciduous forests, it changes seasonally. The effect of riparian canopy diminishes as the stream becomes wider. In large, deep rivers and in lakes, light decreases with depth differentially depending on water turbidity, color, and phytoplankton development. Periphyton growth can occur under ice cover or where light is severely limited by riparian vegetation or depth. This capacity to withstand extremely low light possibly could be linked to temporary heterotrophy (67).

Relationships between light and periphyton biomass are not always clear. In some instances (65,68), the positive effect of light is counterbalanced by grazing: increased illumination gets translated as increased grazer growth. Where grazing appears negligible, a poor relationship of light–biomass could be ascribed to other mechanisms. In streams, sun flecks can provide transient but intense illumination to shaded portions of the streambed (64). In lake littoral areas, at shallow depth where illumination is maximal, wave disturbance can counteract any positive light effect (15). There are some general patterns in the response of different algal classes to light. Chlorophytes, in particular filamentous green algae, are usually found only in well-illuminated sites, whereas diatoms, cyanobacteria, and rhodophytes seem better able to tolerate low light conditions (64).

Recently, because of the thinning of the ozone layer, UV radiation has increased and with it, interest in its effect on periphyton communities. In artificial stream channels in British Columbia, periphyton communities shielded from UV initially grew faster than unshielded controls. However, the effect on periphyton biomass was later reversed because chironomid grazers were reduced in UV-exposed channels (69). UV inhibition is likely to be severe particularly in extreme environments such as mountain lakes and streams (70,71). In these studies, periphyton biomass was reduced and taxonomic composition was altered. Diatoms were particularly sensitive to UV radiation, whereas cyanobacteria became dominant probably because of their ability to produce carotenoids as protection against UV damage (70). Production of mucopolysaccharides also conferred protection to some algae including *Hydrurus* and tube-dwelling diatoms (71).

Nutrients

The relationship between nutrients and periphyton has been examined in many experimental studies and through comparison of natural communities along nutrient gradients. In experiments, one or several nutrients are added to artificial channels or, more rarely, dripped directly into a stream. Increasingly, studies are using nutrient-diffusing substrata. Phosphorus and nitrogen are the most studied nutrients (72). Because most studies are from the temperate zone, in particular North America, findings cannot be generalized to tropical or arctic regions. Phosphorus is most often the nutrient-limiting periphyton growth, but, in regions where soils are phosphate rich, such as the southwestern United States, nitrogen can be limiting. Often colimitation by phosphorus (P) and nitrogen (N) is observed. As for other algal communities, limitation by phosphorus or nitrogen can be predicted from ambient N: P ratio. When this ratio is greater than 20, phosphorus limitation is expected, whereas a ratio less than 10 results in nitrogen limitation, and values of 10 to 20 reflect intermediate limitation.

Few studies have quantified the limiting concentrations for periphyton. For phosphorus, Bothwell (73) noticed in artificial channels that a concentration of 0.3 to 0.6 μg/L was sufficient to saturate growth of a thin diatom community. This growth-saturating concentration for benthic diatoms is of the same order of magnitude as observed for planktonic diatoms. Filamentous chlorophytes seem to require higher phosphorus concentration than diatoms to saturate growth. Because thick benthic mats impede nutrient diffusion, much higher phosphorus concentrations (25 to 50 μg/L) are needed to obtain maximum areal algal biomass (73).

Increased nutrients do not always translate into higher periphyton biomass because of the confounding effects of light, disturbance, and grazing. Variance in the relation between nutrient and biomass could also be linked to growth on a surface. Substratum saturation sets an upper limit to the amount of biomass that can develop before sloughing losses occur. Despite this noise in the response of periphyton to nutrients, it was possible to distinguish impoverished streams flowing through forested catchments from enriched streams in agricultural catchments on the basis of their periphyton biomass (7) (Fig. 3). The taxonomic response to nutrient status is more consistent than the response to biomass, and some general patterns are observed. Large algae, in particular filamentous greens (e.g., *Cladophora*, *Stigeoclonium*), tend to be more important in rich habitats. Epithemiaceae diatoms, which harbor cyanobacterial endosymbionts and probably fix atmospheric nitrogen, tend to become more important in N-limited habitats (74). In phytoplankton, phosphorus enrichment usually results in dominance

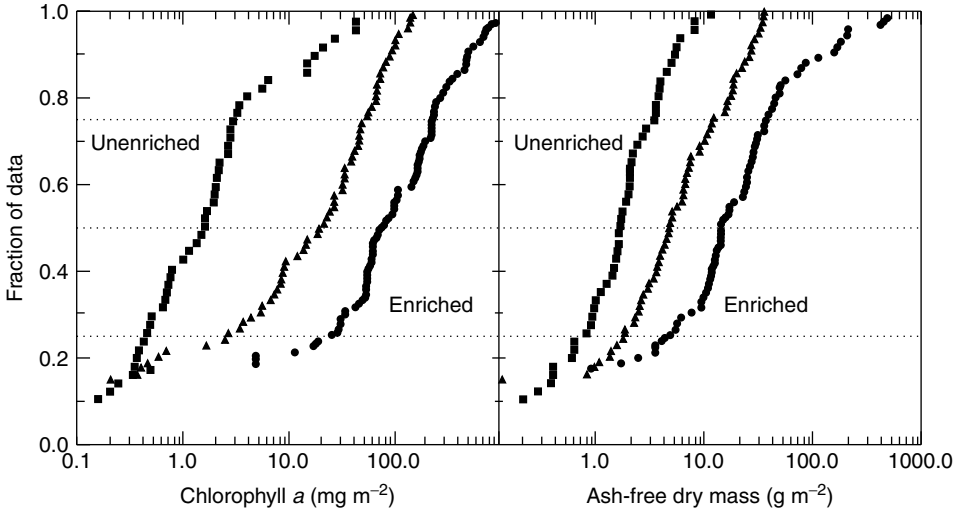

Figure 3. Cumulative frequency curves for periphyton chlorophyll and ash-free dry mass from unenriched (squares), moderately enriched (triangles), and enriched (dots) New Zealand streams, sampled monthly for a year. From B. J. F. Biggs, in R. J. Stevenson, M. L. Bothwell, and R. L. Lowe, eds., *Algal Ecology, Freshwater Benthic Ecosystems*, Academic Press, San Diego, Calif., 1996, pp. 31–56 with permission.

by cyanobacteria, whereas this is seldom the case in periphyton.

Hydrodynamics

Water currents are more obvious in streams and rivers where there is a rather striking alternation of riffles and pools. In the littoral zones of lakes and even in wetlands, however, there are currents generated by wind and waves. Water movement has potentially opposite effects on periphyton accumulation. Current favors nutrient exchanges by decreasing the thickness of the boundary layer around the algae. Increased phosphorus uptake, photosynthesis, and respiration have been observed with increasing current (75). This positive effect is counterbalanced by the negative action of shear drag produced by the current. Drag can detach part of the community from the substratum; filamentous, stalked, and apically attached algae are especially sensitive to such stress (41). Current also negatively affects algal immigration (76) while increasing algal export. Optimum current for different communities and environments is dictated by the equilibrium of these opposing effects of water motion. Maximum periphyton accrual is usually observed at intermediate velocities (10–50 cm/s). In general, saturating current velocity is higher for thick periphyton communities than for thinner ones (75). Evidence from both natural streams and artificial channels indicates that optimum current velocity decreases with nutrient concentration and declining light availability (75,77). Current has a destructive effect during a flood when it increases rapidly in orders of magnitude over baseline conditions. As discussed in the previous section on periphyton distribution, flood frequency is a crucial factor controlling stream periphyton (42).

In lakes, waves generate currents, which can have negative effects on periphyton accumulation. In a Nebraska reservoir, wind-induced turbulence led to a 61% decline in diatom density (78). However, a stimulating effect of wind-induced currents was observed when comparing periphyton biomass in exposed and protected sites along an island in a Quebec lake. This effect was significant at least during the early summer biomass peak (79). In both examples, motile algae were reduced in exposed sites, whereas stalked or rosette forms, which adhere to the substratum by mucilage secretion, were more resistant to wave turbulence.

Substratum

Because periphyton is by definition an attached community, substratum is an important variable in regulating its abundance and composition. Periphyton researchers have studied the effects of size and type of substratum. Size is important because it controls the stability of substrata both in streams and in lake littoral zones. Large rocks are not dislodged by storm events and favor colonization by filamentous and stalked algae. These growth forms are rarer on fine sediments in which motile algae that can escape burial are favored. Rocks are usually more exposed to current and associated water renewal. However, algae on fine sediments have access to groundwater and nutrients released from sediments. When communities on substrata of different sizes are compared, the data are somewhat contradictory. Periphyton is often better developed on large stable substrata (80), but sometimes the greatest biomass exists on fine substrata (81). Flood history before sampling probably explains these discrepancies (7). In a comparison of two different substratum types, periphyton production on fine sediments was 10 times more than that measured on wood in two Michigan lakes (82).

Complex and potentially important interactions with the substratum can be hypothesized for epiphytes that grow on living plants. Nutrient transfer between the host plant and its epiphytes is common (2). However, the importance of this transfer for epiphyton growth is still debated. In the mesotrophic Lake Memphremagog (Quebec), epiphyte biomass and production were similar on natural plants and plastic mimics (83). Interactions between plant and epiphytes seem more important in oligotrophic lakes where nutrients released by plants could provide a significant advantage to attached algae (45,84). Different

macrophytes can harbor epiphytic communities with differing biomass and composition. Allelopathic substances have been isolated from plant tissue (85) and could explain these differences. However, most available evidence suggests that differential colonization is related to the physical structure of the host plant. Macrophytes with dissected leaves tend to have a thicker coating of epiphytes probably because they provide better light and water renewal (86,87).

Grazing

Periphyton constitutes an important source of food for several aquatic animals. It is richer in proteins and lipids than detritus and more easily ingested than plant tissues. Taxa feeding mostly on periphyton are called *scrapers* and have specialized mandibles or bristles to detach the algae (e.g., some caddisflies and mayflies) or a rasping radula in snails. Less specialized invertebrates also are able to use periphytic algae easily dislodged from the substratum. Most studies on grazing focus on macroinvertebrates; however, meiofauna (protozoans, small oligochaetes, and chironomids) can also be important (88,89). Among the vertebrates, tadpoles (90) and fish (91), particularly in tropical streams (92), can feed on attached algae.

The large number of grazing experiments conducted in the laboratory and nature during the last 20 years has been recently reviewed (35,93). In experiments of grazer addition or exclusion, periphyton biomass was reduced by grazers in 70% of the cases. Grazing also decreased productivity but less consistently (60% of experiments). Grazing strongly affected the taxonomic composition of periphyton assemblages (81% of experiments). In particular, the physiognomy of the community changes with a decrease in percentage of overstory forms in response to grazing because they are more vulnerable to direct ingestion or dislodgment by grazers. From these reviews of grazing experiments, it appears that periphyton in lakes and streams is regulated by herbivory at least, if not more frequently than primary producers in other ecosystems (93).

RESPONSE OF PERIPHYTON TO ANTHROPOGENIC STRESSES

Eutrophication

Human activity, especially since the start of the industrial revolution, has resulted in increased inputs of nutrients to lakes and streams. In particular, nitrogen and phosphorus concentrations in inland waters have increased because of intensive agriculture, fossil fuel combustion, and wastewater disposal. There is a remarkable consistency in the response of planktonic algal biomass to nutrients. This has led to successful models to predict the effect of eutrophication on lake plankton (94). The response of periphyton to increased nutrients is less clear. Therefore, establishing guidelines for the management of stream and rivers where periphyton is the major primary producer is more problematic than for lakes.

As noted in the section on nutrients, in benthic communities, the effect of enrichment can be restricted by the importance of other factors such as available light, hydraulic perturbations, and grazing. For example, when the degree of eutrophication is relatively low (<50 μg total P/L), it can be translated into increased invertebrate biomass rather than periphyton proliferation (95). When enrichment progresses, it is accompanied by the appearance of nuisance algae that are aesthetically displeasing and interfere with recreational activities of fishermen, swimmers, and boaters. This nuisance level is usually reached when periphyton biomass exceeds 100 mg/m^2 of chlorophyll (96). Filamentous green algae, in particular *Cladophora*, are often associated with such nuisance growths in both streams (7) and lake littoral zones (97).

From a large comparative analysis of stream enrichment studies, Dodds and coworkers (98) suggested that target nutrient concentrations necessary to avoid proliferation of nuisance algae are 350 μg/L of total nitrogen and 30 μg/L of total phosphorus.

Acidification

In many areas of the world with poorly buffered soil, inland waters have been affected by acid rain. When water acidification is severe (pH$<$5.5), the whole food web is affected. Although this disturbance typically reduces the growth and abundance of aquatic organisms, periphyton biomass tends to increase in acidified lakes (99) and streams (100). Taxonomic composition is also strongly influenced by acidification with the appearance of dense growths of filamentous chlorophytes of the order Zygnematales. Shifts in diatom species are also observed, with the genus *Eunotia* consistently favored at low pH. The casual link between these changes and acidification has been confirmed by similar responses observed in experimentally acidified streams, artificial channels, and in whole-lake acid manipulations.

Abiotic and biotic mechanisms have been invoked to explain these responses in periphyton biomass and composition. Biomass stimulation is often ascribed to increased water transparency found in acidified systems because of phytoplankton reduction or changes in dissolved organic carbon concentration (101). Partial release from grazing pressure due to the sensitivity of many invertebrates to acidification has also been hypothesized (99) but not always confirmed (102). Alternatively, periphyton would benefit from reduced competition for phosphorus with bacteria, whose abundance is decreased by acidification (102). The growth of filamentous Zygnematales is possibly related to their capacity to obtain dissolved inorganic carbon at the low concentrations found in acid waters. This competitive advantage allows these algae to develop blooms and become a nuisance for swimmers and boaters. These algal proliferations are considered an early warning for lake or stream acidification because they usually appear when pH becomes less than 5.5 (103).

Metal Pollution and Other Contaminants

Mining activities in many areas of the world have led to high metal concentrations in some aquatic environments. If trace concentrations of metals are beneficial to algae, high concentrations found in disturbed sites interfere with

their metabolism. The effect of metals has been studied either by comparing impacted and control sites or by experimentally adding different metals to artificial channels. In general, metal stress affects species composition, more rarely community biomass and metabolism (104). Several studies have observed that green algae are particularly tolerant of high metal concentrations. In streams draining a mining region in Cornwall (105), filamentous green algae, particularly *Microspora*, were dominant. Changes in diatom communities are also observed; dominance of *A. minutissima* occurs in several polluted environments (106,107). The presence of deformed diatoms has been reported several times in the presence of metal pollution in both streams and lakes (108,109). These morphological abnormalities, probably linked to metal interference in silicic acid uptake and amino acid synthesis (110), could provide an easy tool to monitor metal pollution.

Organic toxicants enter lakes and rivers from agricultural (e.g., insecticides, pesticides) and industrial (e.g., detergents, dyes, resins) activities. The effects of these substances have been studied more on planktonic rather than on benthic algal communities. Organic toxicants, particularly herbicides, affect the composition of periphyton more than its biomass or production. Diatoms are generally more resistant to such contamination than other algal groups. Species diversity is often lowered in polluted sites. (111).

Climatic Changes

Because of global warming, significant climatic change is foreseen for some decades ahead. In addition to temperature changes that could influence the seasonality of periphyton and their grazers, increased variation in precipitation is predicted (112). This meteorologic instability could lead to more frequent floods and droughts even in regions where water flow has been rather predictable earlier. Hydrologic control would prevail over that from grazing or nutrients. For many systems, a drastic reduction in water level has been forecast. For example, a 1 m lowering of the base level of the St. Lawrence River has been forecasted for the next decade. This change is likely to favor the development of emergent vegetation compared with submersed plants (113). Such a vegetation shift could affect epiphyton development, because the simple stems of emergent plants offer less colonizable surface than submersed macrophytes. In marshes, severe drought, or conversely, periods of unusually high water would alter the balance between epipelon, epiphyton, and phytoplankton (46).

Biomonitoring

The ability of periphyton communities to respond to multiple anthropogenic stresses makes them useful for monitoring water quality. Biomass and production are usually less affected by disturbances than community composition. Therefore, most indices are based on analysis of taxonomic composition. Diversity indices are often calculated, but they do not always decrease in consequence of stress (114). Diatom analysis is the most used for routine monitoring, because these algae are often dominant, readily sampled, and relatively easy to identify. Moreover, information on the tolerance of many diatom taxa is available in the literature. Earlier indices were mainly based on the response of a limited number of indicator taxa to organic pollution. These indices have been subsequently refined both to include more taxa, scored according to their sensitivity and distribution, and to address different types of pollution. Their use has traditionally been more widespread in Europe (115). Numerical approaches using canonical correspondence analysis and weighted average regression are now gaining popularity because they use the entire assemblage to extract information on environmental conditions (116). Despite the traditionally greater popularity of biotic indices based on invertebrates, biological assessment programs in North America are starting to include diatom indices.

Besides taxonomy-based indices, other properties of periphyton appear promising for monitoring. Fatty acid composition has been used successfully to follow stream pollution (117). Size distribution responds to anthropogenic stresses related to nutrients and contaminants usually with shifts toward large algae (118).

Another use of periphytic algae in monitoring relies on their capacity to concentrate a range of substances in their cells. Most accumulation studies have focused on heavy metals, but accumulation of pesticides has also been examined. Coarse filamentous algae such as *Cladophora* have been especially used for this approach (115).

CONCLUSION

In streams, lakes, and wetlands, periphyton is an important primary producer, which is readily available to grazers. Despite periphyton importance in aquatic food webs, the complexity of this attached community has retarded its description and quantification. Further knowledge of periphyton response to anthropogenic stresses is crucial for setting guidelines for management and for effective monitoring of disturbance and recovery of inland waters.

PERMAFROST

DAVID GILICHINSKY
Russian Academy of Science
Pushchino, Russia

Permafrost represents a stable environment that has allowed the prolonged survival of ancient microbial lineage at subzero temperatures. Significant numbers, 10^2 to 10^8 cells per one gram of dry soil (cells/gdw), of viable ancient microorganisms are known to be present within the permafrost. They have been isolated from the cores up to 400 m deep in the Canadian Arctic and at the lowest ground temperatures in Antarctica. The age of the cells corresponds to the longevity of the permanently frozen state of the sediments. The oldest viable cells date back to two to three million years (Myr) in northeastern Siberia, probably older in Antarctica. They are the only organisms known to have retained viability over geologic time periods and, upon thawing, renew their physiological activity. Therefore, the permafrost can be characterized as a unique physical-chemical complex, which can maintain life incomparably longer than any other known habitat.

Permafrost thawing as a result of anthropogenic or natural processes exposes ancient life to modern ecosystems.

The ability of microorganisms, the most ancient life-forms on the Earth, to live in a variety of natural environments has substantially modified our ideas about the viability of microorganisms and continually forces us to redefine the limits of both life and the biosphere. Microorganisms not only survive under conditions that seem unsuitable for life, but they also succeed in maintaining relatively large populations and a high diversity. The soil cover, where they are well studied, is two to three meters thick. Significant numbers of microorganisms also occur in subsoil horizons, which are much thicker than soil. In these subsurface layers microorganisms have been found at depths up to five kilometers (1–3). The discovery of microorganisms in these deep layers has caused the active development of the field of subsurface microbiology over the last two decades. However, outside the permafrost regions, even when working in the least permeable strata, one cannot completely exclude the penetration of viable bacteria from the surface. Therefore, it is impossible to determine the age of microorganisms isolated from cores from these regions, and the reports of viable microorganisms of Precambrian, Paleozoic, and Jurassic age (4–6) were not accepted with due seriousness. Moreover, in finely dispersed impervious strata viable aerobes and anaerobes only exist at depths of up to a few dozen meters (7).

The most fundamental aspect of any environment, the temperature regime, acts as a regulator of all of the physical-chemical reactions and forms the basis of all biological processes (8). More than 80% of the Earth's biosphere is both permanently cold and subjected to significant temperature fluctuations. Because we inhabit a cold planet, cold adaptation of microorganisms would appear to be an important trait. Because of their ability to cope with low temperatures, cold-adapted microbes, first isolated by Forster (9), can be regarded as Earth's most successful colonizers (10). They have adapted to the cold and populate now the all main ecological niches.

A significant volume of the Earth's cold environments consists of permafrost (perennially frozen ground) — a naturally occurring material with a mean annual temperature below 0 °C (11) and a portion of its moisture in the form of solid ice. Permafrost underlies about 20% of the Earth's land surface mostly in the northern reaches of North America and Eurasia (Alaska, Siberia, and Canada). In these regions, the permafrost reaches a thickness of more than 700 to 1,000 m in the north, thinning toward the south. It also occurs in the ice-free regions of Antarctica and Greenland and surrounding Arctic and Antarctica as offshore permafrost. Alpine permafrost can be found in the high mountains of Europe, western China, and both Americas. This considerable mass of frozen soil, up to several hundreds of meters deep, harbors a very large numbers of viable bacteria.

In the permafrost below the seasonally thawed layer, are numerous and various viable paleomicroorganisms (Fig. 1), prokaryotic, and eukaryotic, independent of the depth, with numbers ranging from 10^2 to 10^8 cells/gdw (12–15). This great mass of living matter, in quantities comparable to those of microbial populations in the soil cover, is peculiar to permafrost sediments. If we take into account the thickness of the deep permafrost layers, it is easy to conclude that they contain a total microbial biomass many times higher than that of the soil. Of all the natural environments, frozen fine-grained sediments, firmly bound together by ice, forms a unique system that seems to ensure the viability of microorganisms. In this isolated system, both the age of the microorganisms and the absence of an influx of alien microorganisms, are demonstrable.

The later was not fully realized until recently. The first data on the existence of bacteria in permafrost appeared at the end of the nineteenth century, in relation to the discovery of mammoths and studies of soils in Siberia (16,17). Five decades later, separately, and sometimes unrecognized by each other, microbes were discovered in Holocene and late Pleistocene permafrost of many Arctic regions (18–26). Viable cells in more ancient frozen sediments were found in association with the Antarctic Dry Valley Drilling Project (27). In all of these studies (3,15,28), the procedures and the application of drilling solutions did not guarantee the sterility of cores. Because of these methodological and technical difficulties, the earlier-mentioned reports were not considered with due attention, and the permafrost as a living stratum was not studied. Nevertheless, the authors of these early studies first raised the question of the possible preservation of viable cells in the permafrost. As early as 1975, Pewe (28) emphasized the need for further research in this field.

In recent investigations, new methods of sampling, storage, transportation, and control, as well as new specialized tests, have shown that the microorganisms seen in permafrost samples could not have penetrated from the outside, but are present in situ. The strict protocols for drilling and the subsequent handling of cores are designed to ensure uncontaminated material. These protocols (29,30) include the drilling techniques that do not require the use of drilling fluids and the aseptic methods to shave the cores before sampling.

The occurrence of a viable Cenozoic generation of microorganisms within the permafrost is intriguing because an analysis of their features may provide a window into microbial life as it was before the impact of humans. The recovered organisms may possess unique mechanisms that allow them to maintain viability for very long periods. They are easily involved anew in present-day ecological processes after instances of permafrost thawing, and may be vital in nutrient recycling and in the production and consumption of greenhouse gases over a large portion of the Earth's surface (15).

The viable organisms in the Earth's Cryosphere represent a significant part of Biosphere, the Cryobiosphere (Fig. 2), whose most inhabited part is the permafrost. The remoteness from anthropogenic impacts and the stability of the subzero temperature regime in the subsurface permafrost layers make it one of the more stable and balanced of the natural environments.

This environment provides life support and ensures the formation of microbial communities that realize unknown possibilities of physiological and biochemical adaptation to prolonged cold and remain virtually stable for millions of years. Evidently, the long-term impact of moderately subzero temperatures should be regarded not as the extreme and limiting but rather as a stabilizing factor supporting the viability of microorganisms adapted to these conditions. It is suggested that the mechanisms of such adaptation are universal and operate within the broad limits of modification for heterophasic natural systems.

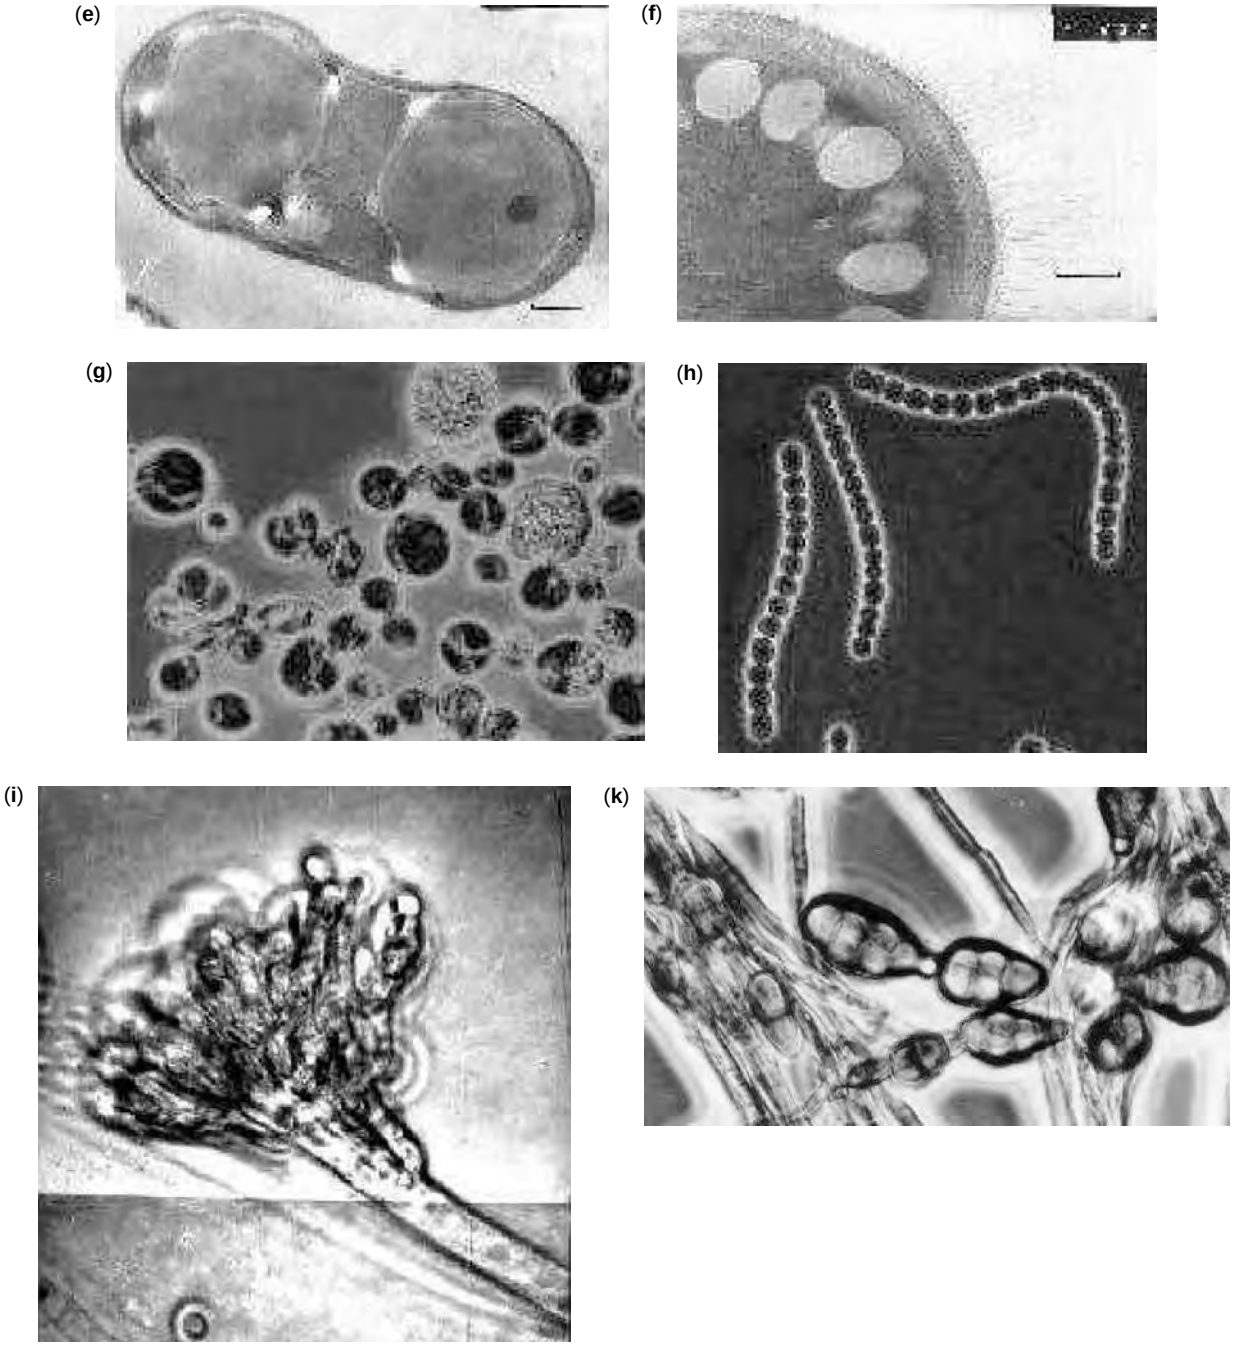

Figure 1. (*Continued*)

PARAMETERS OF PERMAFROST MICROBIAL HABITAT

Active Layer

In Arctic tundra, seasonal thawing starts in June and reaches its maximum (0.3 m in peat, 0.5 m in loam, and 1 m in sands) in mid-September. In forested tundra, the depth of the thaw in mineral soils increases by 20 to 70 cm, whereas in peat, it remains constant. Near the southern border of the permafrost, the maximal depth of the thaw reaches 2 to 3 m. The surface beneath the seasonal thaw layer is called the permafrost table. This is the physical and biogeochemical barrier that sharply restricts the influence of external factors and processes. The underlying cross section is firmly cemented, often totally filled in by ice. In such a closed system, there are no water-bearing horizons and no water infiltration. Thus, within the permafrost, because distinct from other layers, any viable microorganisms could not have been brought in from outside but exist in situ (29,30).

Temperature

The subzero temperature in the permafrost is favorable everywhere to the preservation of biological systems, and is the main factor contributing to the long-term

survival of cells. In the Arctic, the mean annual permafrost temperature (T), as registered at high altitudes, is between −10 and −12 °C (Fig. 3a), rising toward the southern border of the permafrost to between −1 and −2 °C. In Antarctic polar desert, with its background of below freezing air temperatures even in summer, sometimes the temperature at the soil or rock surface is above 0 °C (31,32), but there is no layer of seasonal thaw. From our observations, the upper sandy layers are completely dry and uncemented because of the evaporation of the snow and the sublimation of surface ground ice. As a result, they are easily blown off by storm and spring winds, and a stable soil cover is not formed (similar to the situation on sandy dunes); the permafrost table coincides with the diurnal surface covered slightly by a dry frozen layer about 10 cm thick (33). As a result of this fact and the sharp temperature oscillation on the soil surface, the upper 1 to 2 cm often contains the minimum number of viable cells in comparison with underlying horizons (34,35). A similar distribution, but on a smaller scale, was found for cryptoendolithic microbial communities on and within the Antarctic sandstone (36–38).

The maximal (−18 °C) mean annual permafrost temperature in Antarctic free ice areas, such as the Dry Valleys, is registered at low levels near the coast. This temperature decreases in accordance with the drop in air temperatures when moving inland and toward higher altitudes, reaching the lowest permafrost temperatures on the Earth, between −24 and −27 °C (Fig. 3c). The Dry Valleys permafrost, then, differs from that in Arctic in the much lower temperatures of its sediments, temperatures at which there is an obvious absence of liquid water and water-bearing horizons, and the domination of the active processes of sublimation that excludes any downward infiltration. For this reason, in the Antarctic, even more than in the Arctic, the possibility of the penetration of modern microorganisms into the frozen strata is precluded.

Iciness and Unfrozen Water

The permafrost is characterized by a specific, multiphase state of water, which plays a dual role from the biological point of view (39). The solid phase (ice) makes up 92 to 97% of total water volume in permafrost and serve as a cryoconservant for biological objects. The iciness (W_i) of sandy-loam-based frozen ground in Arctic varies from minimal values of 12 to 20% to a wide range of maximal values, 40 to 50% (Fig. 3b), or 60 to 70%, depending on the presence of ice wedges. At the higher ice contents the pores are completely filled with ice, obviously excluding any migration inside the stratum. The cryogenic structure of these sediments is usually marked by the massive cryogenic texture (segregated ice-cement), typical of sand-based strata, or by the different orientation (reticular, layered) of ice streaks 1 to 2 mm to 2 cm thick in clay- and loam-based strata. The coarse-grained Dry Valleys sands, firmly cemented into a massive cryogenic structure, also contain an unexpectedly high (25–40% or more) iciness values (Fig. 3d).

Simultaneously with the solid water phase, the remaining 3 to 8% of the water is in an unfrozen state ($W_{unf.}$), most commonly as thin films enveloping organic and mineral particles and, possibly, as brine pockets in saline soils. The dependence of unfrozen water on the physical-chemical parameters of frozen strata has been studied by the many scientific schools (40–44). The quantity of the unfrozen water and thickness of its films is independent of the total ground iciness, but decreases (Fig. 4a,b) with temperature (45,46). At Arctic permafrost ($T = -9$ to -12 °C) the magnitude of $W_{unf.}$ in a loam is 3 to 5%. In sands, $W_{unf.}$ is minimal, tending to zero, although there a silt fraction in them that retains a measurable $W_{unf.}$ (only in Antarctic sands, because of the ultra low temperatures, the $W_{unf.}$ values there are so small that the instrumental methods fail to record them). The maximal values of $W_{unf.}$ (10%) are related to saline solutions in thinly dispersed marine facies. When discussing unfrozen water films, we can be sure that the thermal diffusion of

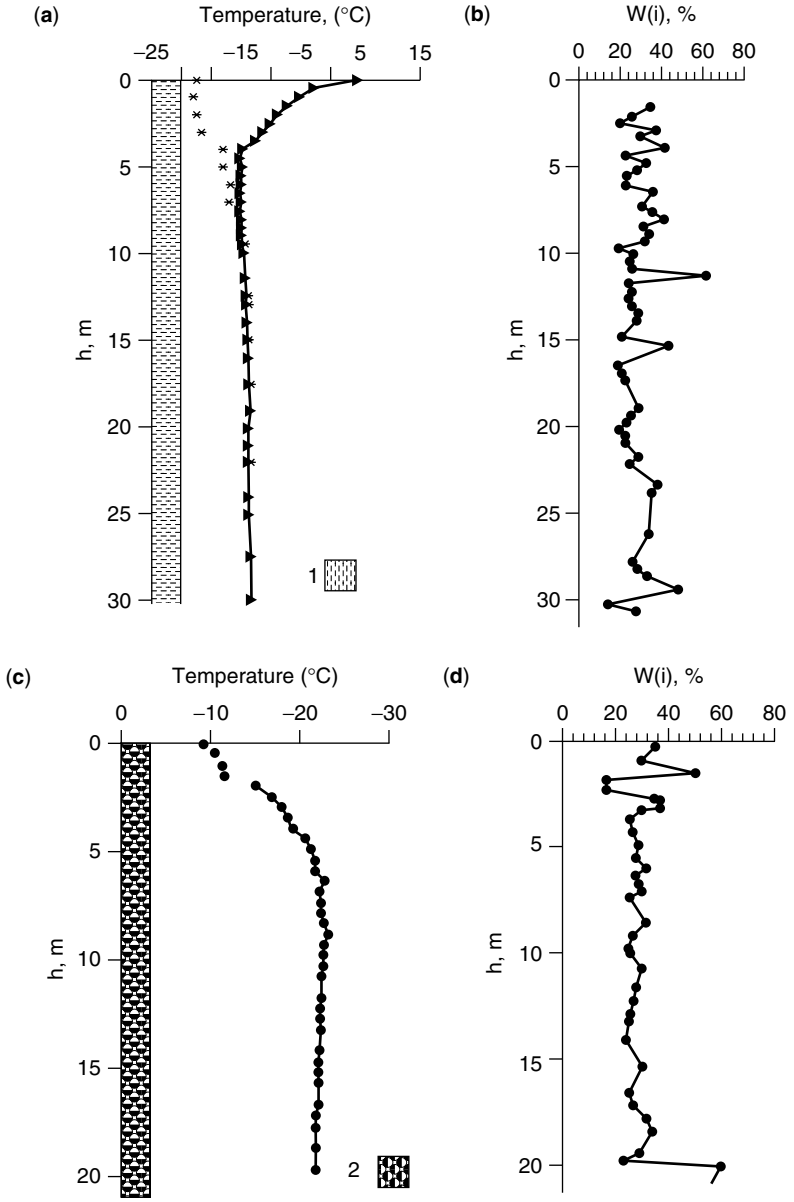

Figure 3. Ground temperatures and the iciness of permafrost sediments in high Arctic (**a**,**b**) and Antarctic Dry Valleys (**c**,**d**). Legend: 1 — sandy-loam; 2 — coarse-grained sands.

cells within the films is impossible because the thickness of these films (5–75 A°) is not comparable with the size of microorganisms, 0.5 to 1 μm (Fig. 4c), thereby precluding the migration of the cell within the unfrozen water.

In contrast to ice, the unfrozen water films serves as cryoprotectant and play a leading role in the preservation of microorganisms for the following reasons (39): these films, by coating the organomineral particles, protect the viable cells sorbed onto their surface from mechanical destruction by growing crystals of intrusive ice; these films make possible the mass transfer of microbial metabolic end-products within the permafrost, preventing the cell's biochemical death; these films may serve as a nutrient medium because the unfrozen water contains high concentrations of various ions and molecules; these films represent firmly bound "liquid" water with binding molecules, and this is why permafrost may be considered as a biologically dry environment.

The increasing content of chemical elements and salts in $W_{unf.}$ enhances their protective and transport role and their significance as a nutrient medium. Therefore, the unfrozen water might be considered as a main ecological niche where the microorganisms might survive. The validity of this assertion can be demonstrated by a comparison between the numbers of viable cells recovered from permafrost cores and the number of viable cells recovered from ice. In contrast to frozen soils with an abundance of microorganisms, the viable cells recovered from cores of the pure ice of the Antarctic Ice Sheet taken at the Vostok station (47) or Greenland Ice Sheets is on the order of a few dozens cells/ml of thawed water and increase (48) with increasing concentrations of dust

particles in the core. It should be noted that reliable data are available only for young, not older than Holocene ice layers. To date, no viable cells have been found in the fossil ices of Arctic — neither in intrusive ice nor in polygonal ice wedges (12,22). Both pure ice and permafrost

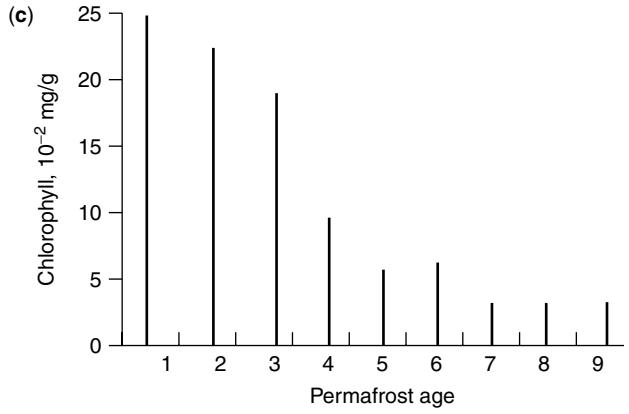

Figure 5. (*Continued*)

are at the same subzero temperatures. The only difference between the two is the amount of W_{unf} associated with suspended solids. In nature, pure ice, lacking suspended solids and their associated unfrozen water, has insufficient cryoprotection and transport abilities, and cells are destroyed mechanically by ice crystals. So, because the W_{unf} and pore space, fine dispersed frozen layers, with paleosols and peat buried in them, provides more favorable environment to microorganisms (49,50).

Gases

The gaseous phase of the permafrost is different from atmospheric air. The pore space of frozen strata is occupied by oxygen, nitrogen, methane, carbon dioxide, and other gases. The concentration of oxygen and nitrogen does not differ significantly from their values in the air, whereas the concentration of biogenic gases may be appreciably higher. The concentration of CH_4 (Fig. 5a) in Arctic permafrost varies from 2 to 40 mL/kg and CO_2 from 1 to 20 mL/kg. It should be noted that carbon dioxide is ubiquitous, whereas the occurrence of methane is determined by the age and genesis of the deposits and by the type of cryogenic stratum. In a generalized geologic cross section, methane-containing layers are sandwiched between layers free of methane (51). The fact that, for at least several hundreds of thousands years, the methane has not diffused from the methane-rich layers into adjacent layers devoid of methane implies that there is negligible diffusion of methane within the permafrost under both present and past conditions. The same conclusion can also be made at the distribution of carbon dioxide in permafrost layers. The facts suggest that these gases are held within the sediments in a clathrate form (52), making it impossible for cells to migrate with them.

The presence of methane, as well as the value of the redox potential ($Eh = +40$ to -250), indicate that conditions in Arctic permafrost are mostly anaerobic; the permafrost is composed of primarily lacustrine-alluvial and marine deposits. The Eh of investigated Antarctic eolian and glacial frozen sands vary from $+260$ to $+480$, indicating that the conditions here are not as anaerobic as in Arctic; this is confirmed by the absence of biogenic methane. In any case, it is the specific character of permafrost soils that, until the moment of transition to the permanently frozen state, they contain both aerobic and anaerobic microzones. This is why the ancient microbial communities consist of comparable numbers of anaerobic and aerobic species.

The ratio of anaerobes to aerobes is different in different geologic facies, that is, the part of the community that dominates depends on the origin of sediments. In one study, the number of anaerobes in swamp and lagoon soils was several orders of magnitude higher than that of aerobes (56), whereas in another study, based on alluvial deposits, aerobic groups dominated (12,50).

From a planetary science perspective, it is important to note that CO_2 and CH_4 do not prohibit long-term preservation of cells in permafrost. CO_2 is expected to be a major constituent of the gas phase in any permafrost on Mars, as is CH_4 in the permafrost associated with the satellites of gas giants (57). And what is more, the reduced state found in permafrost provides a model for possible life-forms on cryogenic planets without free oxygen. The finely-dispersed Martian dust appears favorable for the preservation of the maximum number of viable cells. Anaerobes should be dominant in Martian permafrost, even in the absence of organic carbon (58). Terrestrial anaerobic, chemolithotrophic, psychrotolerant bacteria, with their ability to assimilate CO_2 in an environment similar to that of Mars have been suggested as prospective analogs to the living forms that might be found in subsurface Martian layers (59). We note in closing that the formation of methane clathrate in frozen sediments at low pressures has implications beyond Arctic studies. Similar processes may represent important reservoirs of methane on other icy bodies in the solar system, in particular in the surface materials of comets (57).

CHEMICAL COMPOSITION AND ORGANIC MATTER

The typical acid-base characteristic (pH) of Arctic permafrost sediments is close to the neutral value (6,7), indicating faintly reduced conditions. The content of organic matter ($C_{org.}$) is 0.5 to 7%, a value that is independent of the depth of bedding and the age of soils. If one considers the thickness of the sedimentary cover, it has preserved a tremendous mass of organic carbon. For example, a one-square-meter section of the 100-m thick permafrost may contain 340 to 460 kg of $C_{org.}$ (60). The composition of the hydrocarbons and fatty acids in the permafrost indicates a primarily vegetative origin of the $C_{org.}$ (of the type of *Betula* sp.) in the sediments with a smaller portion of bacterial origin (61). This great mass of organic carbon (Table 1), which has not been processed by microorganisms, is still labile and, in the event of permafrost thawing, could become available for the ancient cells within the frozen soils to renew their physiological activity (53,62–64). In Antarctic cores, in contrast, the pH of medium is alkaline (8,9) and the total content of organic carbon is very low, often close to zero. It varies from 0 to 0.1% in eolian and glacial sands to 0.3 to 0.4% in lacustrine sediments.

Arctic sediments, rich in organic carbon and Antarctic soils, in which both the carbon and the unfrozen water content are close to zero and the temperatures is 10 °C

lower, contain about the same number of microorganisms (10^7–10^8 cell/gdw), as estimated from direct counts using epifluorescence microscopy and staining with acridine orange (50). Furthermore, this total quantity of microbial cells is relatively constant from modern up to 3-Myr-old sediments (Table 2) and independent of the sample origin, depth, physical/chemical composition, and temperature. In other words, there is a minimal constant level of microbial colonization that forms in natural systems in the presence of only mineral soil particles and short-term existence of free water. Possibly, this unexpected result shows that these minimal conditions are enough for the origin of life. For comparison, the total number of microorganisms recorded from depths of 1,500 to 2,750 m in the Antarctic Ice Sheet is also a constant, 10^3 cells/ml (48), less than the numbers from permafrost by several orders of magnitude.

Obviously, the chemical composition of permanently frozen ground differs in different areas and depths in accordance with their origin (Table 3 A). For example, in Antarctic Dry Valleys, Na^+ ions are dominant in water extracts, against a background of the equal presence of basic anions, and the dry residue reflects the freshwater genesis of the sediments. Water extracts from the main stratigraphic horizons in the Eurasian northeast are characterized by the hydrocarbonate-calcium and a freshwater composition. Arctic marine deposits are distinguished by the sodium-chloride salinity.

The results of culturing more than 5,000 frozen samples from different regions indicates that under similar natural conditions, the soil chemical composition is not a leading factor the determination of the structure of the viable microbial community in permafrost. Salinity plays an important, but not yet understood, role. Arctic freshwater terrestrial layers, formed under the same conditions as modern tundra soils, in contrast with their microbial communities, yielded bacterial colonies on media with high salt content, suggesting the existence of strongly halotolerant microbes in permafrost. It remains to be determined whether the salt tolerance of these strains may also be associated with their tolerance to freezing conditions (65). At the same time, the marine sediments did not contain halophylic microorganisms. The same is true of supercooled (up to $-10\,^{\circ}C$) saline groundwater lenses (cryopegs) found within the permafrost. Cryopegs are formed after the retreat of the sea and the freezing of

marine sediments. As a result of the freezing out of salts from the deposits, the concentration of salts in cryopegs, up to 170 to 300 g/l NaCl, is much higher (orders of magnitude) than in the embedding strata. And even in these environments viable cells were found, and were both anaerobic and aerobic and nonhalophylic (Table 3 B).

THE CORRELATION BETWEEN THE AGE OF PERMAFROST ENVIRONMENT AND THE AGE OF VIABLE MICROORGANISMS

There are no methods for the direct determination of the age of viable microorganisms. In general, the duration of cells cryopreservation does not necessarily coincide with the age of the embedding sediments. Instead, it always corresponds to the duration of the existence of permafrost (49). Two ways of permafrost origin are known: (*1*) syngenetically frozen layers, where sedimentation occurred concurrently with freezing from below, in which case the age of permafrost is taken to be equal to the age of sediments; (*2*) epigenetically frozen layers, where freezing occurred from the top after sedimentation, in which case the age of permafrost is taken to be younger than sediments. In syncryogenic horizons, where the age of permafrost is equal to the age of sediments, the age of cells also coincides with the age of sediments. Here, the higher the layer is in the profile, the younger it is with regard to its formation and to the duration of the frozen state. In other words, the upper strata of both the permafrost and the organisms populating it are younger. In the case of epicryogenesis, the duration of cell's preservation is again equal to the permafrost age, that is, to the time from the last freezing of sediments. However, because of the effects of thermal inertia on the penetration of the temperature wave, the deeper lie the sediments, the more recently they were frozen and the younger are their microorganisms (Fig. 6). Consequently, the most reliably proven are the ages of microorganisms in the syncryogenic strata. The northern Eurasia permafrost, in which traces of cryogenesis can be related to Mid-Pliocene shingles (66), is the most ancient in Arctic. The age of microorganisms here corresponds to the longevity of deposits frozen state; the most ancient are known date back to 3 Myr.

The analysis of numerous publications (67–71), best reviewed by Wilson (72) indicates that permafrost has existed under Antarctic climatic conditions for the last dozens of millions of years, greater than the duration of Arctic permafrost by a factor of ten (49,58). Viable bacteria (both aerobic and anaerobic), enzymes, pigments, and biogenic CH_4 were found in boreholes in one prospective site, Mt. Feather (73). The age of glacial syncryogenic soils of the Sirius Group dates back at least 2 Myr (74) or, probably, 15 Myr (75). $^{40}Ar/^{39}Ar$ dates on ash layers suggest that the most ancient ground ice below these layers may be more than 4.5 Myr old in Arena Valley (76) and 8.1 Myr old in Beacon Valley (77). Verifying these ages is critical because viable bacteria have been isolated in the frozen ice below this ash layer and if this age is correct, this is the oldest viable life on Earth.

PERMAFROST BIODIVERSITY

The permafrost microbial community has been described as "a community of survivors" (78). Survival is the result of the combination of cold temperature, desiccation, and starvation (3). Viable bacterial populations in permafrost soils can be viewed as the result of a continuous process of selection for forms that can withstand cell aging and prolonged exposure to subzero temperatures (79). The rates of metabolic activity at these temperatures, over periods of 2 to 3 Myr or longer, and in frozen soils would

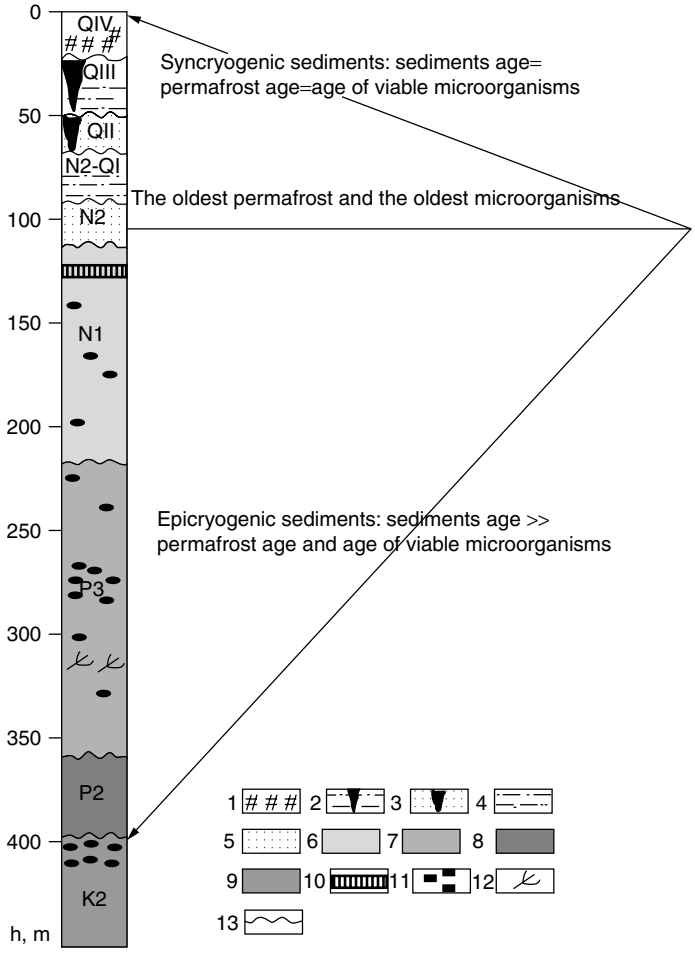

Figure 6. The correlation among age of sediments, the age of permafrost and the age of microorganisms in syncryogenic and epycryogenic thickness. be expected to be extremely low. Therefore, permafrost may represent an example of an environment in which the survival of certain life-forms continues, and in which the stringency of the environmental conditions is such that the continuous evolution of successful adaptations is hindered. According to Morita (3) the permafrost may be considered as anoligotrophic environment in which the starvation-survival lifestyle is the normal physiological state.

After the prolonged exposure of the microorganisms to the permafrost environment, the ratio of readily culturable (hypometabolic) bacteria to those that may represent viable but nonculturable forms (deep resting cells) is determined by the extent and duration of exposure to subzero temperatures (50). It should also be kept in mind that some cells may have died when subjected to the stresses of thawing and exposure to oxygen because the samples were suddenly melted in the laboratory for microbial study at relatively high temperatures. Although these stresses are known to inhibit the recovery of a fraction of the community, strategies and techniques for the low-temperature recovery of bacteria from permafrost environments are only just beginning to be developed (65). Using the new techniques, it has been shown that permafrost bacteria, when isolated on rich media, were less numerous than those in diluted media, but had greater diversity. Similar results were also obtained during the isolation of bacteria from deep subsurface nonfrozen environment (80).

The ancient permafrost microbial community is predominantly bacterial, as is the community in the depths of Antarctic Ice Sheet (47,48). This is in contrast with modern soils in which the fungal mass is much greater than the bacterial mass. In Arctic permafrost, non–spore-formers predominate, whereas in Antarctic permafrost spore-formers dominate. In isolations of aerobic bacteria from Arctic permafrost at +20 °C, a significant fraction was found to be spore-formers (30). This contrasts sharply with isolations carried out at +4 °C, where spore-formers were only rarely obtained. Perhaps this reflects an intriguing paucity of spore-forming bacteria in frozen environments (65). Some isolated microorganisms carried mercury-resistant plasmids (81) and were more or less resistant to antibiotics (82).

Overall, a number of different morphological and physiological groups of microorganisms have been found, including spore-forming and sporeless, aerobic and anaerobic, bacteria, fungi, yeast, actinomycetes, representing more than 50 genera (Fig. 1). Morphologically, they are coccoid, coryne-like, nocardia-like, and rodlike gram-positive or gram-negative bacteria. Seen rather frequently are prokaryotes with thick cell walls and capsules, surrounded

by additional surface layers of low electron density. Eukaryotic cells, although present, seem less able to survive long-term cryopreservation (83). Even these data and well-known widespread existence of modern phototrophs in such environment as Antarctic Dry Valley, best described by Friedmann (36), it was a surprise to discover within the full permafrost darkness numerous viable phototrophs: cyanobacteria and green algae that had preserved their photosynthetic apparatus (84,85). During the last years, green algae were also isolated from Antarctic permafrost and mosses from the Arctic one. Until recently, these two groups of the lower plants represented the highest of known long-term surviving biological systems. Now protozoa were isolated from the buried Arctic soils. Viable seeds of higher plants were found within Siberian and Canadian late Pleistocene permafrost. It was shown that these seeds still were able to grow (86).

RESPONSE OF MICROBIAL COMMUNITIES TO PERMAFROST ENVIRONMENT

The data shows that during the long-term preservation at temperatures from −3 to −4 °C in the interior of Alaska, −5 to −6 °C in the Mackenzie delta and −9 to −12 °C in the Eurasian northeast, the number of viable microorganisms is independent of the permafrost temperature. At the same time near the southern permafrost boundary in western Siberia, with ground temperatures −1 to −2 °C, and in Antarctica, with ground temperatures as low as −18 to −25 °C, the number of viable cells decreases by several orders of magnitude (Table 4 A).

The microbial community, even after its long-term existence within the permafrost, according to their growth temperatures (87), are not psychrophilic bacteria (T_{min} at <0 °C, T_{opt} at <15 °C and T_{max} at <20 °C), known to be restricted to permanently cold habitats (88). Instead, they are predominantly psychrotrophic (T_{min} at <0 °C, T_{opt} at >15 °C and T_{max} at >20 °C). 95% of the isolated cells did not grow at temperatures higher than 30 °C (Table 4 B), but were often capable of grow at temperatures below 0 °C. In the presence of cryoprotectants such as glycerol, added to the nutrient medium in an attempt to simulate natural conditions in permafrost in which unfrozen water plays a cryoprotectant role, growth of ancient cells was observed on Petri dishes incubated at temperatures at least as low as −10 °C for one to one and a half years (39). According to Russell (10), this correlates with the lower temperature limit for growth of psychrophilic microorganisms. So, because these terms are not clearly delimited, one can define the isolated microbes as psychrotrophic-psychrophilic or psychrotolerant organisms.

The microorganisms isolated from the syngenetically frozen sediments, as well as from the modern tundra soils, are resistant to sharp temperature transitions through

Table 4. Viable Microorganisms in Permafrost

A. *The Number of Viable Aerobes in Permafrost at different Temperatures*

0 °C and to freezing/thawing stress. Even after hundreds freeze per thaw cycles, the number and diversity of viable cells did not change, whereas samples from never frozen regions often become sterile after a dozen of these cycles. Microorganisms from epigenetically frozen marine sediments are somewhat intermediate; they are resistant to the long-term impact of subzero temperatures, but very sensitive to the phase exchange in surrounding microenvironment (79).

The number of culturable cells and their diversity is independent of the soil's origin and the depth of bedding, icing and cryogenic texture, chemical composition and organic matter content; microorganisms were isolated even in cases of extremely low levels of organic matter (Table 1). The number of culturable aerobic cells is dependent primarily on the duration of the frozen state, that is, by the permafrost (not sediments) age. The greater is the permafrost age, the lower are the number of viable cells, the lower their qualitative and morphological diversity, and the greater the number of sterile samples (Table 2 B). This suggests that freezing itself is a biodiagenetic factor, and that a long-term existence in the frozen state reduces an aerobe's viability.

These discussions are based on the culturable cells. Analysis of Arctic sediments showed that only 0.1 to 5% of the cells counted by epifluorescence microscopy grew on nutrient media, and in Antarctica, the percentage is reduced to 0.001 to 0.01% (50). Taking into account the temperatures and close-to-zero unfrozen water content of Antarctic layers, this low value could, to a certain extent, be explained by the deep resting state of the cells. At the same time the number of viable anaerobes: methanogens, denitrifying, sulfate- and iron-reducing bacteria (Table 4 C), if the community exists, is determined by the anaerobic origin of the frozen layer and is independent of permafrost age (56).

Because of the importance of unfrozen water, the number of viable cells under similar conditions is dependent on the textural composition of the permafrost, and increases with increasing soil dispersion. The finer the texture of the sediments, the larger the unfrozen water content in them, the thicker the water films, and the greater the number of viable cells. Evidently, good preservation of cell structures is determined by the equilibrium-state of the water inside and outside the cell (i. e., unfrozen water in cells and films). Violation of the equilibrium results in cell death. Consequently, ice formation in the experiments on Petri dishes results in cell death. In sands, with only minimal quantities of unfrozen water, the abundance and diversity of viable microorganisms is substantially lower than in loams, with unfrozen water contents of 5 to 8%. With this in mind, a series of experiments were done (89), and calculations showed that if enough solute had accumulated to achieve a total osmolality of 5.38 osm, then no exosmosis or cell shrinkage would be required for the cell to exist at −10 °C without danger of intracellular ice formation.

The phylogenetic diversity of the permafrost bacterial community has only recently begun to be addressed. For this reason we need to keep in mind that all above-mentioned discussions are based on the culturable cells, and, as is the case in other natural environments, a large portion of the permafrost microbial community remains uncultured. The data based on DNA extracted from modern Siberian tundra soils suggest that the clones are phylogenetically very diverse, and that many probably reflect new genera or families. Hence, most of this bacterial community has never been isolated and the physiology and function of its dominant members is unknown (90). The first molecular data have recently been obtained from ancient permafrost bacterial communities, using 16S rDNA sequencing. Phylogenetic trees derived from this data indicate that the Arctic isolates fall into four major groups, partly determined by the age of the permafrost. Most are high-GC gram-positive bacteria and β-proteobacteria. All γ-proteobacteria came from the late Pliocene-early Pleistocene samples, 2 to 3 Myr old. Most of the low-GC gram-positive bacteria came from the Holocene age, three to eight thousand years old (30). The communities also include members of Archaea, which have only recently been detected in the Siberian permafrost. These results, and as it was first shown in Greenland ice cores two to four thousand years old (91), demonstrated good preservation of ancient genomic DNA in both frozen environments, permafrost and ice.

Free extracellular enzymes were also found in permafrost sediments. Among these, invertase activity was found in all studied samples (Fig. 5b), whereas amylase, protease, and catalase activity were often detected (12,53,62). The association of immobilized microbial cells and organic-mineral complexes containing active enzymes that are resistant to the long-term effects of extremely low temperatures. This enables the enzymes and cells to restore their metabolic activity during permafrost thawing. Interaction with the heterogeneous medium becomes possible due to the availability of active immobilized enzymes. The distribution of enzyme activity in geologic sections differs from that of viable cells. It decreases sharply in the Holocene interval, then is approximately constant, independent of permafrost age (53). Invertase and some catalase activity were detected in permafrost samples from which viable cells were not isolated. This makes some enzymes attractive as a biomarkers. The same situation holds for chlorophyll pigments, which were often found in permafrost under dark conditions (Fig. 5c) (54,55). In Dry Valleys, chlorophyll is produced by green algae or cyanobacteria, which are often found in surface layers. Chlorophyll was found within the Antarctic permafrost samples, in which neither green algae nor cyanobacteria could be isolated. Because all data shows that DNA and microbial end-products can be preserved in permafrost even in the absence of viable cells, these studies may have wide implications.

METABOLIC ACTIVITY IN PERMAFROST ENVIRONMENT

The following features of permafrost microbial communities after their release from the frozen state have been detected: high viability and rate of cell proliferation; high rate of biochemical processes after thawing; intensive RNA synthesis immediately from the beginning of thawing;

and an extremely high thermostability in some microbial enzymes and an ability for them to become instantly activated (53).

A key question regarding the viable bacteria in permafrost is whether they are active in the permafrost environment or present in a suspended "dormant "state. Recent information suggests that permafrost microorganisms are not, as previously thought, in a frozen resting state. There are only a few data about metabolic activity of microorganisms below the freezing point, and only for recent microbial communities. Measurements show that Antarctic lichens may be active at temperature of $-17\,^{\circ}C$ (92). Recently, evidence has been found of low rates of bacterial DNA and protein synthesis in Antarctic snow, indicating that the organisms were metabolizing at ambient temperatures -12 to $-17\,^{\circ}C$ (93). The following facts provides indirect evidence that ancient microorganisms can be active in the permafrost nutritional-temperature regime and allows to speculate on the possibility of biogeochemical processes in situ: the ability of immobilized enzymes in permafrost to become instantly activated (53,62); the presence of usually metastable nitrites and ferrous sulfides (94,95); the simultaneous presence of methanogenic bacteria and methane (51,52,56).

For ancient microbial communities only the results of experiments with use of ^{14}C-acetate, shows that constructive metabolism is possible in permafrost of age 3 Myr down to $-10\,^{\circ}C$, resulting in the formation of bacterial lipids (64). However, the question about the metabolic state of microorganisms, microbiological and biogeochemical processes and life-forms within the permafrost remains open to debate. Recently, Rivkina and Laurinavichyus got a new data about the energetic metabolism–methane-formation in permafrost sediments using the ^{14}C-labeled substrates. The results of the experiment are the following: the activity of the CH_4-formation both from CO_2/H_2 and acetate was observed in native permafrost sediments at temperature down to $-17\,^{\circ}C$. One can suggest that the CH_4-formation below and above the freezing point are realized by different methanogenic community: psychrofilic and psychrotolerant, correspondingly. Remarkably, the incorporation of ^{14}C into methane above freezing point and directly below one just a little differed one each other. At lower subzero temperatures (down to $-17\,^{\circ}C$) CH_4-formation occur in the absence of liquid water, and even the unfrozen water in the sediments is lower than 1%. Realization of these chemical reactions still is not quite understandable. Nevertheless, one cannot exclude cellular activity (but not cell division) at a very low level. These results show that in natural deep frozen environment the metabolic redox reactions realized by ancient microorganisms represent an unknown form of the long-term preservation of viable ecosystems and the life maintenance over the aeons in permafrost.

If in an active state, even if at reduced level of activity, the bacteria should be able to repair cellular damage caused by racemization of amino acids and by radiation from natural radionuclides in the permafrost. Estimation of ground radiation has been made by McKay and Forman, using both elemental analysis of the radioactive elements in sandy and loam samples and direct measurements in the boreholes in the Kolyma lowland on the Eurasian northeast. The radiation dose received by the permafrost bacteria is about 2 mGy per year. Taking into account the age of bacteria, late Pliocene to late Pleistocene, the total dose received by cells would therefore range from 1 kGy in soils dozens of thousands years old to 0.6 kGy at over the 3 Myr age of microorganisms. Experiments with soils have shown that up to 30 kGy are required to sterilize soil at above-freezing temperatures and the results obtained by Japanese researchers, indicate that bacteria in soil have a much greater resistance to irradiation when frozen than when thawed. Our own results demonstrate that, at similar levels of ionizing radiation, a known quantity of viable cells and a total radiation dose of 5 to 50 kGy, most of the cells in frozen samples survived, whereas most of the cells in unfrozen samples died. The ability of cells to produce colonies after being exposed to total doses as high as 3 to 5 kGy shows that freezing increased the cell's resistance to radiation and raises the question of the uniqueness of permafrost as an environment in which microorganisms display a high resistance to radiation. From these data the dose from radionuclides diffused through the permafrost is far from sufficient for complete sterilization, that is, is not fatal for viable cells, but should be large enough to cause some selection effect and to destroy the DNA of ancient cells. Their viability and growth on media implies the capacity for DNA repair. Probably DNA repair is occurring in the frozen environment, that is, at the stable rate of damage accumulation, a comparable rate of repair also exists. From the biological point of view, it is important the permafrost preserves the cells from diffuse ground irradiation for thousands and millions of years. And what is more, in one series of experiments, the oldest, Pliocene cells, which had received an in situ maximal dose during the time of cryopreservation, were found to be more resistant to radiation than microorganisms from modern tundra soils.

PALEOENVIRONMENTAL RECONSTRUCTIONS

As the result of investigations into the microbiology of permafrost, it is now possible for the first time to use actual viable organisms for the purposes of reconstructing a past environment. In contrast to traditional methods using bioindicators, we can use not only of morphological indices of the fossil microflora, but functional indices as well. This highlights the permafrost as a natural biological database of Quaternary events. The microbial communities reflect the conditions at the time of syncryogenesis or the biogeochemical parameters of environment in the embedding strata at the moment of epicryogenesis. This makes possible different paleoecological and paleoclimatic reconstruction of the frozen, that is, most mobile, mantle of the Earth (29). For instance, we can reconstruct the vertical dynamics of the frozen thickness. Climatic oscillations in high latitudes are reflected in permafrost by its agradation in cryochrones, that is, cold periods, and its degradation (thawing) in thermochrones (warm periods). The cryochrones following thermochrones result in the refreezing of thawed thickness

and thus the whole section represents now one monolithic frozen sequence. Refrozen (epicryogenic) and never-thawed parts of this section have the similar physical-chemical and mineralogical characteristics, but differ in microbial and biogeochemical parameters. Therefore, permafrost dynamics in vertical cross sections, can be established by the distribution of viable microorganisms or their metabolic end-products. The depth of seasonal thawing of modern Arctic soils is marked by an accumulative horizon of viable microorganisms at the permafrost table (Fig. 7a), caused by their infiltration with melt-water (96). When the depth of thawing decreases, this horizon returns to the permanently frozen state. Just as the depth of modern seasonal thawing corresponds with present-day climate, the depth of thawing in the past corresponds with paleoclimatic conditions.

Microorganisms accumulate at the bottom of each thawing layer (on the permafrost table) formed during short- and long-term warming. In the Eurasian northeast, the Holocene Global Warming stimulated the local thawing of late Pleistocene sediments. Because of the new late Holocene cryochrone, the thawed thickness is refrozen again and merged with underlying horizons to form one cross section. Here the upper refrozen part, of "young" Holocene permafrost age and epicryogenic origin, contains many more viable microorganisms than the underlying never-thawed "ancient" syncryogenic late Pleistocene layer. The border between these two parts is marked by a horizon with increased numbers of viable cells (Fig. 7b). Thus, stratigraphic levels of thawing can be detected by microbiological data. The deeper the peak of microbial accumulation, the more ancient and stronger is the corresponding thermochrone. It is not important what factor, either climatic or geologic, caused the heat wave — microorganisms have also accumulated at the bottom of talik (nonfrozen) zones, below the sea, river, or lake water tables (15,29,79).

The methane distribution in permafrost can also be used as a biomarker. This gas is a product of the activity of methanogenic bacteria in anaerobic systems during

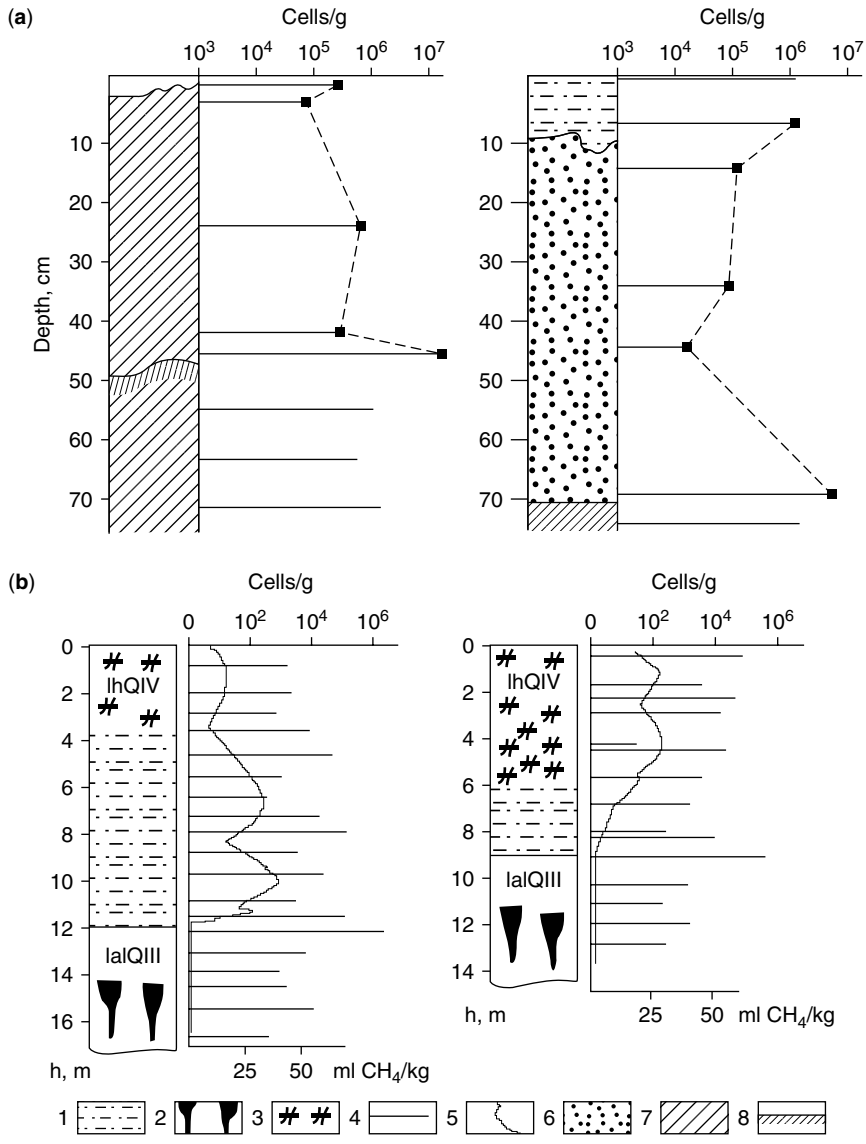

Figure 7. The distribution of viable microorganisms in the modern tundra cryosol profiles and underlying permafrost (97) and the accumulative layer of viable microorganisms on the top of permafrost table (**a**); the distribution of viable ancient aerobic microorganisms and biogenic methane in the refrozen, epicryogenic, and underlying syncryogenic, permafrost and the accumulative layer of viable microorganisms on their border (**b**). 1 — sandy-loam; 2 — late Pleistocene icy complex; 3 — peat; 4 — number of viable microorganisms; 5 — methane concentration; 6 — sands; 7 — loam; 8 — permafrost table.

thermochrones. The refreezing of thawed horizons from the top closes the system and preserves the methane as evidence of the past microbial activity. The depths of thawing detected by distribution of viable aerobic microorganisms correlate (Fig. 7b) with the depths of past activity indicated by anaerobic microorganisms (98). Thus, the same data have been received by two independent methods. The reconstruction, similar to the Holocene, may be used in deeper and more ancient Pleistocene layers, in which it may also be helpful to incorporate microbiological methods into an interdisciplinary study. The earlier-mentioned examples are simple but not the only possibilities for the use microbial data. For instance, using these data one can detect the processes that formed the buried soils, and from them the landscape conditions.

When considering paleoreconstructions, it should be remembered that permafrost not only contains more information because of the high microbial numbers and diversity, it is also much older than ice sheets and glaciers. The oldest glacial ice, 400,000 to 500,000 years old, is found at Vostok Station in Antarctica and in Gyliya ice cap in the Tibetan mountains (97,99). Although the permafrost ages can reach millions of years, stable ice thaws under the geostatic pressure or sunlight even at subzero temperatures.

THE PERSPECTIVES FOR FUTURE STUDY AND POSSIBLE APPLICATIONS

The presence of viable paleosystems within the permafrost is of interest from geologic and biological points of view. Unique to the permafrost environment is it possible to develop a microbiological timescale using a combination of available geologic data, viable paleocultures, and tools of molecular biology. It should be possible, using phylogenetic trees developed from the same organisms (based on RNA sequences) from the modern top layers to the several millions years old in the boreholes, to find out what are the differences among members of the same species as we go back in time. Then, if we compare those differences (mutation rate) with geologic time, we can speculate on how fast or slow evolution or adaptation takes place in that particular environment and for that particular type of organism. This would be a beginning of studies concerning the rate of evolution and biological clocks extending back the duration of the permanently frozen state in the soils, that is, the age of biota. Its prototype is based on the reduction of the microbial community with the increasing permafrost age and the disappearance of some indicator microbial groups in the reference points of the Pleistocene sections (29,49,54).

In biology, established phenomena form the basis for various scientific fields in cryo-, paleo-, and exobiology. Of special interest is the interaction of knowledge to our understanding of microbial evolution, geologic and planetary history, the spatial and temporal limits of the deep cold biosphere on the Earth and other bodies in space (15,49). Among these new scientific directions, one of the most general is the fundamental question of the duration of life preservation. Modeling, calculations, and experiments cannot solve this problem because the length of time cannot be reproduced. From this viewpoint, permafrost is a unique observatory of ancient viable systems. It makes possible the observation of the results of cryopreservation over geologic timescales. However, questions concerning the possibility of microbiological and biogeochemical processes below freezing point and the nature of life in permafrost remain open to debate. This is why it is so important to identify the boundary between inhibited metabolism and anabiosis and to determine how long microorganisms can preserve viability using these different mechanisms. It is also possible that other mechanisms for the long-term preservation of viable ecosystems and vital activity exist in permafrost. The freezing-resistance of the microbiocenoses may depend on the ability of individual microorganisms to enter the anabiotic or similar state upon the freezing of the soil. This is why we call them only viable, not living cells; because of their own cryoprotectant properties, they are not in a frozen state, but only in a cooled state. It has been shown that during freezing, the dehydration of macromolecules and the reorganization of membrane components lead to a considerable decrease of metabolic activity, which can be restored under favorable conditions (83). This mechanism might work for billions of years.

From an exobiological point of view, seven of the nine planets of the Solar System, as well as their satellites, comets, and asteroids are of a cryogenic nature (Fig. 8), that is, the permafrost is a common phenomenon in space. The terrestrial permafrost, which is inhabited by cold-adapted microbes and protects the cells against unfavorable conditions (radiation, gravity, damage by ice crystals, sharp temperature transitions, etc.), can be considered as an extraterrestrial model (100). The cells and their metabolic end-products (enzymes, pigments, and gases) found in the Earth's permafrost provide a range of analogs that could be used in the search for possible ecosystems and potential inhabitants on extraterrestrial

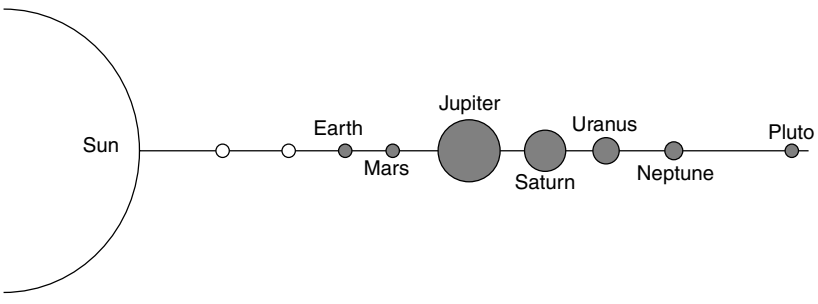

Figure 8. Planets of a cryogenic nature.

cryogenic bodies. If life ever existed on other planets during the early stages of development, then its traces may consist of primitive cryogenic forms at the cell level. By analogy with Earth, they might have been preserved and could be found at depths within the permafrost. Most intriguing is the possibility of traces of past life on Mars. Cameron and Morelli (27) first advanced theoretical concepts for solving the problems of Mars by using terrestrial models. For example, in the upper 500 m of Antarctica Ice Sheet viable cells were found at temperatures −50 °C (43), what is closed to Martian temperatures.

The main difference between Earth's permafrost and the outer planets is their age. In northeastern Eurasia, the oldest continuously frozen permafrost dates back about 3 Myr, whereas on Mars, the age of permafrost is about three billion years. This difference in timescale could have a significant impact on the possibility for life preservation. The Arctic frozen sediments inhabited by microbes are only approximate models for Mars. The Antarctic sediments may somewhat be closer. The limiting age, if one exists, within the Antarctic cores, in which the viable microorganisms were no longer present, could be established as the age limit for life preservation within the permafrost.

CONCLUSION

The permafrost is a reservoir of ancient microorganisms, many of which may remain viable. They are a model for resistance to freezing in both aerobic and anaerobic conditions, but, in contrast to the microorganisms in glacial regions, most of them are not psychrophilic. It was shown that in both Arctic and Antarctic permafrost, not only prokaryotic but also eukaryotic cells are preserved in a viable state and that the total biomass of microorganisms is comparable with the biomass of modern soil cover. Low temperatures should be considered as a stabilizing factor for sustaining life in the permafrost. Permafrost is a depository of ancient biomarkers, including biogenic gases, PAHs, biominerals, biological pigments, lipids, enzymes, proteins, nucleotides, RNA and DNA fragments and molecules, microfossils, and viable cells. The phylogenetic analysis under Tiedje leadership by sequencing their 16S rRNA genes shows that the majority of the isolates are members of eight genera. The gram-negatives are *Flavobacterium, Cytophaga, Sphingomonas*, and *Psychrobacter*. The gram-positives are *Arthrobacter, Rathayibacter, Exiguobacterium*, and *Planococcus*. Unfortunately, viable viruses of already beaten diseases as markers of past epidemics (smallpox, plague, and influenza) might be present there among them. Therefore, permafrost is of great significance for research in cryobiology, biotechnology, ecology, molecular paleontology, and the newly emerging field of exobiology. The psychrotolerant microbes have not received as much study as has been devoted to the thermophyles. Therefore, they represent a fertile area for scientific research. Special areas to be considered include studies of the *in situ* activity below the freezing point and after the thawing. The mechanisms for microbial survival during the long-term anabiosis or low metabolic state and during repeated freeze-thaw conditions must be studied in detail. Experiments with viable microorganisms at temperatures below freezing point suggest the need to develop of more sensitive equipment and methods for studies of this only open slightly unknown microbial world and measurements of their activity within natural frozen environment.

The strategy for the search for extraterrestrial life or its remnants must be based on studies of the most probable environments in which the life might be find, and the maximum period of time over which such life could be preserved. This is why the permafrost environments under the Martian surface may be the areas where the probability of finding life is the highest. The microorganisms of the permafrost may be considered as models for the types that might be encountered in the Solar System, if life should be found to have distribution in the Cosmos beyond the planet Earth. The features of permafrost bacteria suggest the need for development of improved protocols for their recovery from ancient frozen environment preparation for the analysis of life or its traces in extraterrestrial materials that should soon be returned from comets and Mars.

PESTICIDE DEGRADATION IN SOILS

GUY SOULAS
INRA-CMSE Microbiologie des Sols
Dijon-Cedex, France

Industrial countries have developed agricultural practices largely based on the use of synthetic organic pesticides, which since the 1950s have greatly enhanced the quantity and quality of food. However, because of the large amount applied since usage began, pesticides have been translocated throughout the entire environment. Pesticides are commonly found in surface waters and groundwater, leading to potential human exposure. Because pesticides are toxic by design, few public concerns of environmental significance are as fraught with emotion as is pesticide use. Soil is the ultimate receptacle of agricultural pesticides, and soil microorganisms are directly exposed to pesticides. Not only can many soil microorganisms tolerate contamination but many can also degrade pesticides through enzymatic reactions. Advances in the basic knowledge of the physiological, biochemical, and ecological processes involved in pesticide degradation, and their genetic determinants, make it possible to better predict the fate of pesticides in the environment and to design more realistic (bio)technologies for the resolution of problems of pesticide contamination.

The objectives of this review are, first, to present the main physiological mechanisms of pesticides degradation by soil microorganisms and to discuss some aspects of their genetic determinants as they can be deduced from the present knowledge on two families of chemicals, the phenoxy and the triazine herbicides. Then, we will examine how these mechanisms interact in natural environments and what conditions are conducive to the selection of strains or consortia showing increased degradation potential. In the final part, we will briefly describe the present state of the art of two practical applications: modeling of degradation, for improving the predictive capacity of commonly used transport models such as PRZM, GLEAMS, PELMO, PESTLA, ..., and bioremediation, which embraces a body of emerging biotechnologies for decontaminating soils from polluted areas.

HISTORICAL ASPECTS: THE HORMONE HERBICIDES

The Role of Microorganisms in Hormone Herbicide Degradation in Soils

As it was concluded that synthetic plant hormones fail to activate plant growth (1), two different groups of researchers, in the United States and the United Kingdom, were studying the differential inhibitory effect of these chemicals on weed growth. The discovery of the possible use of the 2,4-dichlorophenoxyacetic acid (2,4-D) (2) and the 2-methyl, 4-chlorophenoxyacetic acid (MCPA) (3) as selective herbicides was reported as "the greatest advance in the history of weed killing" (4). 2,4-D was preferred (5) because it was persistent enough to give a good and long-lasting protection compared to more naturally occurring β-indol- and α-naphthylacetic acid compounds.

Even with more stable synthetic compounds, it was observed that the herbicidal activity progressively decreased causing reductions in efficacy in the long term. An early discovery was that herbicidal activity of 2,4-D decreased rapidly in wet soils (6–11). Likewise, a decrease in soil temperature (8–12) or reasonable additions of readily available organic amendments (6,7,11) had similar inhibitory effects on herbicide effectiveness. From these preliminary investigations, soil microorganisms were suspected to be primarily involved in the persistence of the herbicidal activity.

More convincing evidence of microbial involvement in phenoxy herbicide degradation was deduced from the shape of the kinetics of hormone herbicide disappearance from soil. Sigmoidal dissipation curves suggested possible growth of a soil microbial population at the expense of the herbicide (13,14). Lag phases frequently observed in herbicide soil dissipation were assumed to reflect the necessary physiological adjustments required for soil microorganisms to adapt to and use the herbicide as a new substrate. Subsequent rapid dissipation was interpreted as resulting from an exponential-like proliferation of effective microorganisms.

Another evidence that soil microorganisms were responsible for hormone herbicide degradation was obtained from the comparison of the persistence of β-indolacetic acid and synthetic hormone herbicides

in sterile and nonsterile soils (5,8,10,11,15). Definitive evidence of microbial involvement in phenoxy herbicide degradation in soils was given when microbial species able to degrade these compounds were isolated from soils. Audus (16) was the first to isolate and identify a bacterial strain, *Bacterium globiforme*, able to use 2,4-D as the only carbon and energy source after perfusion of soil with a solution of the herbicide. Since these pioneering studies, a number of microbial species able to degrade phenoxyalcanoic acids have been isolated from agricultural soils or even from pristine soils, which had never been in contact with these compounds (17). For the most part, with the exception of *Aspergillus niger* (18), bacteria rather than fungi have been isolated. Achromobacteriaceae (*Flavobacterium*, *Achromobacter*, *Alcaligenes*) are well represented and *Pseudomonas* sp. strains, commonly recognized as ubiquitous and metabolically versatile, only reported in a few examples. Many of the isolated bacterial strains are only able to transform but not mineralize the phenoxy compounds. For instance, among 52 bacterial species isolated from sewage sludge, 41 were able to transform 2,4-D or 2,4,5-T without being able to use them as carbon and energy sources (19). It was later pointed out that conventional isolation procedures give a partial and biased view of the composition of the microbial communities involved in pesticide biodegradation in natural environments (20).

The Role of the Soil Matrix in Phenoxy Herbicide Degradation in Soils

An important aspect of preliminary studies was to show that the soil matrix also greatly influenced the persistence of the herbicidal effect. For instance, after two weeks of recirculation of water through six different treated soils, the solution from a peat soil had lost almost all herbicidal activity demonstrating the inactivating role of soil organic matter (21). By comparison, after six weeks of percolation through a sandy clay soil, the presence of 2,4-D could be detected. Other studies have shown that herbicide mobility and leaching, as affected by soil physicochemical properties, could partly explain the observed loss of efficacy (10,21,22). So, as early as the 1950s, the main microbial and physicochemical determinants of the fate of pesticides in soils had been identified.

BIOLOGICAL ASPECTS OF PESTICIDE DEGRADATION IN SOILS

As compared to the timescale necessary for microbial species to evolve new metabolic capabilities, it is reasonable to assume that most xenobiotic compounds will be biodegraded by "appropriation" or "recruitment" among the vast array of microbial enzymes, which have been acquired by microbes when using the numerous naturally occurring biogenic substrates found in very different ecological niches (23). For Leslie-Grady (24), such transformations, which collectively have been called either "fortuitous" (25) or "gratuitous" metabolism (26), are likely to be the primary processes for microbial degradation of xenobiotic compounds in natural environments. These processes are especially effective for chemicals that are structurally related to natural compounds. Yet a structural resemblance does not warrant biodegradability when the compounds cannot penetrate the cell, or at a rate high enough to induce the corresponding enzymes. Differential enzyme specificity may also generate accumulation of intermediates, such as chlorophenols, which may have deleterious effects, as in the case with phenoxyalcanoic acids. Convincing evidence has accumulated demonstrating that specific enzymes dealing with chlorinated intermediates are involved in their degradation. As stated by Dagley (27), increasing the xenobiotic character of a carbon compound by adding substituents such as halogens may not only modify mesomeric effects, especially important for aromatic structures, but also generate steric hindrance. Chemical analogy may be nonsensical from a biological point of view as far as enzyme specificity is concerned. For instance, chlorine elimination from the 2,4-D molecule is made via a lactonizing enzyme, which differs from its counterpart responsible for the same transformation of the nonsubstituted phenoxyacetic acid. Moreover, as reported by Dagley (27,28), cleavage of the C−Cl bond is not a biologically neutral transformation because it generates hydroxy compounds, which may have different subsequent biochemical pathways as compared to the nonhydroxylated template. In other words, at the enzyme level, benzoate degradation may have nothing to do with that of 4-chlorobenzoate.

Main Physiological Processes Involved in Pesticide Degradation by Pure Cultures

Degradation of the Pesticide as the Only Source of C and Energy: Mineralization. If a pure culture can mobilize enzymes to transform a xenobiotic compound into a form, in which it can feed into primary metabolism, it has the advantage of being able to satisfy its requirements for growth and energy from the "foreign" molecule. This degradation process, which has been described in the past for a limited number of pesticides, has beneficial environmental consequences because it does not generate pesticide residues other than "normal" end-products, carbon dioxide, and new microbial biomass. This enrichment has been successively called *soil adaptation* (15), *acclimation* (29) or, more recently, *accelerated degradation* (30). Initially reported for 2,4-D, it has also been shown for chemicals, which were traditionally thought to be relatively recalcitrant. For instance, atrazine is a moderately persistent herbicide, with half-life ranging from several days to several months (31–33). Recently, however, rapid mineralization of atrazine in soils has been observed (34,35) and several pure bacterial isolates or consortia have been described as having the capacity to use atrazine as carbon, and more frequently, nitrogen source (36–42).

Degradation of the Pesticide in the Presence of Other Carbon Substrate: Cometabolism. It has not been possible to isolate, from agricultural soils, microbial species able to use a large number of pesticides as sources of carbon and energy. Most of the isolated microbial strains can perform only limited transformations without deriving nutrients and energy for growth. These transformations

are collectively called cometabolism (43) because transformations are achieved while the culture is growing at the expense of a *cosubstrate* serving as a carbon and energy source. Different organic compounds, varying from the simple low molecular weight compounds (carbohydrates, easily biodegradable structural analogs), to more complex organic amendments (crop residues, farmyard manure, and sewage sludge) can be used as cosubstrates. Cometabolism does not result in extensive degradation of the pesticide and, in pure cultures, leads to the accumulation of intermediate products as demonstrated many years ago by the transformation of the herbicide 2,4,5-T into 3,5-dichlorocatechol by a *Brevibacterium* sp. (44). Some of these metabolites (e.g., chlorophenols, chloroanilines,. . .) may be more toxic than the parent compound and cause inhibition of the degradation process. There is some controversy about the biological mechanism(s) of cometabolism (45). The concept, initially coined *co-oxidation* by Leadbetter and Foster (46), was further named *cometabolism* by Jensen (47) to extend the concept to other transformations such as dehalogenations. Horvath was the first to try to give cometabolism a biochemical basis and a physiological definition. Cometabolism "describes oxidation of a nongrowth substrate during growth of a microorganism on a utilizable carbon and energy source,. . .. (it) does not infer presence or absence of growth substrate during the oxidation" (43). Hulbert and Krawiec (45) disagreed on the character of the physiological novelty of cometabolism and argued that it did not differ from ordinary catabolism or anabolism, and suggested "that use of the word cometabolism be abandoned." To reconcile the two points of view, Alexander (29) and Dalton and Stirling (48) proposed a practical approach: the term could be maintained for transformations exhibiting particular kinetic features, like a slow rate and pseudo first-order rate law indicating the absence of replication of the responsible microorganisms, and having ecotoxicological consequences as a result of the accumulation of intermediate compounds.

Genetic Aspects of Pesticide Degradation by Pure Cultures

Early Observations. In their experiments Audus (15,49) and Audus and Symonds (50) observed that the "archetype" of degrading strain was very unstable in its degrading capacity, which decreased after several transfers on solid 2,4-D medium and was lost after transfer on agar medium with sugars (glucose, saccharose) as only source of carbon and energy. Walker and Newman made identical observations (51) with a series of nine bacterial cultures isolated from different soils from which seven lost their 2,4-D degrading capacity after serial transfers. Fischer and coworkers (52) and Pemberton and coworkers (53) reported that different *Alcaligenes* sp. strains showed variable capacity to spontaneously lose the capacity to use 2,4-D as C source, and that the phenotype was better maintained in the presence of 2,4-D in the culture medium. By maintaining a *Pseudomonas cepacia* AC1100 strain for 18 generations on a glucose medium, Kilbane and coworkers (54) showed that only half the number of the colonies retained the capacity to degrade 2,4,5-T. Kilpi (55) observed the same instability for a dichlorprop and mecoprop degrading community when cultivated in the presence of benzoic acid. More recently, an atrazine-degrading strain, *Pseudomonas* sp. ADP, has been shown to have an unstable phenotype, especially in the presence of a nitrogen source (41).

By contrast, evidence has accumulated that once adapted, the soil microflora may retain its adaptation for months or even years. It has been assumed that the degrading capacity is maintained because of the presence in the soil of organic compounds that are the primary substrates for the enzyme system that can transform a pesticide through cometabolism (56). Waid (57) was the first to suggest the possible involvement of mobile extrachromosomal elements in maintaining the potential for pesticide degradation in soil communities.

Hormone Herbicides.

Evidence of Plasmid-Borne Degradation Genes. Soil adaptation to the degradation of a chemical such as 2,4-D was reported to result from the enrichment of effective microorganisms able to use the compound as a carbon and energy source. It was shown that soil adaptation could be detected even one year after initial treatment of the soil with the pesticide (14,58). Torstensson and coworkers (59) have suggested that under starvation conditions, adapted microorganisms are not subjected to much pressure to use alternative growth substrates, and could maintain their adaptation longer than under more nutrient-rich conditions. In 1976, Kaufman and Kearney (60) gave another explanation based on the presence in the soil of naturally occurring compounds, which could be alternative substrates of the enzyme systems acting upon the pesticide. To support this assumption, Sandman and Loos (61) have shown that catechol and homogentisic acid were oxidized more rapidly by an *Arthrobacter* sp. after cultivation on 2,4-D as compared to citrate. Waid (57) speculated that mobile extrachromosomal genetic elements described as "genetic transfer factors" were involved in an epidemic-like dispersion throughout the soil microflora of the gene sequences encoding for pesticide degradation. Experimental support for this assertion was given five years later by Pemberton and Fischer (62) who isolated a bacterial strain, *Pseudomonas* JMP116, later known as *Alcaligenes paradoxus*, shown to harbor a conjugative plasmid involved in 2,4-D degradation. This plasmid, pJP1 of the IncPI incompatibility group with a large host specificity, was further characterized as having a molecular weight of 58 Md (52) and also encoded for MCPA degradation. Segregants, which were cured, were no more able to degrade 2,4-D but maintained their capacity to degrade 2,4-dichlorophenol. This suggested either that 2,4-D degradation was entirely encoded by a set of genes present on the plasmid with a second set of genes responsible for 2,4-dichlorophenol degradation present on the chromosome or that only the 2,4-D monooxygenase encoding gene was plasmid-borne.

Localization and Regulation of the Degradative Genes on the Plasmid pJP4. Working with the canonical plasmid, pJP4, an 80-kb broad host range plasmid, very close to

pJP1 and isolated from a *Ralstonia eutropha* JMP134 strain (formerly *Alcaligenes eutrophus*), Don and Pemberton (63) localized five genes *tfd B*, *C*, *D*, *E*, and *F* encoding the transformation of 2,4-dichlorophenol into chloromaleylacetic acid. Kukor and coworkers (64) showed that the gene for maleylacetate reductase was chromosomally located and involved in tyrosine catabolism (Fig. 1).

Using Tn5 and Tn1771 transposon mutagenesis, Don and Pemberton (63) localized genes involved in mercury resistance, 2,4-D and 3-chlorobenzoate degradation.

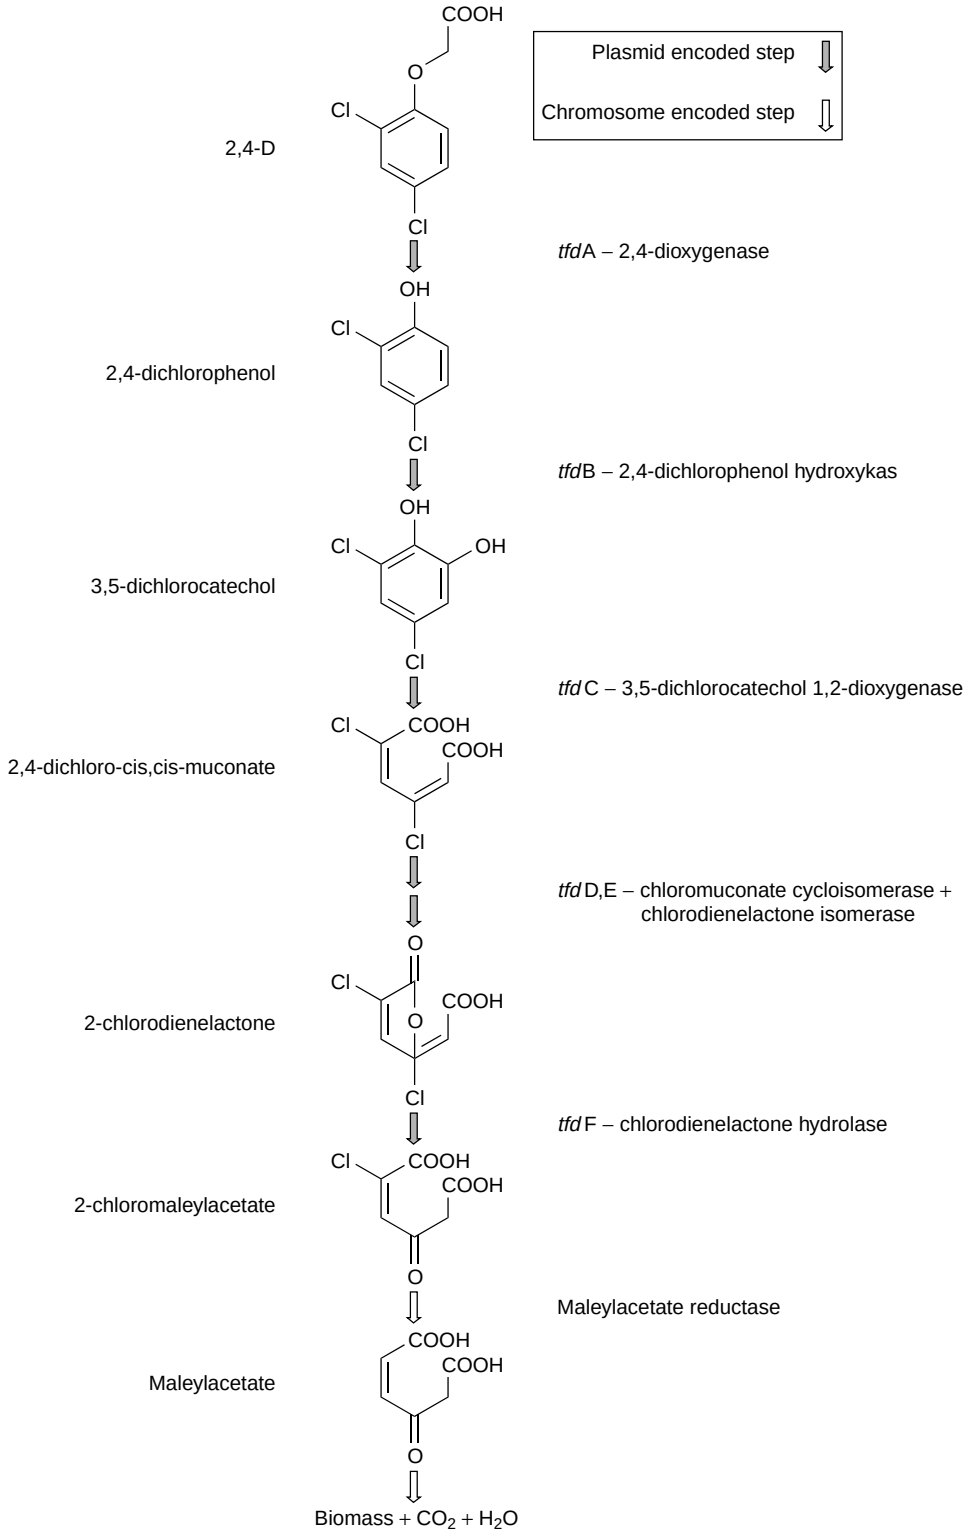

Figure 1. 2,4-D degradation pathway by *R. eutropha* JMP 134.

Locating the origin of the plasmid at the beginning of the fragment EcoRI A, the first genes are located at about 70 kb, whereas others are borne on EcoRI B fragment in between 28.8 and 43.3 kb. Four of the genes, which are also involved in 3-chlorobenzoate degradation, genes *tfdC*, *D*, *E*, and *F*, encoding respectively for dichlorocatechol 1,2-dioxygenase (or pyrocatechase), chloromuconate cycloisomerase, chlorodienelactone isomerase, and chlorodienelactone hydrolase are organized as one operon (65). Ghosal and You (66) also showed that the *tfdC* and *tfdD* genes were overlapping for four base pairs, with a possible coupling at the transcription level. The *tfdC* gene sequence has been elucidated. It is 765-bp long and corresponds to 255 amino acids and a molecular weight of the corresponding protein of 28,000 daltons. Later on, Streber and coworkers (67) located the *tfdA* gene for the 2,4-D oxygenase on the plasmid at a distance of 13 kb of the 2,4-D operon, and Fukumori and Hausinger (68) have shown that it encodes an α-cetoglutarate-dependent dioxygenase. It is largely distributed among gram-positive and gram-negative soil bacteria that do not degrade 2,4-D, suggesting that *tfdA* genes or closely related homologs are widespread among soil isolates, and likely to exist for a purpose other than the degradation of 2,4-D (69). Not all species able to degrade 2,4-D have the corresponding genes located on a plasmid. For instance, it was deduced from plasmid curing experiment that the 2,4-D catabolic genes of a *Burkholderia* sp. strain RASC were located on the chromosome (70).

Using complementation experiments with 3-chlorobenzoate, utilizing *Pseudomonas putida* strains, Ghosal and coworkers (71) suggested the existence on the fragments EcoRI E and F of pJP4 of genes suspected to play a positive regulatory role for the structural genes present on the fragment EcoRI B. The same authors observed that the 3-CB+ phenotype resulted from the constitutive expression of the structural genes borne on seven copies of the EcoRI B fragment. After having isolated a mutant of *A. eutrophus* JMP 134 expressing constitutively the 2,4-D degrading genes, Pieper and coworkers (72–74) made the assumption that a pJP4 negatively regulatory gene had been mutated. From studies with mutants deleted in the BamHI, F and E fragments of pJP4, evidence was given for the presence of a regulatory gene, *tfdR*, which repressed the expression of the *tfdA* gene and *tfdCDEF* operon (75). A second regulatory gene, *tfdS*, was also located on the same fragment and has been proposed to repress and activate the expression of the *tfdB* gene (76). Because *tfdS* and *tfdR* genes are in fact identical inverted repeats located at about 8 kb away from the *tfdCDEF* operon on plasmid pJP4, they should not have different regulatory effects. They are oriented divergently from respectively the *tfdA* gene and a *tfdD*-like gene (tfD_{II}) of a second $tfdC_{II}D_{II}E_{II}F_{II}$ operon. A third regulatory gene, *tfdT* (formerly *tfdX*, 77), highly homologous to the *tfdS* and *tfdR* genes has been located upstream of, and transcribed divergently from, the *tfdCDEF* operon. The presence of regulatory sequences upstream catabolic genes or catabolic operons has been interpreted as signifying that proximal pairs, *tfdA-tfdS* or *tfdR- tfdD*$_{II}$ . . ., and cis effects are perhaps important in the regulation of the TFD pathway (77). Yet, this is probably not true for the *tfdCDEF* operon. The putative regulatory gene, *tfdT*, is inactivated by the presence of an insertion sequence, which disrupts the ORF leading to the production of a dysfunctional protein. It is likely that the *tfdR* or *tfdS* genes can successfully take over the regulation of this operon (78). A new ORF was recently identified on plasmid pJP4, which was designated by *tfdK*. It was proposed to be responsible for the production of a transporter protein involved in an energy-dependent transport process (79). This is the first description of a gene involved in the facilitated transport of a pesticide molecule.

Ghosal and coworkers proposed a higher-level degree of regulation (71) after having observed that under extreme conditions of selection, gene expression is activated only after sequence rearrangement. No specific mechanisms for these rearrangements have been elucidated and nothing is known either about their dependency on host genome, their environmental constraints, or their actual functional significance. More recently, a self-transmissible 2,4-D degradative plasmid, pKA2, has been found either as a free state or integrated into the host chromosome without loss of the 2,4-D+ phenotype. This suggests that a chromosome–free plasmid cycle may occur to optimize fitness under conditions of resource fluctuations (80).

Polymorphism of the 2,4-D Degradative Genes. While the first *tfdA* gene coding for the 2,4-D monooxygenase was detected on pJP4 at a distance of 13 kb of the *tfdCDEF* locus (67), a second dissimilar locus on pJP4 was observed in the region of 2.5 kb adjacent to the *tfdC* gene. Hybridization experiments under low-stringency conditions demonstrated the presence of a related copy of a second gene coding for an active 2,4-D monooxygenase, $tfdA_{II}$ (81). Plasmid pJP4 was also shown to contain a second set of non identical chlorocatechol oxidation gene sequences physically separated by a 7 kb DNA region from the first (66). Later on, a putative ORF coding for a chloromuconate cycloisomerase was identified. This ORF was designated as an isofunctional gene, $tfdD_{II}$, and shared 57.6 % identity at the DNA level over 738 bp with the *tfdD* gene (77). Finally, a whole new additional set of *tfd* genes, that is, $tfdD_{II}C_{II}E_{II}F_{II}$, $tfdB_{II}$ was discovered on pJP4 (79).

A high degree of interspecies variation in 2,4-D degradative gene sequences has also been found. The 2,4-D dioxygenase gene *tfdA* and the 2,4-dichlorophenol hydroxylase gene *tfdB* have been described for different 2,4-D degrading soil isolates (82). It is likely to reflect different substrate specificity. An extensive study with 47 predominant 2,4-D degrading bacteria isolated from different 2,4-D treated or nontreated plots revealed four hybridization groups by using *tfdA*, *tfdB*, *tfdC*, and *tfdD* probes and a probe, *Spa* that detects a distinctly different 2,4-D degrading isolate, *Sphingomonas paucimobilis* (formerly *Pseudomonas paucimobilis*) (83). Hybridization group one strains are very diverse, contain plasmids and most of the plasmids exhibit hybridization to the *tfd* probes. Members of group two, which hybridize only with the *tfdA* probe, are a subgroup of group one. The highest number of isolates was found in group three. It

contained tightly clustered strains, which did not seem to contain small (<350 kb) plasmids and exhibited detectable hybridization only to the *Spa* probe. Group four was the "all other" group with very diverse isolates that did not hybridize to any of the probes. Probing thirty two 2,4-D-degrading isolates representing 19 genomic fingerprints from diverse locations with the *tfdA*, *-B* and *-C* sequences, Fulthorpe and coworkers (84) observed that the majority of the strains exhibited various degree of homology to the first 3 *tfd* genes of the 2,4-D degradative pathway. Moreover, most strains showed different combinations of high- and low-similarity *tfd*-like genes, suggesting that independent interspecies movement of these genes had occurred and that some strains had recruited individual genes from different sources.

Knowledge of the diversity of the genes coding for chlorocatechol dioxygenases (CCD) enzymes seems particularly useful for understanding how extended catabolic capacities have evolved from a few channeled metabolic steps involved in bacterial aerobic degradation of aromatic compounds. Dioxygenases catalyzing cleavage of the aromatic nucleus are an important class of enzymes for they control degradation of the aromatic material of the soil organic matter. It has been established that chlorocatechol dioxygenases of the modified ortho pathway (or type II dioxygenases) are a distinct subgroup of ring cleaving enzymes (85). Many of these enzymes are coded by plasmid located genes found in gram-negative strains, *clcA* on pAC27 (*P. putida*) (71), *tcbC* on pP51 (*Pseudomonas* sp. strain 51) (85), *tfdC* on pJP4 (*R. eutropha*, formerly *A. eutrophus* JMP 134) (65), pEML159 (*Alcaligenes* sp.) (86), pRC10 (*Flavobacterium* sp.) (87), pEST4011 (*P. putida* PaW85) (88) or pMAB1 (*Burkholderia cepacia*, formerly *P. cepacia* CSV90) (89). With the exception of the chlorocatechol 1,2 dioxygenase of *Rhodococcus erythropolis*, which exhibits only 15 to 22% identity to the catechol 1,2 dioxygenase and the chlorocatechol 1,2 dioxygenase (90), it seems that many of the type II pyrocatechases with different substrate specificity show some degree of homology in their amino acid sequences. For instance, it has been shown that some specialization among type II pyrocatechases has taken place: TcbC converts preferentially 3,4-dichlorocatechol, TfdC has a higher activity toward 3,5-dichlorocatechol and 3-chlorocatechol is more specifically transformed by ClcA (91). By comparison, the *R. erythropolis* enzyme has a distinct preference for the 4-substituted catechols (92). In the study of Fulthorpe and coworkers (84), many strains did not hybridize with *tfdC*, although they showed chlorocatechol dioxygenase activity. Diversification of the probes is needed to unravel the diversity of these CCD and other genes in environmental samples. An example of the recognition of the polymorphism of the *tfdC* genes by polymerase chain reaction (PCR) amplification and hybridization is illustrated by a study on 31 2,4-D degrading isolates, all in the α- or β-subdivision of the Proteobacteria (93). Hybridization has been performed with two specific probes produced from *R. eutropha* JMP 134 and a soil isolate, strain PLAE6, respectively. These probes are homologous to the *tfdC* genes of JMP 134 located on pJP4 and to the *tfdC* gene of *P. putida* PaW85 located on plasmid pEST4011. Most of the strains were found to contain *tfdC* genes on plasmids ranging from 78 to 532 kb, and two strains with no detectable plasmid were found to hybridize with the probes revealing chromosomal localization of catabolic genes. Strains and isolates, which carry a *tfdC* gene homologous to that of *P. putida* PaW85 have one copy of *tfdC* with similar restriction fragment length polymorphism (RFLP) patterns. On the other hand, strains carrying a *tfdC* gene homologous to the *tfdC* (pJP4) gene showed more variable RFLP patterns and carried two copies of *tfdC*, one homologous to the canonical tfdC of *R. eutropha* JMP 134 and the other, $tfdC_{II}$ as detected in *R. eutropha*, to *tfdC* of *P. putida* PaW85. This result illustrates the process of duplication of genes or of entire operons, which may occur and be selected in the presence of xenobiotics, recently introduced in the environment. In that case, *tfdC* of *P. putida* may be assumed to be the immediate ancestor of the canonical *tfdC* gene in *R. eutropha*.

Chlorocatechol 1,2 dioxygenase genes are also important from another point of view. They are often found as part of a relatively well-conserved gene cluster known as the chlorocatechol oxidative pathway (85). The cluster is an operational unit made of three or four structural genes, *tcbCDEF* (*Pseudomonas* sp. strain 51), *clc ABD* (*P. putida*) and *tfdCDEF* (*R. eutropha*), regulated by the *tcbR*, *clcR*, or *tfdR* (*tfdS*) genes coding for proteins, which are all members of the LysR family of transcriptional activators. Yet, individual genes have been found in other combinations, illustrating that evolution may proceed through different ways. For instance, a *tfdC*-like gene has been found associated with a *tfdB*-like gene in the degradative plasmid pEST4011. It was assumed that both genes form one operon, *tfdCB* (94), suggesting that isofunctional genes can be found at different levels of organization. This is another indication of independent movement of these genes and/or individual recruitment from different sources. Some of these genes are integrated in regulated polycistronic operons, which are likely to have evolved under a natural selective process that may have been operating before contamination of soils with chlorinated xenobiotic compounds. Others are present in more simple regulated structures, or even as proximal pairs with one structural gene being under the direct control of a regulatory gene.

Diversity of 2,4-D Degradative Plasmids. From 50 soil samples, Don and Pemberton (95) isolated 22 microbial species able to use 2,4-D as a sole source of carbon and energy. 17 of these strains lost the tfd+ character after 15 to 20 subcultures on peptone + yeast extract agar with no 2,4-D. Of the five strains showing a stable tfd+ phenotype, all were identified as *A. eutrophus*. Curing experiments demonstrated that the *tfd* genes are borne on conjugative plasmids, which belong to two different incompatibility groups. pJP2 and pJP9 are of the IncP3 group and show the capacity to degrade the non chlorinated phenoxyacetic acid (71); whereas, pJP3, 4 and 7 are of the IncP1 group. These plasmids encode for mercury resistance and for the degradation of MCPA and 3-chlorobenzoate.

Other 2,4-D degradative plasmids have been found in different bacterial species. The plasmid pEML159

has been detected in *Alcaligenes* sp. EML159 (86). Its size, 56 Md, and its restriction profile are very close to those of pJP4. The 45 kb plasmid pRC10 has been isolated from a *Flavobacterium* sp. (strain 50,001) (87), pEST4011 in a *P. putida* PaW85 (88), pMAB1 in a *B. cepacia* (formerly *P. cepacia* CSV90) (89), pTV1 in a *Variovorax paradoxus* (96), pKA2 in an *A. paradoxus* 2811P and pKA4 in a *Pseudomonas pickettii* 712 (81). The diversity of 2,4-D degradative plasmids has also been examined by complementation in soils that had been treated with 2,4-D for several years. Seven plasmids with different EcoRI restriction profiles, pEMT1 to pEMT7, have been detected. All but pEMT1 belong to the IncP1 incompatibility group (97). Another hybridization study with *tfdA*, *B*, and *C* probes to the DNA of 32 2,4-D degrading bacteria from different geographic locations has revealed a high diversity of hybridization patterns. The simple horizontal transfer of a large piece of DNA that contains all the *tfd* catabolic genes cannot explain this diversity. These results indicate that homologous or even identical genes may be found on different plasmid backbones in different order, suggesting that individual genes or groups of genes as the chlorocatechol oxidative pathway are moving independently to generate different associations as mosaic constructions (84).

There is evidence that plasmids involved in 2,4-D degradation can be exchanged between strains of different species or even different genera. For instance, Pemberton and coworkers (53) detected frequencies of transfer of the tfd+ phenotype varying from 10^{-3} to 5.10^{-2} per donor with six plasmids encoding for 2,4-D degradation. Friedrich and coworkers (98) obtained tfd+ transconjugants with different *A. eutrophus* at frequencies varying from 2.10^{-2} to 10^{-6} per donor cell after conjugation with the pJP4 containing *Escherichia Coli* JMP 397.

Horizontal transfer of a plasmid may result in modifications of its structure. Don and Pemberton (99) reported different molecular weights for the plasmid pJP2 in its natural host (150 Md) or in a transconjugant (37 Md). Friedrich and coworkers (98) observed a reduction in the size of the plasmid pJP4 in tfd+ *A. eutrophus* transconjugants, with the length of the deletion varying with the strain. Moreover, they detected plasmids, which may have resulted from multimeric associations of pJP4. After *E. coli* JMP397 was transformed with pJP4, Amy and coworkers (86) showed that the parent plasmid was present as a nonmodified copy together with a 66 Md plasmid. The formation of this plasmid was interpreted as resulting from the integration of chromosomal DNA. Taken together, these observations lead to the conclusion that spread of a plasmid in a composite microbial assemblage may result in structural diversification adapting the plasmid structure and functionality to the genetic environment of its different microbial hosts. We do not know exactly what are the mechanisms of recombination leading to these new genetic rearrangements in different bacterial strains, even if transposons have been suspected to play a role in the transfer of toluene and chlorobenzoate degradative genes (100). All the recipients cannot express the *tfd* genes. We do not know what are the species determinants, which govern gene expression and what are the functional consequences, which result from changes in gene sequence and organization. The observed gradual shifts in the distribution of the dominant species after long term 2,4-D applications revealed two different groups of successful competitors. The first group consisted of diverse strains of *Burkholderia*, *Alcaligenes*, or related species, all members of the β-subdivision of the proteobacteria class. These strains carry genes, which are highly homologous to *tfdA*, *-B*, *-C* of pJP4. Members of the second group were all included in the α-subdivision of the proteobacteria class. They were mainly related to the *Sphingomonas* genus and carry degradative genes that share no homology to *tfdA* and *−C* genes and only weak homology with *tfdB* of pJP4 (83).

The presence of an effective 2,4-D degrading community has been shown in pristine soils where one would not expect them to have a selective advantage (17). This is consistent with the assumption that *tfd* genes preexist in soils, where they are likely to determine degradation of naturally occurring compounds. Soil microorganisms may naturally produce halogenated and especially chlorinated compounds. For instance, chlorinated antibiotics are produced by Streptomycetes. 2,4-dichlorophenol is another natural compound, which is produced by *Penicillium* strains and suspected to have a hormonal (101) or an antibacterial activity (102). Many studies have demonstrated that the capacity to degrading chlorinated phenols is not uncommon in soils. (103–105). Chapman (106) made the assumption that the presence in soils of a microflora capable of degrading 2,4-D results from the combination of its joint capacity to degrade 2,4-dichlorophenol, for which a degradative pathway has been elaborated, and to cut ether bonds. Consistent with this assumption are the following observations *−i*: a well-organized and autonomously regulated operon of four genes involved in aromatic ring cleavage, the *tfdCDEF* operon in the case of 2,4-D, is commonly found in soil isolates indicating that evolution has already taken place before introduction of the herbicide, *−ii*: *tfdA*-like genes coding for an etherase are widely distributed among soil isolates, which do not degrade 2,4-D (69). Streber and coworkers (67), Harker and coworkers (75) and Pieper and coworkers (73) have shown that the product of the *tfdA*(pJP4) gene was an enzyme with a broad substrate specificity acting indistinctly upon 2,4-D, MCPA, but also on 4-chlorophenoxyacetic acid (4-CPA), 2-methylphenoxyacetic acid (2-MPA) and the nonsubstituted phenoxyacetic acid.

The Triazine Herbicides. Atrazine (2-chloro-4-ethylamino-6-isopropylamino-s-triazine) is the most widely used s-triazine herbicide to control a variety of broadleaf weeds infesting corn, sorghum, and certain other crops. Its widespread use has caused environmental concern because of frequent detection of atrazine in surface water (107,108), rainwater (109), tile drainage (110), and groundwater (111,112) at concentrations exceeding the EU regulatory limit of 0.1 $\mu g\,l^{-1}$ and the U.S. EPA maximum contaminant level of 3 $\mu g\,l^{-1}$ (113).

Atrazine is a moderately persistent herbicide, with half-lives ranging from several days to several months (31–33).

Up to 10 years ago, the most commonly accepted degradative pathway involved oxidative *N*-dealkylation with the formation of deethylatrazine (DEA), deisopropylatrazine (DIA), and deethyldeisopropylatrazine (DIEA) as major metabolites, and other heterocyclic compounds such as ammeline, ammelide, and cyanuric acid at trace concentrations (Fig. 2, left-hand side). Very little ring cleavage has been reported. It is now generally accepted that only alkyl side chains can provide carbon and energy to the degrading microflora (42).

A *Rhodococcus* strain TE1, which can metabolize the herbicide *S*-ethyl dipropyl tiocarbamate (EPTC) has been isolated from soil. This strain also transformed atrazine and other chlorotriazines, propazine, simazine, and cyanazine, under aerobic conditions to produce dealkylated derivatives, which were not degraded further in liquid culture. The atrazine-degrading phenotype was unstable and associated with it was a 77-kb plasmid also involved in EPTC degradation. The *atrA* gene responsible for the *N*-dealkylation reactions is borne on a 6.2-kb KpnI fragment also harboring the *eptA* gene for EPTC degradation (114). An inducible cytochrome P-450 enzyme system has been shown to be involved in the degradation of EPTC and atrazine by a *Rhodococcus* sp. strain NI86/21 (115). The current data provide evidence that in strain NI86/21 the *thcB* (coding for a novel type of cytochrome P-450 enzyme), the *thcC* (coding for rhodocoxin) and *thcD* (coding for rhodocoxin reductase) genes conferred the atrazine-degrading phenotype. Another *Rhodococcus* strain, *Rhodococcus corallinus*, was shown to dechlorinate and deaminate deethylsimazine. The gene responsible for the s-triazine hydrolase, *trzA*, was subcloned and transformed into different *Rhodococcus* strains, where it can be expressed. A plasmid carrying both *atrA* and *trzA* genes was constructed and introduced into three *atrA* and *trzA*-deficient *Rhodococcus* strains. Both genes were expressed in the recombinant cells (116,117). *Trz* genes coding for the s-triazine catabolism were also found in other microbial strains: *Pseudomonas* sp. strain NRRLB-12227, which metabolizes

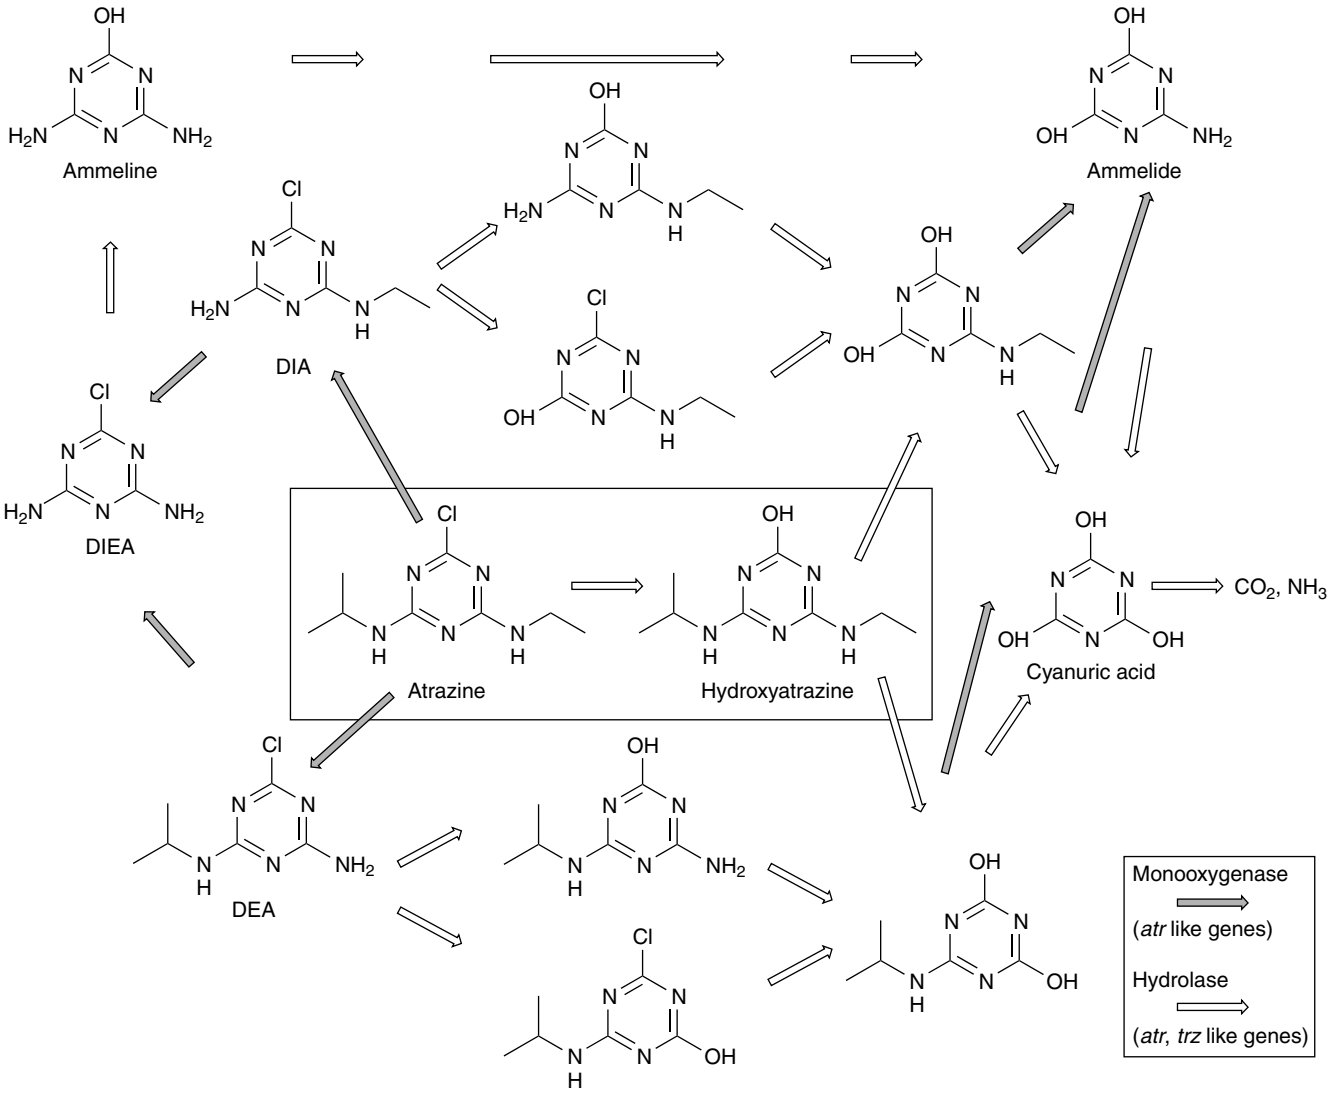

Figure 2. Suspected interconversions between atrazine transformation products in natural ecosystems (for abbreviations, see text).

melamine, *Pseudomonas* sp. strain NRRLB-12228, and *Klebsiella pneumoniae* 99 growing on ammelide and lacking the *trzB* gene coding for the ammeline aminohydrolase. Both *trzC* and *-D* genes share extensive sequence identity on the basis of their restriction enzyme cleavage maps. In *Pseudomonas* sp. strain NRRLB-12227 the *trzB* gene has been located close to the *trzC* gene, and the s-triazine catabolic genes seem to be present on a transposable element. More recently, it has been shown that the genes coding for the ammelide aminohydrolase (*trzC*) and the cyanuric acid amidohydrolase (*trzD*) are borne on an IncPI plasmid in *K. pneumoniae*. As demonstrated for 2,4-D, the presence of s-triazine catabolic genes on mobilizable DNA supports the idea that genetic exchange is an important process in the evolution of novel catabolic pathways (118,119).

Recently, there have been a number of reports on accelerated atrazine mineralization in soils under continuous maize cropping with yearly atrazine applications (34,35). Enrichment culture techniques have permitted isolation of consortia (36,40) and pure bacterial isolates (38,39,41,42) capable of complete mineralization of the chemical. With these strains, peripheral catabolism proceeds first through dechlorination, followed by hydrolytic side chain cleavage and opening of the ring structure. The biuret intermediate compound is further mineralized to CO_2 and NH_3 (Fig. 2, right-hand side). An atrazine-metabolizing *Pseudomonas* sp. ADP was isolated using the "clearing zone" technique on agar plates containing 1,000 mg/L atrazine (solubility 30 mg/L). The strain used atrazine as its sole source of nitrogen and carbon of the triazine ring was almost completely released as CO_2 (41). The genetic determinants behind these transformations have been partially elucidated. The first three genes have been cloned and sequenced. The first gene, *atzA*, codes for a chlorohydrolase and is involved in atrazine dechlorination with hydroxyatrazine being the first metabolite. Hybridization experiments using a probe containing the putative atrazine chlorohydrolase gene with the DNA of different atrazine degrading bacteria has indicated that the formation of hydroxyatrazine is widespread in natural systems (120,121). The protein AtzA shares 41% amino acid homology with the TrzA protein of *R. corallinus* NRRLB-15444R, involved in the dechlorination-deamination of deethylatrazine (CIAT), and deisopropylatrazine (CEAT), but not of atrazine. A second gene, *atzB*, codes for an amidohydrolase, which catalyzes hydroxyatrazine deamidation yielding *N*-isopropylammelide. It is located on the same 21.5 kb EcoRI genomic DNA fragment as *atzA* at a distance of 8.7 kb downstream. The AtzB protein has only 25% amino acid identity with TrzA (121). The *atzC* gene codes for an enzyme that catalyzes the hydrolytic deamidation of *N*-isopropylammelide to cyanuric acid and isopropylamine. This enzyme is also a member of the broad family of amidohydrolases. Sequence comparison of AtzA, -B and -C proteins in the most highly conserved *N*-terminal region containing a metal-coordinating histidine residue suggests that the corresponding genes diverged from a common ancestor (122). The *atz* genes are widespread and DNA sequence comparison of five other atrazine-degrading bacteria has revealed more than 99% identity indicating only limited evolutionary divergence (123). A *Rhizobium* sp. isolate, which was found to actively degrade atrazine with accumulation of hydroxyatrazine, has a chlorohydrolase sharing 92% identity to the chlorohydrolase of *Pseudomonas* sp. ADP (42). Moreover, in *Pseudomonas* sp. ADP, the *atzA*, *-B*, and *-C* genes are located on a 96-kb self-transmissible plasmid, pADP-1, conferring an unstable atrazine-clearing phenotype to *Pseudomonas* sp. ADP (123). Nothing is known on the mechanisms of regulation of the *atz* or *trz* genes except for a *Rhizobium* sp. isolate where the AtzA-like chlorohydrolase was constitutively expressed and not induced by atrazine (42).

PESTICIDE DEGRADATION IN NATURAL ENVIRONMENTS

Microbial Fallibility and Molecular Recalcitrance

In explaining the observed low degradability of some pesticides in soils and considering that soils naturally contain complex compounds difficult to mineralize, such as humic substances, Alexander (124) developed the concepts of "molecular recalcitrance" and "microbial fallibility." He criticized the paradigm of microbial omnipotence, which was speculated to result from the enormous metabolic diversity of the soil microflora together with its potential to adapt to new substrates. Several conditions must be fulfilled for a particular substance to be subject to biodegradation, such as the existence and presence of organisms having alone or in combination the potential for biodegradation, the possibility for the microbial population to proliferate in the environment, the possibility for the compound to be available and to penetrate the microbial cells, and the efficiency of appropriate enzymes. Alexander (125) has enumerated some of the main mechanisms of recalcitrance, which are reported on Table 1. Very often, molecular recalcitrance cannot be predicted from the molecular structure of the compound. Biodegradability is an experimental property, which results from the observation of the repeated failure to isolate degrading microorganisms and to find conditions where effective degradation takes place (24).

Environmental Factors Affecting Biodegradation of Pesticides

The soil is a complex and heterogeneous environment, which plays a crucial role in affecting growth, survival, and activity of microorganisms. Information about the effects of environmental factors on pesticide degradation is relevant from two practical points of view. First of all, a good mathematical description of the environmental factors, which govern microbial activity, is critical for obtaining mathematical models with a good predictive value. Secondly, some of these factors can be managed to optimize bioremediation procedures.

Moisture content and temperature are the most important factors regulating microbial activity. Water is a solvent for pesticide, and other nutrients and is essential to transport them inside the cell and for maintaining microbial activity. Biodegradation of pesticides in soil increases with water content up to a certain level, above which it declines as a consequence of poor oxygen transfer. A great majority of pesticides are better degraded

Table 1. The Main Mechanisms of Recalcitrance of Pesticides Biodegradation in Soils (After M. Alexander, *Biotechnol. Bioeng.* 15, 611–647 (1973))

Limitations due to intrinsic biological limitations
• the lack of the required novel array of enzymes
• the remote likelihood of finding a single mutant or an assortment of mutants with all the requisite enzymes
• a too narrow enzyme specificity
• the lack of sufficient carbon and energy for growth or of essential nutrients like oxygen and water, which control microbial activity,
• the production of toxic intermediates
Limitations due to environmental constraints
• inactivation of extracellular enzymes on the soil matrix
• inaccessibility of the substrate because of poor solubility
• localization in micropores too small for microbial penetration
• retention on soil organic and inorganic adsorbents
• complexing of the substrate with high molecular weight polymers
• formation of stabilized condensation products (126)

under aerobic conditions. However, under anaerobic conditions, other soil components such as nitrate ions are used as potential alternative electron acceptors. There is limited knowledge about anaerobic biodegradation processes. Some organochlorine chemicals (e.g., DDT) are better degraded in anaerobic conditions through reductive dehalogenation.

Soil temperature has a direct effect on the reaction rate of pesticide degradation, enzyme activity being optimum at mesophilic temperatures. Temperature is also important in modifying solute concentrations in the water phase. Under certain latitudes, some adaptation of the microflora to higher or lower temperatures has been described. Seasonally, soil temperature and moisture content do not vary independently. As a rule, in winter when the soil water content is optimum, temperature is the limiting factor. The reverse is true in summer, when water deficit limits microbial activity.

Other soil characteristics and properties are also of importance in regulating microbial activity. Soil pH may affect the ionic state of pesticides and hence their solubilization and sorptive properties. For instance, it has been demonstrated that accelerated degradation of atrazine in agricultural soils is dependent on pH (127). Organic matter and clays are crucial soil components and play a major role in the sorptive processes, which regulate availability of pesticides and protect them from microbial attack.

For pesticides that are cometabolized, the presence of easily available and biodegradable organic substances may increase the rate and extent of biodegradation. There is a rough positive correlation between the soil organic matter content and the rate of pesticide degradation (128). This is to be related to the higher level of microbial biomass combined with a higher biochemical diversity and a higher level of metabolic activity. Taken together, these biological characteristics increase the probability of finding effective microorganisms or the occurrence of evolutionary fitness with the possible emergence of an organism showing novel metabolic capacity.

Degradation by Microbial Assemblages Primary and Ultimate Degradations

Degradation of a pesticide in soil is a complex phenomenon involving the contributions of different kinds of microorganisms acting on the molecule at different rates, using different metabolic pathways, based on different physiological features. Again the example of 2,4-D gives an illustration of the actual biological nature of pesticide biodegradation. It has been observed that mineralization of 2,4-D in the soil follows a two-wave process. In the few days following its application, there is a first flush of mineralization achieved by a consortium of microorganisms, which are inhibited at high 2,4-D concentration (129) but respond positively to organic amendments (Soulas, unpublished). At this stage, the degradation process is interpreted as the result of the combination of cometabolic transformations by the opportunistic fraction of the soil microflora. The rate of mineralization increased again after one week to reach a maximum at about 15 days after application. The peak likely results from the taking over by a specific microbial population or community able to grow at the expense of the herbicide. At the phenomenological level, there is evidence that the same compound can be converted by both metabolism and cometabolism. An illustration of the inability of some microorganisms to completely mineralize 2,4-D is given by Bauer and coworkers (130), who isolated a *Pseudomonas* sp. strain able to cooxidize this herbicide in the presence of benzoate with the formation of monochlorophenol. There is no report of the accumulation of these phenolic intermediates in soils, as it is likely that degradation can proceed further through the action of other microbial strains.

Noting that degradation of 2,4,5-T by a *Brevibacterium* sp. resulted in the accumulation of 3,5-dichlorocatechol, and that this intermediate could be degraded by an *Arthrobacter* sp. (131), Horvath (43) suggested that an association of both organisms had the potential to completely mineralize 2,4,5-T. Chakrabarty and his collaborators have added experimental evidence in support of this assumption. In long-term chemostat co-cultures of a complex mixture of microorganisms from waste-dump sites, or chosen because of the presence of plasmids involved in the catabolism of aromatic compounds (plasmids TOL, SAL), Kellog and coworkers (132) isolated a mixed culture of three or four strains able to use 2,4,5-T as growth substrate after 8 to 10 months. A number of chemicals have been shown to be degraded by microbial consortia. This is the case with trichloroacetate (TCA) (133), parathion (134), silvex [2-(2,4,5-trichlorophenoxy) propionate] (135), mecoprop [2-(2-methyl, 4-chlorophenoxy) propionate] (57,136), and, more recently, atrazine (40).

For some chemicals, naturally occurring microbial communities fail to go to the point where transformation products can be channeled into central metabolic pathways, making carbon and energy available. These incomplete transformations have been collectively called

primary biodegradation (137). They generate the accumulation of intermediate compounds as demonstrated by DDT, which is converted into the more stable DDE and DDD in soils. By comparison, *ultimate biodegradation* denotes the process by which mixed cultures can account for complete mineralization (137). Probably, this situation is prevalent in soils. At the community level, primary and ultimate biodegradations are the functional equivalents of metabolism and cometabolism as defined for pure cultures. The possibility for a chemical to be used as a growth substrate causes the proliferation of microbes involved in the metabolic process. While maintaining a selective pressure by applying the chemical repeatedly on the same plot, long-term enrichment of responsible microorganisms may be enough to cause accelerated degradation of the pesticide as demonstrated in the 1950s for 2,4-D and other phenoxy herbicides (15). From a practical point of view, repeated applications of soil treatment chemicals may contribute to alter their efficiency against target organisms. Since the discovery of this phenomenon it has occurred with an increasing number of chemicals, carbofuran (138) and, more recently, atrazine (34) being two examples with practical significance.

Ecological and Evolutionary Advantages of Natural Microbial Communities

If microbial diversity is an important factor in metabolic complementation and efficiency, it may also help microbial communities to maintain activity under changing environmental conditions. Microbial communities have a greater fitness than pure cultures. This potential mainly results from enzymatic redundancy, which gives the community enough flexibility to tolerate small differences in substrate structure and to compensate for changes in environmental conditions regulating enzyme activity. Another reason for the ecological superiority of microbial communities is their potential for hosting alternative metabolic pathways, which may act as temporary by-pass routes that offer new possibilities for the flow of energy when adverse conditions prevent the main metabolic pathway to be fully operative. Moreover, the possibility for the microbial consortia to function on a partnership basis, for example, through enzyme complementation, exchange of growth factors,... contribute to give them additional metabolic capabilities that no single cell can exhibit separately.

It is also likely that, in soil, the different members of a functional community are in close proximity to one another, such as microbial aggregates. This spatial organization promotes efficient exchange and spread of mobile genetic elements such as plasmids, and increases the probability for the emergence of individuals endowed with a novel catabolic capacity. Within microbial communities, the potential for each individual species to adapt to new conditions depends not only on its genetic material but also on the genetic material it may receive from other species through horizontal transfer. For Reanney (139), spreading of some genes through horizontal transfer is a conservative process ensuring survival of the communities when conditions are no longer favorable for their maintenance.

In conclusion, if microorganisms are individually able to cope with xenobiotic organic compounds, their adaptive capabilities are enhanced when this potential is expressed within microbial communities. In communities, the genetic diversity is enhanced, as is the potential of occurrence of combinatorial events favorable to the emergence of new catabolic pathways.

Application 1: Bioremediation of Pesticide Contaminated Soils

Soil Bioremediation Techniques

Bioremediation technologies derive from the realization that microorganisms mainly mediate the destruction of pesticides in natural environments. The use of a microbial inoculant for the removal of a pesticide from soil was first suggested by Audus (15) for 2,4-D. Bioremediation techniques are called for in different circumstances (*1*) the lack or insufficient amount of cells (mostly microorganisms) or enzymes that can degrade a pesticide and (*2*) the insufficient level of metabolic activity of these cells or enzymes. Two different bioremediation technologies have been developed to remove or get rid of soil contaminants. They include *biostimulation* in which degrading activity of naturally occurring organisms is stimulated, and *bioaugmentation*, which consists of supplying the soil with selected strains of organisms. In situ technologies aim at stimulating degradation directly in the contaminated site. They are well suited for large-scale and non-point-source pollution, and stimulation of the naturally occurring microflora has been preferred to addition of potentially active microorganisms. Ex situ treatments are needed when conditions at a site are not conducive to microbial activity. In such cases, the soil is excavated and treated on specialized disposal areas or in bioreactors. Bioslurries are one type of treatment process, in which appropriate conditions for microbial growth are maintained in a bioreactor. Another process, composting, is conducted in piles where soil is humidified, mixed with degradable organic material such as straw and other inorganic nutrients, actively aerated, and, if necessary, enriched with selected microorganisms. Another large-scale method is land farming in which soil is spread out and tilled to promote aeration, homogenization of nutrients and inocula. Because of cost constraints, ex situ approaches are usually used for small volumes of soil with high levels of contamination.

Case Study: Bioremediation of Atrazine in Soil

Since its discovery in the 1950s, atrazine has been extensively applied as herbicide, especially in maize crops. It has long been recognized as a moderately persistent chemical with a half-life varying between a few weeks to a few months, and has become a major contaminant of soils and waters. For this reason, different approaches of soil bioremediation have been developed to treat atrazine.

The stimulation of atrazine biodegradation by the autochthonous microflora has been achieved in acidic soils that do not show accelerated degradation of atrazine. Liming of the soils has been proved sufficient to treat

two soils while two other soils responded positively only after inoculation with a selected atrazine-degrading strain (A. Yassir, personal communication). This result indicates that, in some soils, environmental conditions rather than the biological potential, limit biodegradation. This result was substantiated by another study indicating that dairy manure incorporation could stimulate rapid mineralization of atrazine in a maize-cropped soil (140). Enhancement of the degrading activity of the native microflora after addition of organic amendments may fail, however, especially when stabilization of pesticide residues by sorption to soil particles limits their bioavailability and rate of biodegradation, as has been demonstrated with soil-compost mixtures (141). Organic carbon can be added by growing plants in a contaminated area. Plants may secrete 10 to 20% of their photosynthates as root exudates, which can support the growth and metabolic activities of fungal and bacterial communities in the rhizosphere. Densities of rhizospheric bacteria can be as much as two to four orders of magnitude greater in rhizosphere than in bulk soils. It is not surprising, therefore, to find more microorganisms able to rapidly degrade in vegetated than in nonvegetated soils. Herbicide tolerant plants, such as *Kochia scoparia* (L) Roth, may enhance microbial degradation of atrazine in the presence of the other herbicide metolachlor and trifluraline, and at concentrations largely exceeding the field application rates (142). However, the effect of a crop on herbicide dissipation is not clear and may depend on other soil properties and environmental variables. In a field experiment, it was demonstrated that atrazine dissipation was more rapid in no-crop plots than in maize crop, and that reduction in the soil water content in the maize plot was speculated to be responsible for greater atrazine persistence (143).

Bioaugmentation has also been evaluated as a means to accelerate biodegradation of atrazine in soils. In laboratory experiments, it was demonstrated that a *Pseudomonas* strain YAYA6 isolated from a mixed microbial community could efficiently degrade atrazine, probably via *N*-dealkylation and dechlorination, when inoculated in soil. However, degradation rates were reduced in soils with a high organic matter content and with a low pH. Only 10% of initial activity was retained after a preincubation period of 42 days without atrazine (144). In another comparable study conducted with an *Agrobacterium radiobacter* strain J14a using atrazine as a sole nitrogen source, two soils were found to respond differently to J14a inoculation. This difference was probably related to differences in the indigenous atrazine-degrading communities and to differential competitiveness of the inoculated strain. The inoculant was unable to increase total atrazine mineralization in the most effective soil (145). *Pseudomonas* sp. strain ADP, capable of mineralizing atrazine with dechlorination as the first degradative step, is successful for bioaugmentation of subsurface soils where the indigenous microflora degrades atrazine, mainly via dealkylation. It was concluded from this study, that even if the potential for atrazine degradation exists in all soil strata, the most important factor is the presence of an atrazine-mineralizing community, and that bioaugmentation may be preferable to biostimulation for avoiding accumulation of undesirable metabolites (146).

White rot fungi are also good candidates for bioremediation. These organisms have a large array of exoenzymes with a high oxidative activity and a broad substrate specificity (peroxidases, laccases), which are involved in lignolytic activity. They tolerate a number of toxic compounds and can grow at the expense of low-cost organic substrates such as plant residues or industrial wastes, which can be used as carriers for soil inoculants. Among these fungi, *Phanerochaete chrysosporium* has been extensively studied for its capacity to transform atrazine into *N*-dealkylated metabolites in liquid culture. In one study, however, the observation of some fungal growth after inoculation of spores in a nonsterile soil, was not correlated with increased atrazine mineralization, not affected by the presence of the fungus (147).

Microbial consortia capable of complete mineralization of atrazine through ring fission in liquid culture and soil have been reported. For instance, in an uninoculated soil, 7% and 25% of applied atrazine was mineralized after 30 and 145 days, respectively, compared to 63% and 87% over the same periods of time in the same soil inoculated with a mixed microbial culture. Soil bound residues accounted for only 8% of applied atrazine in the inoculated soil and for 40% in the noninoculated control soil (148). It was also demonstrated that long-term survival of an inoculated microbial consortium was better in a rhizosphere soil (149).

Bioremediation: Unresolved Questions

There are several major issues concerning bioremediation that remain to be resolved. These issues include how to select an appropriate bioremediation technology, how to extrapole laboratory results to real situations, what are the long-term ecological consequences of introducing massive amounts of selected microorganisms into the soil, and what are future prospects of the use of genetically modified organisms.

Research on atrazine has illustrated the relative strengths and weaknesses of the different technologies now available to enhance pesticide degradation in soil. From an operational point of view, it would appear that bioaugmentation with mineralizing microbial strains or consortia, if available, is to be preferred to avoid accumulation of intermediates compounds, which may adversely affect the inoculum and other naturally occurring organisms. Nevertheless, there are limitations to the use of acclimated microbial cultures to degrade toxic chemicals. Strains selected in the laboratory in appropriate culture media may be subjected to stresses when they are reintroduced into the soil. Chemical shock, extremes of soil physicochemical and climatic conditions, starvation, competition, preferential use of other organic compounds, and predation, may destroy or harm the inoculum and suppress its degradative capability. Numerous studies have shown that not only do declines in the degrading activity of inocula result from a decrease in the number of microbial cells, but also from a decrease in the specific activity of surviving cells as a result of the loss of the corresponding encoding genetic

material. The maintenance of a successful detoxification potential also needs suitable environmental conditions, which may be achieved by using appropriate additives, substrates, or carriers, which may be added to the cell suspension for stimulation and protection. The demonstration of how survival of an inoculated mixed culture mineralizing atrazine is enhanced in a maize-planted soil (149) is a promising example. The question of whether microbial consortia are ecologically superior to pure cultures is critical especially when, as often happens, a mixture of pollutants is present in the contaminated environment. Most bioremediation research has been restricted to laboratory and microcosm studies under conditions that do not challenge a microbial community to compete and survive, as it would have to do under the fluctuating and heterogeneous soil conditions in the field. A more realistic approach of the efficacy and safety of a bioremediation application must be gained from studies at an appropriate scale and for a long enough period.

Enhancing evolution of new degradative pathways in microorganisms or even in plants may help in solving problems of chemical pollution. Not all pesticides have been found to be easily biodegradable and for many, extensive mineralization can be accomplished when the biochemical activities, present in mixed microbial communities, complement one other. The construction of a hybrid single organism can be achieved by taking advantage of natural or induced gene transfer to collect all the genes for the emergence of new metabolic pathways. Using chemostat selection, it has been possible to isolate from waste-dump sites and after several weeks continuous subculturing a genetically engineered variant, *B. cepacia* (formerly *P. cepacia*) AC1100, that rapidly uses 2,4,5-T as its sole source of carbon and energy (150). More recently, different recombinant strains have been constructed to degrade atrazine. Cloning on the same plasmid, the *atrA* and *trzA* genes, responsible for *N*-dealkylation and hydrolytic dechlorination respectively, and transferring the plasmid into an *atrA* and *trzA*-deficient *Rhodococcus* sp. strain resulted in full expression of the genes. The same procedure was unsuccessful when the plasmid was transferred into an *E. coli* strain (151). Several problems must be worked out with genetically engineered strains. Little is known on their competitiveness and stability in natural conditions, on the possibility for the constructed pathway to be disseminated in the indigenous microflora and possible consequences on the composition and structure of the indigenous microbial community. The last but not least difficulty to overcome, is the public acceptance of these emerging technologies based on the use of genetically manipulated organisms.

In conclusion, bioremediation appears to have a promising future. It has the potential to be an efficient and cost-effective strategy for reclamation of soil and aquatic environments. Further technical advances can be expected from a better understanding of soil microbial ecology, namely, how organisms interact with each other to perform new functions, generate new metabolic capabilities, and respond to environmental fluctuations.

Application 2: Modeling of Pesticide Degradation in Soil

Spreading of a pesticide in the environment depends on interactions among physical, chemical, and biological phenomena. Modeling is probably one of the most powerful approaches to obtain a comprehensive understanding of all these processes, which collectively contribute to the environmental fate of a pesticide. For these reasons, regulatory experts are asking for meaningful models they can rely on. Model calculations simulating pesticide behavior in the environment are increasingly used for research purposes and, in the last decade, for regulatory purposes. In the first case, models are used to validate mechanistic assumptions about the nature and rates of the different processes that govern the fate of pesticides in the environment. In using the second type of models, the objective is to obtain comparative estimates regarding accumulation, exposure, and leaching of pesticides to assess the ecotoxicological risk and the risk of their transport into the groundwater. These predictive and comparative aspects are especially important for evaluating new agrochemicals for which no monitoring data exist, which could provide more realistic exposure information.

A major challenge is to reduce uncertainty in the model outputs. More accurate and reliable predictions may be obtained in using better estimates of the parameters controlling the sorption and the transformation processes, to which soil persistence and leaching models are very sensitive (152–154). Since Hill and coworkers' early work (155), simple first-order rate reaction kinetics are commonly used to describe kinetics of pesticide degradation in soil, based on the assumption that only pesticide concentration limits degradation and microbial populations are present in excess (156). More recent research has amply demonstrated that degrading activity is often restricted to a small fraction of soil microorganisms, and the size of the degrading community may also limit the rate of degradation. As discussed earlier, some strains have the potential to grow at the expense of the pesticide, while others show increased degrading activity in response to organic amendments. All these changes of size and/or activity will dictate the rate at which a compound will be transformed in the environment. Considering these issues, one might expect that introducing more conceptual descriptions of microbial reactivity to pesticide and nutrients additions to soils may reduce the uncertainty of predictions of persistence and leaching models.

Metabolism and cometabolism have different implications for biodegradation kinetics of xenobiotic compounds because they correspond to different underlying biological processes. Metabolic degradation result in the formation of both transformation products and new active biomass. These reactions can be compared to autocatalytic chemical reactions, with a progressive increase of the rate in the early stage of the transformation. Moreover, a lag-phase of a few days or weeks often occurs before degradation starts. This phenomenon is often attributed to the limited number of active microorganisms that are commonly found in agricultural soils. It mainly reflects the time necessary

for those degrading microorganisms to reach a population level that is consistent with a rate of transformation that can be detected by common analytical procedures. In contrast, cometabolic transformations are performed by nongrowing microbial agents and follow simple enzymatic kinetics. The rate of the transformation starts at its maximum and decreases with the chemical concentration.

Basic Mathematical Formulations

It is expected that the rate of transformation directly reflects both the concentration of the chemical and the density of the active microflora. Paris and coworkers (157) proposed a second-order rate model based on the following equation:

$$-\frac{dC}{dt} = k_2\, CB$$

where k_2 is the second-order rate constant, C the concentration of the chemical and B the density of the active microbial population. In practice, pseudo first-order kinetics may be derived when soil microorganisms are in abundance and do not limit the degradation process and/or when they cannot grow at the expense of the chemical. In these circumstances, the transformation reaction is zero-order with respect to the concentration of active microorganisms (156). The pseudo first-order rate constant, k_1, is:

$$k_1 = k_2\, B$$

and the rate law:

$$v = -\frac{dC}{dt} = k_1\, C$$

The theoretical half-life, $t_{(1/2)}$, is the time necessary for obtaining a 50% decrease of any chemical concentration. It is related to the first-order rate constant by the equation:

$$t_{1/2} = \frac{\ln\, 2}{k_1}$$

and is approximated by the experimental parameter DT50, the 50% disappearance time of the initially added concentration. As stated by Hamaker (158), "for such a complex system as soil, it is somewhat unreasonable to expect that there will be a simple rate law" to fit observed disappearance curves that often deviate from first-order. Considerable modeling effort has been directed at obtaining more conceptual representations based on the consideration that soil degradation of pesticides depends on the contribution of different types of microorganisms and the effects of environmental parameters (temperature, water content, pH. . .) or soil properties (sorption).

In many cases, changes in population density resulting from using either the pesticide as carbon and energy source or any other easily mineralizable carbon substrates must be taken into consideration. For growth-linked or metabolic pesticide biodegradation, two additional equations must be written: one for the rate of growth of the degrading microflora:

$$\frac{dB}{dt} = \mu_{\mathrm{m}} \frac{SB}{(K_{\mathrm{s}} + S)}$$

with μ_{m} and K_{s} being respectively the maximum specific growth rate and the saturation constant, and the other for the mass balance:

$$B = B_0 + Y(S_0 - S)$$

where Y is the gross growth yield, B_{o} and S_{o} the initial biomass density and substrate concentration respectively (159). For cometabolic transformations, it is assumed that degrading microorganisms can grow at the expense of naturally occurring or added carbon substrates. Exponential growth is maintained until the microbial biomass approaches some limit value, B_{m}, known as the carrying capacity. With r being the maximum growth rate, the complete equation for these microbial dynamics is (160):

$$\frac{dB}{dt} = \frac{rB}{(1 - B/B_{\mathrm{m}})}$$

Several experiments have confirmed that temperature and water content are major soil parameters conditioning microbial activity and therefore pesticide degradation. Temperature effects have been described using two types of equations. A first series of equations is derived from the Arrhenius equation (161–163) and is based on the activation energy concept. Other equations make use of the Q_{10} coefficient, which is defined as the relative increase in the rate of transformation every 10 °C change in temperature. All these equations have in common the disadvantage of ignoring that for biological processes the activity-temperature relationship is a bell-shaped curve showing an optimum.

Likewise, the influence of soil moisture on transformation rates has almost exclusively been described using an empirical exponential equation initially proposed by Walker (161). Several examples of application (161,164) can be found in the literature.

The retention of pesticides on the soil matrix is a major process governing their fate in soils. It has been shown that sorption of pesticides on soil colloids controls their release into the soil solution, and it is commonly accepted that only the fraction in the soil solution is available for biodegradation (165). A diffusion-sorption-biodegradation (DSB) model has been developed to describe biodegradation under conditions of substrate limitation (166). The model correctly simulated the experimental data for biodegradation of glutamate and phenol diffusing out of synthetic aggregates of different sizes (167). Likewise, 2,4-D disappearance from soil has been adequately described by a model, which accounted for sorption to soil surfaces, diffusion into the internal matrix of soil organic matter or aggregates and microbial growth (168).

Practical Applications

Because leaching of pesticides to groundwater is of worldwide concern, there is a growing body of literature on the development of simulation models for quantitatively predicting the fate of chemicals in the root zone of agricultural crops and in the underlying unsaturated zone. Simulation models have been constructed for various

uses: research, management, regulatory, and screening purposes.

In the early 1970s, Walker (161) developed a mathematical model to simulate herbicide persistence in the top-soil layer under variable temperature and water content conditions that prevail in the field environment. The model combines first-order reaction rate law with equations describing the dependence of the rate constant, through the DT50 parameter, on environmental variables temperature and water content. Implementation of the model requires performing preliminary laboratory experiments to validate equations for soil temperature and moisture effects using inverse modeling. The predicted residual concentration of the herbicide in the field is then calculated with the model for actual values of moisture and temperature deduced from weather records.

Persistence and leaching management models are in their infancy and, except for particular situations, are unable to adequately simulate experimental data. Because biodegradation is the primary factor controlling persistence, this process deserves detailed attention. Descriptions in terms of overall first-order kinetics have been shown to have their limits. Consideration of the major microbiological phenomena underlying degradation may contribute to making management models more operational and of better value for the quantitative prediction of the contamination of ground waters.

CONCLUSION

As xenobiotic compounds, pesticides have revealed some aspects of microbial functioning in complex ecosystems, which were unknown from preliminary studies with pure cultures. We have learned that, when confronted by new chemical structures, which have not been previously registered in their genomic "memory," soil microorganisms respond collectively, taking advantage of metabolic capabilities, which are originally distributed among different strains and normally used for the biodegradation of naturally occurring compounds. Such a "cooperative metabolism" may be the starting point of a new evolving biochemical activity, which is further subjected to successive functional improvements through the selection of trial and error combinations of isolated genes or entire fully operative genetic structures. Horizontal transfer may contribute to the stepwise building of integrated mosaic gene assemblages in one microbial cell. We have to learn more about the determinism and processes governing exchange and stabilization of these emerging genetic structures and the timescale of this natural genetic engineering. This knowledge would be very fruitful from two points of view. Linking biodegradation rate to the biochemical pattern of natural microbial communities would help in elaborating the basis of predictive metabolism, which would be useful to predict and manage the persistence of a new chemical in the soil, to define improved agricultural practices for a better weed control, and to design new compounds compatible with sustainable agriculture. Basic knowledge of microbial ecology of pesticide biodegradation in natural complex ecosystems is also a prerequisite for elaborating more successful bioremediation technologies when bioaugmentation by inoculation with naturally occurring or genetically engineered microorganisms known to readily metabolize persistent chemicals has failed. Overcoming environmental constraints that limit survival or activity of introduced organisms or genes is one of the challenges for increasing effectiveness of bioremediation technologies.

PETROLEUM AND OTHER HYDROCARBONS, BIODEGRADATION OF

ROGER C. PRINCE
Exon Mobile Research and Engineering Co.
Annandale, New Jersey

Petroleum, literally rock oil, has been a part of the biosphere for millennia, but in the last hundred years it has become the fossil fuel that drives the modern world. It is used on an enormous scale; the global use of petroleum in the year 2000 was on the order of 1.2×10^{12} U.S. gallons crude oil per year [4.5×10^{12} liters/year; (1)], and this seems likely to increase. Crude oils are very complex mixtures of molecules, principally hydrocarbons, and although the major classes are well defined, we have no inventory of all the individual species in oil. Nevertheless, we do know that the vast majority of molecules in most crude oils are biodegradable. Hydrocarbon biodegradation can cause problem while the oil is under human control because it can lead to product deterioration, corrosion, and the potential accumulation of microbial biomass in critical locations. In the last decade or so, however, it has become clear that stimulating biodegradation (in a process known as *bioremediation*) offers an opportunity to reduce the environmental impact when crude oils and refined products escape into the environment. For many years, all biodegradation was thought to be aerobic, and indeed the very existence of petroleum reservoirs was taken as evidence that anaerobic biodegradation of hydrocarbons was a very limited phenomenon, if it occurred at all. More recently, it has become clear that hydrocarbon degradation can occur under a range of anaerobic conditions, including sulfate-reducing, nitrate-reducing, metal-reducing, and methanogenic conditions.

THE COMPOSITION OF CRUDE OIL

Crude oil is a fossil fuel, and the average age of commercially important crude oils is about 100 million years (71% between 180 and 85 million years ago (2)). It is generally accepted that aquatic algae, albeit usually with some terrestrial material, gave rise to petroleum, whereas terrestrial plants gave rise to the great coal reserves of the world. The oldest commercially valuable oils are from biomass generated in the Ordovician (486 million years b.p.), whereas others are as young as the late Tertiary (a few million years ago). Unusual circumstances such as those that prevail at the Guaymas hydrothermal vent site can even result in the formation of petroleum from biomass that is only approximately a thousand years old (3).

Petroleum has been a part of the biosphere for aeons because it has escaped through seeps on land and sea. Terrestrial seeps were the first locations to be drilled when oil production began in earnest in the nineteenth century. For example, the 1860 Drake well in Pennsylvania, the first U.S. well, was drilled on a seep site. Most of the known terrestrial seep sites had been drilled by the 1920s, but marine seeps continue to be explored today. It has been estimated that the annual input of crude oil into the sea from seeps is about 70 million gallons (about 300 million liters), accounting for approximately 8% of the total input (4). Some have even argued that the biodegradation of this oil contributes significantly to the local food web and to commercial fisheries (5).

Crude oils are principally hydrocarbons, with hydrogen to carbon ratio of between 1.5 and 2.0; the organic molecules are thus generally saturated molecules (i.e., the predominant form of carbon is $-CH_2-$). The convention in the oil industry is to call linear alkanes "paraffins," branched paraffins "isoparaffins," and cyclic alkanes "naphthenes" (Fig. 1). There are also significant amounts of aromatic carbon in all crude oils (Fig. 2) and polar molecules (Fig. 3) containing the heteroatoms oxygen, nitrogen, and sulfur. These latter compounds are known by a variety of names, including resins, NSOs, polars, and asphaltenes. Tissot and Welte (2) quote the average composition of 527 crude oil samples as 58.2% saturates, 28.6% aromatics, and 14.2% polar compounds, although the absolute values vary widely in different oils. On an average, there is rough parity among paraffins, naphthenes, and aromatics.

The paraffins (Fig. 1) span the range from a single carbon (methane) up to waxes with at least forty carbons and sometimes more. The largest alkane reported in petroleum is $C_{79}H_{160}$. Linear alkanes typically make up 15 to 20% of a crude oil, although their content can be essentially undetectable or as high as 35%, depending on source and reservoir conditions. There are

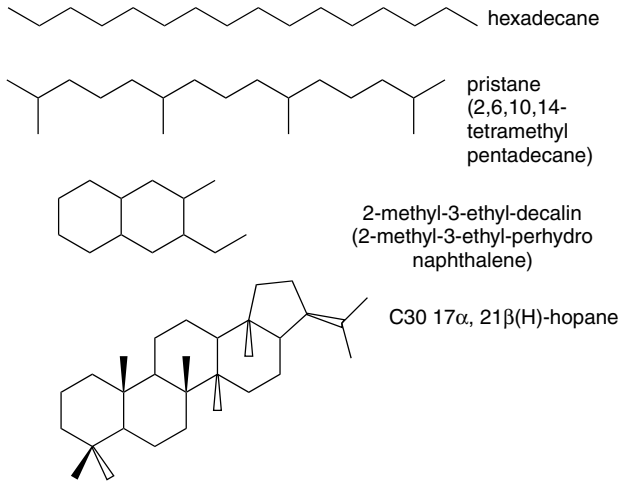

Figure 1. Saturated hydrocarbons. An alkane, an isoalkane, a small naphthene, and a naphthenic biomarker found in crude oils. As in all the figures in this article, hydrogen atoms are not shown unless on a heteroatom.

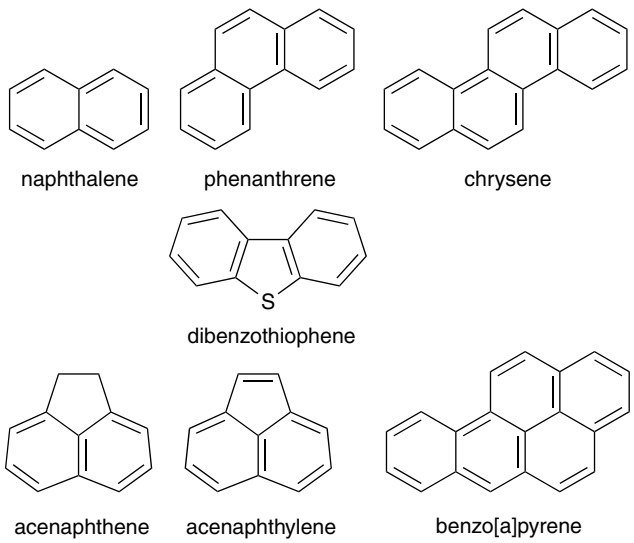

Figure 2. Aromatic hydrocarbons. A two-, three-, and four-ring polycyclic aromatic hydrocarbon found in crude oil, together with dibenzothiophene, an example of a sulfur-containing aromatic compound. The lower three compounds are typical pyrogenic polycyclic aromatic hydrocarbons that are only present at trace levels in most crude oils but are abundant in creosotes and coal tars.

also branched alkanes; most are found in the C_6 to C_8 range, but pristane ($C_{19}H_{40}$, Fig. 1) and phytane ($C_{20}H_{42}$), molecular relics of the phytol chains of chlorophylls, and perhaps other biomolecules are usually the most abundant individual branched alkanes. Pristane is thought to be the result of initial partial degradation of phytol in the presence of oxygen, whereas phytane is thought to be the result of initial degradation in the absence of oxygen. Alkenes, which are unsaturated alkanes, are present in only trace levels in crude oils, but they are produced during catalytic refinery processes

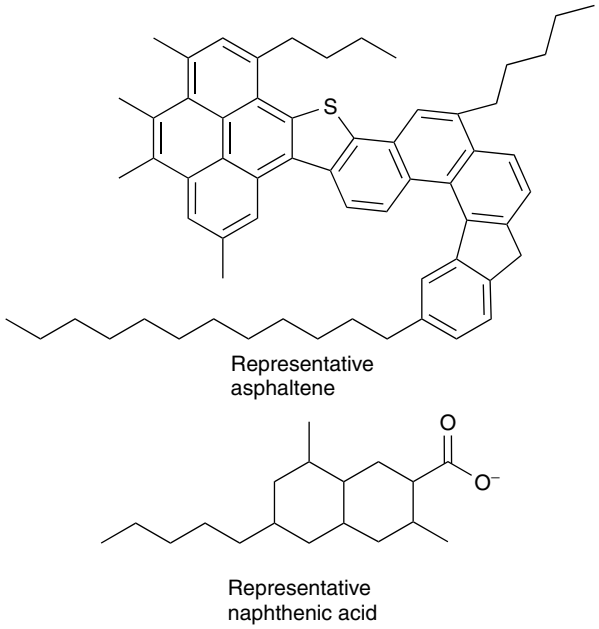

Figure 3. Polar oil components. Representation of what are thought to be a typical asphaltene and a typical naphthenic acid found in crude oils.

and can be abundant in refined products such as gasoline.

The naphthenes (Fig. 1) include parent compounds, such as cyclopentane, cyclohexane and decalin, together with their alkylated congeners. Tissot and Welte (2) quote the average composition of the naphthene fraction of 299 crude oils as 54.9% one- and two-ring naphthenes, 20.4% tricyclic naphthenes, and 24.0% tetra and pentacyclic naphthenes. These latter molecules are among the better-understood molecular biomarkers in crude oils, and they are used extensively in correlating reservoirs and source rocks (6), in assigning the depositional environment of source rocks (6), and more recently as conserved internal markers during biodegradation (7).

Because of the separation procedures used in the characterization of crude oils, any molecule containing at least one aromatic ring is included in the "aromatic" fraction, regardless of the presence of saturated rings and alkyl substituents. Sulfur aromatic heterocycles, such as thiophenes, benzothiophenes, and dibenzothiophenes (Fig. 2), are included in the aromatic category. Indoles and carbazoles, usually the most abundant nitrogen-containing species, and the less abundant basic nitrogen species such as quinolines are also included in the aromatic category but they are present at much lower concentrations. Alkylated aromatic species are usually more abundant than their parent compounds, with mono-, di-, and tri-methyl derivatives usually being most abundant. Nevertheless, the median aromatic structure probably has one or two methyl substituents together with a long-chain alkyl substituent (8).

The polar molecules are the most difficult to characterize because they are often unamenable to gas chromatography, which is the usual method of choice for the molecular characterization of petroleum. All are thought to contain

heteroatoms such as nitrogen, oxygen, and/or sulfur, and the category includes the porphyrins, usually nickel or vanadium species, naphthenic acids (Fig. 3), and large molecules known as asphaltenes. Some of these molecules have molecular weights that are into the thousands and even higher, and many are suspended in the oil rather than dissolved in it. Others are dissolved in the whole oil but are precipitated if more alkanes (e.g., pentane) are added. The polar fraction of the oil contains the majority of the color centers in crude oil, and in isolation these materials are difficult to distinguish from more recent biological residues such as the humic and fulvic acids that are common in soils.

Crude oils are classified commercially by several criteria, and among the most important is the specific gravity. The oil industry uses a unit known as American Petroleum Institute (API) gravity, which is defined as [142.5/(specific gravity)] — 131.5, and is expressed as degrees (°). Thus, water has an API gravity of 10°, and denser fluids have lower API gravities. Less dense fluids, for example, most hydrocarbons, have API gravities greater than 10°. For convenience, oils with API gravities greater than 40° are said to be light oils, whereas those with API gravities of less than about 16° are said to be heavy. Light oils have higher proportions of small molecules; heavy oils are rich in larger molecules. Viscosity is inversely proportional to API gravity, but it is also dependent on the physical state of the polar compounds and longer alkanes in the oil and is highly dependent on the temperature.

OTHER HYDROCARBONS

Petroleum is not the only source of hydrocarbons in the environment; it is not even the main one. Plants, especially conifers, emit large amounts of hydrocarbons (9), including isoprenes, that can lead to the generation of atmospheric haze (giving rise to names such as the Blue Mountains). Citrus fruits contain substantial amounts of terpenes such as limonene in their peels. Many beetles produce hydrocarbons (10). Some bacteria produce toluene (11) and termites produce naphthalene (12). Considerable amounts of polycyclic aromatic hydrocarbons and dioxins are generated during the partial combustion of biomass and solid waste (13). Similarly, coal and wood gasification, especially in the production of "town" or "manufactured gas," released substantial amounts of tar and polycyclic aromatic hydrocarbons into the environment (14). Creosote, which is made by high-temperature carbonization of wood or coal and widely used as a wood preservative, led to significant localized soil contamination with polycyclic aromatic hydrocarbons (15). These sources can be distinguished from petroleum by their composition. For example, the relative distribution of pyrogenic polycyclic aromatic hydrocarbons is different from its distribution in petroleum; anthracene is abundant in pyrogenic materials such as tars and creosotes but rare in petroleum, and four- and five-ring aromatics are abundant in coal tar but not in petroleum. Furthermore, the distribution of alkylated forms is different; unalkylated species are most abundant in creosotes and coal tars, while alkylated forms are most abundant in petroleum (16). Such differences are very important in determining the source of contamination at contaminated sites, and they are important at the basic microbiological level because the four- and five-ring aromatics are much more resistant to bacterial degradation than smaller aromatic compounds. Even more important in this regard is the potential presence of other contaminants; for example, creosote-contaminated sites are often cocontaminated with pentachlorophenol at potentially toxic levels. The focus of this entry is on the biodegradation of hydrocarbons from any source.

BIODEGRADATION OF HYDROCARBONS IN AEROBIC ENVIRONMENTS

Hydrocarbons have been a natural part of the biosphere for millennia, so it is no surprise that microbes take advantage of this food supply. Oil-degrading organisms have been found in almost all habitats in which they have been diligently searched for. They have been isolated from the bottom of the sea, including the Guaymas deep-sea site, the tops of mountains, soils, and shores everywhere, including the Arctic and Antarctic, and from the deserts. Extreme halophiles have been isolated, as have thermotolerant organisms. No extreme thermophiles have been isolated to date, but there is every reason to expect that they will be found. Table 1 lists the bacterial genera that contain species known to degrade hydrocarbons. Many can grow with hydrocarbons as the sole source of carbon and energy, although some such as the photosynthetic autotrophs only degrade aromatic hydrocarbons as an adjunct to their photosynthetic growth and cannot grow on

them alone. Table 2 shows the much shorter list of aerobic archaeal genera known to degrade hydrocarbons; Table 3 lists fungal genera; and Table 4 lists algal genera with species able to degrade polycyclic aromatic hydrocarbons, although again all are obligate photoautotrophs. There is no reason to believe that these lists are exhaustive, but they illustrate the diversity of organisms that are able to degrade hydrocarbons. This diversity of organisms is mirrored in the diversity of mechanisms for activating and degrading hydrocarbons shown as follows.

BIOCHEMICAL PATHWAYS OF AEROBIC HYDROCARBON DEGRADATION

Aerobic pathways of hydrocarbon degradation have been studied in considerable detail, and pathways are beginning to be clearly defined, at least for relatively simple hydrocarbons. It is the insertion of the initial oxygen atoms into hydrocarbons that initiates hydrocarbon degradation, and the discussion that follows will focus on these reactions. Subsequent oxidation is often through pathways with a much broader specificity, and often these pathways are essentially ubiquitous.

Linear Alkanes (Paraffins)

The biodegradation of alkanes has been elucidated in some detail, in particular in the organism *Pseudomonas oleovorans* (17). This organism oxidizes alkanes with 5 to 12 carbons, but similar systems seem to be involved in organisms that grow on alkanes with up to at least 20 carbon atoms. The initial reaction is the terminal oxidation of the alkane to the alcohol, the aldehyde, and the fatty acid, with subsequent "ß-oxidation" yielding acetyl fragments, attached to Coenzyme A, for cellular metabolism (Fig. 4). The initial hydroxylase is a monooxygenase, meaning that one atom of oxygen from a diatomic oxygen molecule is incorporated into the alkane, whereas the other is reduced to water. The electrons for this latter reduction come from NADH; thus, each hydroxylation represents a considerable energetic input by the organism. The subsequent oxidation to the aldehyde and the acid releases reducing equivalents, probably both to NAD^+; therefore, the NADH investment in the first step is amply repaid.

Subsequent ß-oxidation releases substantial amounts of energy for the organism.

In *P. oleovorans*, the genes for the alkane oxidation pathway are arranged as two clusters on a plasmid known as the OCT-plasmid (17). Interestingly, the nucleotide composition of the alkane oxidation genes is quite different from that of the chromosome, suggesting that the alkane oxidation genes may have come from quite a different organism, which in turn suggests that the genes may be quite widespread. At least nine genes are involved, and their function and sequences have been determined. Perhaps most interesting is the alkane monooxygenase catalyzing the initial oxidation. This enzyme is a 401 amino acid membrane-bound polypeptide, with six putative membrane-spanning regions. It contains ferrous iron in a nonheme environment, and contains no cysteines. The enzyme has quite a broad specificity; it is most active against *n*-alkanes with 5 to 12 carbon atoms, but it is also active against alkanes with 1 or 2 methyl substituents and a range of cyclic alkanes and substituted benzenes (17). This is reminiscent of the broad substrate range of soluble methane monooxygenase (18), albeit shifted to slightly larger compounds. Considerable progress is being made in understanding the catalytic cycle of this enzyme, which has a dinuclear iron center at its active site (19).

Some organisms seem to activate the oxidation of *n*-alkanes at both ends of the molecule. This is most often seen with larger alkanes, suggesting independent activation at the two ends of the molecule. As is discussed later, such diterminal attacks are apparently common for isoalkanes. Other organisms seem able to initiate the oxidation at a carbon other than the terminal one. This activity may be related to the systems that degrade cyclic alkanes and is discussed later.

A rather different pathway has been suggested by Finnerty (20). It involves the initial oxidation by a dioxygenase that puts both oxygen atoms into the alkane to form an alkyl hydroperoxide and the subsequent manipulation of this through the peroxy acid to the aldehyde (Fig. 5). The pathway has been most extensively studied in *Acinetobacter*, and the dioxygenase, which acts on *n*-alkanes from C_{12} to C_{20}, has been characterized as a flavoprotein that may contain a copper at the active site (21). The enzyme does not require a source of reductant beyond the substrate, as monooxygenases do, so the initial energetic investment in this pathway is much less than that described in Figure 4.

Eukaryotic oil-degrading organisms, for example, yeasts such as *Candida*, catalyze the hydroxylation of alkanes to primary alcohols with enzyme systems that involve Cytochrome P-450, a heme protein named for its prominent optical absorption feature generated by binding CO to the reduced form (22). P-450 systems are also found in some bacteria. Subterminal oxidation of *n*-alkanes to secondary alcohols has also been reported.

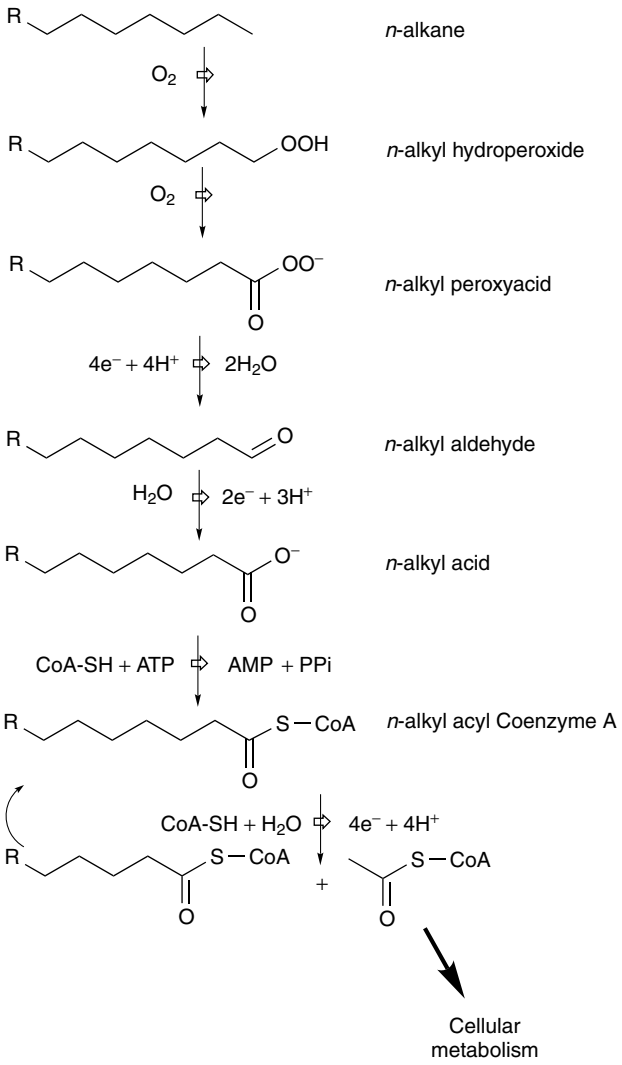

Figure 5. The pathway of alkane oxidation thought to occur in *Acinetobacter*, based on Finnerty (20), and Maeng and coworkers (21).

Branched Alkanes (Isoparaffins)

Linear alkanes are generally degraded preferentially to branched forms, so a decrease in the ratio of *n*-alkanes to branched forms (e.g., *n*-heptadecane: pristane) serves as an indicator of the onset of biodegradation in the environment. Nevertheless, simply branched alkanes such as pristane are reasonably readily degraded, for example, the pristane-degradation pathway has been worked out in a *Brevibacterium* (23); it involves diterminal oxidation to pristanedioic acid, with subsequent ß-oxidation, much as outlined in Figure 4 but potentially at both ends of the molecule. Interestingly, this work with *Brevibacterium erythrogenes* revealed a clear example of hydrocarbon diauxie; when provided with both *n*-hexadecane and pristane, no pristane degradation was seen until the *n*-hexadecane had been degraded to less than 5% of the total hydrocarbon (23). Other organisms seem completely unable to degrade branched alkanes, whereas they have a broad ability to degrade even very long *n*-alkanes (24).

Alkanes with more complicated branching, particularly those with tertiary carbon atoms, are generally much more resistant to biodegradation than pristane and phytane, but even compounds such as 2,2,4,4,6,8,8-heptamethylnonane are degraded by mixed consortia (25). Here, degradation

seems to involve the oxidation of an internal carbon to the ketone, further oxidation to the ester, and subsequent hydrolysis prior to ß-oxidation (Fig. 6). Presumably, the first reaction is catalyzed by a monooxygenase, but this has not been studied in detail. A similar pattern of degradation has also been seen for pristane. Adjacent quaternary carbons may pose a more difficult problem, and no pathway that can degrade this motif has been identified yet.

Cyclic Alkanes (Naphthenes)

The biodegradation of naphthenes has not received as much attention as that of the linear alkanes and aromatics, but degradation occurs quite readily. The octane hydroxylase has significant activity against cyclopentane and cyclohexane (17), and much degradation may be carried out by organisms that preferentially degrade linear alkanes. Some *Acinetobacters* can grow on cyclohexane as the sole source of carbon (26), and these organisms possess a cyclohexane monooxygenase that converts cyclohexane to cyclohexanol. Subsequent degradation of the cyclohexanol proceeds through the ketone, the cyclic acid lactone, and ring cleavage to the diterminal carboxylic acid (Fig. 7). The enzyme that converts the ketone to the lactone is another monooxygenase, and after the lactone is hydrolytically cleaved, there is probably another monooxygenase involved in the conversion to adipate. Because each monooxygenase turnover requires an NADH, there is a rather larger energetic investment in activating cyclic alkanes than in activating linear ones. Bacteria that are able to grow with decalin (perhydronaphthalene) as the sole carbon source have been isolated from Arctic oil seeps (28), but many organisms seem able to degrade naphthenes only cometabolically when supplied with a more degradable substrate such as a linear or simply branched alkane (29).

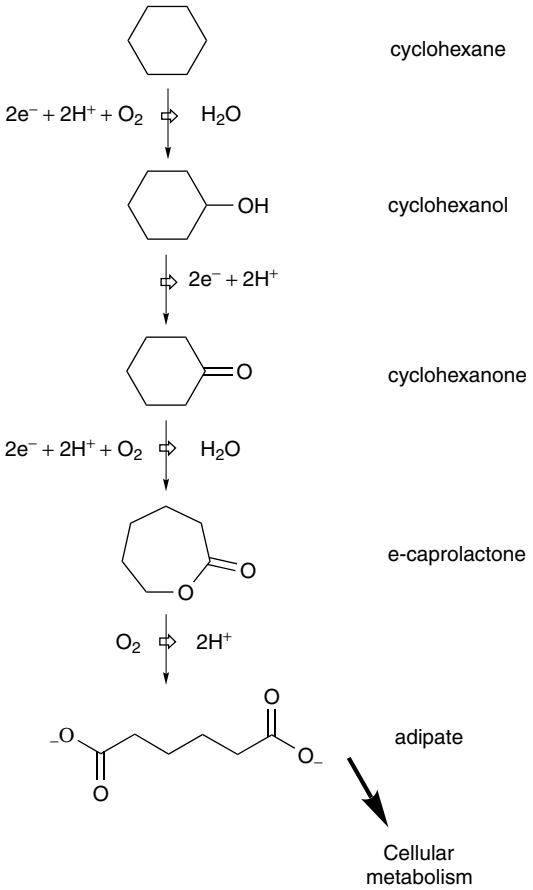

Figure 7. The pathway of cyclohexane biodegradation by a *Nocardia* species, based on Perry (26).

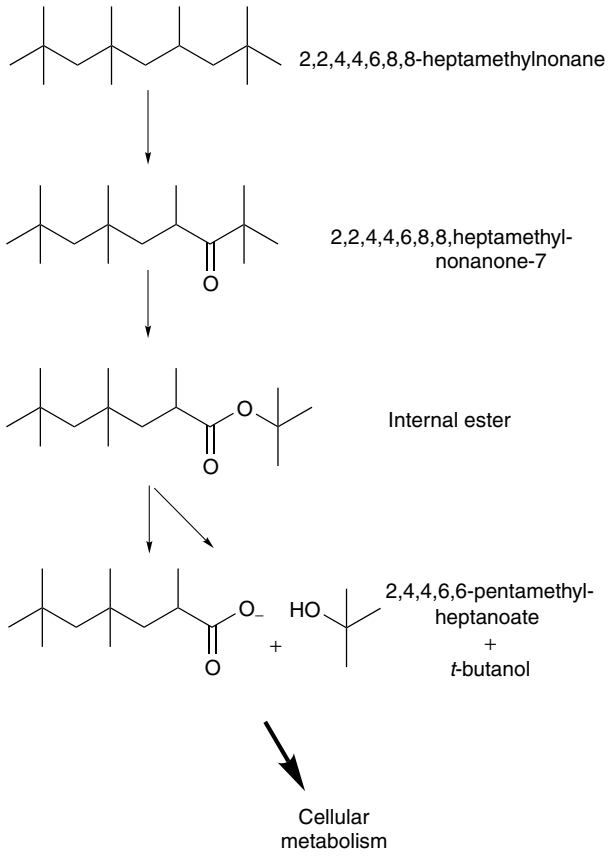

Figure 6. Proposed pathway of degradation of 2,2,4,4,6,8,8-heptamethylnonane, based on Rontani and Giusti (25). Presumably, both oxygen insertions are by monooxygenases, but this has not been shown.

Substituted polycyclic saturated hydrocarbons, such as the hopanes and steranes, are particularly resistant to biodegradation (30), and they are widely used in petroleum geochemistry to correlate oil reservoirs with their source rocks (6). They have also proven very useful as conserved internal markers for following oil biodegradation in the field (7).

Alkenes

Alkenes are essentially absent from crude oils and straight distillate fuels but can be quite abundant, that is, up to 20%, in modern gasolines. Some representative gasoline alkenes are shown in Figure 8. The best-studied biodegradation pathway is that of propylene by *Xanthobacter* strain py2 (30), which can grow with

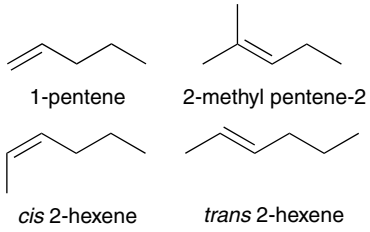

Figure 8. Some representative gasoline alkenes.

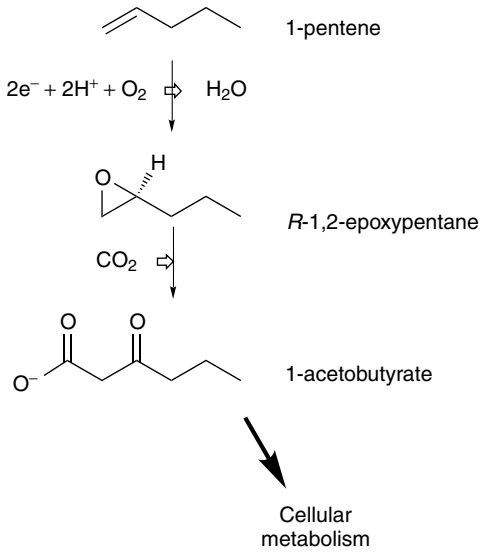

Figure 9. The pathway of alkene biodegradation. The figure shows the biodegradation of pentene; this is speculative, although based on the pathway elucidated for the biodegradation of propylene by Zhou and coworkers (30).

propylene as the sole carbon and energy source. The initial enzyme of the degradation pathway (Fig. 9), the alkene monooxygenase, has been extensively studied; it is an $\alpha_2\beta_2\gamma_2$-hexamer, containing two dinuclear iron active sites that seem rather similar to the active site of methane monooxygenase. Interestingly, although the enzyme catalyzes the epoxidation of a wide range of alkenes, it shows remarkable enantiomeric specificity in producing the *R*-enantiomer. It shows no activity toward alkanes, although it does attack benzene and toluene. Further metabolism of the epoxide involves carboxylation to generate an aceto-fatty acid (Fig. 9) that can then enter cellular metabolism.

Aromatic Hydrocarbons

The biodegradation of aromatic hydrocarbons, particularly under aerobic conditions, is a very active field of investigation and it is dealt with in detail elsewhere in this volume (31). Just as with alkane, isoalkane, and cycloalkane degradation, the initial reaction is the addition of oxygen, and just as with the alkanes, there is a marvelous diversity in the way this is achieved by different organisms. For example, as discussed by Zylstra (31), different organisms attack toluene by inserting oxygen into what appear to be all the possible positions on the

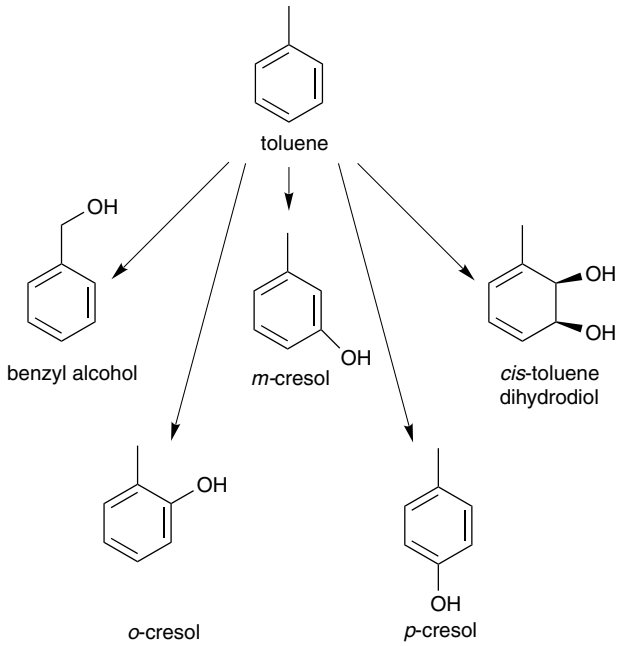

Figure 10. The diversity of toluene-activating systems found in different bacteria, based on Zylstra (31). All these reactions require NADH.

molecule (Fig. 10). This is true even within one genus, for example, *Pseudomonas*. Thus, *P. putida* mt-2 attacks the methyl substituent with a monooxygenase that converts toluene to benzyl alcohol, *P. cepacia* G4 attacks the ring at the *ortho* position to generate *o*-cresol, *P. pickettii* PK01 attacks the *meta* position to generate *m*-cresol, whereas *P. mendocina* KR attacks the *para* position to generate *p*-cresol; all these reactions are monooxygenases and use NADH to reduce the other atom of oxygen to water. *Pseudomonas putida* F1 uses a dioxygenase to generate *cis*-toluene dihydrodiol in a reaction similar to the initial oxidation of benzene that leads to the production of *cis*-benzene dihydrodiol. Again, there is substantial breadth in the substrate ranges of many of these enzymes, all of which require NADH as a source of reductant and all of which are usually plasmid-borne. Other organisms such as *Rhodococcus rhodocrous* seem to carry out several of the different reactions in one organism (32).

Subsequent oxidations convert the initially oxidized intermediates to substituted catechols and these are then cleaved to noncyclic structures. In *P. putida* mt-2, the benzyl alcohol is converted to benzaldehyde and then benzoic acid in reactions that are similar to those that convert *n*-alkanes to *n*-alkanoic acids. The acid is attacked by a dioxygenase to form a dihydrodiol, and this loses a carbon dioxide to become catechol. In the pathways that generate cresols and *cis*-toluene dihydrodiol, these are converted by various routes to methyl catechols (*o*- and *m*-cresols and *cis*-toluene dihydrodiol) or protocatechuate (3,4-dihydroxybenzoate) (31). The catechols and substituted catechols are cleaved by ring-cleaving dioxygenases either between the two alcohol functionalities (intradiol or *ortho*-cleavage) or adjacent to one of them (extradiol or *meta*-cleavage). The former have Fe^{3+} at

the active site and the latter have Fe^{2+} or Mn^{2+}, and crystal structures of representatives of the two types of iron-containing enzymes are available. Protocatechuate-3,4-dioxygenase, an intradiol cleaving enzyme, has Fe^{3+} coordinated in approximately trigonal pyramidal geometry by equatorial histidine, tyrosine and water, and axial histidine and tyrosine (33). 2,3-dihydroxybiphenyl-1,2-dioxygenase, an extradiol cleaving enzyme, has Fe^{2+} coordinated in square pyramidal geometry by two histidines, a glutamate, and two water molecules; one of the histidines is the axial ligand (34). Plausible models for catalysis in both enzymes have the catechol moiety displacing the water molecule(s) and the subsequent insertion of dioxygen cleaving the aromatic ring. The ring cleavage enzymes do not require NADH as a cosubstrate. Many intra- and extradiol enzymes have been partially characterized, and some have a very broad range of substrates, whereas others are very specific (35). Some even seem to catalyze both intra- and extradiol cleavage (36).

The degradation of longer-chain alkyl benzenes and alkyl polynuclear aromatics shows a similar diversity to that exhibited by toluene; the initial oxygen insertion can be either on the ring, usually to form *cis* dihydrodiols, or on the alkyl substituent, typically with the generation of the primary alcohol (37). The degradation of biphenyl proceeds by oxidation to the 2,3-dihydrodihydroxybiphenyl and then to the catechol with subsequent extradiol oxygenation to open the oxygenated ring. Dialkylated benzenes are readily degraded, sometimes as sole source of carbon (e.g., *Pseudomonas*) and sometimes cometabolically (e.g., *Nocardia*). Remarkably, organisms able to degrade *m*- and *p*-xylene seem unable to degrade *o*-xylene, and *vice versa*.

Bacterial degradation of naphthalene is usually by dioxygenase attack to yield the 1,2-cis-dihydrodiol, with subsequent reduction to 1,2-naphthohydroquinone. Subsequent extradiol cleavage yields 2-hydroxybenzalpyruvate, and the side chain is removed as pyruvate to eventually yield salicylate (Fig. 11,31). The genes that encode the enzymes for these reactions are usually plasmid-borne in Pseudomonads. Similar pathways degrade phenanthrene and anthracene, and the degradation of larger polynuclear aromatics may follow a similar route. Polycyclic aromatics with heteroatoms, such as dibenzothiophene and carbazole, can be attacked in the same way or by an angular dioxygenase attack, in which the carbon bonded to the heteroatom and the adjacent carbon in the aromatic ring are both oxidized, or by a direct oxidation of the heteroatom (38). This latter reaction is exploited in the biodesulfurization of fossil fuels (39). Similarly, some organisms degrade naphtheno-aromatics such as fluorene in a manner analogous to naphthalene, whereas others use monooxygenases to convert the naphthenic carbon to the alcohol and then to the ketone. This is followed by dioxygenation at the adjacent aromatic ring and cleavage of the naphthenic ring to yield, in the case of fluorene, a biphenyl derivative (38). As is the case with so many of the systems described here, the initial enzymes of this pathway have a very broad specificity and are able to cleave the naphthenic or aromatic rings of a wide range of substrates.

Alkylated polycyclic aromatic compounds are abundant in petroleum, usually being far more abundant than the parent polycyclic compound. Although the degradation of these compounds has not been studied in great detail, it is clear that they are readily degraded. The degradation of methyl naphthalenes by *Sphingomonas paucimobilis* has been studied in some detail (37), and it is clear that all mono-, di-, and triisomers are readily degraded and that this is initiated either on the methyl group or on the ring.

We have thus seen that aromatic molecules are degraded in several alternative ways by different organisms and that many organisms are able to degrade a wide range of compounds. It is noteworthy that this degradation is usually complete; radiolabeled experiments have demonstrated the complete mineralization of many polynuclear aromatic hydrocarbons by a diversity of bacteria. Nevertheless, bacterial degradation is generally most effective on compounds with four or fewer aromatic rings; molecules larger than this tend to be more resistant to bacterial degradation.

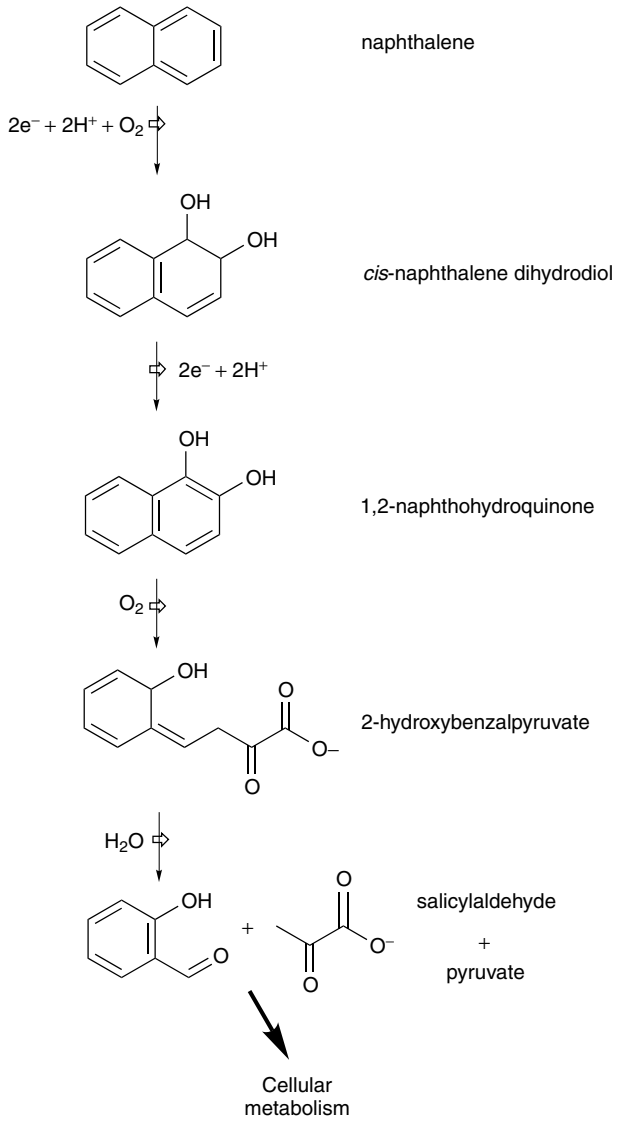

Figure 11. The pathway of naphthalene degradation in a *Pseudomonas*, based on Cerniglia (40) and Zylstra (31).

Fungal systems are also effective at oxidizing polynuclear aromatic hydrocarbons, but the products (intermediates) are often different from those produced by bacteria, and complete mineralization, although performed by some species, is not the norm. Perhaps the best-studied nonlignolytic fungus is *Cunninghamella elegans*. This filamentous organism uses a P-450 monooxygenase system to incorporate one atom of molecular oxygen into the polynuclear aromatic substrate while reducing the other oxygen atom to water. The polynuclear aromatic hydrocarbon is thereby converted to the arene oxide, which is hydrolyzed by an epoxide hydrolase to generate the *trans*-dihydrodiol. This in turn may be dehydrogenated to catechol. Alternatively, and apparently nonenzymatically, the arene oxide can rearrange to the phenol (Fig. 12). The phenol can then form conjugates with sugars or sulfate and can be excreted (40). P-450 monooxygenases seem to be widely spread in fungi, and they are known to attack larger polynuclear aromatic hydrocarbons with up to at least five and six rings.

A quite different degradation occurs if polynuclear aromatic hydrocarbons become substrates of the lignolytic system of white-rot fungi. This system, which has been extensively studied in the last decade, generates reactive species that oxidize lignin at some distance from the fungal hyphae. When confronted with polynuclear aromatic hydrocarbons, the lignin-degrading system can oxidize phenanthrene and anthracene to the respective quinones (41) and these are then mineralized, either by the fungus or by the bacteria, or become polymerized to other material in the system so that they can no longer be extracted. Early optimism that white-rot fungi might be broadly useful in degrading polycyclic aromatic compounds in contaminated soils seems to be fading (42).

Polar Components of Crude Oil

As discussed earlier, most crude oils contain significant quantities of polar, heteroatom-containing material; this material is difficult to analyze at the molecular level because it is essentially nonvolatile, and therefore unamenable to gas chromatography, although suggestions for typical molecules have been made (Fig. 3). Porphyrins in oil are very resistant to biodegradation, and like the steranes and hopanes, they are used in petroleum geochemistry to correlate oil reservoirs with potential source rocks (60). There is good evidence that naphthenic acids can be degraded by microorganisms (43), and if the structure suggested for a representative asphaltene in Figure 3 is reasonably accurate, it suggests that at least parts of the asphaltene fraction might be biodegradable. Some work suggests that this is indeed the case (44), but it seems likely that the majority of the polar materials in crude oil are not subject to significant biodegradation, and they may be as inert as the humic and fulvic acids of modern sediments.

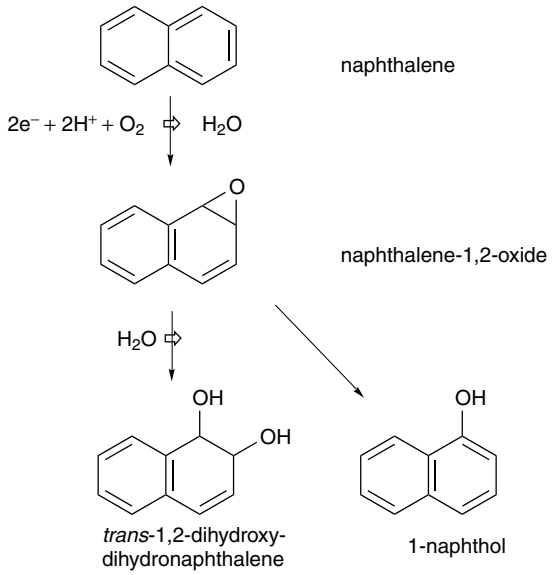

Figure 12. The pathway of naphthalene oxidation in fungi, based on Cerniglia (40).

Fuel Oxygenates

Although fuel oxygenates such as ethanol and MTBE (methyl *tert*-butyl ether) are not hydrocarbons because they contain oxygen, they may make up to 15% by volume of some fuels. Reviews of the current understanding of MTBE biodegradation are available (45,46).

OVERALL RATES OF AEROBIC BIODEGRADATION

Although the majority of compounds in crude oils and refined products are all biodegradable, their disappearance from the environment following a spill follows a well-defined order. Thus, the smaller linear alkanes (up to about 12 carbon atoms) and one- and two-ring aromatic molecules are degraded before branched alkanes such as pristane and phytane and polynuclear aromatic hydrocarbons with more rings. Three-ring aromatics, such as fluorene, phenanthrene, and dibenzothiophene are degraded at similar rates, and these are substantially degraded before much degradation of four-ring compounds is usually seen. Within each of these categories of aromatic compounds, the parent compound is degraded in preference to the alkylated forms, and the less alkylated species are degraded before the more alkylated ones (47).

This hierarchy of degradation has proven very useful in identifying the onset of biodegradation in the environment and in quantifying biodegradation. The ratio of the straight-chain alkane *n*-heptadecane to the branched pristane decreases during early stages of biodegradation and provides a qualitative measure of the process. Both heptadecane and pristane are, however, removed quite rapidly once biodegradation is well established. More resistant molecules, such as hopanes and steranes, can serve as internal standards once pristane biodegradation begins. Provided all the oil under consideration is from a single source, the conserved internal markers can provide a reference for the quantitation of biodegradation (7).

The overall pattern of biodegradation also provides a way of distinguishing oils from different sources in the environment. Alkylated phenanthrenes and dibenzothiophenes are degraded at very similar rates in the environment and the more alkylated forms are

among the more slowly degraded compounds. The ratio of trialkyl-dibenzothiophenes to trialkyl-phenanthrenes thus remains essentially constant as degradation proceeds. Because the absolute value of this ratio is often different in different oils, it can be quite useful for discriminating different sources. Furthermore, since alkylated dibenzothiophenes and phenanthrenes are usually degraded more rapidly in the environment than the corresponding alkylated chrysenes, the ratio of trialkyl-phenanthrenes to trialkyl-chrysenes provides a useful indicator of the extent of degradation when more conserved molecules, such as hopanes, are unavailable (48).

ROLE OF SURFACTANTS

Hydrocarbons present a particular challenge to biological systems because they are hydrophobic. Smaller hydrocarbons, particularly aromatic hydrocarbons, have a reasonable solubility (49), but larger alkanes are very poorly soluble. Different organisms seem to have developed different ways to get around this problem. Many produce surfactants that solubilize hydrocarbons, whereas others develop molecules in their cell membranes that adhere to the oil–water interface. Allen and coworkers (50) provide an example of how difficult it is to make broad generalizations; they examined the ability of *Pseudomonas* and *Sphingomonas* to degrade naphthalene and phenanthrene in the presence of a nonpolar, nondegradable (by these organisms) solvent (2,2,4,4,6,8,8-heptamethylnonane) or the nonionic surfactant Triton X-100. The heptamethylnonane increased the rate of degradation of both substrates for both microorganisms. The Triton X-100 increased the rate of degradation by the *Pseudomonas* but inhibited that by the *Sphingomonas*.

Nevertheless, the oil spill response community often recommends the use of dispersants to aid in the biodegradation of oils spills at sea (51), and although there has been controversy in the past, recent work demonstrates that some products clearly stimulate oil degradation in a safe and effective manner (52). Dispersant application was particularly successful in the recent *Sea Empress* incident off the southern coast of Wales (53).

ANAEROBIC DEGRADATION OF CRUDE OIL

For many years it was assumed that oil biodegradation could only occur under aerobic conditions. This was a logical view because any degradation must involve oxidation, and the very existence of oil reservoirs indicated that anaerobic degradative processes in such environments must be very slow. But in the last decade, it has become clear that at least some hydrocarbons are oxidized by bacteria under completely anaerobic conditions (54). Hydrocarbon biodegradation has now been shown under sulfate-, nitrate-, chlorate-, perchlorate-, carbon dioxide-, and ferric iron-reducing conditions. The number of organisms able to degrade hydrocarbons anaerobically that have been isolated in pure culture is still rather small (Table 5), and it is indeed likely that anaerobic hydrocarbon degradation under methanogenic and (per)chlorate-reducing conditions will require consortia of organisms, which will complicate isolation and characterization. Nevertheless, some progress has been made in understanding the basic biochemistry of the process under sulfate-reducing and nitrate-reducing conditions.

BIOCHEMICAL PATHWAYS OF ANAEROBIC HYDROCARBON DEGRADATION

Since the phenomenon of anaerobic hydrocarbon degradation is so recently established, it is not surprising that pathways are only beginning to be understood. We can expect substantial progress in this area in the next few years.

Linear Alkanes (Paraffins)

The anaerobic degradation of *n*-alkanes has been demonstrated under nitrate-reducing (55), sulfate-reducing (56), and methanogenic (57) conditions, and microbes able to reduce sulfate and nitrate at the expense of alkanes have been isolated. Recent work (58) suggests that the initial step in the oxidation of *n*-alkanes is the addition of an internal carbon, probably C2, to the double bond of fumarate to produce an alkylsuccinate, as shown in Figure 13. This is probably followed by the addition of

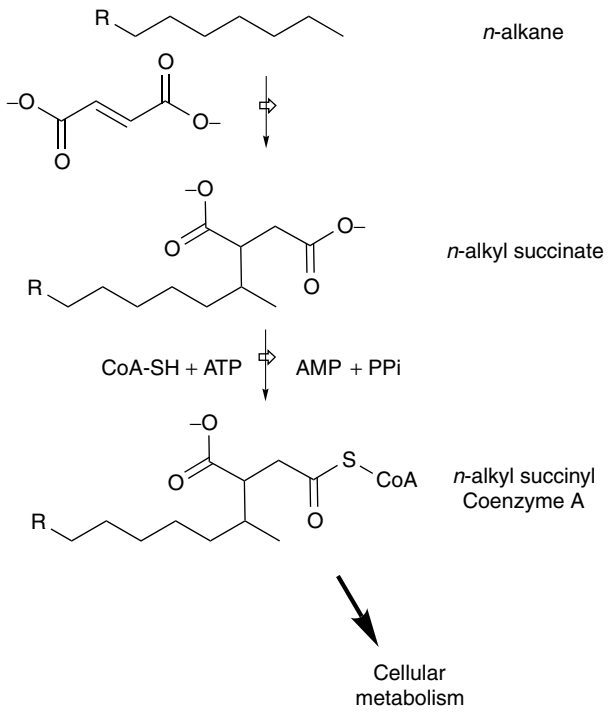

Figure 13. The pathway of anaerobic degradation of alkanes, based on Kropp and coworkers (58).

Coenzyme A to allow β-oxidation, as shown, although this has not yet been demonstrated.

Branched Alkanes (Isoparaffins)

Pristane and phytane undergo biodegradation under sulfate-reducing (56), nitrate-reducing (59), and methanogenic (60) conditions.

Aromatic Hydrocarbons. The biodegradation of aromatic hydrocarbons under anaerobic conditions is a very active field of investigation because it is the water-soluble benzene, toluene, ethylbenzene, and the xylenes (BTEX) fraction of gasoline that is often found as an environmental contaminant. Toluene is perhaps the most readily degraded of the group, and it has been shown to be degraded under sulfate-, nitrate-, chlorate-, perchlorate-, carbon dioxide-, and ferric iron-reducing conditions (61). Under nitrate-reducing conditions, the pathway of degradation again involves the addition of fumarate, as shown in Figure 14. The enzyme that catalyzes the first step, benzylsuccinate synthase, has been cloned and sequenced (61). It seems to be an $\alpha_2\beta_2\gamma_2$-complex with native mass of 220 kDa and shows strong similarities to glycyl radical enzymes such as anaerobic ribonucleotide reductase. Interestingly, the product is optically pure (R)-(+) benzylsuccinic acid, and the proton removed from the methyl substituent of the toluene is retained in the succinyl moiety of the product.

A similar activation has been seen with the xylenes, but an alternative pathway has been suggested for ethylbenzene. This involves hydration and carboxylation of the ethyl moiety to produce benzoylacetate, which is then added to Coenzyme A for further metabolism (61). All components of BTEX have been seen to undergo biodegradation under a variety of anaerobic conditions, although benzene seems the most recalcitrant. There are as yet no details of how benzene is activated anaerobically. Similarly, larger aromatic molecules, including naphthalene and phenanthrene, have also been seen to be biodegraded, but again there is less detail of how this occurs.

Although it thus seems that anaerobic degradation of hydrocarbons is a far more important process than was previously imagined, we are only beginning to understand the diversity of organisms that are able to carry out the reactions (Table 5), and are woefully ignorant of the range of substrates that can be degraded. All experiments to date suggest that anaerobic degradation in the environment is a much slower process than aerobic degradation, and as the vast reserves of ancient fossil fuels indicates, it must be severely inhibited in many environments.

We have seen that hydrocarbons serve as the carbon source for a broad diversity of microbes, bacterial, archaeal, and eukaryotic, in aerobic and anaerobic environments that span a range of temperatures and salinities. What seems to distinguish hydrocarbon-degrading microorganisms from their nondegrading relatives is their possession of enzymes to activate the relatively inert carbon-carbon bond in the substrate. In aerobic prokaryotes, this process of activation usually begins with a monooxygenase or a dioxygenase, whereas the anaerobes characterized to date either attach a fumarate moiety or hydrate and carboxylate an alkyl group. Although there

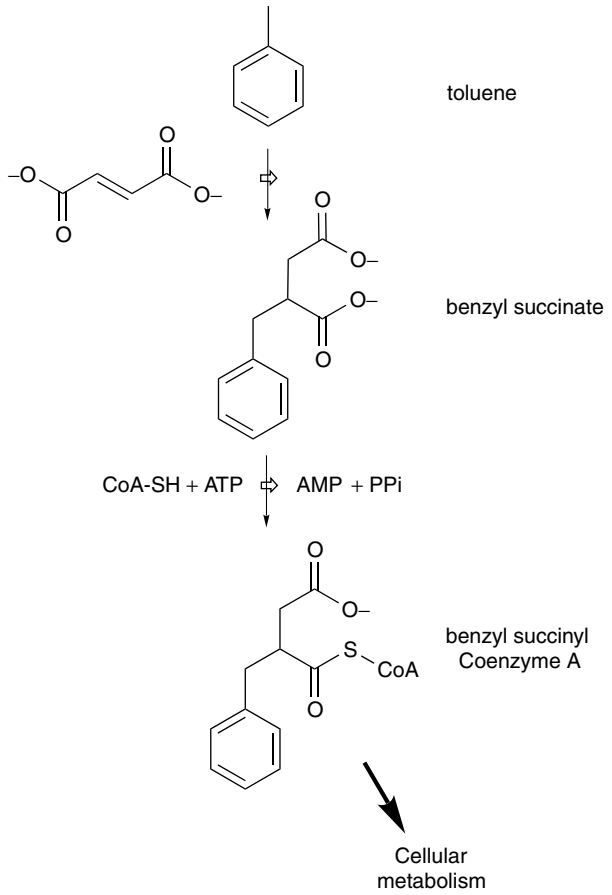

Figure 14. The pathway of anaerobic degradation of toluene, based on Heider and coworkers (61).

are still many areas in which our knowledge is minimal, such as how benzene and cyclic alkanes are activated anaerobically, it is apparent that the initial activation usually requires a substantial metabolic input into the molecule by the degrading organism. There is thus a strong selection pressure for the organism to get a return on this investment in subsequent metabolisms, and at least in aerobic environments, it is unlikely that metabolic intermediates are deliberately excreted into the environment. In anaerobic environments, the issue is complicated, and some environments, such as those in which methanogenesis is predominant, probably rely on symbiotic associations of hydrocarbon degraders and methanogens. Even here, however, there must be a strong selection pressure to maximize biological consumption, and if free energy is available, we may expect some organism to be exploiting it. Nevertheless, trace amounts of intermediates can sometimes be detected in the field (62), providing strong evidence that anaerobic degradation is indeed underway.

The situation in eukaryotic systems may be more complicated and is certainly less well understood. Very few fungi have been characterized in terms of their biodegradation ability, and it is likely that many of the organisms listed in Table 3 oxidize hydrocarbons only adventitiously and are not able to fully metabolize the molecules. Sometimes, this leads to the incorporation

of the majority of the hydrocarbon into inextractable soil material, and sometimes the activated molecules are consumed by bacteria that could not initiate the hydrocarbon degradation themselves.

FATE OF HYDROCARBONS IN THE ENVIRONMENT

Spills and Contaminated Sites

With the foregoing description of the biodegradation of hydrocarbons, with the final products being carbon dioxide, water, and microbial biomass, we are in a position to discuss the importance of this process in the biosphere. When hydrocarbons are released into the environment, the smallest molecules, those containing up to about 15 carbons, are likely to volatilize. This process can remove one- to two-thirds of surface spills of crude oils (4) and potentially all the gasoline spilled on impervious surfaces. Some terrestrial crude oil seeps produce so much volatile material that they may periodically ignite, but in the absence of ignition, it is thought that almost all the volatilized material is photochemically oxidized in the atmosphere or captured by rain and brought back to the ground where it is biodegraded. The residuum is much more viscous, and some seeps, for example, in Los Angeles, Azerbaijan, and Trinidad, give rise to large lakes of pitch (2). Some molecules are sufficiently soluble that they are washed out of exposed seeps or dissolve from slicks at sea or on freshwater (49), and this process also increases viscosity. Floating slicks will absorb large amounts of water (20 to 80%), and stable water-in-oil emulsions, known as *mousses*, often form (4). If enough energy is available, such as in a major storm, a floating oil spill will disperse as tiny drops of oil in water. This is what happened in the *Braer* spill off Shetland in 1993 (63). This process can be aided by the addition of dispersants (51,52,64). An alternative response to spilled oil is to burn it under controlled conditions (65).

Regardless of the initial fate of spilled or natural hydrocarbons, if they are not burned or photochemically oxidized, they will persist until they are biodegraded. As we have seen, the extent of biodegradation is dependent on many factors. It not only depends on the chemical composition of the oil but also on the environment in which the biodegradation is to occur. Gasoline and diesel fuels are very biodegradable, and it is not unusual for them to be essentially completely degraded under favorable conditions (66–68). Crude oils, and heavy fuel oils such as Bunker C used in ships, contain some molecules that are very resistant to biodegradation. McMillen and coworkers (69) have examined the short-term biodegradability of 17 crude oils in soil microcosms as a function of 78 different parameters that might determine the extent of biodegradation. These included 67 individual chemical species, percentage of sulfur, and so on. They found that the API gravity was the most useful predictor of biodegradability, at least for the most degradable fraction of the oils. At loadings of 0.5 wt% oil in a loam soil with appropriate nutrients, moisture, and aeration, more than 61% of the most degradable oil (API = 46°) was lost in four weeks, whereas only 10% of the least degradable oil (API = 15°) was consumed under the same conditions. Further degradation occurred on a longer timescale, and the literature reports biodegradation potentials as high as 97% for particularly light oils (70).

Many factors can conspire to hinder biodegradation in the environment. Temperature extremes are likely to inhibit degradation, especially low temperatures such as those found in Antarctic (71) and Arctic environments (72), although there are psychrotrophic isolates that are able to grow at subzero temperatures (73,74). On land, excess salinity, such as that found in some produced water brines, can have a strong inhibitory effect on oil biodegradation (69) until the salt is washed out by precipitation. Extreme exposure to sunlight may prevent all microbial growth.

Perhaps the most acute limiting factor is oxygen, for there are radical differences in the extent of biodegradation and its kinetics in oxic and anoxic environments. In the presence of adequate oxygen, nitrogen, phosphorus, and iron are likely to be the most limiting nutrients because they are not present in oils. The relief of these limitations has been the underlying strategy in the successful use of bioremediation in treating crude oil spills. Thus, the addition of oleophilic and slow-release nitrogen- and phosphorus-containing fertilizers was successful in substantially increasing the rate of biodegradation of oil after the *Exxon Valdez* spill in Alaska (7,75), and nutrient addition has been successful in several terrestrial applications as well (76).

In anaerobic environments, it seems that biodegradation is controlled by the presence of alternate electron acceptors. In general, the most energy-providing reactions occur most readily, and it is not unusual to see a succession of microbial processes as biodegradation proceeds. Thus, underground plumes of degradable hydrocarbons, such as dilute solutions of BTEX in groundwater, first undergo aerobic degradation until oxygen becomes limiting. If present, nitrate, (per)chlorate, or oxidized metal ions then serve as terminal electron acceptor until these are exhausted, in turn followed by sulfate, if it is present. Finally, methanogenesis takes over (77). There have been discussions about stimulating anaerobic biodegradation in the field by adding one or more of the limiting electron acceptors but this has not yet achieved widespread use.

Biodegradation of Oil and Refined Products During Use and Storage

Oil and refined products are frequently stored for some time before use, and several nations have strategic oil reserves in underground caverns. These caverns usually become contaminated with water, and oil-degrading microorganisms, whose activities potentially threaten oil integrity, are readily isolated from such environments (78). Diesel, kerosene, and jet fuel storage facilities, and even airplanes, can have similar problems, and this is a particular concern because some of the organisms can block fuel filters with potentially disastrous results (79). Other problems associated with fuel biodegradation include an increase in tank and fuel line corrosion and production of surfactants that encourage

water in oil emulsions. Proprietary biocides are often added to slow biodegradation in such situations (80).

Biodegradation in Oil Reservoirs

Oil reserves that have been "invaded" by aerobic surface waters have often been subject to substantial biodegradation. This is recognized by the absence of linear alkanes, the smaller aromatic hydrocarbons, and even some of the naphthenes. The Athabasca deposits of northern Alberta are thought to be one example of this phenomenon. Typically, biodegradation increases the specific gravity and viscosity of an oil, and indeed the Athabasca deposits are very viscous (2).

Although early production of oil from an oil field may occur owing to the inherent high pressure in the reservoir, later production is usually aided by pumping water into injection wells. Often this is accompanied by a "souring" of the production, an industry term for an increase in H_2S in the produced oil. Some of this may be the result of subterranean geochemistry; however, it is likely that the majority is the result of the activity of sulfate-reducing bacteria. These organisms typically grow by oxidizing small organic acids at the expense of reducing sulfate to sulfide (81), and they are widely implicated in metal corrosion. As discussed earlier, sulfate-reducing hydrocarbon degraders have now been found, and they may also play a role under reservoir conditions. To date, however, none of the reservoir sulfate-reducing isolates has been reported to degrade hydrocarbons. Thermophilic and mesophilic sulfate-reducing bacteria have been isolated from many wells (82–84) but it has usually been assumed that they have entered during drilling and production. More recently, it is becoming accepted that oil reservoirs may contain microorganisms even in the absence of substantial water incursions. Thus, L'Haridon and coworkers (85) have shown that anaerobic hyperthermophilic microorganisms are abundant even in previously untapped oil reservoirs, and may well be abundant throughout the deep crust of the earth. All of the organisms isolated to date have grown either autotrophically with hydrogen or sulfide as electron donor (84) or heterotrophically (82) as sulfate-reducers consuming small organic acids. As mentioned in the following text, there are now several examples of anaerobic hydrocarbon-degrading isolates and consortia isolated from surface environments. Whether such bacteria play any role in the maturation and/or degradation of crude oils remains to be seen.

APPLICATION

With the foregoing discussion in mind, we can ask how hydrocarbon biodegradation can be harnessed to beneficial uses for humankind. Three areas are worth brief discussion: bioremediation, bioprocessing, and biodesulfurization.

Bioremediation

Bioremediation is the term applied to a stimulation of biodegradation to minimize the environmental impact of a spill, whether recent or historical. As we have seen, the majority of hydrocarbons in refined products and most crude oils are biodegradable, but they do not provide a complete food for bacterial growth because they only provide carbon and hydrogen. In almost all aerobic environments, the biodegradation of significant concentrations of hydrocarbons is likely to be nutrient-limited. Ameliorating this limitation by adding fertilizers is the basis of most successful bioremediation strategies for soils and shorelines (7,75,76,86), and the technique is widely used. Nitrogen and phosphorus are the probable limiting nutrients in most marine environments, and care must be exercised that these are not added at high enough levels to cause problems such as eutrophication or toxicity. Adding oxygen, perhaps by sparging air, or adding a peroxide is often beneficial in stimulating hydrocarbon biodegradation in groundwater (86), where typically the concentrations of hydrocarbons are sufficiently low that nitrogen- and phosphorus-limitation is unlikely to be a significant problem. Early expectations that adding laboratory-selected or genetically engineered cultures of hydrocarbon-degrading bacteria onto spills or into aquifers would be a useful bioremediation technology have not been born out by subsequent experience. Rather, it is clear that indigenous hydrocarbon-degrading bacteria are ubiquitous and that adding microbes is usually unnecessary. One exception may be the inoculation of fungi to composting systems to degrade the heaviest polycyclic aromatic hydrocarbons (87).

Bioprocessing

Bioprocessing is the term applied to carrying out a desired chemical reaction biologically rather than chemically, and the expectation is that the biological process will have advantages in selectivity, environmental impact, or cost. Perhaps the best-studied hydrocarbon bioprocessing system is the alkane oxidation system of *P. oleovorans*, which has been proposed for the production of medium–chain length polyoxyalkanoate plastics (88) and octanoic acid (89). Biocatalysts for the production of (S)-styrene oxide (90) and optically pure aryl epoxides (91) have also been proposed. Bioprocessing of hydrocarbons is in its infancy, and we may expect significant developments in the near future.

Biodesulfurization

Biodesulfurization is the term applied to the microbial removal of sulfur from fuels. The principal sulfur-containing molecules in crude oils and refined products are the thiophenes and their congeners, with dibenzothiophene being particularly important. Current refinery practice is to reduce the sulfur to H_2S with hydrogen over a catalyst at high temperatures and pressures, and even so there are problems that some alkylated forms are sterically hindered and are only poorly removed. Biocatalysts, particularly those derived from *Rhodococcus* and related genera, offer the potential for removing sulfur from dibenzothiophenes at ambient temperature and pressure (39), although significant developments seem to be required before the process is ready for commercialization.

CONCLUSION

The majority of the molecules in crude oils and refined products are biodegradable under appropriate conditions. These hydrocarbons are in commerce; however, this biodegradation can be prevented by careful storage and by the addition of biocides. If the hydrocarbons get into the environment, they will be biodegraded, and this biodegradation can be stimulated by the alleviation of limiting factors. There has been well-documented success in this enterprise with the addition of fertilizers and oxygen, both on the land and on the shorelines.

PETROLEUM RESERVOIRS, INFLUENCE, ACTIVITY AND GROWTH OF SUBSURFACE MICROFLORA IN

Catherine Bass
Hilary Lappin-Scott
University of Exeter
Devon, United Kingdom

Naturally occurring oil seeps have provided a source of fuel, particularly for lamps, for over 5,000 years and the 'perpetual fires' of Baba Gurgur in Iraq were lit on the site of escaping natural gas deposits. The petroleum industry, as we now recognize it, was founded on two principal events, which took place in the mid-nineteenth century. First was the filing of an English patent in 1850 by James Young who had devised a fractional distillation process to refine oil seeping from a coal deposit and an oil shale. Second, just nine years later in North West Pennsylvania, Edwin Drake set out to find the source of oil seeping from the ground in Oil Creek near Titusville. He correctly anticipated the possibility of finding a "rock oil" reservoir below the surface by directed drilling, hoping to provide a commercially significant source of oil. Finding that, initially he was drilling through gravel beds and suffering numerous well bore collapses, he came up with the idea of inserting a string of tubes into the bore, through which he could operate the drill at greater depth; the principal method used ever since to protect lengthening well bores. Thus, the two major activities of the petroleum industry, exploration and production (E&P) and postproduction refining, were born.

This review will briefly examine the nature of petroleum hydrocarbons and their generation and then describe the reservoir as a habitat for subsurface microorganisms, either indigenous or introduced. The consequences of exploitation of oilfield reservoirs have brought microbial problems to the industry, which with the benefit of the present knowledge of the subsurface biosphere, might have been avoided. The final section will address the potential benefits of oil recovery, enhanced microbially to increase yields and describe some of the emerging technologies.

ORIGINS OF HYDROCARBON RESERVOIRS

Naturally occurring petroleum ranges in appearance from an almost colorless mobile liquid to a green–black viscous substance mixed with sand and water. Within one oil field there may be a wide compositional variation, both horizontal and vertical. The main constituents of crude oil

are true hydrocarbons, comprising a mixture of aliphatic compounds (alkanes, general formula C_nH_{2n+2}), and cycloalkanes (C_nH_{2n}) with aromatics (C_nH_n). A number of nonhydrocarbon constituents are found in oils. These are commonly heterocompounds of sulfur, nitrogen, and oxygen and organo-compounds of vanadium and nickel. The lower molecular weight hydrocarbons that occur as natural gas may also contain hydrogen, helium, or argon.

There are two prevailing theories to account for the presence of the petroleum hydrocarbon reserves in the Earth's crust, which being separated by geological time and space, may not be mutually exclusive (1). The theory adhered to by Thomas Gold since the late 1970s is that natural gas and crude oil are derived not from biological debris but from the initial materials that formed the earth for more than 4.5 billion years ago. This is the abiogenic or deep-earth gas theory and is described in Gold's book *The Deep Hot Biosphere* (2). Hydrocarbon reserves are described as having been originally condensed as solids at great depth, 100 to 300 km below the Earth's surface, liquefied or vaporized by increasing internal heat and forced nearer to the surface. Some of the mobilized hydrocarbons have been temporarily trapped in porous rocks under impermeable caps at depths which are accessible to the oil operator's drill bit; others have burst violently to the surface and have been vaporized as methane, carbon dioxide, and water vapor in volcanic eruptions.

The greatest weight of evidence is currently on the side of the biogenic theorists, whose case is put authoritatively by North and Cornford (1,3). This theory holds that the association of oil and gas with thick sedimentary sequences, together with geological, isotopic, and chemical evidence from trapped organic remains buried in the sedimentary rocks is clear proof that hydrocarbons are ultimately derived from deposition and transformation of macro and microbiota. Examination of accessible ancient igneous rock extruded from the Earth's surface by vigorous geological activity, for example, the metamorphic shield areas of Scotland and Scandinavia bordering the North Sea sedimentary basin offers no evidence of significant hydrocarbons (3) to support Gold's igneous rock theory as a source for hydrocarbons.

The majority of petroleum hydrocarbons represent the result of organic deposition following global atmospheric change to an aerobic state, with an intact ozone layer (currently thought to have occurred at about 1200 Ma). This followed the evolution of primitive life, photosynthetic exchanges and establishment of the principal elemental cycles. The Cambrian era was a time of extraordinary growth and proliferation; the majority of petroleum deposits being exploited currently originate from organic material generated in late Cambrian through to Jurassic epochs (between 400 and 150 Ma). Figure 1 shows the principal geological horizons currently yielding oil and gas.

Source rocks result from sediments that have generated sufficient oil or gas, which are commercially significant. Such rocks are classified as immature (hydrocarbons not yet generated), mature (rocks, where HC generation has commenced), and postmature (those which have already generated and often expelled all hydrocarbons). The

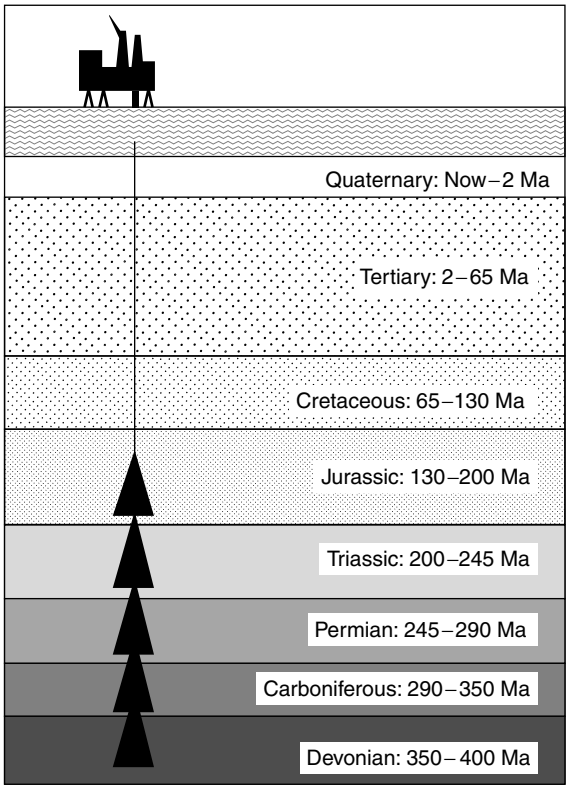

Figure 1. Schematic showing the geological horizons yielding subsurface hydrocarbon deposits.

indigenous organic matter in a source rock is called *kerogen* (solid or solvent insoluble), *bitumen* (liquid or solvent soluble), or gas (predominantly methane). These materials vary widely in character, depending on the source of the deposited organic material and the nature of deposition. By the time these hydrocarbon precursors have developed, the sediment may be several kilometers thick, and the deepest layers will have been irreversibly compacted into shales, sandstones, or limestones with pore spaces containing a mixture of the hydrocarbon precursors and water. Kerogen degenerates to bitumen and gas when temperatures increase during the slow burial process, releasing oil and gas. The achievement of a minimal temperature for this degeneration involves a minimum depth of burial, which is dependent on the immediate temperature gradient. The depth of burial itself is dependent on the time taken for sediments to accumulate.

The final steps in transformation to a crude oil are not fully understood, but result from the combinations of microbial, geothermal, geostatic, and temporal influences. Present day sediments in the deep ocean trenches yield important information on the diagenesis of organic matter into petroleum precursors. Claude ZoBell, at Scripps Oceanographic Institute, initiated the studies on bacterial activity in ocean sediments in the 1930s (4,5). During most of the 1940s and early 1950s, when actively involved in the petroleum industry, ZoBell tried to establish an incontrovertible case for production of

petroleum hydrocarbons by bacteria, particularly sulfate-reducing bacteria (6–8). Subsequent research has shown the presence and activity of bacteria at 80 meters below sea floor (mbsf) in the Pacific Peru margins (9) and 518 mbsf (age about 4.3 Ma) in the Japan Sea (10), which are capable of a wide range of functions in clearly separated zones of sediment cores. Any oxygen available in the uppermost layers of the sediment is rapidly utilized in ammonification processes, leaving an environment, in which bacterial distribution and activity are controlled by the availability of terminal electron acceptors (e.g., sulfate, nitrate), the bioavailability of organic carbon and methane gas.

Active bacterial migration through the porous sediments raises the possibility of preferential association in bacterial communities according to functionality, availability of electron donors and acceptors, and other parameters such as redox, temperature, hydrostatic pressure, and fluid incursion. All these contribute to the diagenetic processes. Cragg and coworkers (10) demonstrated the activity of nitrate and sulfate reducers, ammonifiers (aerobic and anaerobic), and acetogens with heterotrophs to depths of 518 mbsf with methane concentrations increasing with depth. Total counts of bacterial cells, dividing bacterial cells and total viable anaerobic bacterial counts showed the presence of an active population at the limit of their sample core. This indicated that bacteria continue to be present and active in still deeper sediments. Hence, by implication, these become the foundation of the indigenous rock *microflora* present in sedimentary core samples taken from many locations (11).

Maturation of the source rock is followed by expulsion of the hydrocarbons if sufficient quantities are generated to saturate the rock, allowing the excess to migrate. Migration occurs along the porous rock beds, diagenetic pathways (dissolution channels), and fracture pathways. Often the migration ends in a trap or reservoir either in domelike configurations, capped by impervious lithified rock or in deeper strata, confined by tectonic movement (folding and faulting) to zones on the shoulders of cap rock or the margins of anticlines or synclines (Fig. 2).

Deposition of mineral particles with decaying remains of macro- and microbiota between 400 Ma and 140 Ma became the source rock for the majority of petroleum hydrocarbons currently being exploited. About 30% of known reserves have already been produced in the past 150 years since the commercial extraction began, much of the remaining petroleum being less accessible than the lighter fractions first released from reservoir rock. Alternative strategies for exploiting these reserves include employment of microbially enhanced recovery techniques, which is discussed later in this chapter.

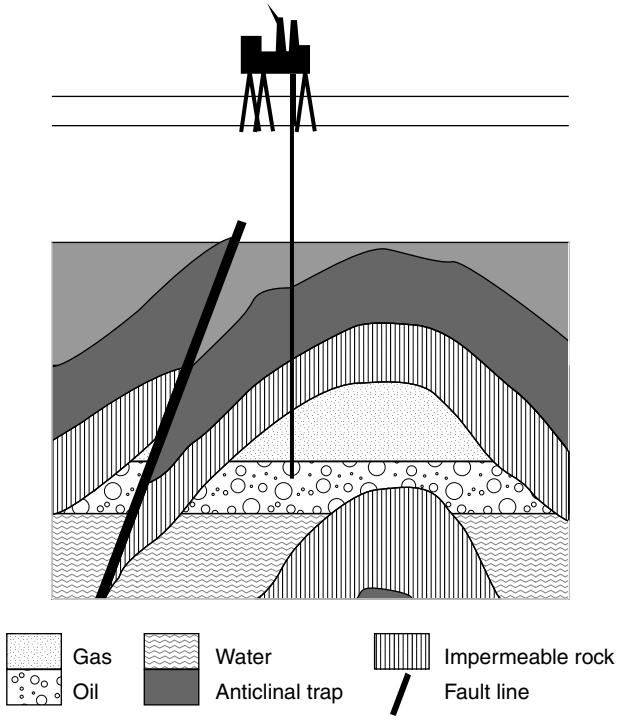

Figure 2. Cross section of porous rock, showing reservoirs of hydrocarbons in place following migration from source rock to trap.

OIL-BEARING ROCK FORMATIONS AS MICROBIAL HABITATS

Almost all sedimentary rocks have been formed under shallow and principally marine seas (3), resulting in sandstone, shales, and limestones either at depth in some areas or closer to the surface where glacial erosion has occurred (e.g., the Canadian Shield). Irrespective of the composition of a sediment during formation, water is an integral part of it. The nature of the available water has a very important influence on the activity of subsurface microorganisms. Water deposited with a sediment from the beginning is termed *connate water*. When the water-wet sediment is buried and increasingly compacted, some or all of its connate water is altered in composition: diluted, replaced, or even expelled by other waters. Water displaced by entry of oil or gas is called *free water*. Interstitial water resists displacement by invading hydrocarbons because it occupies pore spaces that are too fine for entry by the larger hydrocarbon molecules. The space occupied by interstitial water may be between 10 and 40% of the total pore space in a hydrocarbon-bearing rock, but does not necessarily constitute part of the general water column (which includes connate and free water) in the rest of the rock. The collective name for these three water types is *formation water*, with chemistry as complex as that of the hydrocarbons. They tend to be saline ranging from 1000 to 40,000 mgL^{-1} total dissolved solids (seawater contains approximately 3,500 mgL^{-1}) with the principal ions (sulfate, bicarbonate, chloride, sodium, magnesium, and calcium) distinguishing four main chemical types of oilfield brine (1,12). A comprehensive survey of formation water analyses has been compiled from 263 separate samples from 70 North Sea oil fields (12) identifying the distribution and abundance of ionic components. Additional data on depth, temperature, pH, pressure, total dissolved solids and potential bacterial carbon sources, the short-chain fatty acids acetate, propionate, and butyrate is also provided.

Reservoir rock can therefore be considered to be an intricate solid matrix, containing a complex mixture of hydrocarbons and waters in pore spaces and channels that vary in connectivity because of variations of cross section, transverse area and longitudinal shapes (13). The hydrocarbons and waters interact, depending on their relative abundance and specific constituents, resulting in matrix surfaces that are oil or water-wet and pores, which may contain water alone, oil alone, or mixtures of the two, creating fluid–fluid interfaces.

Temperatures in oilfield reservoirs are principally dependent on depth and latitude. Shallow land-based oil resources may lay only 50 mbs (meters below surface), similar to the fields of North America. Well bottom temperatures may be little more than 40 °C, yet in the deepest North Sea oilfields, at 1.2 to 6 km, the temperature may reach 200 °C with pressures between 15 and 80 Mpa (14,15).

MICROBIOLOGY OF OIL-BEARING ROCKS

For the purposes of this review we have confined our discussion principally to deep reservoirs in excess of 1000 mbs. Although there is an active microflora associated with shallow reservoirs, in both land and offshore formations, the intrusion of organisms from normal soil and water environments blurs the distinction between the "regular" soil–subsurface micro flora and that which could be considered to be intrinsic to a hydrocarbon-bearing sedimentary deposit. Recent studies throughout the world have revealed the presence of many organisms in waters from oil-bearing sediments. Both sandstone and carbonate formations, some over 3-km deep, have yielded bacteria from France and North Africa (16), the North Sea (17,18), Alaska (19), Indonesia (20), Russia (21), offshore California (22), Vietnam (23), and Japan (24). The physiology of these organisms is usually found to be consistent with the original habitat in terms of salinity and temperature that increases with depth (i.e., they are well adapted to their subsurface environments). Great emphasis has been placed on the presence or absence of sulfate-reducing bacteria (SRB) in most sampling programs because they are the most prolific members of the oilfield community and of economic importance to oilfield operators. SRB, including some spore-formers, have been recovered from deep (2–4 km, 60–120 °C) North Sea oil formations, derived from situations, which have no connectivity with injected fluids used to improve oil recovery (17,18).

In a study published in 1996 (15), the question was addressed as to whether some of the bacterial species that were observed to grow in production-tubings and facilities on oil-production platforms were derived from the reservoir source. Nilsen and coworkers (15) concluded that the thermophilic and hyperthermophilic sulfate reducers that they recovered were indigenous to the reservoir and belong to a deep subterranean biosphere. If organisms are associated only with the production facilities, then fluid samples taken from different wells, supplying one production platform, should yield only one strain of a particular species. Their sampling technique included thorough flushing of the common collection point on the production platform with each successive sample to avoid cross-contamination from the separate wells supplying the platform. Using a combination of enrichment culture and genus-specific fluorescent antibody staining for a range of previously identified members of the production platform population, it was possible to confirm that different strains were derived from waters produced by different wells and that their sampling technique did not promote cross-contamination.

Bernard and coworkers (25) carried out a survey of indigenous microorganisms in connate waters from 24 oilfields, using direct microscopic counts (fluorescent acridine orange) and enrichment culture in a range of selective media to reveal that most of the organisms selected were previously not known. Each field ecosystem offered a limited diversity of species, which consistently contained associations of anaerobic, fermentative (*Halobacterioides*, *Thermatoga*, and unknown spore-formers) sulfate-reducing bacteria (*Desulfovibrio*, *Thermodesulfobacterium* and *Desulfotomaculum*), methanogenic bacteria (*Methanohalophilus*, *Methanobacterium*), and unknown thermophiles. The conclusion drawn was that each ecosystem was in equilibrium, perpetuating itself through symbiosis of a limited number of genera and species. They also argued that because there was no injected fluid breakthrough in the wells sampled, the organisms were indigenous to the formation at sample depth.

This conclusion is supported by many recent publications, demonstrating the presence of previously unknown organisms, both bacteria and archaea. Methods used ranged from total count and culture techniques, followed by characterization on the basis of nutrient requirements, temperature range and optimum, antibiotic susceptibilities, and 16S rRNA or rDNA analysis (23–26).

Grassia and coworkers (27) conducted a systematic survey for thermophilic fermentative bacteria and archaea in production waters from 36 high-temperature (50–148 °C) reservoirs across the world, from Australia and New Zealand, the Middle East, United Kingdom, United States, and Venezuela. Salinities varied from 2,800 to 200,000 mgL^{-1} and pH varied from 5.5 to 8.5. The organisms recovered were assigned to three morphologically distinct groups: (*1*) nonsheathed rod-shaped bacteria, (*2*) sheathed rod-shaped bacteria, and (*3*) irregular coccoid archaea. The occurrence of these groups of organisms was compared in nonwaterflooded and waterflooded petroleum reservoirs (see next section for discussion of waterflooding).

Group 1 bacteria were glycolytic thermophiles that fermented glucose to one or more of lactate, acetate, ethanol, hydrogen, and carbon dioxide. All grew principally in low-salinity reservoirs, and on the basis of morphology and physiology were allied with the genera *Thermoanaerobacter* and *Thermoanaerobacterium*. Spore formation was not observed.

The Group 2 glycolytic thermophiles had very distinctive morphologies; some were similar to *Fervidobacterium*, a genus reported to occur in deep and hot subsurface environments but not otherwise associated with oilfields. Other members of this group were seen to be physiologically and

morphologically related to members of the Thermatogales, (*Thermotoga*, *Geotoga*, *Petrotoga*, and *Thermosipho*). All but the last of these have been isolated from petroleum reservoirs elsewhere (19,24). The G+C ratios were in the range 31 to 40%, typical of these genera. They produced similar end products from glucose and were resistant to almost 70 gL^{-1} rifampicin.

Group 3 contained a single strain of an extremely thermophilic archaea, which resembled members of the genus *Thermococcus*. A coccoid cell, this organism can grow to almost 91 °C, using complex nutrients, such as yeast extract and peptone. Carbohydrates do not support growth. Members of this genus have been found in other petroleum reservoir studies (19).

Reservoir salinity did affect the type of organisms recovered in the course of the work by Grassia and coworkers (27); few thermophiles that were able to grow in salinities over 40,000 mgL^{-1} were isolated. The global distribution of organisms with similar characteristics was well demonstrated in this work, and those recovered were capable of tolerating reservoir conditions that apparently determined the types of organisms present. Sheathed members of groups 1 and 2 were present irrespective of waterflooding activity by oil field operators, suggesting that these organisms were truly indigenous to the environment.

Several new genera of SRB and archaea, which thrive in North Sea reservoirs (28–30), have been described because research has focused on hot, petroleum reservoirs as a source of deep indigenous subsurface organisms. These have been isolated from produced water samples by enrichment in a variety of media. Characterization has been made by techniques such as morphology, tolerance of temperature, and salinity ranges, carbon source utilization in the presence of sulfate, ability to grow autotrophically with hydrogen, use of alternative electron acceptors, DNA base composition, and phylogenetic comparisons of 16s rRNA. Oligonucleotide probes have been produced to target specific members of sample populations for rapid assessment of community composition (31). Voordouw and coworkers (32) developed the reverse-sample genome probe method to compare community diversity in oilfield SRB populations by hybridization assays.

The studies mentioned in the preceding sections have focused on analysis of bore-hole fluids obtained at production well heads with precautions against cross-contamination of water samples at common collection points (15). Other workers have obtained fresh core samples from exploration oil well–drilling operations in pristine environments and observed the organisms in situ (33,34). Stringent techniques are required to prevent contamination of inner rock core with organisms from drilling equipment, drill fluids, and transporting containers. Samples of sandstone core from 1000 mbsf on the United Kingdom Continental Shelf were prepared for scanning electron microscopy by fracturing, following repeated solvent extraction to remove hydrocarbons from the pore spaces. Structures resembling bacterial cells were observed in every field of view (33) in close association with the rock grain surface. Other portions of the same core were crushed using aseptic techniques and distributed in a range of media selective for sulfate-reducing bacteria and other anaerobes yielding cultures, which proved the presence of active populations in the oil-bearing rock.

MICROBIAL CONSEQUENCES OF OIL RESERVOIR EXPLOITATION

The stages from initial exploration for a new oilfield and conversion of the field to full production may take years. It involves many progressive activities, all of which affect the reservoir environment with consequences for both microflora and operators. Many unforeseen problems have been encountered during the development and productive phases of oilfields, some of which may be attributed solely to the activity of microorganisms either from the formation or introduced from other sources inseparable from the process. A brief description of the processes employed may assist readers unfamiliar with production practice. Broadly, following production well drilling, the hydrocarbon recovery processes may be divided into three phases:

1. *Primary production* occurs under the influence of reservoir pressure alone, because reservoir fluids take the path of least resistance to the production well. Fluids produced at the wellhead, during this phase contain a mixture of varying ratios of oil and formation waters. Over a period of time, the reservoir pressure is gradually reduced so the rate of production decreases. Migration of the oil toward the production well must be improved to restore flow rates.
2. *Secondary recovery* is often achieved by drilling strategically placed injection wells into which water is pumped. The injected water is derived from whatever source is convenient; seawater, inland lake water, aquifer water from a suitable subsurface location or when it is increasingly used, re-injection of waters separated from previously produced fluids. As long as the injection well has been correctly sited to direct flow, where required, and the crude oil characteristics are suitable, the water-flood front displaces oil to the production well. Analysis of the waters produced with oil will indicate the time when the water breakthrough has occurred, that is, when the injected waterflood front has broken through into the production region of the formation. Improvement of the secondary recovery technique can be achieved by modifying the injected fluids with a variety of polymers to improve the mobility ratio between oil and water; residual oil may have been bypassed and left behind in disconnected oil ganglia or trapped by capillary forces. The viscous-to-capillary force balance between the water and oil phases may be changed by altering the viscosity of the water phase through addition of polymers (35).
3. Even after primary depletion and secondary recovery methods have been employed, it is possible that much oil still remains in the reservoir. Depending on the geology, as much as 70% can be left untouched in a heterogeneous reservoir system. *Tertiary recovery*

methods to exploit this oil are varied but are usually aimed at improving mobility of what are often heavier classes of hydrocarbons, with high viscosity and strong affinity to the rock surfaces. Methods include injection of chemical surfactants, caustic solutions or foam, gas injection (either carbon dioxide or reinjection of natural gas), or thermal methods (steam soak and drive, or in situ combustion) to mobilize the oil. It is in this area of oil recovery operations that microbially enhanced oil recovery (MEOR) finds a place, although this is as yet a relatively under-utilized technology.

Physicochemical Effects of Hydrocarbon Extraction on Reservoirs

Pressure. The drilling of an exploration well into a potential oil reservoir intrudes into an otherwise pristine environment, which has evolved in the absence of external influences from any source other than natural percolation of fluids in the porous rock matrices or exchange via aquifer sources. The immediate result of puncturing the surrounding impervious layers confining hydrocarbon reserves is a pressure release because gas, oil, and associated fluids seek to escape (primary production). In the early days of oil exploration this would often lead to rapid expulsion of some of the reservoir contents (a "gusher"), requiring considerable skill to control and cap off. Present day well-drilling equipment is fitted with blowout prevention valves. Nevertheless, the immediate effect in the near well borewell bore area is a perturbation of established equilibria because a pressure differential is created. The tendency will be for contents of the pore matrix to move toward the well bore when the advancing drill bit breaks and removes rock chips to the surface via circulating drill fluids.

Drilling fluids or mud are frequently highly saline and typically consist of water or organic phase emulsions, continuously circulated through the drill string where they transport drill cuttings to the surface. They also function as lubricating coolants for the drill bit. The pressure applied to inject the mud into the drill pipe contributes to controlling the down-hole pressure changes and assists in stabilizing the well bore. Drilling fluids return to the surface via the annular gap between well bore and drill pipe where they are separated from the cuttings before reuse, thus providing a continuous cycling of displaced material throughout the length of the well bore.

It is common for exploration wells to be drilled several years before any production commences at the site. In this case the well may be capped off before further work continues. Any fluids shut into the well are therefore in contact with bacteria indigenous to rock penetrated by the drill.

Temperature. Temperature gradients established in oil fields before exploitation are altered as a result of hydrocarbon extraction. Movement of the gaseous and fluid reserves from storage zones to producing wells initiates mixing in the reservoir. As primary production rates slacken and secondary recovery methods are applied, further changes are imposed. Cooling of the reservoir may come about as a result of injection of water to assist in secondary recovery. This is particularly evident in the deep oil reservoirs underlying the North Sea. The injected waters may be at 8 to 10 °C and enter a reservoir with a temperature of more than 100 °C. Thermal cracking is frequently caused by cold water injection into hot rocks. This results in substantial alterations in the sweep efficiency of the water flood, which may or may not be to the operator's advantage.

Temperature effects are less extreme in the reservoirs of the Gulf of Mexico as the differential between the reservoir and injected seawater is less marked. The rate of heat transfer in a reservoir is dependent on injection rate and rock characteristics, which vary from field to field. In general, however, cooling occurs at the injection well bore and the cooled zone extends gradually with the flood front. Where rock is highly fractured and connectivity between injection and production wells is established, a scenario emerges where the passage of injected water creates a cold finger through the reservoir.

Alongside the direct effect on reservoir temperatures, the cooling can also promote precipitation and deposition of scale in the reservoir. Mineral solubility in formation water is reduced as temperature and pressure decrease with increasing hydrocarbon production, resulting in precipitation of carbonates.

Water Chemistry. As formation of insoluble carbonate scale is principally a result of temperature and pressure reduction, sulfate scales are a frequent consequence of incompatibility between seawater and reservoir formation water chemistries (36). Seawater injection introduces a high level of sulfate ions (about 2,800 mgL^{-1}) with small amounts of calcium (Ca^{2+}, 420 mgL^{-1}) and traces of barium and strontium ions (Ba^{2+} and Sr^{2+}) to the reservoir. The original reservoir formation water may have traces of sulfate SO_4^{2-}, up to 3000 mgL^{-1} Ba^{2+} and or Sr^{2+} and tens of thousands mgL^{-1} of Ca^{2+}. The salinity of both waters classifies them as brines, and both are stable under normal oil field conditions when kept apart. Comingling of these brines in various locations of the reservoir and production systems results in deposition of sulfate scales of barite ($BaSO_4$), celestite ($SrSO_4$), or gypsum / anhydrite ($CaSO_4$) in North Sea reservoirs. Water chemistries vary from reservoir to reservoir and field to field, requiring constant monitoring and analysis by reservoir engineers to maintain efficient production.

Reservoir Chemical Treatments. Further chemical modification of the reservoir environment results from the injection of a comprehensive array of treatment chemicals such as chemical biocides, corrosion and scale inhibitors, oxygen scavengers, sulfide scavengers, emulsifiers, polymers, and surfactants. Some treatments are chemical combatants deployed to solve a chemical problem. For example, the majority of injected waters are deaerated before entry to the reservoir, as addition of oxygen to the otherwise hot, saline, and anaerobic system promotes anodic corrosion of the ferrous metals used in construction of the process equipment (37). Final traces of oxygen are eliminated by incorporation of reducing agents such as

ammonium bisulfite in the injected fluid to serve as an oxygen scavenger. However, the use of chemical biocides, and to a great extent hydrogen sulfide scavengers, is a direct response to the problems caused by active communities of bacteria throughout the system.

Reservoir Souring and Plugging

The combined effects of the physical and chemical changes imposed on hydrocarbon reservoirs are complex. All have an effect on the deep subsurface environment that was described earlier and are likely to affect the activity of both the indigenous microbial population and newly introduced organisms.

It is indisputable that microbial contamination by drilling operations occurs. For the purposes of microbiological sampling programs, lengthy methods are employed to distinguish native from introduced bacteria (38,39), which are not applicable in an industrial arena. Nonindigenous organisms are introduced to the environment as soon as the exploratory drill bit penetrates an oil-bearing horizon. Material from the overlying rock is carried with the advancing drill string, drill cuttings mixed with drilling fluids transport resident bacteria from one stratum to another. In the same way, subsequent drilling of production and injection wells contribute to further mixing of the contents of otherwise separate strata. Any fluids shut into the well following evaluation for production purposes are therefore in contact with a mixed population of bacteria.

Degradable components of drilling mud, particularly the diesel grade hydrocarbons used in oil-based mud are easily utilised by the microflora, in spite of the incorporation of preservative biocides. The biocides may be added only at a level to preserve the product until deployment in drilling operations. Dilution of the biocide will occur once the drilling fluid is in the rock formation, and thermal degradation may occur subsequently. The implications of this are that on reopening an exploration well or drilling in close proximity to an existing well there may be a detrimental and numerically enhanced microflora in place, which has already been exposed to typical oilfield biocides. These include oxidants, such as chlorine or ozone, cross-linking, nonoxidant aldehydes, or membrane-active quaternary ammonium compounds (40).

Alteration of the temperature profile within a reservoir has a profound effect on the activity of the microbial community, especially at the injection well bore. This is an area where microorganisms introduced from overlying strata and injected fluids, growing optimally at lower temperatures than the bulk of the reservoir may become well established in relatively narrow zones along the injection flow path. Similarly at the production wellhead, a microflora tolerant of intermediate temperatures becomes established.

Sulfate-Reducing Bacteria (SRB)

Discussion in the preceding sections has not dwelt on those members of the subsurface reservoir microbial community, which are acknowledged to be the principal problem for oilfield operators, namely the diverse assembly of sulfate-reducing bacteria. Postgate (41) describes SRB as having numerous roles in the context of oil and gas technology, both as indigenous inhabitants of waters in oil-bearing formations and colonizers of surfaces throughout the process. It has already been shown that these bacteria are prevalent in samples of reservoir fluids obtained from all depths, temperatures, and geologies.

SRB are opportunistic organisms implicated in economically deleterious activities throughout the industrial arena. Probably, the most important influence they have occurs throughout the oil and gas industry, where SRB biofilms are the tenacious and resilient focus for the corrosion of production and pipeline equipment, while the principal reservoir problems directly attributable to SRB are sulfide 'souring' and formation plugging. Almost every aspect of oil recovery can be hindered by the ubiquitous and opportunistic assemblage of sulfidogenic microorganisms (42).

The hydrogen sulfide generated by SRB is a serious problem for operators, whether from corroding biofilms in separator tanks or issuing from the wellhead in production gases and fluids. In the reservoir, hydrogen sulfide is soluble in crude oils, highly volatile and partitions into the natural gas phase. Concentrated or generated within the production facility, it poses a serious health risk to platform workers, being a highly toxic respiratory inhibitor. Crude oil and natural gas containing excessive amounts of sulfide must be treated before refining to reduce emissions of toxic sulfur products to the atmosphere. Regulatory mechanisms to ensure that no operator produces excessively "sour" products bring high cost implications to bear, for many operators.

A physical problem resulting from microbial activity in porous rock matrices is one of biomass. The influx of suitable nutrients and electron acceptors with injected waters and advancing flood fronts deeper in the reservoir results in active growth of bacteria attached to the rock surfaces. Biofilm development, eventually, bridges individual pore throats, blocking water access into the deeper reservoir and can ultimately result in loss of injectivity at the well bore and diversion of directed waterflood operations away from the desired zone. Extensive pore-blocking within one zone of a reservoir can result in substantial loss of production because mobile reserves of oil are protected from the waterflood front designed to sweep crude oil from the formation to the production well. Unchecked, the flow diversion could so reduce production efficiency of the reservoir that the operator is forced to abandon the field.

The link between water injection and reservoir souring has been demonstrated many times in the North Sea oil fields (43). Oilfields are occasionally sulfide sour from the start, in which case the sulfide may be thermochemical in origin, the result of earlier bacterial activity during maturation processes or thermal decomposition of sulfur compounds in the hydrocarbon reservoir (44). Following the commencement of water injection, sulfide souring can escalate rapidly because zones near well bore cool, allowing growth of a wider range of bacteria. Nutritional requirements of some organisms are satisfied by the influx of additional carbon sources, which are found in varying concentrations in injection waters. Away from

the immediate well bore area, temperatures are higher and here the indigenous micro flora is likely to be in a dormant condition until production operations promote the mobilization of hydrocarbons and associated waters, thus promoting microbial activity.

Survival of microorganisms in the natural environment is of great interest to the scientific community, particularly in relation to the subsurface (45). The deep subsurface is not accessible for in situ observation; therefore, any prediction of the activity of organisms must be based on simulated laboratory experimentation. Suspensions of dormant and actively growing thermophilic SRB (tSRB), derived from North Sea production fluids and exposed to pressures of 1000 ψ and 150 °C for up to 24 hours, were checked for metabolic activity and growth. A higher proportion of the dormant cells were capable of metabolic activity following this treatment (46). tSRB can survive conditions of temperature simulating both prolonged nutrient depletion in deep hot reservoirs and also cold aerated conditions for up to 21 months (47). These two different conditions are encountered in the North Sea oil industry when produced waters are either ejected overboard after separation from the oil production or mixed with seawater before reinjection into the reservoir for secondary recovery operations. Cells were seen to undergo a reduction in size when deprived of carbon sources. Following restoration of suitable electron acceptors and donors, it was possible to demonstrate metabolic activity in the tSRB populations and some growth.

Consortia of reservoir, derived thermophilic sulfidogens, inoculated into clear growth media in a series of vials containing different amounts of sand, produced significantly more sulfide, when there was more sand available for colonization (48). Planktonic tSRB passed through sand pod columns or sandstone cores attach to surfaces where they grow and develop biofilm under conditions, which simulate reservoir temperature, pressure, and water chemistry (49–51). It is reasonable to suppose therefore that there is active growth not only in the near well bore areas of oilfield reservoirs but also deeper in the formations when conditions are suitable. It is considered that most bacterial activity will occur in the mixing zone between the reservoir formation waters and the advancing waterflood front and subside once the waters have been depleted of utilizable components by the bacteria. Sulfide is more soluble in oil than the water phase and is often pushed ahead of the advancing waterflood to the production well head, some time in advance of injection water breakthrough.

The emphasis for oil field operators in recent years has been to learn new techniques for reducing deleterious bacterial activity. Most particularly, the early prediction of potential souring problems is important in order that suitable treatments can be applied in the near well bore area either before bacteria are forced deeper into the reservoir or before the water mixing zone contacts populations further from the injection well. One of the greatest problems facing reservoir engineers is how to predict the location, activity and potential for transmission of bacteria through reservoirs, given that it is unlikely to be possible to access the moving water mixing zone with biocides, once souring has become established. Laboratory core-flood experiments have provided useful information on the rate of transport of reservoir bacteria in porous matrices simulating the formation rocks. For example, it has been concluded that in rocks of moderate to high porosity, single planktonic cells of tSRB will spread at the same velocity as the advancing waterflood front (51). However, this does not aid prediction of the fate of large portions of biofilm which may detach from rock surfaces for a variety of reasons, including change in fluid flow, temperature, application of surface active agents or biocides. There is little information on the activity of cells in detached portions of biofilm. It is not known whether the cells remain in contact with one another following detachment, and if so, do constituent members of a detached agglomeration of cells enjoy a selective advantage over single cells shed to the planktonic phase from the parent biofilm.

Core flood experiments can give indirect information on the activity of the bacterial population in place by monitoring parameters relating to pressure changes, fluid flow rates and metabolic products, but to directly observe the biofilm attached to the rock, destructive sampling is necessary. New research techniques that use image analysis are evolving, and this enables direct observation of cell attachment, biofilm development and detachment. There are many factors influencing a range of control parameters that will contribute to a greater understanding of the behavior of bacterial populations in many environmental situations, including the porous matrices of oil field reservoirs (52).

Microbially Influenced Corrosion

We include a brief reference to microbially influenced corrosion (MIC) because it is directly related to the presence and activity of SRB, which are the principal cause of problems for oil field operators. In the oil and gas industry, corrosion of production "hardware," such as pipeline and other tubings, pump equipment, storage or separation tanks and hydrocyclones is invariably found to be associated with heavy surface colonization by SRB. Hundreds of millions of dollars every year are channelled by the oil and gas industry into efforts to reduce the effects of bacterially mediated corrosion of carbon steel (37,40). The problems arise not only in the "upstream" production equipment but also in "downstream" refined products storage and transport. In any setting where a water layer develops in contact with steels (inside or outside pipelines), either through condensation or washing processes, and most particularly when any period of stagnation and deaeration is intrinsic to a procedure, the risk of corrosion is high.

The sources of SRB contributing to the corrosion damage of oilfield-processing equipment are many. Although populations of SRB have been identified from many different deep subsurface environments (38,53) and also oil-bearing reservoirs (33,34,43,46–51), they are also ubiquitous throughout aqueous and surface environments (41,54). It is certain that many of the sulfate-reducing bacteria retrieved from corroding production

equipment on oil or gas production rigs will have been derived directly from the same deep subsurface environment as the production fluids themselves. Other SRBs will have contaminated the structure through general contact with the environment and established corrosive biofilms wherever conditions are conducive to their proliferation (55).

APPLICATION OF MICROBIAL TECHNOLOGY FOR EXPLOITATION OF PETROLEUM RESERVOIRS

Background

Petroleum microbiologists have endeavored for over 50 years to develop technology suitable for improving the recovery of hydrocarbon resources, using either microorganisms directly or the products of their activity. A variety of techniques have been attempted and with varying levels of success.

The microbial mechanisms with potential for improving oil recovery have probably been well defined in ZoBell's 1946 U.S. patent (56). He listed six different activities that have the potential to increase mobility of recalcitrant hydrocarbon deposits:

1. solubilization of calcareous material,
2. dissolution of sulfate minerals to increase permeability,
3. generation of gases to repressurize the reservoir and improve oil migration from rock pores,
4. growth of biofilm on rock pore surfaces to physically displace oil,
5. production of biosurfactants, and
6. reduction of oil viscosity by direct modification of oil or by solution of produced gases.

ZoBell had explored the idea of using sulfate-reducing bacteria because he saw that their activity fulfilled several of the qualifications in his list. Much of his research was based on results he obtained from shallow land wells, where injected water for secondary waterflooding was low in sulfate, and therefore the immediate problem of excessive sulfate reduction may not have been apparent in relatively small fields with low output (40). However the attendant disadvantages of hydrogen sulfide production coupled with corrosion, sour reservoirs, and iron sulfide plugging are now clearly recognized to outweigh the benefit of employing SRB. Nonetheless, ZoBell's original list of bacteriological functions as potentially valuable tools still deserves a place in any discussion of microbially enhanced oil recovery (MEOR).

A later patent, filed by Updegraff in 1957 (57) used the ability of the clostridial anaerobes and molasses to produce large amounts of acid and gas to aid oil recovery. Similar treatments using injection of cheap carbon sources, such as molasses alone, to stimulate indigenous populations were also tested. Field trials in Eastern European oil producing regions were applied to single wells, which were shut in after the treatment to allow growth, the cleaning effect of acids, and repressurization with gas to take effect. Improved oil recovery was generally observed, and this treatment is still applied in small-scale recovery operations.

Competitive inhibition of SRB or bacterial scavenging of hydrogen sulfide by injection of mixed communities of selected organisms is another approach that has been considered. Data were published from a small-scale field trial resulting in the replacement of the regular biocide and corrosion inhibitor dosing with a mixed community of naturally occurring select microorganisms and a suitable nutrient (58). Injectivity of the well was not compromised nor was oil production affected.

Microbial treatment of the larger fields that were developing throughout the world during the middle decades of the twentieth century was less easy to control. The direct benefits of similar treatments were difficult to justify, largely because the reservoir characterization was inadequate and the locations of waterflood fronts were difficult to identify with sufficient confidence.

Current Status

MEOR has still to find favored status in major oilfield operations. It has been applied on a small scale by comparison with more traditional reservoir treatment technologies, such as biocide dosing, sulfide scavenging, application of emulsifiers, scale inhibitors, and so on. However, these traditional methods are finding less favor with environmental control agencies whose global responsibility is to reduce the amount of potentially toxic and damaging pollutants in the environment.

The problem of pore plugging, loss of injectivity, and formation blockage during secondary recovery operations was recognized to be because of the detrimental bacterial activity. During the 1980s, researchers began to consider using the ability of bacterial cells and biofilm to divert flow as a tool to access residual and bypassed oil (59). This was seen as an important adjunct to secondary water- flooding techniques, which perform well until water breakthrough occurs. A water flood may leave behind oil, either because it is trapped by capillary forces in disconnected oil ganglia (residual oil) or because the flood front takes a path through the heterogeneous rock, which bypasses the oil. The watered route is called a "*thief*" *zone* and is of higher permeability than the surrounding rock, which still contains recoverable oil (35).

Conventional treatment for these problems is to employ additional chemicals in the water flood. Operators recover residual oil by use of surfactants to reduce interfacial tension between trapped oil and the aqueous phase. The remedy for recovering oil bypassed because of large-scale rock heterogeneity is addition of polymer to the water. This increases the viscosity of the water and effectively reduces the mobility ratio between the oil and water, thus remobilizing the oil by hydraulic pressure transfer in the pores between rock strata of different permeabilities (35). The polymers used are either synthetic polyacrylates or bacterially generated extracellular xanthans (this can be considered to be a form of MEOR). However, both these polymer types are degraded by a combination of reservoir conditions and metabolic activity of indigenous microflora and become ineffective. Data from sand pack and core flood experiments described the addition of bacteria to

a simulated waterflood, either in a starved state as ultra microbacteria, thus aiding deeper dispersion in the matrix, or as vegetative cells. Emplacement of the bacteria was followed by addition of nutrients, promoting growth and biofilm development of the injected bacteria (60,61). In a reservoir, diversion of the waterflood into less permeable zones of the surrounding matrix could be brought about and this would achieve the purpose of sweeping bypassed oil to the production well head.

An alternative approach has been suggested (62), which involves selection of bacteria from oilfield-produced waters. Following enrichment culture, starved cell suspensions would be prepared before reinjecting them to the reservoir. The starved bacteria would be dispersed with the waterflood to highly permeable reservoir zones, to await the arrival of a nutrient subsequently injected with the waterflood. The starved cells would then resuscitate, grow and plug the thief zones, thus promoting beneficial flow diversion.

Operators have been reluctant to attempt large field trials for flow diversion techniques, for the reason that a poorly located bacterial treatment could cause irreparable reservoir damage, costing lost production. There is still insufficient knowledge of the deeper reservoir geologies and flow patterns to be sure that the treatment will reach its intended destination. Computer models of reservoir flow characteristics have yet to include variables accounting for the movement and transport of bacteria in a reservoir.

Currently, the most promising route to the use of bacteria for improving oil recovery is the one that does not necessarily result in increased oil production. Returning to the detrimental effects of SRB in oil field reservoirs and their generation of hydrogen sulfide, more research effort is being devoted to competitive bacterial activity designed to suppress the effects of SRB growth. Pilot scale treatments of fields with *Thiobacillus denitrificans*, which oxidizes inorganic sulfides, have demonstrated a successful bioaugmentation technology for the treatment of sulfide-laden produced waters (63), particularly with nitrate addition (64). Sulfide levels were reduced by almost up to 92%, when the faster growing nitrate-reducing bacteria consumed available carbon sources more rapidly than SRB.

Future areas where MEOR techniques could develop include application of in situ anaerobic microbial desulfurization of heavy crude oils in South American oilfields alongside anaerobic degradation of bitumens and tars. These recalcitrant fractions of the global hydrocarbon complement are still largely in place in reservoirs throughout the world.

CONCLUSION

No deep subsurface environments have been more disturbed than those yielding hydrocarbons to fuel global energy requirements. The results of this exploitation have been instructive for oil field operators, who were unprepared for the consequences of their intrusion. The microbiological revelations, which have come to light, will surely yield new insights into the molecular origins of life and offer new technological solutions for the future.

Because of the high temperatures and salinity gradients, oil reservoirs were long thought to be sterile environments, intolerable to life. However, soon after the advent of commercial oil production more than 140 years ago, workers noticed oil souring, that is, an increase in hydrogen sulfide. Hydrogen sulfide, which is toxic, damages production by reducing the value of the oil and degrading the drilling equipment. In an effort to explore whether these problems stemmed from biological processes, Bastin undertook the first microbiological study of oil wells. In 1926, Bastin reported the presence of sulfate-reducing microbes in oil reservoirs and questioned whether these microbes were autochthonous or introduced into the subsurface by drilling operations (1). This issue is still unresolved today. Within the last 25 years, numerous studies have been conducted to determine how microbes affect the quality of petroleum production, specifically their role in the biodegradation of oil and drilling equipment, as well as their potential to increase petroleum yields.

GEOPHYSICAL AND GEOCHEMICAL CHARACTERISTICS OF OIL RESERVOIRS

In commercial petroleum wells, water is usually extracted along with the oil. Microbes have been found in the aqueous phase of produced fluids and associated with oil (Fig. 1). The geochemistry of the reservoir, mineralogy, and the water determines the types of microbes found in reservoirs. Although the exact composition varies among petroleum reservoirs, the wells are generally anoxic. The gases usually found are carbon dioxide, methane, ethane,

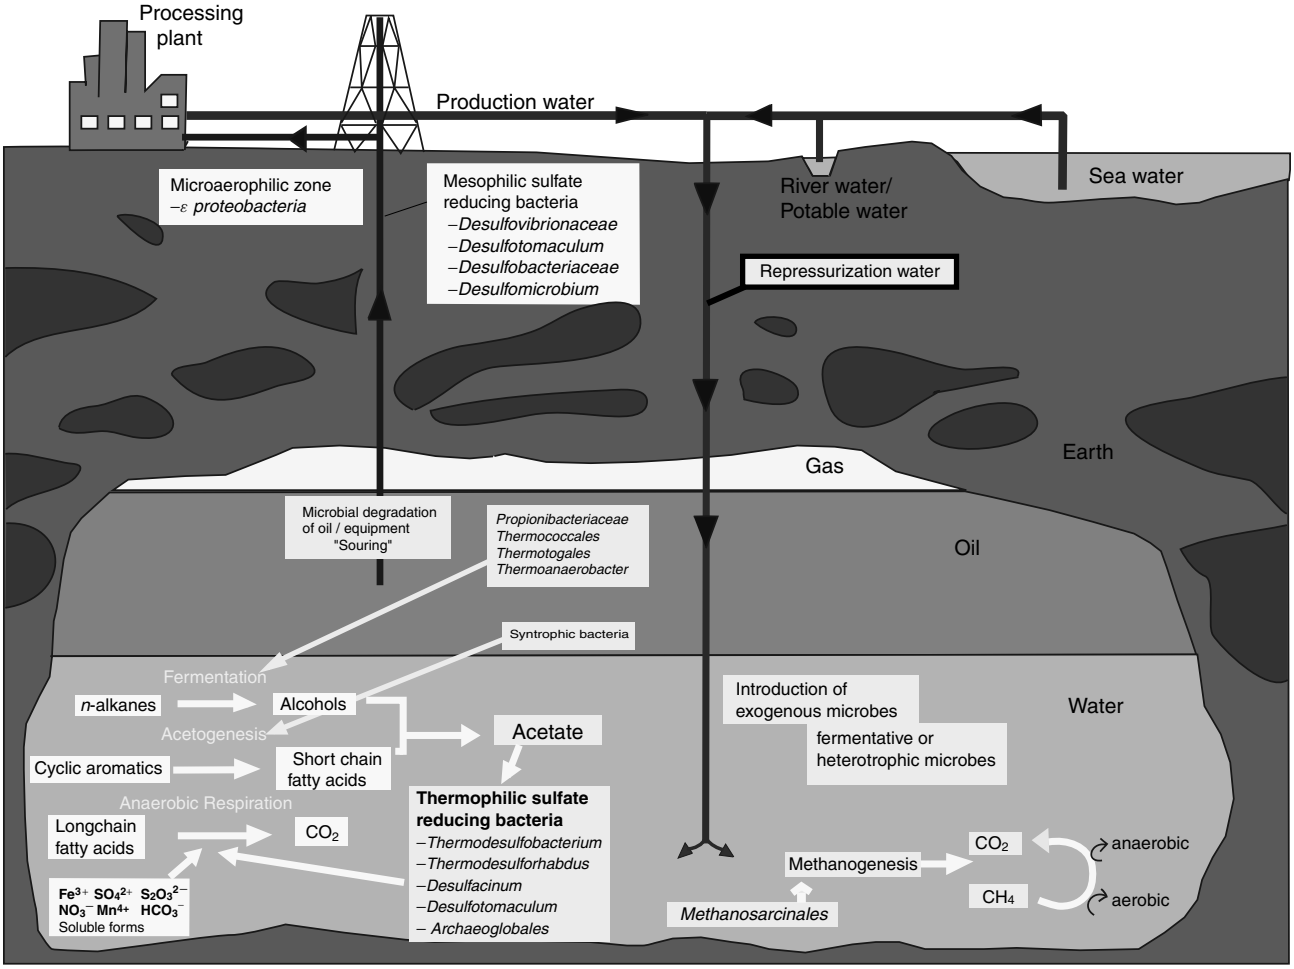

Figure 1. Cross section of a petroleum reservoir.

propane, butane, isobutane, and hydrogen sulfide. Oxygen may be introduced into the reservoirs by near-surface groundwater or via injection of seawater during secondary extraction of the oil. Oil companies do not measure the level of hydrogen; therefore, little information is available. The in situ pH ranges from 3 to 7.

In addition to pH, temperature and salinity of the reservoirs are considered the major factors that influence microbial activity. Temperature is a function of depth, with an average rate of increase of 3 °C per 100 m; the highest temperatures recorded from petroleum reservoirs are 130 to 150 °C. The salinity of the formation water is influenced by the surrounding rock layers and can range from freshwater concentrations to salt saturated. In addition, pressure also depends on depth and can reach up to 500 atm. Pressure may influence the physiological and metabolic properties of microbes in the reservoirs, but it is not believed to inhibit microbial activity in situ (2).

The chemical composition of reservoirs influences the types of metabolic processes that can occur, and hence the kinds of microbes that are able to grow in these environments. Routine chemical analyses performed by petroleum companies has revealed that the redox potential of the production waters is extremely low and that electron acceptors, such as oxygen and nitrate are generally absent. Sulfates, carbonates, and iron oxides, which are generally present in stratal waters, probably, support a diverse community of microorganisms. The primary electron donor is most likely H_2, derived from abiotic and biological sources. For example, H_2 is widespread in the deep subsurface and can serve as an electron donor for sulfate-reducers, methanogens, acetogens, and iron-reducers. Under certain environmental conditions, H_2 is produced through a chemical reaction between water and ferrous silicate minerals found in basalt (3). In addition, organic acids such as acetate, formate, propionate, and butyrate have been detected in many, but not all, petroleum reservoirs. In some wells, more complex organic acids have also been detected. Aerobic degradation of many of the organic molecules present in the petroleum reservoirs such as n-alkanes and alkylbenzenes has long been recognized; however, microbial, anaerobic degradation of complex organic acids has only been demonstrated within the last 20 years (4,5). Both aerobic and anaerobic microbial degradation of the hydrocarbons may contribute to oil decomposition (6,7).

Data concerning the presence of crucial biosynthetic elements, such as nitrogen and phosphorus, is either

limited or absent. If present, N_2 could be utilized by nitrogen-fixing bacteria. Also, resins and asphaltenes, significant components of crude oil, are made up of complex hydrocarbons that can contain nitrogen, sulfur, and oxygen (2), providing potential nitrogen, carbon, and energy sources for microbes.

MICROBIAL DIVERSITY OF PETROLEUM RESERVOIRS

Numerous mesophilic and thermophilic microbes have been isolated from oil reservoirs. However, it is estimated that as much as 99% of a microbial community is not easily cultivated; therefore, molecular phylogenetic-based approaches that do not rely on cultivating microbes have recently been used to assess the microbial diversity of oil reservoirs (8). By collecting samples from the environment, extracting total DNA, and then selectively amplifying the evolutionarily conserved small subunit (16S) ribosomal RNA (rRNA), environmental rRNA gene sequences can be obtained and compared to known sequences. These "phylotypes" can then be placed in a phylogenetic framework. Although sulfate-reducers have been the primary focus of microbial research at petroleum mines because of their damaging effects on industrial petroleum production, many other mesophilic and thermophilic microbes belonging to both domains *Archaea* and *Bacteria* have been classified by this approach.

Colonization of Allochthonous Microbes in Petroleum Reservoirs

To recover samples that would only contain truly indigenous microbes, the core material must be obtained aseptically; however, due to economical constraints, such samples are rarely available (9). To date, wellhead sampling is the sole means of sample collection. As a result, exogenous microbes can be introduced into the reservoirs through several channels and, consequently, take advantage of the energy sources present in (and introduced into) the reservoirs. For example, ground or surface water is often injected into the reservoirs to maintain pressure and improve oil recovery; this repressurized water can be of many origins such as seawater, river water, or production water. Allochthonous microbes can also be introduced into the reservoirs via drilling equipment. Moreover, the drilling equipment acts as a cathode that can generate H_2 which, in turn, can serve as an electron donor (2). Microbes multiply in the wells, and their metabolic by-products accelerate the degradation of the equipment.

Careful analysis of the data from petroleum reservoirs is crucial to distinguish indigenous microbes from exogenous ones. Several studies have developed useful criteria to aid in recognizing indigenous microbes. For instance, although temperatures in reservoirs have surpassed 100 °C, in situ oil biodegradation has not been observed above 82 °C (6). Furthermore, analysis of 87 water samples from North American oil reservoirs showed that microbial fatty acid concentrations were at a maximum at 80 °C in the reservoir (2,10,11); thus, the temperature limit for microbial life in petroleum reservoirs has been estimated to be between 80 and 90 °C. Thermophilic and hyperthermophilic microbes that grow at temperatures above 90 °C have been isolated from oil reservoirs (12,13); however, the ecology of subterranean hyperthermophiles is not completely understood, and these microbes may or may not be endemic to the reservoir environment. It is possible that these organisms originally are derived from hydrothermal vents and that they have been introduced into the reservoirs via injected seawater.

If the physiological characteristics of the recovered microbes correlate with the environment from which they were isolated, it is likely that they are autochthonous to the reservoir. Interpretation of the data is simpler when samples are obtained from high-temperature or high-salinity environments than it is when low-temperature, low-salt samples are retrieved. Because existing data implies that only strict anaerobes should be considered autochthonous to oilfields, the presence of aerobic microorganisms is used as an indicator of contamination.

MICROBES FROM OIL RESERVOIRS

Diversity of microbes in petroleum reservoirs has been gleaned through culturing and molecular phylogenetic approaches. Both mesophilic bacteria that grow optimally between 25 and 40 °C and thermophilic bacteria that grow best at temperatures between 45 and 80 °C have been cultivated from petroleum reservoirs. Within these physiological groups, aerobic, microaerophilic, and anaerobic organisms from reservoirs have been isolated or identified. The detection of closely related anaerobic bacteria in separate oil fields (14,15) supports the existence of a widespread anaerobic biosphere in these habitats.

The following sections provide an overview of distinct types of microbes identified and cultivated from petroleum reservoirs and their distinguishing metabolic processes. However, microbes do not exist as independent entities, rather their metabolic processes are intertwined and may be beneficial or inhibitory to the other members of the reservoir community. For example, the anaerobic breakdown of hydrocarbons may be the result of acetogens, methanogens, and sulfate-reducers. Each type of organism catalyzes a distinct reaction that ultimately leads to the formation of CH_4 and CO_2 (16).

Sulfate-Reducing Microbes

The majority of microbial research on petroleum reservoirs has focused on the identification and isolation of sulfate-reducers because of their detrimental effects on the economy of the oil industry (8). Moreover, hydrogen sulfide can be dangerous to the health of petroleum workers: at high concentrations, it can cause suffocation. Table 1 provides a compilation of sulfate-reducing microorganisms cultivated from petroleum reservoirs (2,17–24). These strict anaerobes, belonging to both the archaeal and bacterial domains, use sulfate as their primary electron acceptor, reducing it to hydrogen sulfide. Whether contaminants or indigenous, sulfate-reducers seem to be ubiquitous in oil wells, growing over a range of

temperatures and salt concentrations. The mesophilic sulfate-reducing microbes are involved in the corrosion of top well facilities, whereas the thermophilic sulfate-reducers appear to be involved in oil deterioration in situ (2).

Methanogens

Belonging exclusively to the domain *Archaea*, methanogens are strict anaerobes that produce methane through the concomitant reduction of CO_2 and oxidation of H_2. Certain methanogens are capable of utilizing other C1 compounds such as methylamine (CH_3NH_2), methanol (CH_3OH), and dimethyl sulfides ($(CH_3)_2S$) (25,26). Moreover, acetate (CH_3COO^-), which is present at very high concentrations in some reservoirs, may also serve as a substrate for acetoclastic methanogens, either directly or syntrophically from acetogenic organisms. Mesophilic and thermophilic methanogens that reside in slight to highly saline reservoir waters have only recently been reported (Table 1) (27–30). Hyperthermophilic methanogens — organisms that have a growth optimum of 80°C or higher — have not been cultivated from petroleum reservoirs; however, molecular phylogenetic analysis has detected phylotypes closely related to the hyperthermophilic *Methanococcus infernus* in a deep oil reservoir from Western Siberia (31).

In addition to SRB, methanogens may contribute to oil degradation. Recent research suggests that methanogens are involved in the anaerobic breakdown of long-chain hydrocarbons to methane. Whether methanogens catalyze this reaction alone or if they are part of a syntrophic community consisting of SRB and acetogens has not been fully assessed (16,32).

Fermentative Microbes

Fermentation is an anaerobic process through which microbes produce ATP. Organic compounds serve as both the primary electron donor and ultimate electron acceptor, and energy is produced by substrate-level phosphorylation (25). Organic acids that are present in oil reservoirs are potential substrates for both the mesophilic and thermophilic bacteria that are integral inhabitants of petroleum reservoirs (33).

Mesophilic Fermentative Bacteria. Mesophilic fermentative bacteria isolated from oil reservoirs are of industrial interest for microbially enhanced oil recovery (MEOR). These include anaerobic, moderate halophiles belonging to the genus *Haloanaerobium*. Increased petroleum yields are delivered as an indirect result of their metabolic products produced during growth (34). Other mesophilic, fermentative bacteria such as *Spirochaeta smaragdinae* (35), *Fusibacter paucivorans* (36), and *Dethiosulfovibrio* (37) have also been isolated. Molecular phylogenetic analysis of 16S rRNA genes from the enrichment samples have led to the detection of potentially strict anaerobic or facultative microbes associated with the genera *Clostridium, Eubacterium*, and *Synergistes* (38).

Thermophilic Fermentative Microbes. As most petroleum wells are characterized by high temperatures, thermophilic, fermentative bacteria have been isolated more often than their mesophilic counterparts (2). The thermophilic bacteria are generally of the order *Thermotogales*, namely, *Thermotoga*, *Thermosipho*, *Geotoga*, and *Petrotoga* (2,8,13,39,40). In addition to the sulfate-reducing microbes, *Thermotoga* may also play an important role in oil degradation by reducing sulfur and/or thiosulfate to sulfide (41,42). Sulfur reduction occurs among members of *Thermotoga* as a detoxification mechanism when the fermentation by-product, H_2, is oxidized. Evidence exists that may implicate thiosulfate-reducing microbes in the biodegradation of top well facilities (2,37), but the concentration of thiosulfate in oil reservoirs has not been studied extensively.

Other fermentative bacteria have also been isolated from petroleum reservoirs that may contribute to oil biodegradation. For example, the family *Thermoanaerobiaceae* includes members that are capable of reducing thiosulfate to elemental sulfur (*Thermoanaerobacterium*) or to sulfide (*Thermoanaerobacter*) (8,14). Additionally, the organism *Anaerobaculum thermoterrenum* is capable of reducing sulfur and thiosulfate to sulfide (33).

Fermentative microbes belonging to the domain *Archaea* have also been identified from petroleum reservoirs (2,8,12,13,43). They belong to the genera *Thermococcus* and *Pyrococcus*. That these organisms are endemic to the reservoirs has been questioned

(12,13,43), but their ability to reduce sulfur at elevated temperatures makes these organisms potential candidates in the biodegradation of oil (14,15,44). In fact, it has been postulated that these types of microbes may be the major source of hydrogen sulfide production, rather than the SRB (8).

Acetogenic Microbes. Acetogens produce acetate from CO_2 and H_2. In addition to the use of H_2 and CO_2, acetogens can utilize other C1 substrates or complex sugars as anabolic and catabolic substrates. At present, *Acetobacterium romashkowii* is the only acetogenic bacterium that has been identified in petroleum reservoirs (45).

Iron-Reducing Microbes. Ferric iron can exist in petroleum reservoirs in mineral form or bound in the layers of clay; some reservoirs contain ironstone belts that are tens of meters thick. Thermophilic iron-reducers that are able to couple H_2, organic acid, and hydrocarbon oxidation to iron reduction have also been isolated from petroleum reservoirs (Table 1) (46,47). Because of their ability to metabolize hydrocarbons, iron-reducers probably contribute to oil biodegradation. Iron reduction seems to be a conserved characteristic of thermophilic prokaryotes (48,49); however, iron reduction may not be the primary metabolism for these organisms. For example, *Deferribacter thermophilus* can take advantage of several electron acceptors, including manganese, and can also utilize many organic acids (2,46). Furthermore, species belonging to the genera *Thermotoga*, *Thermoanaerobacter*, and *Thermococcus* are able to utilize various sulfur compounds as electron acceptors (see section Fermentative microbes). *Shewanella putrefaciens*, a mesophilic iron-reducer detected from oil reservoirs (50) is able to reduce elemental sulfur, sulfite, and thiosulfate to sulfide (51), and thus, it may also play a part in oil souring.

CONCLUSION

Although the study of microbes in petroleum reservoirs began nearly a century ago, the bulk of existing knowledge has been obtained within the last 20 years. The degradation of oil and equipment continues to have a tremendous economical impact on petroleum companies. As neither the role that sulfate-reducers play in oil degradation nor the impact of introducing foreign bacteria and substrates via repressurization water is completely understood, further studies of reservoirs may reveal methods of inhibiting the biodegradation of oil. Conversely, increased awareness of oil-degrading microbes might aid in the cleanup of oil spills such as the *Exxon Valdez* disaster that occurred near Alaska in 1989. MEOR — the use of microbes to increase petroleum yield in situ — has been proposed, but many hurdles need to be overcome to make this process viable. Additionally, questions remain concerning whether exogenous bacteria are more effective for this process than indigenous ones and it is still not understood which metabolic types would best enhance oil recovery. Besides benefiting industry, the study of petroleum reservoirs may extend the perception of known life on this planet and elsewhere in the universe. Data obtained by microbiologists, geologists, and petroleum companies have begun to elucidate the biodiversity of oil reservoir ecosystems; however, further research involving interdisciplinary collaborations and continued molecular analyses is necessary for better comprehension of these ecosystems.

PFIESTERIA: THE TOXIC PFIESTERIA COMPLEX

JoAnn M. Burkholder
North Carolina State University
Raleigh, North Carolina

The toxic *Pfiesteria* complex (TPC) is treated separately from other dinoflagellates (Division Pyrrhophyta) in this encyclopedia because *Pfiesteria* spp. have certain traits that, considered separately, are not unusual but that, considered collectively, changed several generalizations about toxic dinoflagellates (1). In addition to the fact that *Pfiesteria* significantly expanded scientific understanding about toxic dinoflagellates, *Pfiesteria* science — which is "young," having only begun in 1988 — rapidly was enmeshed with socioeconomic and environmental policy issues in the mid-Atlantic and southeastern United States, which led in turn to strengthened surveillance programs for harmful algae and fish disease in those regions (1–3). The TPC thus far includes two species, *Pfiesteria piscicida* Steidinger and Burkholder (4) (pronounced as fee-STEER-ee-uh pis-ki-SEED-uh) and *P. shumwayae* Glasgow and Burkholder (5) (species pronounced as shum-WAY-eye). Toxic strains (individual cells or populations derived from them) of these species have all of the following characteristics: (*1*) strong attraction to live fish; (*2*) toxic activity triggered by live fish or their fresh tissues and excreta; and (*3*) production of toxin(s) (6) that cause fish stress, disease, and death under ecologically relevant conditions [live cells tested with fish using the standardized fish bioassay procedure (1,6,7), at similar densities as those encountered during *Pfiesteria*-related fish kills (1)]. Additional species probably remain to be detected. Thus far, however, tested "pfiesteria lookalike" or "pfiesteria-like" species that physically resemble the two known toxic *Pfiesteria* species (e.g., various *Gymnodinium* spp. such as *G. puchellum*, various *Gyrodinium* or *Karlodinium* spp., *Cryptoperidiniopsis* (gen. ined.) spp., species informally named as "shepherd's crook") have not shown all three traits and, thus are not considered truly *Pfiesteria*-like species or members of the TPC (1). This writing will describe the presently understood biology, ecology, toxicity, and impacts of *Pfiesteria* spp.

GENERAL CHARACTERISTICS, SYSTEMATICS, AND LIFE CYCLE

Comparison with Other Toxic Dinoflagellates

Pfiesteria spp. technically are not algae (defined as primitive plantlike, photosynthetic organisms) but, rather, animal-like protozoans that do not have their own chloroplasts (8). Nevertheless, they are usually included within the broad group of organisms known as "harmful algae" (8), in part because they are close relatives of the so-called "red tide" toxic dinoflagellates that are nearly all plantlike (9). Although they cannot photosynthesize on their own, *Pfiesteria* species can be photosynthetic by consuming algal prey, retaining the prey chloroplasts and allowing the "kleptochloroplasts" to maintain function for hours to days to supplement their nutrition (5,10).

Pfiesteria spp. represent only two among many species of toxic dinoflagellates that have been newly described in the past 15 years (1). *Pfiesteria piscicida* was (*1*) the first toxic dinoflagellate demonstrated to have a strong attraction to live fish and their fresh tissues, secreta, and excreta (separated from the live animals for $\leq$3 h (11); (*2*) the first shown to be triggered to produce toxin by live fish (1,11); (*3*) the first shown to have a complex life cycle containing amoeboid as well as flagellated and cyst stages (1,12,13); (*4*) the first reported to be extremely diverse in its nutrition, able to take up diverse dissolved organic and inorganic nutrients, and also prey spanning trophic levels across the entire estuarine food web (11,13); and (*5*) the first linked to production of aerosols that promote serious neurocognitive impairment in humans (exposure to toxic *Pfiesteria* has been linked to other human health impacts as well; see below) (14,15). *Pfiesteria* additionally was shown to have a cyst stage unlike that of any other dinoflagellate but closely

resembling the cysts of a different division of organisms, the chrysophytes (5,12). Some of these characteristics do occur among other dinoflagellates (2,9,11,16), but had not previously been reported for toxic dinoflagellates (Table 1).

It is important to note that *Pfiesteria* spp. are similar to many other so-called "toxic algae" in that they have both toxic and benign naturally occurring strains that may be considered as one of three functional types with respect to toxicity status (1). Toxic strains can be induced to produce toxin in the presence of live fish (1,6,11), and can be characterized as weakly to highly toxic on the basis of the time and cell densities required for fish death. When zoospores of these strains are actively toxic, they are referred to as the TOX-A functional type; when separated from live fish so that they cease toxin production, they are referred to as the TOX-B functional type (1,6). TOX-B zoospores are regarded as nontoxic and appear to have negligible to very low toxicity, but they can engage in toxin production and become TOX-A zoospores when sufficient live fish are again detected (1,6,11). In contrast, "benign" strains are referred to as noninducible (NONIND functional type) because they cannot be induced to make toxin when fish are present (1,6). NONIND strains consistently fail to show toxicity (evidenced by a lack of distress, disease, or death in test fish), both when freshly isolated from field samples and after extended time in culture (1,6). Thus, the presence of *Pfiesteria* does not necessarily indicate a problem — in some years and in some locations, only NONIND *Pfiesteria* has been found (1). The three functional types of *Pfiesteria* respond differently to nutrients, algal prey, and fish (see following text). In other locations, the proportion of toxic versus benign strains has varied over time, from years when most collected strains have been tested as NONIND to years when most have been toxic to fish (1). The reasons for this variation in toxicity among populations of each *Pfiesteria* species, as for populations of other toxic algal species, are poorly understood. Expression of toxicity is probably controlled by environmental conditions (e.g., nutrition, history of recent feeding, availability of certain required organic substrates) as well as genetic traits, and is further complicated by aberrancies that can develop over time in culture (below).

In most toxic algae, the environmental signals that influence toxin production and the benefit derived from toxicity are poorly known. By contrast, toxicity in *Pfiesteria* spp. is stimulated by substances from live fish, and its toxin(s) narcotises, then kills fish that *Pfiesteria* then consumes as prey (Fig. 1; 1,11). *Pfiesteria* is chemosensorily attracted to live fish and their fresh excreta, secreta, and tissues (Fig. 2; 1,11). Most live fish stimulate *Pfiesteria* to complete its sexual cycle (1,5,11), and sexual reproduction is believed to be of general importance in strengthening the

Table 1. Comparison of Major Traits Between TPC Species and Other Dinoflagellates (including other toxic species), Indicating Features Shared in Common

Trait[a]	Freshwater	TPC Estuarine[b]	Other Estuarine	Marine	Other Toxic[b,c]
Attack behavior toward fish or other prey	+	+	+	+	(−)

Source: From 1. J. M. Burkholder, H. B. Glasgow, and N. J. Deamer-Melia, Phycologia 40, 186–214 (2001), (in press).

[a]Traits are indicated as present (+); absent (−) or, for toxins, no; not known (n.k.); or not applicable (n.a.).

[b]Toxin producers are segregated into the "TPC" and "Other toxic" columns and are not also included in the "Freshwater," "Other Estuarine," and "Marine" categories.

[c]Includes more than 55 marine species (1,2).

[d]Although mixotrophy and heterotrophy have been reported in various toxic dinoflagellates, this is a poorly known, pioneer area of toxic dinoflagellate research (14).

[e]Before *P. piscicida* was discovered, complex life cycles had not been reported for estuarine dinoflagellates and were known in only a few species belonging to the Dinamoebales (6). Complex life cycles have been observed among two undescribed species within the nontoxic estuarine dinoflagellate taxon, "*Cryptoperidiniopsis*" *gen. ined.* (2,17). Similarly, chrysophyte-like cysts were not known in dinoflagellates before the discovery of *P. piscicida* (15), but are now known for *P. shumwayae* and *Cryptoperidiniopsis gen. ined.* (7,17). Note that complex life cycles may be more highly developed among shallow freshwater than marine species (18). However, many dinoflagellates have not been examined using techniques that would induce transformations to amoeboid stages if present. There is need for more thorough examination of dinoflagellate life cycles, especially in estuarine and shallow coastal species (19).

[f]Number adapted from published references 1. J. M. Burkholder, H. B. Glasgow, and N. J. Deamer-Melia, Phycologia, 40, 186–214 (2001). 2. J. M. Burkholder, Ecol. Appl. 8, S37–S62 (1998).

[g]While some dinoflagellate toxins are well characterized (e.g. brevetoxins, with more than 25 years of effort, and saxitoxins, okadaic acid, and some ciguatoxins), many are only partially characterized (*Pfiesteria*) or uncharacterized (19).

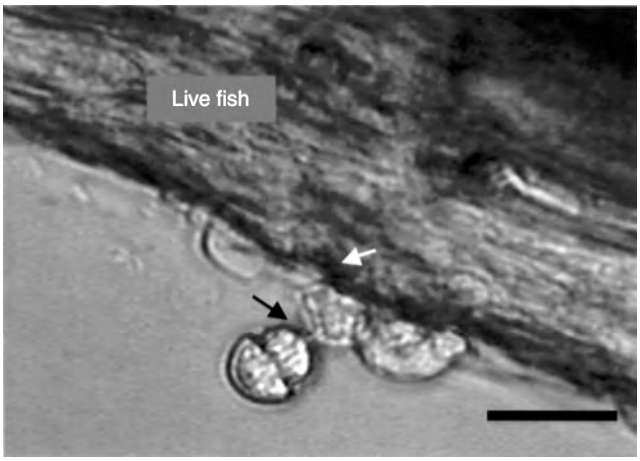

Figure 1. Light micrograph of a *Pfiesteria shumwayae* toxic zoospore (TOX-A functional type) with its peduncle (extended appendage used for attachment and feeding, arrow) attached to a larval sheepshead minnow (*Cyprinodon variegatus*), engaged in suctioning the contents from the tissue in active feeding (process called myzocytosis) (scale bar = 10 μm). (From 1. J. M. Burkholder, H. B. Glasgow, and N. J. Deamer-Melia, Phycologia 40, 186–214 (2001).) See color insert.

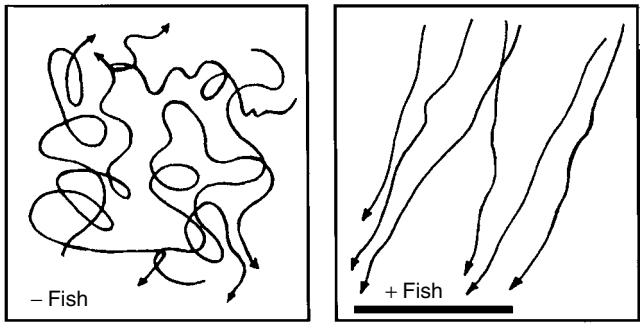

Figure 2. Chemosensory stimulation of *Pfiesteria* piscicida by fresh tissue indicated by motion analysis of six groups of toxic zoospores (TOX-A functional type) without fish (left panel) versus with a piece of epidermal tissue taken from a live tilapia (*Oreochromis mossambica*; right panel, with tissue position indicated by the black bar). Each arrow represents the mean of 10 cells per group. Directed movement is shown as net-to-gross displacement (NGD), a relative measure of path twistedness or convolution, in the absence versus the presence of fresh fish tissue (each trial = 120 seconds; a value of 1 describes a straight-line path of travel, whereas a value of 0.5 describes a random path at a 45° angle). (From 11. J. M. Burkholder and H. B. Glasgow, *Limnol. Oceanogr.* 42, 1,052–1,075 (1997).)

viability (fitness) and survival of species through genetic recombination.

SYSTEMATICS AND CELLULAR CHARACTERISTICS

The genus *Pfiesteria* was named in honor of the late Dr. Lois Pfiester, for her elegant research, which greatly strengthened general understanding about the biology of dinoflagellates, including species with complex life cycles (4). The species name in *P. piscicida* is Latin for "fish killer." The second known species, *P. shumwayae,* was named in honor of Dr. Sandra Shumway, for her research that has significantly advanced understanding about worldwide impacts of toxic dinoflagellates, especially on shellfish species and aquaculture (5). The two species have been placed within Division Pyrrhophyta, Class Dinophyceae, Order Dinamoebales, and Family Pfiesteriaceae (4,5). They can be identified (although the zoospore thecal plate structure is peridinoid), by the arrangement of the thin cellulose deposits (thecal plates) in the cell covering (amphiesma) of the zoospore stages (flagellated vegetative or asexual cells) (4,5,12).

The small, biflagellate zoospores of *Pfiesteria* spp. (diameter usually 7–14 μm, with known range of ca. 3–24 μm) closely resemble zoospores of various other estuarine dinoflagellates, and cannot be differentiated under light microscopy. Their identification requires swelling the sutures between the thecal plates (5), or stripping away the outer membranes that obscure the plates (4), so that the number, shape, and arrangement of the plates can be discerned under scanning electron microscopy (SEM; Fig. 3). *Pfiesteria piscicida* zoospores have plate tabulation Po, cp, X, 4′, 1a, 5″, 5c, 4s, 5‴, 2⁗, with a three-sided anterior intercalary plate (4; Fig. 3). *Pfiesteria shumwayae* zoospores have an additional precingular plate and this results in a four-sided anterior intercalary plate; thus, the tabulation is Po, cp, X, 4′, 1a, 6″, 6c, 4s, 5‴, 2⁗ (5). In addition to these differences in cellular structure, the two species also have been shown to have genetic differences (20). Although molecular probes, targeting the ribosomal DNA or other genetic material, have been developed for each *Pfiesteria* species and cross-corroborated by independent laboratories (17,20), there remains the possibility that the probes may also react with as-yet-undescribed estuarine dinoflagellates. Moreover, chemical substances, detritus, sediment, and other materials in natural samples or cultures with fish can sometimes cause spurious results with molecular probes. Therefore, SEM remains the "gold standard," that is, the most reliable technique for identification of *Pfiesteria* species (1,6).

Pfiesteria spp. have typical dinoflagellate organelles (1,4,5,9), including a "mesokaryotic" nucleus (with chromosomes remaining condensed during interphase) in zoospores but a typical eukaryote nucleus in amoebae (1). The chromosome number of *P. pisciaida* TOX-A zoospores recently isolated from estuarine habitat is 23 ± 2, as determined using flow cytometry, light microscopy, and transmission electron microscopy procedures on clonal populations (note, however, that chromosome number becomes variable and ploidy generally changes over time in culture) (1). This chromosome number is intermediate between the chromosome numbers of parasitic dinoflagellates (4–8 chromosomes) and some free-living species ($\geq$20), on the one hand, and certain photosynthetic, free-living dinoflagellates that have $\leq$270 chromosomes (18).

There is precedent for amoeboid stages in other dinoflagellate species from freshwater as well as estuarine and marine habitats (4,16,19). In addition to the direct observations reported by several independent laboratories

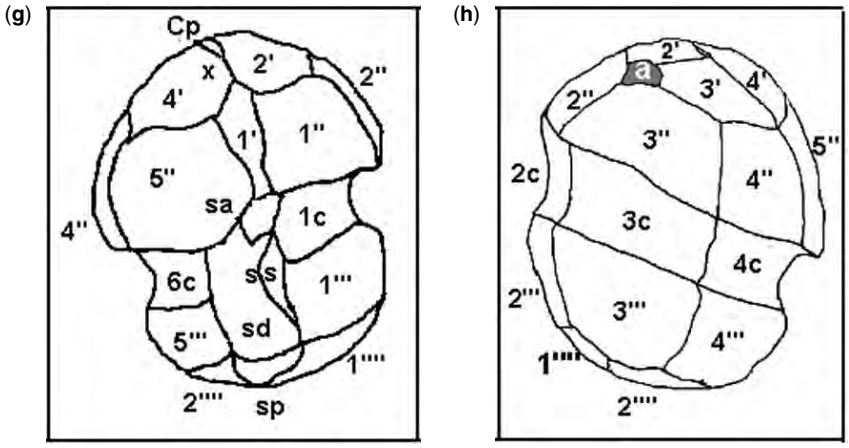

Figure 3. (*Continued*)

(1), polymerase chain reaction (PCR) and fluorescent in situ hybridization (FISH) molecular probe testing recently was performed on amoeba isolates to assess their identity (1,17). To retain pure cultures of amoebae without other life stages, and thereby avoid the potential for uncertainty in interpretation, we maintained the subcultures used for molecular probe analyses for long periods (months to years) without altering the prey source used in feeding to depress the potential for transformations from amoebae to other stages (1). Throughout the observations, no zoospores were noted in the amoeba cultures. The PCR analyses were positive for *Pfiesteria* spp., and were cross-corroborated by an independent laboratory (1).

Most *Pfiesteria* research has focused on zoospores because they are the most toxic known stage in the complex life cycles of *Pfiesteria* spp. The cell biology, behavior, and ecology of *Pfiesteria* amoebae are less well understood. Evidence of ichthyotoxic activity by a lobose amoeboid stage has been reported (11). On the basis of laboratory experiments with clonal *Pfiesteria* spp. cultures, most flagellated cells from TOX-A cultures are capable of transforming to amoebae (1,4,5,11–13). These stages rapidly settle out of the water column and remain active if abundant prey (bacteria, algae, fish remains) are available. Thus, amoeboid stages represent an important link between planktonic and benthic habitats in the life cycle (below), especially for toxic *Pfiesteria* strains.

COMPLEX LIFE CYCLES

The life cycles of most toxic dinoflagellates are incompletely known (21). Among these organisms, *Pfiesteria* spp. have been very intensively examined using multiple prey types and other food sources (1,11). Perhaps partly for that reason, *Pfiesteria* spp. have been confirmed by several independent laboratories to have complex life cycles with about 20 or more flagellated, amoeboid and cyst stages (Figs. 4,5; 1,11). Transformations among these stages are controlled by the type and abundance of available prey, especially finish (1,5,11–13). The *Pfiesteria* life cycle includes zoospore stages that can be produced by vegetative cysts and zoospore-derived palmelloid masses, and by at least one amoeboid stage (Fig. 4). The zoospores produce cysts that range from 6 to 25 μm in diameter (1). They can be chrysophyte-like with an outermost covering of organic and siliceous scales with bracts (4,5,11–13), or smooth with several wavelike markings on the thickened outer wall (Fig. 4; 11,12). Under sudden stressful conditions, within minutes zoospores can also form temporary cysts with a protective thick outer layer of mucilage (Fig. 4).

Sexual reproduction in *Pfiesteria*, with gamete fusion to form the sexual product or planozygote, occurs mostly in the presence of live fish, but can also occur in some strains fed algal prey (Fig. 4; 1,11,12). Gametes are produced by TOX-A zoospores, and may be of equal (isogamous, similar to the zoospores in size) or unequal size (anisogamous; the "−" gametes are 7 to 9 μm in diameter; the "+" gametes are 4 to 5 μm in diameter, with a very long longitudinal flagellum (12)) (1). Gamete fusion has been observed to take place via at least two mechanisms. In one mode, the gametes align so that horizontal groove (cingulum) of one cell is perpendicular to the cingulum of the other, with the longitudinal groove (sulcus) of the cells in direct contact. In the second mode, a conjugation tube forms between the two gametes and the protoplast of the (+) gamete moves through it to fuse with the (−) gamete. The resulting sexual product or motile planozygote (diameter 14–60 μm) is triflagellate, with one transverse and two longitudinal flagella (1,11). Planozygotes are usually ephemeral, lasting only for hours before producing four zoospores, if in cultures with fish; or under some conditions with algal prey. Alternatively, each forms a resistant, nonmotile, thick-walled sexual cyst (hypnozygote; Fig. 4; 1,26).

Amoebae in *Pfiesteria* spp. may be produced by zoospores, gametes, planozygotes, or cysts, resulting in considerable size variation (length ca. 5–120 μm for cultures recently isolated from estuarine habitat; Figs. 4,5) (1,5,11). They may be filose, lobose, or rhizopodial (the latter observed thus far in *P. piscicida*), with a smooth or rough outer covering (1,4,5,11). Amoebae are mostly produced in actively toxic, fish-killing cultures,

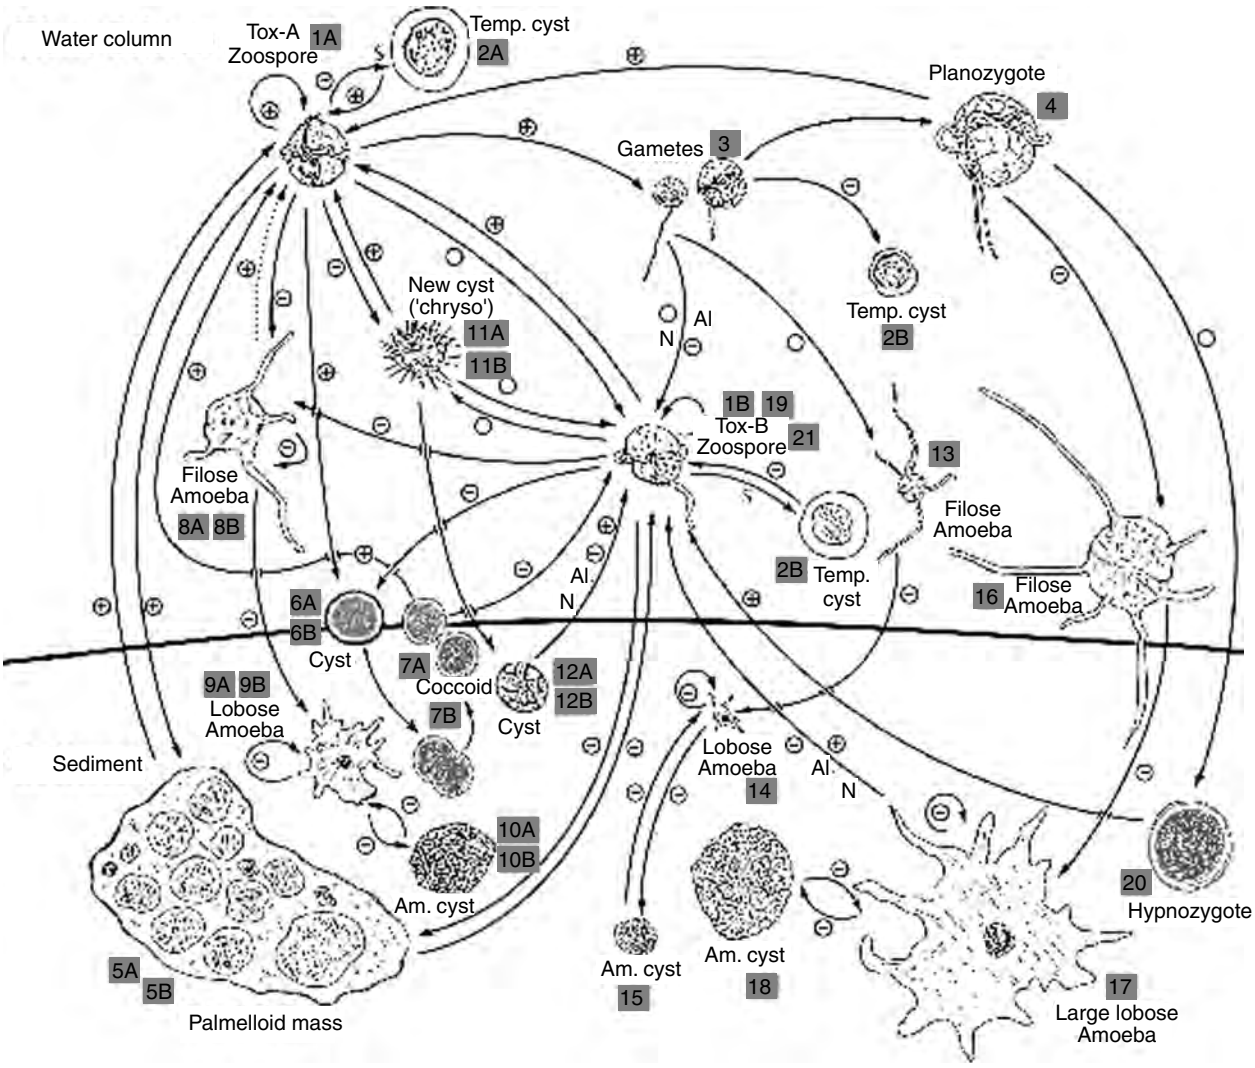

Figure 4. The complex life cycle of *Pfiesteria* showing stages and pathways that have been verified for both *P. shumwayae* and *P. piscicida* (note that *P. piscicida* has been under study for a longer period, and several additional stages and pathways have been determined for that species as well (14)). The pathways indicate the presence (+) versus the absence (−) of live finfish; A = presence of cryptomonads and certain other algal prey; N = nutrient enrichment as organic and/or inorganic N and P; S = environmental stressor such as sudden shift in temperature or salinity, physical disturbance, or prey depletion). Solid lines = verified pathways; dashed lines = hypothesized pathways. TOX-B zoospores (haploid; ploidy confirmed as in (1); temporarily nontoxic functional type in the absence of live fish prey, but capable of producing toxin when sufficient live fish are added (1,7); called nontoxic zoospores or NTZs in the *P. piscicida* schematic (14) are shown as one stage to simplify the schematic, but actually represent at least two stages in the life cycle because they are produced by both stages to which they can directly ("chrysophyte-like ["chryso"] cyst, temporary cyst, palmelloid mass — all haploid stages) or indirectly transform (from coccoid cells excysted from another cyst stage [both haploid] produced by TOX-B zoospores), and by large diploid lobose amoebae. TOX-B zoospores can also be formed from gametes through "reversion" or loss of sexual activity, and, importantly, by TOX-A zoospores (haploid; actively toxic functional type (1,7); called toxic zoospores or TZs in the *P. piscicida* schematic (14)) through cessation of toxin production when sufficient live fish are no longer available. TOX-B zoospores are similar to the larger or "–" anisogamous gametes (shown here) or to isogamous gametes (also possible in both *Pfiesteria* spp.) in appearance, although their size can vary fourfold depending on feeding activity. Zoospores can produce haploid filose, lobose, and rhizopodial amoebae. Cysts include stages with roughened or reticulate covering (from amoeboid stages, haploid except when derived from diploid amoebae); scaled covering (± bracts; from TOX-A and TOX-B zoospores; these cysts also can lose their scales and bracts over time so that they have a smooth covering (14) [not shown; and transitional forms to these cysts are not shown occur in *P. shumwayae* as in *P. piscicida* (14)), and hyaline covering (small cysts that can divide as in Spero and Morée (22), with darkened contents; and hypnozygote (*Caption Continued*)

although filose amoebae can also be produced by nontoxic cultures (1,4). *Pfiesteria* amoebae produce spherical to oval cysts with a roughened or reticulate outer covering (diameter ca. 4–25 μm) (1,4,5,11).

CULTURING *PFIESTERIA*

Pfiesteria spp. have been cultured with high cell production for sustained periods only by adding a prey source, and it has not been possible to induce strong toxin production unless live fish are added (1,11). *Pfiesteria* must be isolated (i.e., cloned as 1 axenic cell of *P. piscicida* or *P. shumwayae*) from natural estuarine water or sediment samples, and then maintained with prey. Therefore, a clonal culture of *Pfiesteria* is formally defined as consisting of a clonal population of *P. piscicida* or *P. shumwayae*, together with added prey (6). The most commonly used prey are algae, especially cryptomonads (13) and fish (11,12). Algal prey can be used to maintain toxic strains in nontoxic mode for short periods (up to 4–6 weeks is recommended), but live fish must be used to maintain toxic strains in actively toxic mode.

Addition of algal prey such as cryptomonad species (13) to natural estuarine water or sediment samples can support increased growth of dinoflagellate species that acquire nutrition through partial or complete reliance on heterotrophy or animal-like feeding on algae, following published procedures (1,13). Nontoxic strains of *Pfiesteria* spp. (TOX-B or NONIND functional types) can be cultured using this approach, among other dinoflagellates. However, algal assays commonly fail to detect toxic strains of *Pfiesteria* species in natural estuarine phytoplankton samples, whether they are actively toxic when collected or in a temporarily nontoxic mode (1,6). It is also important to note that although TOX-B and NONIND *Pfiesteria* can be grown indefinitely on algal prey, TOX-B strains can rapidly (within weeks) lose their ability to resume toxin production and become NONIND, unless they are periodically reexposed to live fish (1).

Maintenance of actively toxic (TOX-A) *Pfiesteria* cultures, and assessment of *Pfiesteria* involvement in fish kills, is accomplished using the standardized fish bioassay (7,27). The technique, which has been cross-corroborated with extensive quality control/assurance procedures, follows standardized steps while allowing flexibility to simulate the environmental conditions under which estuarine samples yielding the culture isolates were collected (1,7,27). Therefore, it is currently the "gold standard" for culturing actively toxic *Pfiesteria* spp., and also for evaluating their presence in estuarine water and sediments, given that a field-reliable assay for detecting *Pfiesteria* toxin(s) is not yet available (below; 1,7,28). The standardized procedure for this "fish bioassay" follows Henle-Kochs' postulates (29) modified for toxic rather than infectious agents. It has been relied upon since 1991 both to culture TOX-A *Pfiesteria* and to assess its involvement in estuarine fish kills (below) (1,11,12,30).

Actively toxic *Pfiesteria*, grown with live fish, should be held in biohazard III containment systems to protect laboratory workers from neurotoxic aerosols emitted by fish-killing cultures (1,7,11). Separate facilities are required for culture of healthy fish without *Pfiesteria* contamination, and with minimal associated microbial contaminants (11). Environmental conditions conducive for growth of toxic *Pfiesteria* spp. should be imposed (Table 2). Toxic *Pfiesteria* cultures with fish require high maintenance. The medium should remain clear and colorless to pale yellow, rather than clouded and/or discolored from high bacterial/fungal growth. The cultures also require rigorous sampling of environmental conditions and microflora/fauna to ensure that predatory microfauna, which inevitably are associated with fish, do not prevent or significantly reduce *Pfiesteria* cell production (7). Such steps are also necessary to ensure that fish health is not compromised by other factors (below). Even with these efforts, when given live fish consistently, and when cultures are regularly cleaned using serial dilution or other techniques, many toxic strains exposed to live fish have lost their ability to produce toxin and have become NONIND over time in culture. Toxicity can be sustained significantly longer (months to years) when *Pfiesteria* toxic strains are given live fish as opposed to other prey (10). The loss of toxicity in culture has also commonly occurred for various other toxic algal species, and appears to be an artifact of the highly artificial conditions (1). Thus far, techniques for long-term storage of viable cultures such as cryopreservation have not succeeded in maintaining toxin-producing strains (1).

ASSESSMENT OF TOXIC *PFIESTERIA* INVOLVEMENT IN FISH KILLS

Rationale

On the basis of numerous field investigations and laboratory experiments, the Center for Applied Aquatic Ecology at North Carolina State University has developed

Figure 4. (*Continued from previous page*) [diploid "cyst" at lower right]). Zoospores and gametes also form temporary cysts with thick mucus covering, which may settle out of the water column (arrows not shown). The triflagellated planozygote (diploid, from gamete fusion; with two longitudinal flagella and one transverse flagellum) can transform to diploid filose and lobose amoebae (right side of figure). Note that the life cycle stages and pathways shown here have been verified for both *P. piscicida* and *P. shumwayae*. *Pfiesteria piscicida* has been under study for a longer period, so other pathways in addition to those shown here have been determined for that species (14). Several stages in addition to TOX-A zoospores are believed to be toxic in *P. shumwayae* as in *P. piscicida* (14), and testing of these stages is underway. Other stages have been observed for both *P. piscicida* and *P. shumwayae*, but have not been included because of their as-yet-uncertain position in the life cycle.

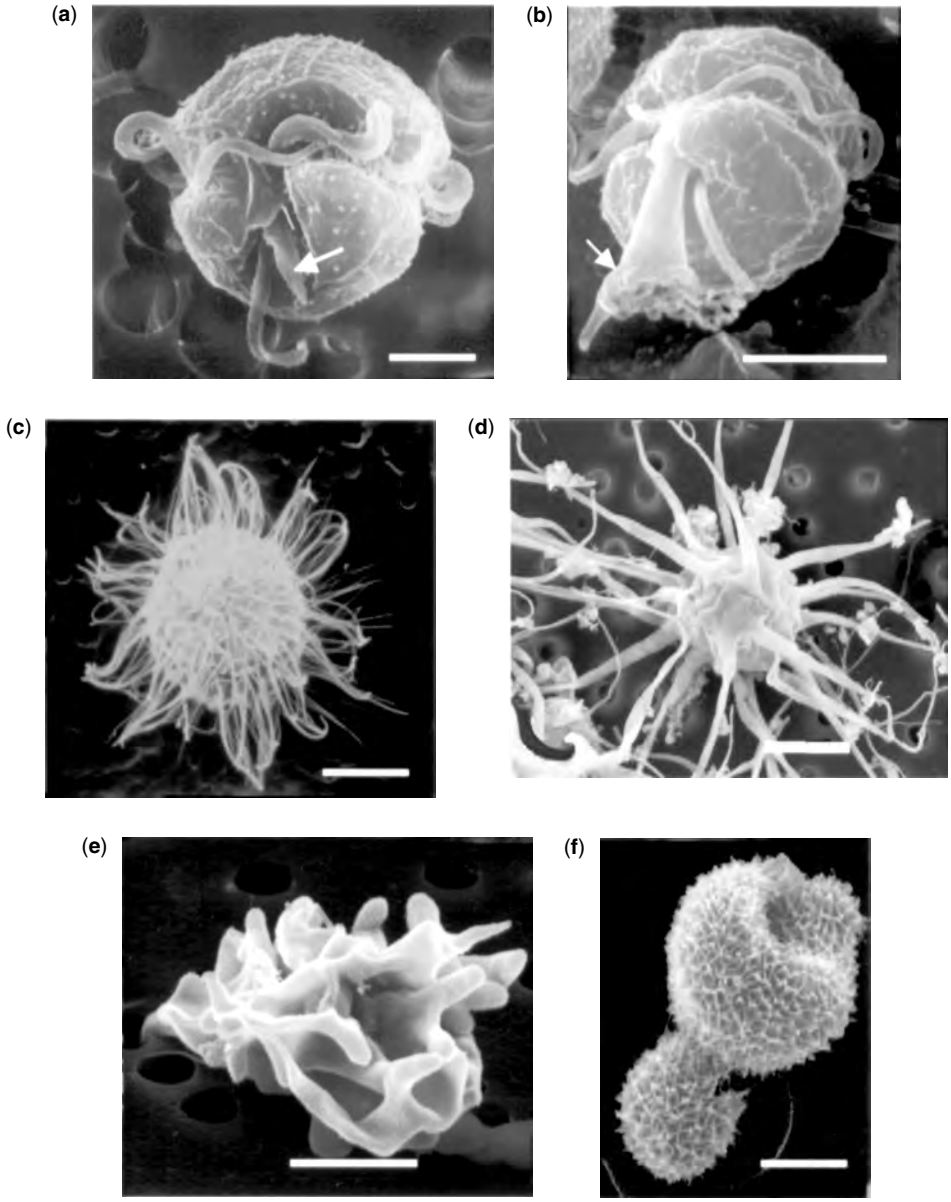

Figure 5. Scanning electron micrographs of *Pfiesteria* including (**a**) a *P. piscicida* actively toxic zoospore (biflagellated vegetative cell, toxic strain, TOX-A functional type), the most toxic stage in the life cycle, with retracted peduncle (arrow; organelle used to attach to and suction the contents from prey cells; scale bar = 3 μm; from 11. J. M. Burkholder and H. B. Glasgow, *Limnol. Oceanogr.* **42**, 1,052–1,075 (1997).); (**b**) a *P. piscicida* nontoxic zoospore (toxic strain, TOX-B functional type) showing the organelle called the peduncle (arrow) fully extended in feeding mode (scale bar = 5 μm; from 10. A. J. Lewitus, H. B. Glasgow and J. M. Burkholder, *J. Phycol.* **35**, 303–312 (1999).); (**c**) a cyst produced from a toxic zoospore (toxic strain, TOX-A functional type) of *P. piscicida* after fish death (scale bar = 3 μm; from J. M. Burkholder et al., *Nature* **358**, 407–410, (1992); J. M. Burkholder et al., *Nature* **360**, 768 (1992).); (**d**) a filose amoeba produced from a zoospore of *P. shumwayae* (scale bar = 20 μm); (**e**) a lobose amoeba of *P. shumwayae* (scale bar = 10 μm); and (**f**) two amoeboid cysts, with roughened or reticulate outer coverings (scale bar = 1 μm; figures d-f from H. B. Glasgow et al., *Phycologia* **40**, 234–245 (2001)).

a conservative protocol for assessing toxic *Pfiesteria* involvement in major fish kills (defined as affecting 1,000 or more fish (1,11)). The protocol depends on the standardized fish bioassay procedure as the presently available "gold standard" to diagnose whether an actively toxic population of *Pfiesteria* was present at a fish kill while the kill was in progress, that is, while fish were moribund but not yet dead (1). An assay to detect *Pfiesteria* toxin(s) would be more desirable because it would enable determination of whether the toxin(s) itself was present, which is the primary concern of public health officials as well as natural resource managers.

Table 2. Conducive Conditions for *Pfiesteria* Zoospore Production, Compiled from Experimental Laboratory and Field Data

Variable	Conducive to Cell Production	Negligible or Slow Cell Production
Temperature	>20-30 °C (>26 °C)	<20 °C, >30 °C
Salinity	>5-20 (10-15)	≤5, ≥20
Light (Quantity, Photoperiod)	0–300 μmol m^{-2} s^{-1}	>300 μmol m^{-2} s^{-1}
Nutrient Regime[b]	≫100 μgN_i,P$_i$ L^{-1}	<100 μgN_i,P$_i$ L^{-1}
pH	6.6-8.6 (>7.5)	<6.6, >8.6
Water Motion	low turbulence	mixed
Acclimation Period (after transport, for cell production, toxic activity)	>3-7 days	≤3-7 days
Algal Prey (zoospores, amoebae)	cryptomonads	cyanobacteria, other picoplankton
Finfish Prey (zoospores)	many species	*Gambusia*

Note: Optima are indicated in parentheses, where known, with ranges indicating data for isolates from different geographic regions.

Such an assay has been developed for use in laboratory research (28,31). However, estuarine waters contain organic substances and other debris that are known to interfere with the assay (28,31), either by obscuring the presence of the toxin so that a "false negative" is reported, or by reacting with the assay reagents to give a "false positive" for the presence of the toxin. Sufficient quantity of purified toxin standard is not yet available to enable use of internal standards with estuarine water samples. Their addition in known quantity to replicate subsamples of the estuarine water sample of interest would enable detection of, and correction for, such interfering substances. Until enough purified toxin standard is produced to make that correction step possible, no laboratory assay for *Pfiesteria* toxin can be regarded as "field-reliable" to determine whether the toxin is present in natural estuarine samples (28,31).

In the meantime, and in recognition of the fact that causality of fish death by microbial pathogens or other factors can be inferred, but usually cannot be proven conclusively in a field setting, assessment of actively toxic *Pfiesteria* involvement follows a conservative approach. This assessment is restricted to in-progress kills in (7,11,30) consideration of the known behavior of *Pfiesteria* spp. These organisms commonly cease toxin production and leave the water column (by settling to the bottom sediment of the estuary, or by forming colorless amoebae that attach to the fish remains) shortly after fish death (1,11). Thus, the appropriate period to sample for actively toxic *Pfiesteria* is while fish are dying. The mere presence of *Pfiesteria* cells after fish death indicates nothing about whether *Pfiesteria* had actually been involved in the kill since, as stated, there are naturally benign as well as toxic *Pfiesteria* strains. Nor can detection techniques (e.g., molecular probes) discern between actively toxic *Pfiesteria* versus populations that were not engaged in toxic activity when collected (1). Even when purified toxin standard becomes available for use in a reliable field assay to detect *Pfiesteria* toxin, efforts probably will have to be restricted to sampling while fish kills are in progress or very shortly thereafter, because the toxin(s) is known to be highly unstable and commonly breaks down quickly (often within several hours) in water and aerosols (1,11,28,31).

In this conservative approach, *Pfiesteria* is ruled out as a primary cause of a major estuarine fish kill if other causative factor(s) can be detected (1,6,7,11). For example, about 90% of the fish in kills related to toxic Pfiesteria have been juvenile Atlantic menhaden (*Brevoortia tyrannus*), which are surface-schooling fish (1,30). In kills of surface-schooling fish, we have implicated low-oxygen stress as the primary cause, even when actively toxic *Pfiesteria* was verified, if anoxia (condition of acutely low dissolved oxygen [D.O.], ca 0 mg/L^{-1}) is present in more than the lower one-third of the water column of the affected area or immediately adjacent areas; or if hypoxia (D.O. < 4 mgL^{-1}) is present in more than the lower one-third of the water column over widespread areas within the kill zone, despite the fact that much of the upper water column would have remained available to provide oxygen-replete habitat (1,11,30). Thus, the protocol is biased in favor of low dissolved oxygen rather than *Pfiesteria* as a primary causative agent in fish kills.

Moreover, assessment of *Pfiesteria* involvement in fish kills is applied to areas with appropriate environmental conditions for toxic *Pfiesteria* activity (1,7,11,32). This range of focus includes in-progress, major estuarine fish kills that occur in quiet, warm, poorly flushed brackish waters (Table 2), especially kills involving large schools of menhaden or similar fish. In addition, waters that have been degraded by nutrient pollution from human sewage, animal wastes, cropland and lawn fertilizer runoff, urban runoff, and atmospheric sources appear to be preferred habitat (1,11,30,32). TPC species have broad temperature (active at 9–33 °C) and salinity tolerance (active at 2–35; active at 0–1 if calcium ion is present at ≥4 mg Ca^{+2} hardness/L (1,11)) (Table 2). Nutrient over-enrichment can stimulate *Pfiesteria* spp. by providing habitat with an abundance of other food resources to sustain these dinoflagellates in a nontoxic mode when fish are not available (below) (1,11,30,32). *Pfiesteria* does not become actively toxic under conditions of high volume of flow or high wave action or sudden decrease in salinity to near-freshwater or freshwater conditions (salinity <0.1 (33));

thus it would not be expected to be involved in fish kills following major storm events such as hurricanes (1,11,32).

The protocol to assess actively toxic *Pfiesteria* in estuaries has been focused on fish kills, rather than on epizootics (fish disease) in the absence of dying fish because the uncertainties inherent in attempting to diagnose the initial cause fish diseases — especially chronic diseases — are so much greater than those confronted in fish kills that often occur in response to an acute, more readily identified stressor that affects the fish in or near the area where they die (1,7). Nevertheless, it is of interest that nearly all *Pfiesteria*-related kills have involved a high percentage of menhaden with ulcerated lesions (referred to as fish kill/disease events (1,7,11,32)). Thus, within the context of appropriate environmental conditions, the occurrence of ulcerated lesions can also be helpful information. Fish lesions cannot be used as an 'absolute' indicator of *Pfiesteria*, since many stressors and microbial pathogens can be involved in chronic lesion development (1,11,32). Use of dying fish as sentinels, especially of dying menhaden with high incidence of disease, is in accord with renowned fish pathologists (29), while recognizing that few population indices (such as the existence of deep, bleeding lesions that are often chronic (34)) are disease-, disorder-, or condition-specific.

Sequence

Given appropriate conditions for toxic *Pfiesteria* activity, the procedure to determine whether it was involved in a major estuarine fish kill considers several points:

1. At least 300 pfiesteria-like zoospores/mL^{-1} must be present ("presumptive count" (7), light microscopy, 600x) where/while fish were dying. The basis is more than 1,000 laboratory experiments that have shown that actively toxic *Pfiesteria* can be lethal to fish at densities $\geq$300 TOX-A zoospores/mL^{-1} (1,11). Note that sampling must be conducted carefully to follow this caveat. In practice, it is difficult to arrive at the scene of a fish kill while fish are still dying but not yet dead, because fish often float just below the water surface when they are moribund and float at the surface only after death. Nevertheless, to implicate toxic *Pfiesteria*, fish kills should not be sampled hours or longer after the fish are all dead. Spatial as well as temporal mismatches between the fish kill and sampling must be avoided. By the time fish are sampled after capture, the boat may have drifted or the tide may have flushed out the water that was associated with the fish contained in, for example, a cast net held over the side. Commonly when *Pfiesteria* is involved in a kill, samples taken in the immediate location of the dying/diseased fish have contained $\geq$300 zoospores/mL^{-1}, but samples taken only about 70 meters from the site have contained little or no *Pfiesteria*. The stipulation that water samples must be sampled while dying/diseased but not yet dead, is highly conservative and probably underestimates toxic *Pfiesteria* activity. For example, water samples collected about 24 hours after fish death could contain about 200 *Pfiesteria* zoospores/mL^{-1}, representing a portion of the population that was actively toxic during the kill but which subsequently switched to other prey that were abundant in the area. Yet, by criterion #1, the kill technically could not be related to toxic *Pfiesteria*. A field-reliable assay for *Pfiesteria* toxin, applicable for use in water samples as well as fish tissue, will enable consideration of events detected and sampled post kill.
2. Active toxicity of *Pfiesteria* cells collected at the in-progress fish kill must be confirmed by standardized fish bioassays (7), wherein these cells are tested in the natural sample, then cloned and retested with fish (1,7,11);
3 Species identifications are made from scanning electron microscopy of suture-swollen (5) or membrane-stripped cells (4); and
4. Both toxicity and species identity are cross-confirmed by independent specialists with demonstrated expertise in dinoflagellate systematics and research with toxic *Pfiesteria* (7).

Standardized Fish Bioassays

The standardized fish bioassay procedure is used to culture actively toxic *Pfiesteria* as stated, and is also of critical importance in diagnosing the presence of toxic strains and their involvement in fish kills within estuaries and aquaculture facilities (1,6,7,11,32). Henle and Koch originally developed a set of standardized steps to assess whether a given infectious organism had caused disease (29). Application of this rigorous set of steps to assess actively toxic *Pfiesteria* involvement in fish kills required modifications because *Pfiesteria* is a toxic agent (note that there is no evidence, as yet, that *Pfiesteria* can act as an infectious organism; Fig. 6) (1,7,11).

In Henle-Kochs' first postulate, the infectious organism of interest must be present in the host (29). In the modification, *Pfiesteria* must be present at a fish kill or during disease, and must be detected in standardized fish bioassays (in association with fish death, and in the absence of other apparent causality) of samples taken where and while fish are dying (Fig. 6). *Pfiesteria* can be lethal to fish at densities $\geq$300 zoospores/mL^{-1} (11); thus, as a rapid screening technique with light microscopy ("presumptive count"), *Pfiesteria* can be eliminated as a potential cause of a fish kill if there were $<$300 pfiesteria-like zoospores/mL^{-1} present where and while fish were dying (1,6,7,11). In Henle-Kochs' second postulate, the infectious organism must be isolated from the host and grown in pure culture (29). In the modification, *Pfiesteria* must be isolated from fish-killing bioassays (1,6,7,11) and grown in clonal culture.

Henle-Kochs' third postulate states that the organism must be injected from pure culture into a healthy host, resulting in infection (disease) in the host (29). In the modification, clonal *Pfiesteria* must be added to healthy fish cultures (in a second set of fish bioassays, essential to confirm toxicity of a *Pfiesteria* isolate) and result in fish deaths (7); this often occurs after the fish develop lesions or hemorrhage, whether the *Pfiesteria* cultures are allowed

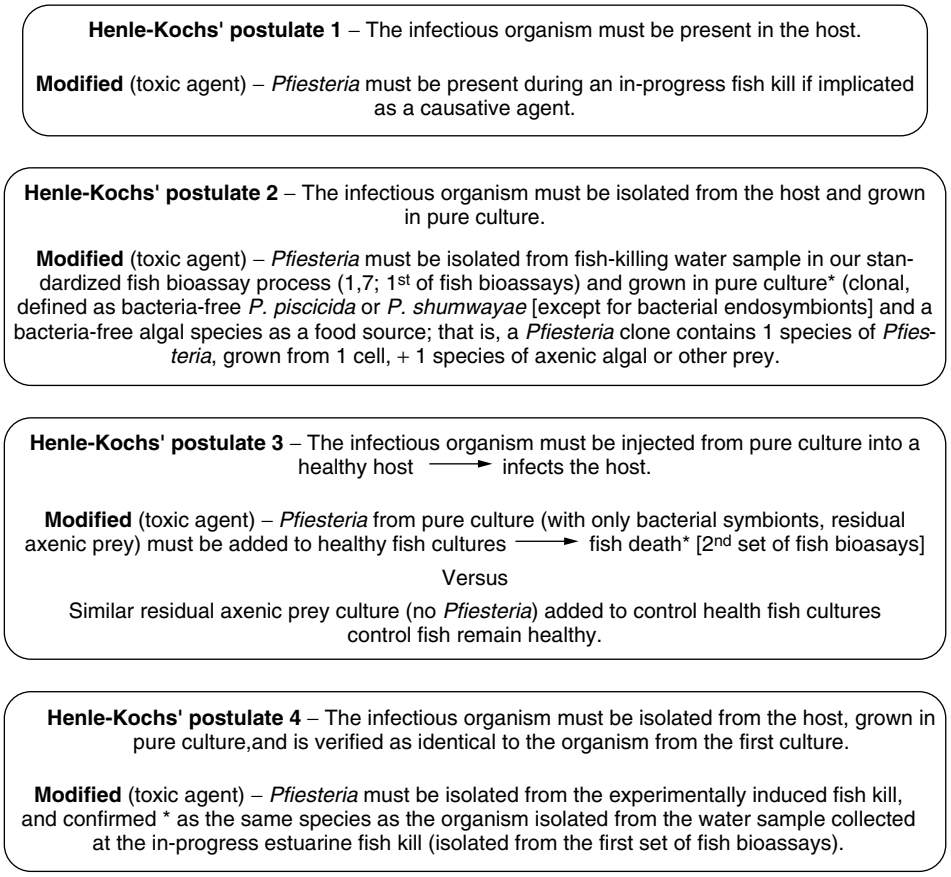

Figure 6. Schematic depicting use of the standardized fish bioassay procedure to diagnose whether actively toxic *Pfiesteria* was involved in a major estuarine fish kill, following Henle-Kochs' postulates modified for toxic rather than infectious agents (7,31). Asterisks (*) indicate the steps at which cross-corroboration should be complex by independent specialists with demonstrated expertise in *Pfiesteria* species identifications and toxicity (1). (From 32. H. B. Glasgow et al., *Environ. Health Perspect.* **109**(Suppl. 5), 715–730 (2001).)

direct contact with the fish, or are maintained within dialysis membranes (0.22 μm porosity) (11). By contrast, control fish remain healthy when residual cryptomonad culture (without *Pfiesteria*) is added (Fig. 6). In Henle-Kochs' fourth and final postulate, the organism must be reisolated from the experimentally infected host, grown in pure culture, and compared with the organism from the original culture (29). Here, *Pfiesteria* must be isolated from the second set of fish-killing bioassays, recloned, and the identification reconfirmed (7).

During the fish bioassay procedure, many environmental variables additionally are measured to compare test versus control fish cultures, to ensure that other causative factor(s) were not involved in fish death (7). Operating parameters are: temperature $\geq$20 °C (recommended); salinity >7; light (no established preference); pH $\geq$6.8–8.5; dissolved oxygen $\geq$5 mg/L (not supersaturated); nitrite $<0.7 mgL^{-1}$; and ammonium $<1 mgL^{-1}$ (7). Other nutrients are also measured. *Pfiesteria* and pfiesteria-like dinoflagellates are identified and enumerated, as well as a suite of other microorganisms, with focus especially on certain bacterial and fungal pathogens of fish, phytoplankton (including other species that can harm fish), and certain protozoans and copepods that can harm fish.

The Critical Importance of Timing

Pfiesteria spp. gradually become actively toxic when they detect live fish, but toxic stages are not attracted to dead fish and transform to nontoxic (TOX-B zoospores, nontoxic amoebae, or cysts) stages shortly after fish death (1,11,23). The biochemical pathways involved in toxic production apparently require time for activation if the population has not recently been in toxic mode, so that a previously inactive (encysted or temporarily nontoxic) population can require days to weeks to become active in producing toxin, whereas a toxic population that killed fish recently (hours) can be lethal to fish within a few hours (7,32).

Thus, *Pfiesteria* species have shown a biochemical and/or genetic predisposition for toxic activity stimulated by recent exposure to live fish (1,11,12), but actively toxic zoospores are highly sensitive to separation from live fish and rapidly encyst (usually within hours). Following such a separation period (<3 days), they typically excyst and resume lethal activity toward newly added test fish within 4 to 9 days (90% confidence interval, n = 20 fish bioassays with 10 fish per replicate; 95% confidence interval at less than 21 days; Fig. 7) (7). Populations that were not previously in actively toxic mode require considerably longer to kill fish in bioassays (typically 6–8 weeks or more) (7). These characteristics about *Pfiesteria* behavior were considered in designing an effective fish bioassay procedure to diagnose actively toxic *Pfiesteria* involvement in estuarine fish kills. Also note that field diagnostics are not available for many microbial pathogens which are considered harmful to aquatic life (7). Samples frequently are incubated to analyze for their presence, but the strains detected usually are not checked to determine whether

they were benign or virulent (7). Somewhat analogously, we "incubate" water samples with live fish to assess whether actively toxic *Pfiesteria* was present at estuarine fish kills (Fig. 7). However, the standardized fish bioassay is used to confirm, for every estuarine fish kill event that has been linked to *Pfiesteria*, that the population was not only present, but also actively toxic during the kill (analogous to a check for "virulence" or infectivity of an infectious agent) (7).

DISTRIBUTION, NUTRITIONAL ECOLOGY, AND PREDATION

Geographic Distribution

The distribution of toxic *Pfiesteria* outbreaks (TOX-A functional type) is restricted, thus far, to the largest and second largest estuaries on the U.S. mainland (Fig. 8; 1). The Albemarle-Pamlico Estuarine System of North Carolina has sustained 4–9 major fish kills (conservatively quantified, involving well over a billion fish) related to *Pfiesteria* as the primary cause (1,32). Several tributaries of Chesapeake Bay in Maryland have also been affected by actively toxic *Pfiesteria* (4 events involving ca. 50,000 fish) (1,2).

Nevertheless, toxic strains of *Pfiesteria* spp. in temporarily nontoxic mode (TOX-B functional type) are much more broadly distributed. Their known range extends from New York estuaries along the Atlantic Coast of the northeastern United States, south and west to Mobile Bay, Alabama on the Gulf Coast (1,11,35). They have also been documented from other geographic regions including the eastern Atlantic (Scandinavia) in the Northern Hemisphere, and New Zealand in the Southern Hemisphere (36). The recent availability of species-specific molecular probes to detect *Pfiesteria* species (17,20) has rapidly expanded the known distribution of these organisms (36). Areas testing positive for the presence of *Pfiesteria* are then tested with standardized fish bioassays to assess the potential for toxic activity of the detected

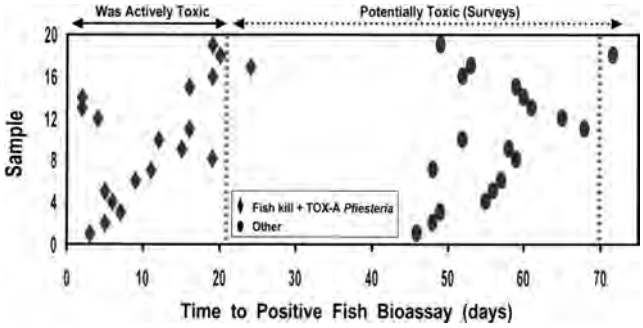

Figure 7. Comparison of the time interval required for positive fish bioassays (with fish-killing activity) for samples collected from estuarine fish kills in which actively toxic *Pfiesteria* spp. (TOX-A functional type) were implicated as primary causative agents (black diamonds; n = 20), versus samples that yielded toxic *Pfiesteria* in fish bioassays of samples taken during survey efforts in estuarine waters without diseased or dying fish (ovals; n = 20) (7). The latter estuarine areas were interpreted to contain potentially toxic populations of TPC species (TOX-B functional type). In all cases, sample transport and other delays extended for 1 to 2 days. Such handling is regarded as especially important for recently toxic populations, for example in efforts to implicate versus rule out involvement of actively toxic *Pfiesteria* from in-progress estuarine fish kills. Note that 19 of the 20 samples from events that were diagnosed as having involved actively toxic *Pfiesteria* tested positive for fish-killing activity within 20 days (longest lag period, 1 sample within 24 days). To err conservatively, we consider that samples appropriately handled (with <3 days' lapse, including transport, following collection during an in-progress fish kill) should produce fish-killing activity within ≤21 days for actively toxic *Pfiesteria* to be implicated as a causative agent involved in the kill. Also note that samples that contained potentially toxic *Pfiesteria* populations which had not been recently in actively toxic mode toward fish did not show fish-killing activity until incubated with live fish for more than 6 weeks; 19 of the 20 samples from that set were ichthyotoxic by 10 weeks, with 1 sample requiring slightly longer. On the basis of well over 1,000 fish bioassays with estuarine samples, thus far we have not obtained toxic isolates of TPC species that have required more than 10.5 weeks to exhibit fish-killing activity, with two exceptions that required more than 12 weeks (7). (From 7. J. M. Burkholder et al., *Environ. Health Perspect.* **109** (Suppl. 5). 745–756 (2001).)

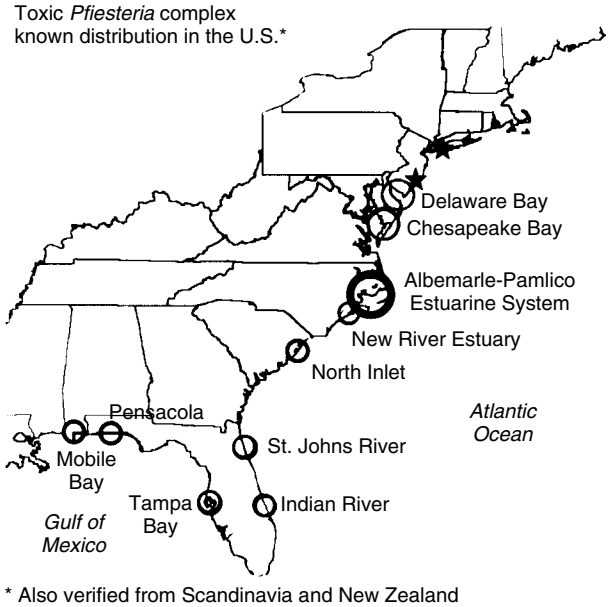

Figure 8. Known distribution of toxic strains of the toxic *Pfiesteria* complex (TPC) in U.S. estuaries. The circles indicate locations where potentially toxic strains (TOX-B functional type) of *Pfiesteria* spp. have been documented through the standardized fish bioassay procedure; and for the Albemarle-Pamlico Estuarine System, Chesapeake Bay, and the New River Estuary, locations where actively toxic *Pfiesteria* spp. have been confirmed during major fish kills, using the same procedure. The stars indicate locations where *Pfiesteria* has been detected using molecular probes (17), but these populations have not yet been tested to include toxic strains (thus, toxicity status is unknown). As indicated, toxic strains of *Pfiesteria* spp. have also been verified from Scandinavia (both species) and New Zealand (*P. shumwayae*). (From 35. H. B. Glasgow et al., in G. M. Hallegraeff et al., eds., *Proceedings of the Ninth Conference on Harmful Algal Blooms*, Intergovernmental Oceanographic Commission of UNESCO, Paris, France.

populations (6,7,11,36). Given that toxic strains of *Pfiesteria* have been confirmed to occur across wide gradients in environmental conditions (36), the data thus far indicate that toxic *Pfiesteria* will likely be found in many geographic regions throughout the world.

Nutritional Ecology

The nutritional ecology of *Pfiesteria* spp. is complex, and nutrient enrichment can stimulate these dinoflagellates through several general mechanisms. Nitrogen (N) and phosphorus (P), two major constituents of nutrient pollution from human activities, have been shown experimentally (as both organic and inorganic forms) to both directly and indirectly stimulate toxic *Pfiesteria* strains (1,11,23). Organic nutrient forms (e.g., glycerophosphate, amino acid mixtures, urea) can be taken up directly by actively toxic as well as nontoxic functional types of *Pfiesteria* zoospores, and by amoebae (1,11). Inorganic nutrient forms (nitrate, phosphate) can be taken up directly by kleptochloroplastidic *Pfiesteria*; or, inorganic nutrients can indirectly stimulate *Pfiesteria,* mediated through abundance of algal prey (1,10,11,23).

Pfiesteria spp. graze algal prey and bacteria, and zoospores have shown preference especially for cryptomonad algae (10,13). When cryptomonads and certain other flagellated algal prey are abundant, zoospores predominate among *Pfiesteria* stages, but if nonmotile prey are abundant (e.g., the cyanobacterium *Synechococcus Cyano the* or the diatom *Thalassiosira*), a higher proportion of the *Pfiesteria* population can consist of amoebae (11). Amoebae also consume cryptomonads and other flagellated algae; commonly in culture, individual lobose amoebae have been observed in the process of capturing up to eight cryptomonads at a time along the cell periphery. Accumulating evidence indicates that *Pfiesteria* thrives in nutrient over-enriched environments that characteristically have abundant food resources (e.g., 10^4–10^5 algal prey mL^{-1}) (1,11,23,32); and that, rather than competing for resources, when preferred prey in the water column begin to be depleted, it switches prey type or moves to the estuarine sediments where alternate prey are in abundance (1,23,32). On the basis of a decade of intensive field studies supported by many laboratory experiments, a conceptual model of the seasonal dynamics of toxic strains of *Pfiesteria* spp. has been constructed to serve as a framework for additional research to strengthen understanding about environmental controls on these dinoflagellates (32).

Pfiesteria spp. zoospores and amoebae can act as predators of macro- and microfauna including rotifers, ciliates, copepods (especially wounded individuals as known for other dinoflagellates such as *Katodinium fungiforme*) (11,13,37); shellfish and finfish (larvae, juveniles, adult stages); and mammalian tissues (e.g., red corpuscles and macrophages) (1,11). Zoospores show swarming activity toward shellfish (e.g., bay scallop *Argopecten irradians*, eastern oyster *Crassostrea virginica*) and finfish larvae (various species) under light microscopy, and appear to show similar attraction toward juveniles and adults (1,11,24). The dominant life cycle stages in the water column with live fish cultures are zoospores, periodically shifting to high gamete production. Under controlled laboratory conditions, TOX-A *Pfiesteria* zoospores have been lethal to all fish species and all individuals tested, including juvenile and/or adult stages of nine estuarine and seven exotic species of finfish, as well as juveniles or adults of four shellfish species (1,11). The only exception has been eastern oysters (24), wherein some adults have survived acute, long-term exposure (weeks; below). Zoospores consume bits of tissue and organic substrates from dying fish, and also attack and feed upon the live animals (1,5,11,13). After fish death, zoospores may remain in the water column if abundant algae and other prey are available; alternatively, if the dead fish are available, zoospores may transform to amoeboid stages that attach to and feed upon the fish remains (11,13,22).

The three functional types of *Pfiesteria* spp. show significant differences in response to nutrient enrichment, algal prey, and fish prey. In experiments with cryptomonad prey, NONIND zoospores attained highest cell production, TOX-A zoospores showed negligible cell production, and TOX-B zoospores were intermediate (38). A similar trend was shown among functional types in response to inorganic nitrogen (nitrate) or inorganic phosphorus (phosphate) enrichment (1). Test of short-term response to fresh fish mucus and excreta, and to shellfish and finfish larvae, usually has yielded the opposite trend, with highest chemosensory attraction shown by TOX-A zoospores of both *Pfiesteria* spp., intermediate response by TOX-B zoospores, and lowest attraction by NONIND zoospores (1,23,39).

Predators of Pfiesteria

Toxic *P. piscicida* zoospores (TOX-A and TOX-B functional types) can be grazed by various microfauna, including ciliates such as *Stylonichia* cf. *putrina*, rotifers (*Brachionus plicatilis* Müller, *Brachionus* sp.), and microcrustacean copepods (*Acartia tonsa* Dana) (11,13,40). Few ill effects on the grazers were apparent in early experiments, except for significant depression of rotifer fecundity after consumption of toxic *P. piscicida* zoospores for more than seven days (11,13,40). Microfauna such as tintinnids (*Tintinnopsis* spp., *Flavella* sp.), ciliates such as *Strombidium* sp. and *Mesodinium pulex*, and the colonial heterotrophic dinoflagellate *Polykrikos* sp. also were shown to graze *Pfiesteria piscicida* zoospores in natural estuarine plankton communities (41). Tintinnids and oligotrichous ciliates generally showed significantly lower grazing on recently TOX-A zoospores than on TOX-B and NONIND zoospores, although some ciliates grazed all three functional types similarly (1,41). Thus far, the data have indicated that although microfaunal grazing may be a significant source of mortality to "nontoxic" (NONIND and TOX-B) zoospores, grazing by these microfauna on toxic or recently toxic zoospores may be relatively low.

Shellfish macrofauna (northern quahog *Mercenaria mercenaria* juveniles; eastern oyster *C. virginica* pediveliger larvae, juveniles, sub-adults and adults; and bay scallop *A. irradians* pediveliger larvae and adults) have been shown experimentally to consume *Pfiesteria* zoospores, with varying consequences. High mortality occurred within minutes to hours for larval and juvenile stages, and for adult bay scallops fed TOX-A zoospores,

with no mortality of control animals that were not exposed to toxic *Pfiesteria* (11,24). In contrast, adult oysters were sometimes narcotized with depressed filtering activity, but were still alive after being fed TOX-A *P. piscicida* zoospores for three weeks (1,11,24). For scallop and oyster pediveliger larvae, mortality appeared to involve both physical and toxin effects. Larvae that had discarded their vela were physically attacked and devoured by the zoospores within minutes (Fig. 9; 24). In other experiments, oyster pediveliger larvae were maintained for 60-min trials with treatments as TOX-A zoospores, TOX-B zoospores, a mix of half TOX-B zoospores and half benign cryptomonad algae, and cryptomonad algae alone (controls) (24). The zoospores and/or cryptomonads were held within dialysis membrane tubing (0.22 μm porosity) to prevent direct contact with the larvae. Within 45 minutes, 100% of the larvae in containers with TOX-A zoospores were dead (n = 5 with 100 larvae per replicate); mortality was intermediate with TOX-B zoospores (ca. 50%) and with the mixture of TOX-B zoospores and cryptomonad algae (ca. 30%); and there was no mortality in the controls (36). These data indicate a toxin effect (24), since there was no direct contact between *Pfiesteria* and the larvae, and since the dialysis membrane would have allowed chemical communication (passage of *Pfiesteria* toxin) (1,11).

Grazing experiments indicated that juvenile oysters filtered significantly more NONIND than TOX-A zoospores over a 24-hour period, with intermediate filtering of TOX-B zoospores (24). Subadult oysters, in contrast, showed comparable filtering of NONIND and TOX-B zoospores, and significantly lower filtering of TOX-A zoospores. The data indicated that TOX-B zoospores retained residual toxicity that was detected by the sensitive larvae, but that the toxicity of that functional type/isolate was too low to affect filtering by the sub-adults (24).

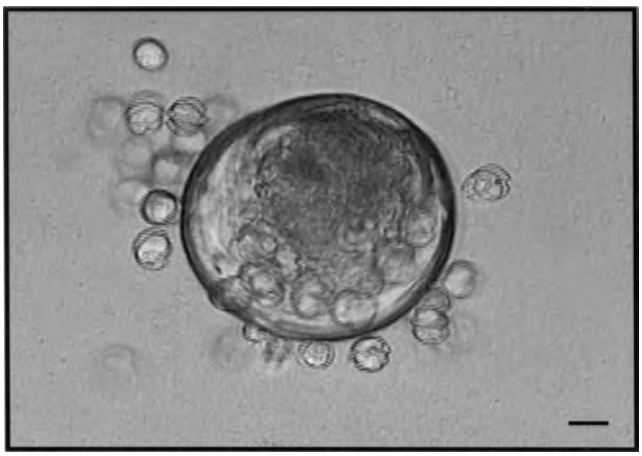

Figure 9. Actively toxic zoospores of *Pfiesteria piscicida* in the process of devouring an oyster pediveliger larva (scale bar = 10 μm). Note that many zoospores are swarming around the larva, and that some had used their peduncles to pry open the larva's shells to gain access to the soft tissues of the still-live organism which were being rapidly consumed. The tissues of this larva were completely consumed by the zoospores within less than 30 minutes, except for the tough adductor muscle which was not attacked. (Photo from 24. J. Springer, *Interactions Between Two Commercially Important Species of Bivalve Molluscs and the Toxic Estuarine Dinoflagellate*, Pfiesteria piscicida, MS Thesis, North Crolina State University, Raleigh, N.C., 2000.)

Given that subadult and adult oysters can remain viable after extended exposure to toxic *Pfiesteria*, the question remained: Is *Pfiesteria* killed and digested as it passes through the oyster gut tract? When feces from the subadult oysters used in the grazing experiment were examined, they were found to contain high numbers of *Pfiesteria* temporary cysts (24). These cysts were isolated and tested for excystment and zoospore motility over the next 24 hours (n = 5, 100 cysts per replicate). Within 20 hours after gut tract passage, about 90% of the previously TOX-A zoospores had excysted and regained motility, with lower (ca. 40-70%) survival by TOX-B and NONIND zoospores (24). These experiments collectively indicate that toxic *Pfiesteria* zoospores could potentially affect recruitment and survival of commercially important shellfish species, whereas adult oysters might be of value in trophic mitigation or control of toxic *Pfiesteria* (24). Shellfish that have consumed *Pfiesteria* zoospores before being transported for aquaculture could provide an important mechanism of dispersing toxic *Pfiesteria* to other geographical regions (24). These data also suggest the potential for certain shellfish species to concentrate viable, toxic *Pfiesteria* strains, supporting concerns about these toxic dinoflagellates in relation to seafood safety (24).

SUBLETHAL AND CHRONIC IMPACTS OF TOXIC *PFIESTERIA* ON FISH AND MAMMALIAN HEALTH

Finfish Disease

In controlled laboratory trials, toxic clonal *Pfiesteria* spp. have caused finfish disease in subacute exposure. Tested species have included juvenile tilapia (*Oreochromis mossambica*, *O. aureus*), striped bass (*Morone saxatilis*), and hybrid striped bass (*Morone saxatilis* x *M. chrysops*) (1). Toxic zoospore densities of ≥100 to 5,400 cells mL^{-1} have induced destruction of fish epithelium and skeletal muscle both as superficial, nonfocal lesions that destroy the osmoregulatory system over most of the fish body (42), and as deep focal lesions that often occur on the ventral surface of the fish where the epithelium is thinnest (Fig. 10; 1). Lesions typically develop within ≤2 to 12 hours, frequently involving hemorrhaging and exposure of viscera (1). The occurrence of lesions and the period required for their development from exposure to toxic *Pfiesteria* depend on the zoospore densities and the specific isolate used (1). Exposure to toxic *Pfiesteria* can also cause damage to finfish gill, hepatopancreas, cornea, kidney, liver, and brain (1,32). Control fish, treated similarly except without exposure to toxic *Pfiesteria*, have remained healthy without signs of disease except for occasional mild granulomas (1,32).

Recovery from sublethal exposure to toxic *Pfiesteria* has been tested by removing fish with mild to moderate lesion development from further exposure to toxic *Pfiesteria*, and tracking their health for six weeks. Control fish, treated similarly except for no prior exposure to toxic *Pfiesteria*, remained healthy without lesions (42). Although the test fish recovered from their earlier lesions, most developed infections from opportunistic bacteria and fungi and about

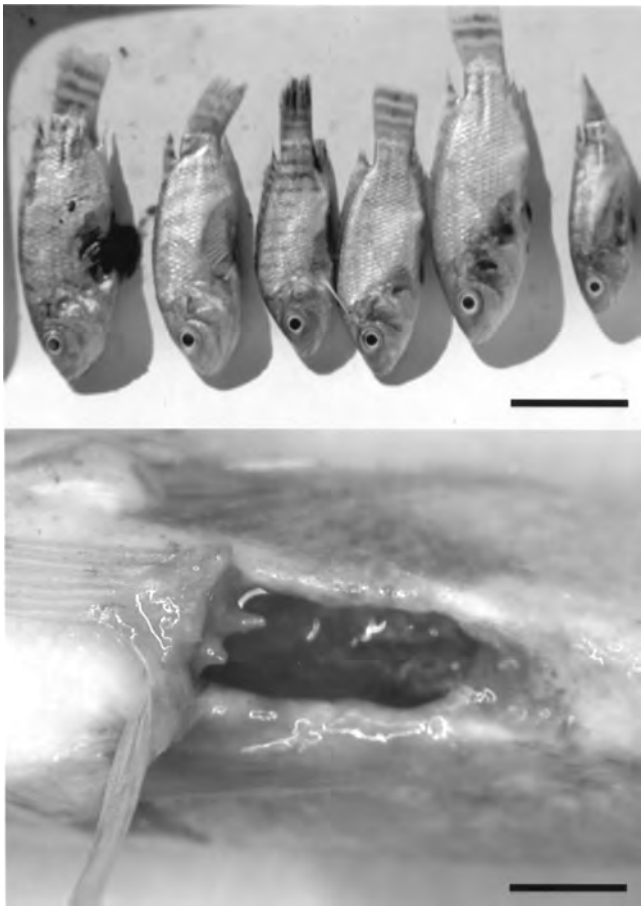

Figure 10. Focal lesion development resulting from exposure of tilapia (*Oreochromis mossambicus*, total length 5–7 cm) to actively toxic, clonal *Pfiesteria piscicida* in controlled laboratory trials, including (upper panel) Tilapia after 8 to 12 hr of exposure to 2.3 to 5.4×10^3 toxic zoospores/ mL (scale bar = 5 cm); and (lower panel) Oblique lateral view showing a deep, bleeding, ulcerated focal lesion posterior to the pectoral fin (scale bar = 1 cm). See color insert.

80% developed bleeding lesions (42). The data suggest that fish given sublethal exposure to toxic *Pfiesteria* may have a compromised immune system as a long-term impact. Experiments are underway to test this premise.

Pfiesteria has been implicated in some ulcerative disease events in juvenile Atlantic menhaden, and probably acts as a primary or secondary stressor in diseases of wild fish, depending on the specific circumstances (1). Two isolates of an *Aphanomyces* fungus (*A. invadans*) have been tested as being capable of acting as primary invaders with high virulence in causing menhaden lesions (43). Limited tests have been run to link cultured menhaden disease to the presence of invasive, highly virulent strains of *A. invadans* and weakly toxic strains of *P. shumwayae* (tested as incapable of causing deep focal lesions) (44). From such limited testing, the fungus has been assessed by some researchers as the primary initiator of menhaden lesions with toxic *Pfiesteria* involvement ruled unlikely or rejected (43,44), despite the fact that the fungus has been commonly described as a secondary opportunistic pathogen or a highly virulent invader, depending upon the strain (34,42). Virulence within a given pathogen species is known to vary widely, from benign to highly invasive (34). It is hypothesized here, instead, that toxic *Pfiestera* can interact (by physical attach and/or toxin effects) with his hind other pathogenic microbes to cause, promote, and/or advance ulcerated lesions and other estuarine fish disease (1,30). Field-reliable assays for purified *Pfiesteria* toxin will greatly advance efforts to clarify the role of *Pfiesteria* in estuarine fish epizootics (1,32).

Mammalian Health Impacts

Laboratory staff sustained respiratory, visual, and neurological impacts when they inhaled aerosols from fish-killing *Pfiesteria* cultures or had contact with culture water. The cultures had consisted of cell densities that were within the range of cell concentrations found at estuarine *Pfiesteria*-related fish kills (14). The most striking symptom was severe cognitive impairment involving learning disabilities, manifested as Alzheimer's-like short-term memory dysfunction, which required days to about three months for recovery to within normal range of function. Other symptoms indicated autonomic and peripheral nervous system dysfunction, asthma-like respiratory problems, skin lesions that did not respond to antibiotics, severe headaches that did not respond to normal treatment, joint and muscle pain, vomiting and stomach cramping, and problems with vision (14). Long-term effects, lasting for years and linked to the same exposures, have included autoimmune system dysfunction and chronic respiratory infections suggestive of immune system suppression. Experimental laboratory research repeatedly documented significantly reduced cognitive function and chronic learning disabilities in rats after they were exposed to toxic *Pfiesteria* culture (filtered, 0.2 μm porosity; or unfiltered) by subcutaneous injection (45).

Little information is available about human health impacts from environmental exposure to actively toxic *Pfiesteria*. In the absence of available purified toxin standard to enable field-reliable assays to detect *Pfiesteria* toxin (below), the most reliable symptom of toxic *Pfiesteria* exposure has been severe cognitive impairment with learning disabilities (14,15). The previously mentioned laboratory staff had recovered to within normal range of cognitive function within approximately three months or less, indicating that people suspected to have sustained environmental exposure to in-progress estuarine fish kills (only kills that were verified to have involved actively toxic *Pfiesteria*) should be evaluated for learning disabilities as soon as possible after exposure. However, thus far there has been only one clinical examination that was conducted shortly (within $\leq$3 weeks) after subjects had been exposed to major estuarine fish kills that were linked to actively toxic *Pfiesteria* (15) (it should be noted that the species identifications were confirmed as *Pfiesteria piscicida* at three of four events, and as *P. piscicida* with subdominant *P. shumwayae* at one event, but cross-corroboration of the identifications by three independent laboratories was not completed until after the clinical study (15) went to press (1)). That study described

"profound learning disabilities" in some subjects who were evaluated in the bottom 2% of the U.S. population in ability to learn or remember (data were normalized for age and education). These people required three to six months to recover to within normal range of learning ability (15).

Other efforts have been conducted to determine whether people sustain health problems after "exposure to estuaries," but in the absence of fish kills verified to have involved actively toxic *Pfiesteria* (46,47). Such efforts, logically, cannot be related to *Pfiesteria*, and would be analogous to an attempt to study burn victims without a fire. As mentioned sufficient purified toxin standard is not yet available to enable field-reliable diagnostic tests to verify whether people have sustained toxin exposure, and to quantify the exposure. Field-reliable assays for purified *Pfiesteria* toxin will greatly advance efforts to clarify the extent to which environmental exposure to actively toxic *Pfiesteria* causes human health impacts in estuaries (1).

Water-Soluble Pfiesteria Toxin

The mass-production of *Pfiesteria* toxin, an expensive undertaking in biohazard III containment systems, has remained severely restricted because the required funding has not been directed to support such efforts of specialists with demonstrated expertise and appropriately sized/equipped facilities (1,7). Despite this restriction, a water-soluble toxin from *Pfiesteria piscicida* has been purified and characterization of its chemical structure is nearly complete (48,49). A reporter gene assay has been developed to detect the toxin, using GH4 mammalian (rat) pituitary cells together with a c-fos-luciferase reporter gene (28,31). The c-fos promoter is ligated to a "reporter" — here, firefly luciferase — which, when activated, can be measured by light emission. The construct is stably expressed in rat pituitary tumor cells, so that the cells behave as a biosensor by generating light when they sense the *Pfiesteria* toxin. At low doses, the reporter gene is induced; at higher doses, a cytotoxic effect causes a decrease in the amount of light generated from the cells. This assay has been used to guide final purification of the toxin (28,48). Once sufficient purified toxin standard is available, the assay will be modified to make it "field-reliable" for use in detecting *Pfiesteria* toxin from estuarine water and fish tissue.

Kimm-Brinson and coworkers (28) presented peer-reviewed, published data on the mode of action of *Pfiesteria* toxin wherein clones from natural estuarine samples were tested in the standardized fish bioassay process and the clonal status, species identification, and ichthyotoxicity of the cultures were cross-corroborated by independent specialists in toxic *Pfiesteria* research. The water-soluble *Pfiesteria* toxin (described as putative because the toxin had not been purified at the time the paper was written) mimics an ATP neurotransmitter, and increases intracellular calcium membrane permeability in GH4C1 rat pituitary cells by a mechanism consistent with activation of $P2X_7$ purinoreceptors (24). $P2X_7$ receptors are mostly located on the surface of immune cells; they are well characterized in activated macrophages in peripheral tissues and microglial cells in the brain, and are key effectors of chronic inflammation (28). Microglial cells are specialized cells that act as the brain's immune system counterpart to macrophages in other organs. Targeting of $P2X_7$ receptors by *Pfiesteria* toxin presents a mechanism that could explain seemingly disparate impacts of toxic *Pfiesteria* exposure, such as lesions and inflammatory responses in finfish (e.g., following tissue damage by *Pfiesteria* cells), and central nervous system dysfunction as well as inflammatory responses such as asthma-like symptoms in humans (14,28).

CONCLUSION

Species of the toxic *Pfiesteria* complex thus far include *P. piscicida* and *P. shumwayae*. These species share morphological and genetic similarities, and have toxic strains that (*1*) show strong attraction to live fish; (*2*) exhibit toxicity that is triggered by live fish or their fresh tissues and excreta; and (*3*) produce toxin(s) that cause fish stress, disease and death under ecologically relevant conditions (the standardized fish bioassay process involves testing live *Pfiesteria* cells at similar densities as those encountered during *Pfiesteria*-related fish kill/disease events). Both *Pfiesteria* species also have a complex life cycle with multiple amoeboid, flagellated, and cyst stages, several of which are ichthyotoxic. TPC species have broad temperature and salinity tolerance. Their prey span the estuarine food web from bacteria to mammalian tissues, and they can be stimulated directly or indirectly by nutrient pollution. Zoospores of toxic strains can be either actively or potentially toxic (TOX-A and TOX-B functional types, respectively). Other naturally occurring populations can be benign (noninducible or NONIND functional type, apparently lacking the ability to produce toxins that cause fish disease or death). The three functional types of *Pfiesteria* spp. zoospores differ significantly in response to algal prey, predators, nutrients, and fish. Moreover, as an apparent artifact of culture conditions, toxic strains generally lose their ability to cause fish death and disease and become NONIND over time in culture. Toxic strains of *Pfiesteria* species have been confirmed from mid-Atlantic and Gulf Coast estuaries in the United States, and from northern Europe and New Zealand, indicating that these toxic dinoflagellates are cosmopolitan in distribution. At low cell densities, toxic strains can be causative agents of acute and/or chronic, diffuse and focal lesions, and of other fish diseases, as demonstrated in appropriately conducted fish bioassays. Respiratory, visual, and neurological impacts have been sustained by people exposed to aerosols from fish-killing *Pfiesteria* cultures, or to water and aerosols during estuarine fish kills associated with toxic *Pfiesteria*. Neurocognitive impacts from exposure to toxic *Pfiesteria* have been replicated experimentally in small mammals. A purified, water-soluble *Pfiesteria* toxin disrupts calcium metabolism in rat pituitary cells and mimics an ATP neurotransmitter that targets $P2X_7$ purinoreceptors found predominantly in fish and humans on microglial cells, the immune system cells that line the brain. Sufficient quantity of purified toxin standard is not

yet available, and is needed to develop field-reliable assays for use in early warning systems, and to resolve the role of toxic *Pfiesteria* in fish disease, seafood contamination, and human health impacts in affected estuaries.

PHOSPHORUS CYCLING IN AQUATIC ENVIRONMENTS: ROLE OF BACTERIA

JAMES W. AMMERMAN
Rutgers University
New Brunswick, New Jersey

Phosphorus is an essential nutrient for life and often the limiting nutrient in aquatic ecosystems, especially freshwater ones. As the most abundant component of the aquatic biota and usually the component with the largest surface area, bacteria have an important role to play in the cycling of phosphorus in aquatic ecosystems, a role that has not always been recognized. They have high cellular phosphorus concentrations and provide an important source of phosphorus-rich particles for grazers. Bacteria also compete with phytoplankton for phosphorus uptake, and they regenerate inorganic phosphate from organic phosphate with enzymes near the cell surface, although this regenerated phosphate is often only available to the bacterial cell itself.

BACKGROUND

Definitions, Abbreviations, and the Aquatic Phosphorus Cycle

Varying definitions and abbreviations of environmental phosphate pools are a significant source of confusion for those new to phosphorus cycling studies. In this article, these will be limited to a few essential categories. Phosphorus (P) refers to any form of the element and may also be called phosphate (although strictly speaking this is the inorganic ion). Dissolved inorganic phosphorus (DIP) is the inorganic component of the dissolved pool; another commonly used term is soluble reactive phosphorus (SRP). DIP includes orthophosphate (P_i) and polyphosphate, composed of various polymers of orthophosphate, is also in this fraction. Dissolved organic phosphorus (DOP) is the organic component of the dissolved fraction; this has also been referred to as soluble nonreactive phosphorus (SNP). DIP and DOP together make up the total dissolved phosphorus (TDP). Particulate phosphorus (PP) may sometimes be separated into organic and inorganic fractions. Unlike the nitrogen cycle, the phosphorus cycle includes neither gaseous components nor oxidation state changes. Most of the transformations are from dissolved to particulate or the reverse, or from inorganic to organic or the reverse. Different phosphorus components dominate in different aquatic environments. In oligotrophic low-nutrient environments such as the open ocean and some lakes, the DOP is dominant. In many turbid rivers, the PP may dominate. Unlike the nitrogen cycle, the phosphorus cycle includes no gaseous components or oxidation state changes. Bacteria refers specifically to heterotrophic bacteria; cyanobacteria are discussed separately. Phytoplankton include all photosynthetic plankton, both eukaryotes and the prokaryotic photosynthetic cyanobacteria.

Figure 1 shows a simplified phosphorus cycle. The dissolved components are outlined in ovals, the particulate components in squares. The abbreviations are defined above. The arrows show the major interactions, although not every pathway is illustrated. For this article, the pathways to and from the bacteria are particularly important. Phosphorus may be sequestered or released by the sediments, depending on the redox state (see following section).

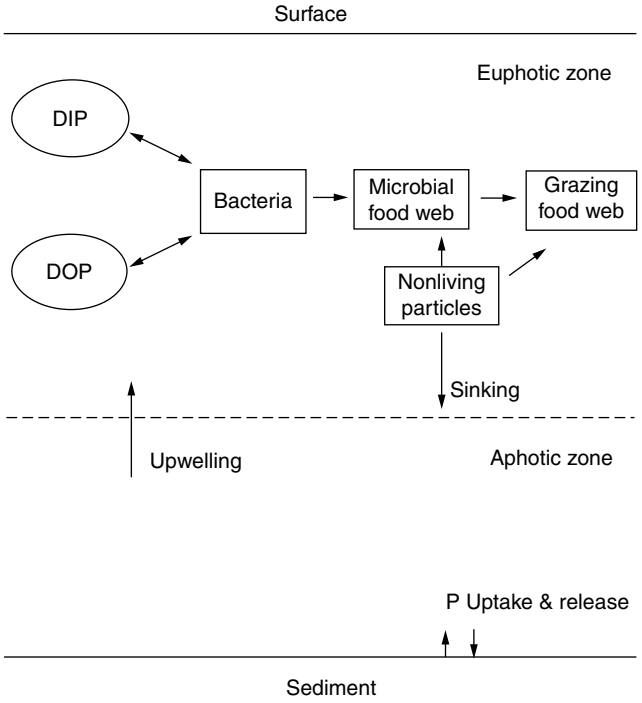

Figure 1. A simplified phosphorus cycle. Dissolved components are outlined in ovals, the particulate components in squares. Arrows indicate the major interactions, although not every pathway is illustrated. DIP is dissolved inorganic phosphorus, DOP is dissolved organic phosphorus, see text for more details. Modified from C. R. Benitez-Nelson, *Earth-Sci. Rev.* **51**, 109–135 (2000).

Pho Regulon of *Escherichia coli*

The molecular model used to describe bacterial transformations and assimilation of phosphorus has been the Pho Regulon of the gram-negative bacterium *E. coli*. This system has been studied for a long time and is the best described. Under P-sufficient conditions, *E. coli* cells use a low-affinity P_i transport system known as the Pit system, which is energized the cell's protonmotive force (2). At submicromolar concentrations this system becomes inefficient, and the Pho Regulon is turned on, as signaled by a rapid induction of alkaline phosphatase (AP) activity. A diagram of the Pho Regulon is shown in Figure 2. The Pho Regulon is a suite of genes that code for proteins that facilitate P-assimilation under low-P conditions, including the high-affinity Pst transport system for P_i. These include (examples only, not comprehensive) outer membrane porins (PhoE), periplasmic enzymes (AP or PhoA) and binding proteins (PstS), membrane-associated transport proteins (PstA, PstC), as well as cytoplasmic proteins with regulatory and other functions (PhoB, PhnO).

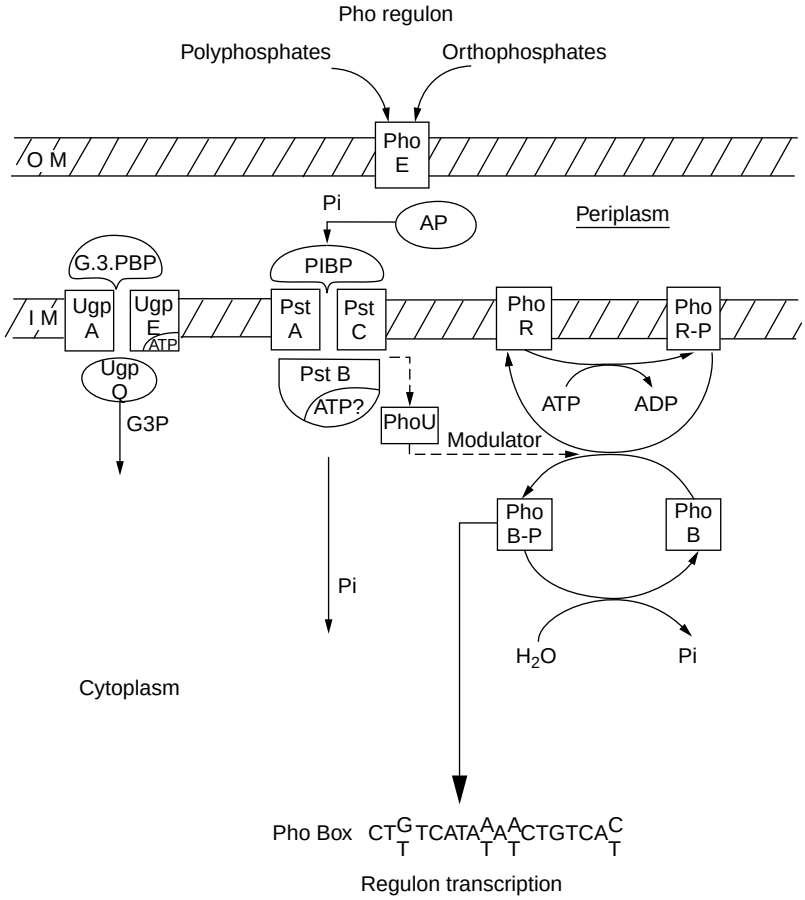

Figure 2. Illustrates the bacterial outer membrane (OM), periplasm, inner membrane (IM), and cytoplasm, working from the top down. The Pho Regulon is a suite of genes that code for proteins that facilitate phosphorus-assimilation under low-phosphorus conditions, including the high-affinity Pst transport system for P_i. Components of the Pst transport system are listed as PstA, PstC, and so on. PhoE is the outer membrane porin and AP is the periplasmic enzyme alkaline phosphatase. Proteins labeled Ugp are part of the transport system for glycerol-3-phosphate. Most of the other Pho proteins are involved in the regulation of the Pho Regulon expression. From A. Torrani-Gorini, in E. Yagil and S. Silver, eds., *Phosphate in Microorganisms: Cellular and molecular biology*, ASM Press, Washington, D.C., 1994, pp. 1–4.

The diagram of the Pho Regulon (Fig. 2) demonstrates that *E. coli* and most other bacteria transport phosphate largely in the inorganic form as orthophosphate (P_i), few organic phosphate compounds are taken up directly, most are hydrolyzed by alkaline phosphatase or other enzymes first. These enzymes remove the P_i group, allowing it and remaining organic component to be assimilated separately. Among the few exceptions to the rule that only P_i is directly transported, *E. coli* has a transport system for glycerol-3-phosphate, the Ugp system shown in Fig. 2, which is also considered a component of the Pho Regulon (2). *Escherichia coli* also has a UhpT system, which exchanges external glucose–6-phosphate for internal P_i (3). Only bacteria that are intracellular parasites, such as *Rickettsia* and others, which live in an environment with high organic phosphate concentrations, seem to gain a large fraction of their required phosphate through transport or exchange organic phosphate compounds (3).

Studies of the marine cyanobacteria *Synechococcus* and *Prochlorococcus*, which are important components of the marine foodweb, have shown that these organisms have a P_i-binding protein, homologous to the PstS gene product in *E. coli*. Expression of this protein was observed in lab cultures of *Synechococcus* when the P_i concentration declined below 50 nM (4). PstS expression by these organisms was also shown in field samples collected to a depth of 100 m at the Bermuda Time-series Study site (5), which is a microbially dominated, oligotrophic open-ocean station 82 km southeast of Bermuda. Others have reported evidence for phosphorus-limitation of heterotrophic bacterial growth at this site (6) where DIP concentrations in the euphotic zone can be as low as 1 to 10 nM (7) when measured with a highly sensitive method (8). Kinetics studies of Pi uptake at the same location show half-saturation constants in the same range (Ammerman, unpublished). The complete genome sequence of the freshwater cyanobacterium, *Synechocystis* sp., also reveals two genes that are highly homologous to the PstS gene in *E. coli* (9), as well as the rest of the Pst transport system. The draft genome sequences of both marine cyanobacteria discussed earlier, *Synechococcus* and *Prochlorococcus*, also clearly show the presence of the complete Pst system. These sequences are currently unpublished but are found on the website of the Institute for Genomic Research (*www.tigr.org*) under microbial genomes in progress.

Vibrio cholerae, the agent of cholera, is the first representative of this commonly isolated genus of heterotrophic marine bacteria to have its genome completely sequenced (10). It apparently has multiple high-affinity Pst phosphate transport systems on its two chromosomes, including two genes homologous to the *E. coli* PstS (10,11). Another component of the Pho Regulon in *V. cholerae* is the Ugp transport system for glycerol-3-phosphate. However, although *V. cholerae* is an enteric bacterium closely related to *E. coli*, it surprisingly has no homolog to PhoA,

the alkaline phosphatase gene. Alkaline phosphatase is an important component of the *E. coli* Pho Regulon and an enzyme activity commonly measured as an indicator of phosphorus limitation in aquatic environments (discussed later). It is apparent that the *E. coli* model of phosphorus assimilation will not be sufficient for all aquatic bacteria, even some of those closely related to it. Fortunately, however, the increasing availability of the genome sequences of aquatic microbial species will allow us to better address these questions.

BACTERIAL P CYCLING IN NATURE

Carbon to Phosphorus Ratios of Bacteria Cells

Bacteria have large phosphorus requirements and a relatively low carbon to phosphorus (C:P) ratio of about 50 (12). Interestingly, this ratio greatly exceeds the C:P ratio of phytoplankton; it is about double the well-established Redfield ratio of 106 : 1 (13). The bacterial C:P ratio in cultured cells is also extremely variable (varying by a factor of 50), much more than the C:N ratio, and reflects the C:P ratio of the growth media (12). The major phosphorus-rich components of bacterial cells are nucleic acids, membrane phospholipids, and sometimes the storage product polyphosphate, whereas protein is the major nitrogen-containing component. The fraction of bacterial biomass devoted to nucleic acids (particularly RNA) and phospholipids varies significantly with growth conditions, growth rate, and cell volume. The cell volume is also inversely related to growth rate. In contrast, the fraction of biomass that is protein, varies little with growth rate. This explains why bacterial C:P is more variable than C:N (12). The small size of heterotrophic bacteria relative to phytoplankton (including cyanobacteria) may also explain why bacteria are phosphorus-rich relative to phytoplankton. In smaller cells, the surface to volume ratio is greatly enhanced, and this means more phosphorus-rich membrane phospholipid (12).

Bacterial Role in Phosphorus Uptake and Regeneration

Phosphorus cycling has long been studied in lakes because of the importance of phosphorus as a limiting nutrient in freshwater environments. There have been fewer studies of phosphorus cycling in marine and estuarine environments because of the focus on nitrogen, not phosphorus, as the limiting nutrient. Most early studies of aquatic phosphorus cycling, at least those in the water column, emphasized the role of phytoplankton, rather than bacteria. Water column studies of phosphorus cycling by phytoplankton through the early 1980s have been extensively reviewed (14,15).

In the past, bacteria in aquatic ecosystems were considered to be important only in phosphorus regeneration, or mineralization of the organic to the inorganic form, followed by release to the environment. Only a few early papers suggested that they might be important in phosphorus uptake, see references in (16). However, since the development of the microbial food web paradigm in the early 1980s (17), many studies have examined the role of aquatic bacteria in phosphorus cycling, including the following reviews (16,18,19). Among other important roles in aquatic food webs, bacteria are very effective competitors with phytoplankton for P_i, as shown more than 15 years ago (20). Heterotrophic bacteria are now known to be responsible for about 60% of the inorganic phosphate uptake in various aquatic ecosystems (19), as determined by the radiolabeled-P_i taken up by the plankton fraction passing through 0.8 or 1.0 μm polycarbonate filter. Some of this uptake may be due to cyanobacteria or other small phytoplankton found in the same size fraction. Studies that were specifically corrected for phytoplankton found a somewhat lower fraction of uptake by the heterotrophic bacteria (19). Phosphorus-limited bacteria and cyanobacteria are also capable of "luxury uptake" of P_i beyond the immediate cellular requirements when additional P_i is provided (5,16).

In addition to competing directly with phytoplankton for uptake of DIP, heterotrophic bacteria can be important in the regeneration of phosphate and other nutrients (12), the role that they have been traditionally assigned. However, in P-limited systems, bacteria are probably not net mineralizers at all, but rather a sink for inorganic phosphorus (16). Any DOP regenerated to DIP by bacteria would be immediately taken up by the same cell. In this scenario, the bacteria would still be an important link in the regeneration process, as a major phosphorus-rich source of particles for grazers (particularly bacterivores) in aquatic ecosystems. Because bacterivory accounts for a large fraction of the bacterial production in many aquatic environments (21), this is an important connection. In non-P-limited systems, however, DIP that has been regenerated from DOP by bacterial "ectoenzyme" activity (discussed later) is made available for other organisms in the food web (22).

Bacteria have high-affinity transport systems, presumably because of the presence of the P_i -binding proteins discussed above. Vadstein (16) reviewed P_i uptake parameters for bacteria from his and other studies. In seven different bacterial strains or communities analyzed, the median half-saturation constant (K_m) for P_i uptake was 90 nM, with a range of 10 to 250 nM. This contributes to their effective competition with phytoplankton for P_i. However, they also have large cellular phosphorus requirements, as discussed earlier (12). Although bacteria are often considered more efficient at P_i uptake than phytoplankton (20), others suggest that this competitive ability varies with a uniform or pulsed nutrient supply (16). None-the-less, phosphorus-limitation of bacterial growth is common during summer stratification in lakes (16), and also occurs in marine systems (6,23,24).

Enzymatic Hydrolysis of DOP

Cell-surface enzymes of aquatic microbes together with "extracellular" enzymes that are dissolved or adsorbed to other than their original particles (25), are important catalysts in the decomposition of dissolved organic matter (DOM) and particulate organic matter (POM). In aquatic science these are sometimes collectively referred to as "ectoenzymes" to distinguish them from other types. Polymer hydrolysis can be the rate-limiting step in microbial DOM and POM utilization (26). Efficient hydrolysis and

utilization of these polymers is important to the rapid microbial growth seen in many aquatic ecosystems (27). In a review, Chrost (28) lists 18 different microbial ectoenzymes whose activities have been measured in natural waters and sediments. A major component of these are phosphatases, such as alkaline phosphatase, enzymes that hydrolyze phosphate groups from organic phosphate compounds (specifically phosphate esters) making the phosphate group available for assimilation.

Other ectoenzymes include those that hydrolyze polymeric carbohydrates or proteins, such as glucosidases and peptidases. Most of these ectoenzymes are found on the cell surface or in the periplasmic space of gram-negative heterotrophic bacteria (29), and appear to be ubiquitous in aquatic isolates (27). Certain ectoenzymes, such as alkaline phosphatase (AP) and leucine aminopeptidase, are also found in some species of cyanobacteria and eukaryotic phytoplankton (30–32). Alkaline phosphatase is typically induced by phosphorus deficiency, and in *E. coli* and some other prokaryotes, this enzyme is part of the Pho regulon discussed earlier. Alkaline phosphatase activity in eukaryotic phytoplankton is also a response to phosphorus-deficiency, as has been known for some time (14,33), however, phosphatase regulation in eukaryotic phytoplankton is not as well understood as in prokaryotes (5).

Marine field studies of phosphatases using high-sensitivity fluorescent substrates date back more than twenty-five years (34). In the last fifteen years there has also been increased interest in many different ectoenzymes in a variety of aquatic environments (28), particularly since the introduction of the fluorescent methylumbelliferyl and related derivatives (35). These derivatives offer the advantages of low background fluorescence and are available as substrates for many different enzymes. There have also been recent improvements in the analysis methods for the fluorescent hydrolysis products, such as the use of flow-injection (36) or of fluorescence microplate readers (37,38). Recently, alkaline phosphate activity has been measured by continuous flow methods aboard ship, allowing its surface distribution to be mapped in detail (39).

Alkaline phosphatase activity is easier to interpret than many other ectoenzyme activities, because it usually is a response to phosphorus-deficiency. Many of the early AP studies, mostly in phytoplankton, have been extensively reviewed (14,15). Although there is often a positive relationship between AP activity and biomass, it is probably not the controlling factor, as suggested by some (40). Very high AP activities were found in three different estuarine and coastal ecosystems only when DIP concentrations were less than 200 nM (18). Criteria for P-limitation based on AP activity normalized to chlorophyll *a* have been developed for freshwater, although not widely applied (41,42). The use of this or similar biomass-corrected criteria should eliminate the concern the AP activity is dominated by biomass effects.

Nonetheless, "alkaline phosphatase" activity, as commonly measured in the field, is a mix of different enzyme activities from different organisms that can hydrolyze the substrate, which is usually a fluorescent or chromogenic analog of natural substrates. These different enzymes probably also have different kinetic properties. Aggregate kinetic properties for AP activities measured in the field, typically range from 1 to 10 μM for the half-saturation (K_m), and 0.1 to 1.0 $\mu mol\, l^{-1}\, h^{-1}$ for the maximum activity (V_{max}) (38,39). Activity is also found in different size fractions, including phytoplankton greater than 2 μm, bacteria and cyanobacteria less than 2 μm (often referred to as "picoplankton"), and sometimes a "dissolved" fraction less than 2 μm. In a recent example from the oligotrophic Red Sea (42), most of the AP activity was associated with *Synechococcus* or dissolved. In contrast, in the eutrophic Mississippi River plume, about half of the AP activity is in the size fraction greater than 10 μm (Ammerman, unpublished). The function of dissolved activity is difficult to understand, but occurs regularly enough such that methodological or functional explanations are needed.

Clearly, new approaches are needed to better understand the sources of AP activity and its regulation. As discussed earlier, the genome sequence for *V. cholerae* does not even have a gene homologous to the *E. coli PhoA* gene for alkaline phosphatase, although we assume that most aquatic bacteria have this enzyme. An example of a novel approach to these issues is the use of the fluorescent ELF substrate to label the alkaline phosphatase of phosphate-stressed dinoflagellate, Prorocentrum minimum, in the lab and the field (43,44). ELF (Enzyme-Labeled Fluorescence; Molecular Probes, Eugene, Oregon) is an enzyme substrate that forms an insoluble precipitate at the site of the activity.

Another periplasmic ectoenzyme involved in phosphorus cycling, that has also been measured in aquatic ecosystems is 5′-nucleotidase, which is specific for 5′-nucleotides (45–48). This enzyme is involved in nucleotide and nucleoside salvage and metabolism, and is sometimes included in the Pho Regulon (2). However, at least in aquatic systems it apparently responds more to the demand for carbon rather than phosphorus (18), and is largely independent of the DIP concentration. Although it can regenerate significant amounts of DIP from nucleotides, its primary function may be to remove the Pi group from nucleotides, allowing further metabolism of the remaining nucleoside (18). Although apparently a prokaryotic enzyme, there is at least one report of 5′-nucleotidase activity in a eukaryotic phytoplankter (49). Both the *V. cholerae* and *Synechocystis* sp. genome sequences contain multiple proteins homologous to the 5′-nucleotidase gene (UshA) in *E. coli* (11).

Figure 3 shows the major steps in the breakdown of DOP polymers and monomers into P_i and an organic carbon moiety. Nucleases first hydrolyze nucleic acid polymers to monomers. AP and 5′-nucleotidase enzymes then hydrolyze these DOP monomers and those from other sources, including nucleotides and phosphate esters. Other unstudied enzymes may also be involved. The resulting P_i group and carbon moiety may then be taken up by separate transport systems in the same cell, or released to the environment in which they may be exploited by other cells. The fate of these groups apparently depends on the current nutritional status of the cell in terms of phosphorus and organic carbon.

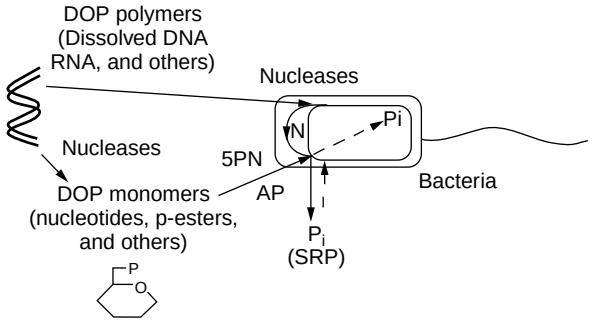

Figure 3. Diagrams the function of the bacterial ectoenzymes alkaline phosphatase (AP) and 5′-nucleotidase (5PN) in the hydrolysis of dissolved organic phosphorus (DOP). Other abbreviations include orthophosphate (Pi) and soluble reactive phosphorus (SRP). The "N" shows the path of a nucleotide after its production by nuclease and before hydrolysis by 5PN. From (47).

Sediments

Detailed discussion of bacterial phosphorus cycling in sediments is beyond the scope of this chapter, although a current review of the marine phosphorus cycle including the sedimentary component is available (1). Although most organic phosphorus that reaches the sediment is released into the water column, a small fraction is buried as organic matter, or through precipitation or other processes, including phosphorite burial in marine systems (1). If the deep water and surface sediment becomes anoxic, some of this sedimentary phosphorus may be released, a seasonal occurrence well known in the Chesapeake Bay and some other estuaries (50). Bacterial involvement is suspected in some of the processes that take up and release phosphorus from sediments, including phosphorite formation (1,51), but more study is needed.

CONCLUSION

The importance of bacteria to phosphorus cycling should be clear from the foregoing. Bacteria compete with phytoplankton for phosphorus uptake, hydrolyze organic phosphate compounds with ectoenzymes, and provide phosphorus-rich particles for grazers. Although there are many questions remaining to be answered, novel approaches are providing new opportunities for progress. The ongoing revolution in microbial genomics will allow us to describe the molecular mechanisms of phosphorus transformation and assimilation by aquatic bacteria. New enzyme substrates such as ELF (44), discussed above, and continuous enzyme assays (39), will improve the specificity and utility of enzyme data. New chemical and bioassay methods for P_i and other forms of phosphorus are pushing the detection limits and in situ concentrations ever lower, down to the nanomolar and picomolar levels (8,52). These are just a few examples of some of the exciting new developments in the field.

Various topics closely related to this subject have also recently been reviewed and the reader may want to consult them for further information. These include a general review of marine phosphorus cycling (1) and a review of marine DOP, including its properties and transformation processes (40). Also, there is a new monograph on marine microbial ecology (53), and a review of bacterial phosphorus cycling in lakes from a quantitative and modeling perspective (16). Finally, there is a review of the application of molecular methods to the assessment of P-limitation in marine bacteria and phytoplankton (5).

PHOTOSYNTHETIC PIGMENTS IN MARINE ALGAE AND BACTERIA

Giacomo DiTullio
Mark E. Geesey
University of Charleston
Charleston, South Carolina

Photosynthetic organisms have evolved a diversity of chemically distinct Chlorophylls (Chls) and bacteriochlorophylls (BChls). In most marine photoautotrophs, Chl *a* represents the major light-harvesting pigment and no plant without it is known to be able to trap light energy for photosynthesis. Recently, a new class of photoactive protein pigment compounds (rhodopsin family) has been discovered in marine bacteria, which may represent the basis of a new phototrophic pathway (1,2). It is not known at this time, however, whether rhodopsin-containing marine bacteria can fix CO_2.

Light-harvesting antenna pigments may also include Chl *b* and Chl *c* type pigments. Other types of Chl molecules observed in marine algae are more obscure (e.g., Chl *d* in Rhodophyta; (3)). In addition to Chls, photosynthetic organisms have evolved two main types of nonchlorophyllous pigments: carotenoids and phycobilins. Xanthophylls (the oxygenated derivatives of carotenoids) are present in all marine algae and have been used to chemotaxonomically identify major algal classes present in oceanic waters (4,5). Various xanthophylls can serve either a photoprotective function (e.g., diatoxanthin, zeaxanthin) or a light-harvesting function (e.g., fucoxanthin). Phycobiliproteins occur as the main light-harvesting pigments in cyanobacteria and some eukaryotic algae (Cryptophyta and Rhodophyta). They are important in harvesting energy in the low Chl-absorbing region of the spectrum and transferring this energy to

Chl *a* in the reaction center (6). This article describes the structure, general function, biochemistry, and ecology of marine bacterial and algal pigments.

BIOCHEMISTRY OF PIGMENTS IN ALGAE AND BACTERIA

Photochemistry of Pigments

When a pigment molecule in the ground state absorbs a photon of light, an electron in the molecule is excited to a higher energy level, by an amount equal to the energy contained in the photon. Multiple excited states are possible corresponding to the range of energy contained in photons, that the pigment can absorb. Pigment molecules can remain in an upper excited state for only a very short period before the electron loses energy, as heat, falling to the lowest excited state. This thermal relaxation from higher excited states is very rapid, occurring in less than 10^{-11} seconds, while the return to ground state is a slower decay process (10^{-8} to 10^{-10} sec). Therefore, the resulting energy state of the molecule is the same regardless of the energy contained in the absorbed photon (7). The amount of energy available for further photochemical processes is the same whether the molecule absorbed a photon of blue light or a photon of red light.

A pigment in the lowest excited state releases energy, thereby returning to ground state, in one of these three ways: thermal loss, fluorescence, or inductive resonant transfer to another molecule. Thermal loss is the slowest of these three processes, occurring in about 10^{-8} seconds for Chl. Fluorescence, the emission of a photon, is also a slow process (10^{-8} to 10^{-9} sec). Chl has a characteristically deep-red fluorescence, especially when illuminated with ultraviolet or blue light, which is the basis behind fluorometric determination of pigments. Fluorescence is prominent from intact cells exposed to intense light (in vivo fluorescence), overwhelming the faster resonant transfer of energy to other molecules; and also in solutions of Chl extracted in an organic solvent (e.g., 90% acetone) where resonant interactions are not possible. The fastest mode of return to the ground state (10^{-10} to 10^{-11} sec) is by inductive resonant transfer of the energy to another molecule. For this to occur, the two molecules must have an overlap in their resonant frequencies and be in a highly ordered arrangement. These ordered arrangements between pigments occur within the protein matrix of the light-harvesting complex and allow for the highly efficient (98%) transfer of light energy from the accessory pigments to the reaction center Chl for use in photosynthetic chemistry (8).

Chlorophylls

The basic structure of the Chls is a magnesium-containing porphyrin ring (Fig. 1). The variations in the composition of side groups attached to specific carbon members of the ring determine the different varieties of Chls (Table 1). A major difference among Chls is the presence of a long hydrocarbon chain attached to C7. The three varieties of Chl *c* and Mg DVP (see Table 2 for pigment name abbreviations used in this chapter) do not have this chain, making them much more polar than the other

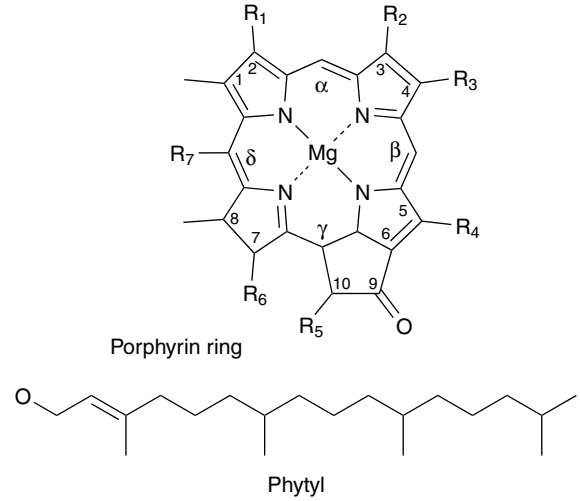

Figure 1. Basic porphyrin ring and Phytyl chain structures of Chlorophyll. Numbering system follows the Fischer system. Refer to Table 1 for the composition of each R-group.

Chls. Most Chls have the phytyl chain ($C_{20}H_{39}$), while BChls *a*, *c*, *d*, and *e* have a farnesyl chain ($C_{15}H_{25}$). These chains make them very nonpolar compounds. These chemical differences are manifested in the differing absorption spectra (Fig. 2a,b; Table 2). BChl *a* has two strong absorption peaks: one in the near ultraviolet between 300 and 400 nm and another in the infrared between 700 and 800 nm. By contrast, Chls *a*, *b*, and *c* have peak absorption bands in the blue (430–450 nm), the Soret band, and in the red (630–670 nm). About 50 chemically distinct and photosynthetically active Chls are known (9). All Chls absorb light poorly in the green part of the spectrum (480–550 nm). When extracted from cells into organic solvents Chls fluoresce strongly to release the light energy absorbed. The fluorescence spectrum is also indicative of the compound. Chl *a* has an excitation maximum at 430 nm and an emission maximum at 668 nm when dissolved in acetone.

The first step, of more than 25 reactions, in the biosynthesis of Chls begins with succinic acid, glycine, Coenzyme A, and the enzyme amino levulinic acid (ALA) synthetase to produce the precursor molecule ALA: 5-aminolevulinate ($NH_2CH_2COCH_2CH_2COOH$) (7). A full review of the biosynthesis of Chls can be found in Porra and coworkers (33). The next sequence of reactions produces protoporphyrin IX, a molecule containing the basic porphyrin ring structure common to all Chls. Insertion of an iron atom in the central ring creates the basic heme structure, the prosthetic structure of many enzymes including the cytochromes, which are important elements in the electron transport chain. Insertion of a magnesium atom into protoporphyrin IX, followed by four further steps, produces Mg DVP. This pigment has two names in common use in the scientific literature. Under the older Fischer nomenclature, the full name is Mg-2,4-divinyl phaeoporphyrin a_5 monomethyl ester. Under the newer IUPAC nomenclature the full name is Mg-3,8-divinyl phytoporphyrin-13^2-methylcarboxylate. Some authors have mistakenly combined these names.

Table 1. Comparison of Chemical Structures of Side Groups for the Various Chls in Algae and Bacteria

Pigment	R_1	R_2	R_3	R_4	R_5	R_6	R_7	Note
Chl *a*	$CH{=}CH_2$	CH_3	CH_2CH_3	CH_3	$COOCH_3$	CH_2CH_2COO-phytyl	H	
DV Chl *a*	$CH{=}CH_2$	CH_3	$CH{=}CH_2$	CH_3	$COOCH_3$	CH_2CH_2COO-phytyl	H	
Chl *b*	$CH{=}CH_2$	CHO	CH_2CH_3	CH_3	$COOCH_3$	CH_2CH_2COO-phytyl	H	
DV Chl *b*	$CH{=}CH_2$	CHO	$CH{=}CH_2$	CH_3	$COOCH_3$	CH_2CH_2COO-phytyl	H	
Chl c_1	$CH{=}CH_2$	CH_3	CH_2CH_3	CH_3	$COOCH_3$	$CH{=}CHCOOH$	H	1
Chl c_2	$CH{=}CH_2$	CH_3	$CH{=}CH_2$	CH_3	$COOCH_3$	$CH{=}CHCOOH$	H	1
Chl c_3	$CH{=}CH_2$	$COOCH_3$	$CH{=}CH_2$	CH_3	$COOCH_3$	$CH{=}CHCOOH$	H	1
Mg DVP	$CH{=}CH_2$	CH_3	$CH{=}CH_2$	CH_3	$COOCH_3$	CH_2CH_2COOH	H	1
Chl *d*	CHO	CH_3	CH_2CH_3	CH_3	$COOCH_3$	CH_2CH_2COO-phytyl	H	
BChl *a*	$COCH_3$	CH_3	CH_2CH_3	CH_3	$COOCH_3$	CH_2CH_2COO-farnesyl	H	2,3
BChl *b*	$COCH_3$	CH_3	$=CHCH_3$	CH_3	$COOCH_3$	CH_2CH_2COO-phytyl	H	2
BChl *c*	$CHOHCH_3$	CH_3	CH_2CH_3	CH_2CH_3	H	CH_2CH_2COO-farnesyl	CH_3	
BChl *d*	$CHOHCH_3$	CH_3	CH_2CH_3	CH_2CH_3	H	CH_2CH_2COO-farnesyl	H	
BChl *e*	$CHOHCH_3$	CHO	CH_2CH_3	CH_2CH_3	H	CH_2CH_2COO-farnesyl CH_3		

Notes: 1. For Chl *c* and MgDVP the $C_7{-}C_8$ bond is a double bond. 2. For BChl *a* and BChl *b* the $C_3{-}C_4$ bond is a single bond (10). 3. Various forms of BChl *a* have the phytyl, farnesyl, or geranyl-geranyl chain at R_6 (10,11). Refer to Figure 1 for the numbering system used to identify the carbon numbers and bonds. See Table 2 for pigment name abbreviations.

Two more chemical steps involving NADPH and light result in Chlorophyllide a (Chl-ide *a*), which is modified by the addition of the C_{20} phytyl chain (geranylgeraniol) to produce Chl *a*. Chl *b* is produced from Chl *a* by an oxygenase reaction on the methyl group attached to C #3, followed by a dehydrogenase reaction. BChl *a* is produced from Chl *a* via an oxygenase reaction on the ethyl group attached to C #2, and BChl *b* is derived from BChl *a*. The various Chl *c* compounds are produced by the modification of Mg DVP.

A Chl molecule resides in the photosynthetic reaction center at the beginning of the electron transport chain in all photosynthetic organisms, and is the final recipient of light energy transferred from the accessory pigments. The reaction center Chl absorbs light energy to attain an excited state. Upon transfer of an excited electron to the first electron receptor of the electron transport chain (Phtin *a*), Chl *a* oxidizes an electron donor to replace the lost electron. The green and purple sulfur bacteria use H_2S or other reduced sulfur compounds as the electron donor, with the resulting production of elemental sulfur. The nonsulfur bacteria can use a variety of organic compounds (e.g., succinate), H_2, or sulfides as the reductant. All other photoautotrophs use water as the electron donor with the resulting formation of molecular oxygen.

When associated with the reaction center apoproteins, the wavelength of maximum absorption shifts from the absorption measured while extracted in an organic solvent. This wavelength is used to identify the reaction center (e.g., P870, P700, or P680). Only three of the Chls listed in Table 1 actually reside in the photosynthetic reaction center. In the photosynthetic bacteria the reaction center Chl is BChl *a*. Purple bacteria (Rhodospirillaceae and Chromatiaceae) have only one photosystem (P870), which delivers electrons into a cyclical electron transport system (7). In a cyclic electron transport system there is no net oxidation of electron donors or reduction of acceptors, but a proton gradient across the membrane is still produced, which is used to synthesize ATP, and the electrons eventually return to P870 via cytochrome *c*. Green sulfur bacteria (Chlorobiaceae) have a noncyclic electron transport chain in which electrons from the oxidation of sulfide pass through cytochrome *c* and are excited within P840 by light to pass into the electron transport chain. Other photosynthetic prokaryotes and all photosynthetic eukaryotes contain two photosystems for the absorption of light energy and the excitation of electrons. Oxidation of water and the production of molecular oxygen occur in photosystem II (PS II), containing P680. Electrons excited by PS II pass into the first part of the electron transport chain containing plastoquinone, cytochrome *f*, and plastocyanin. Photosystem I (PS I) accepts electrons from plastocyanin, contains P700, and absorbs light energy to excite this electron for transport into the final part of the electron transport chain containing iron-sulfur proteins (ferredoxin). In prochlorophytes, the reaction center Chl is DVChl *a*, and in cyanobacteria and all eukaryotic algae the reaction center Chl is Chl *a*. Other Chls serve as accessory pigments to collect light energy and transfer the energy to the reaction center via resonant interaction.

Chlorophyll Degradation Products

Chls and carotenoids can degrade through a variety of processes both in natural and in laboratory settings. Numerous algae contain enzymes, which degrade Chl within cells. For this reason, 100% acetone (and not 90%) is recommended as an extractant to prevent the activity of the chloropyllase enzyme from degrading Chl *a* to Chl-ide *a* (34). Grazing processes (cell breakage and digestion of compounds) can degrade Chls and carotenoids in some specific ways (35,36). Recent evidence suggests that Chls are intrinsically more labile than carotenoids under protozoan grazing pressure (37). In addition, size appears to be an important determinant of carotenoid break down efficiency as it was observed that small protozoans ($<25\mu m$) degraded carotenoids with greater efficiency than did larger ($>80\mu m$) protozoans (37). During laboratory analyses, the actions of light, heat, and oxygen can degrade Chls into various breakdown products, such

as the 10-hydroxy lactone derivatives (38). For this reason pigment extractions and analyses are typically done under subdued light and at cold temperatures.

The primary categories of Chl degradation products are phaeophytins, chlorophyllides, phaeophorbides, and cyclic phaeophorbides. Ph-tins are created by the removal of the magnesium atom from the center of the porphyrin ring. In laboratory settings, this is accomplished by a simple acidification of the extract solution. Cleaving off the phytyl chain while leaving the remainder of the molecule intact creates Chl-ides. Ph-ides are created by a combination of these actions; removing both the Mg atom and the phytyl chain. Examples of typical Chl breakdown products are depicted in Figure 3.

A new class of degradation compounds (cyclic phaeophorbides) was recently discovered in marine sediments (39). It is believed that these compounds are formed via cyclization of either pyrophaeophorbide *a* or pyrophaeophytin *a* (39). High concentrations of the Chl *a* breakdown compound, CPP516, a cyclic phaeophorbide (40) were also detected in fecal matter collected in sediment traps in the Eastern Equatorial Pacific Ocean (41).

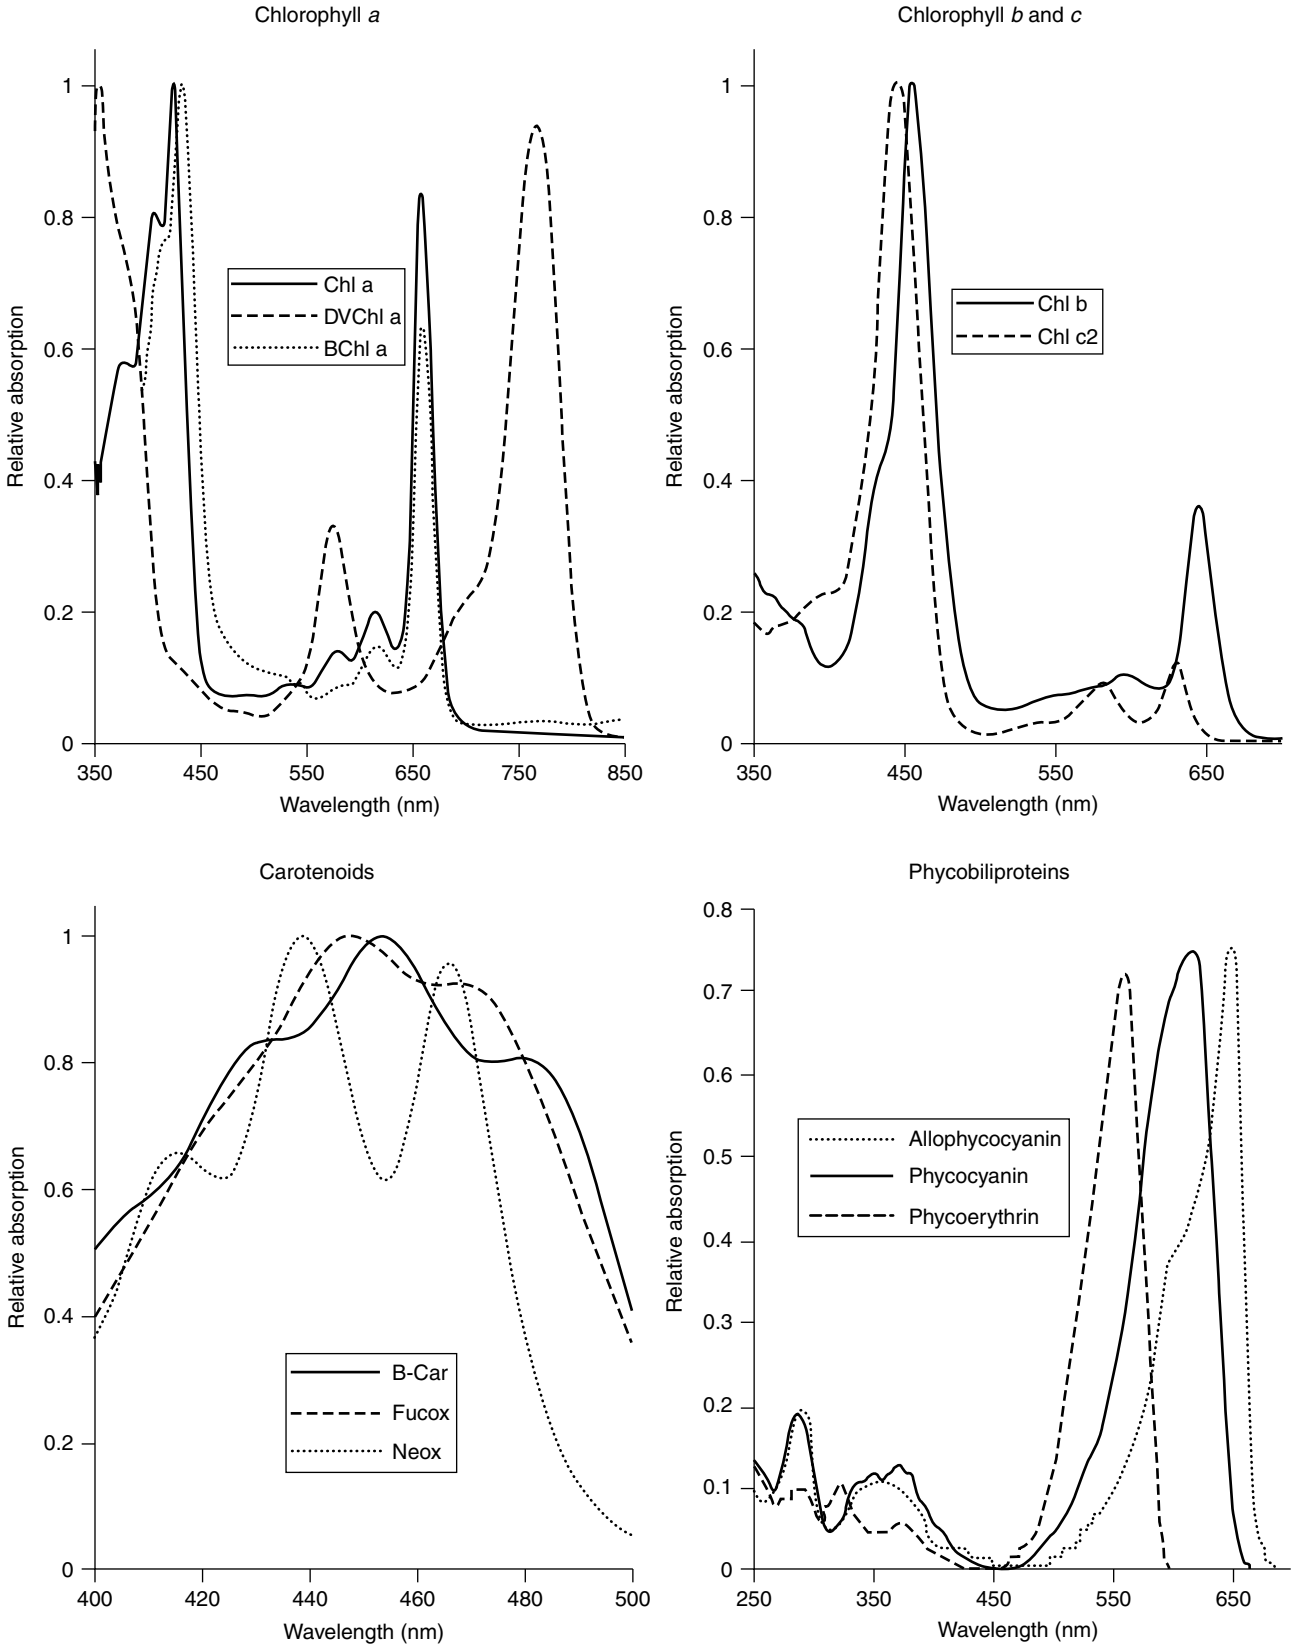

Figure 2. Absorption spectra of some representative (**a**) chlorophylls *a*, (**b**) chlorophyll *b* and *c*, (**c**) carotenoids, and (**d**) phycobilins. BChl *a* is from *Rhodopseudomonas sphaeroides*.

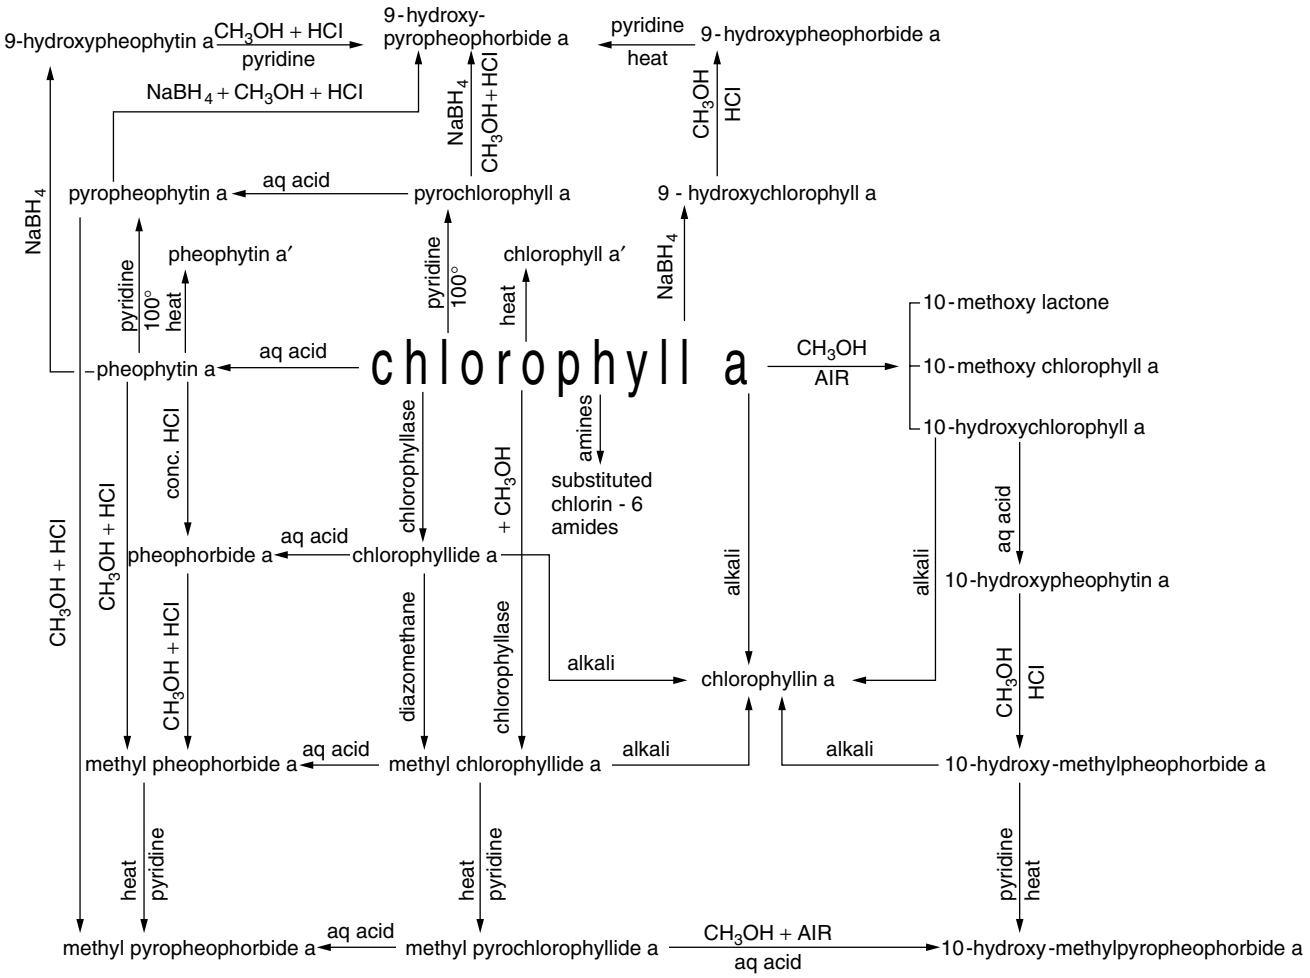

Figure 3. Pathways for the formation of chlorophyll degradation products (From Rowan, 1989).

The presence of cyclic phaeophorbides in fecal matter suggests that anaerobic sediment processes are not the only source of these compounds; macrozooplankton grazing process in the marine water column may also be a significant source of these cyclic phaeophorbide compounds (41). In one study of marine sediments, cyclic phaeophorbides contributed up to 70% of all Chl *a* degradation compounds (41). Further studies are warranted to determine the prevalence and abundance of these compounds in other marine environments.

Carotenoids

Carotenoids are present in bacteria and algae in a wide variety of forms. They are usually red, brown, yellow, or orange in color and have absorption peaks in the blue part of the spectrum (400–500 nm) (Fig. 2c; Table 2). Chemically, carotenoids have the basic structure of lycopene (Fig. 4) and are classified as hydrocarbons (the carotenes) or oxygenated derivatives (the xanthophylls) (8). While more than 600 carotenoids have been identified, the de novo synthesis occurs only in prokaryotes, fungi, algae, and higher plants. Carotenoids found in animals are the chemically modified products following ingestion (19). All carotenoids are derived from the basic structure of lycopene by any combination of the processes of hydrogenation, dehydrogenation, cyclization, or oxidation.

Photosynthetic bacteria synthesize a wide variety of carotenoids. The basic synthetic pathway is a sequence leading to the final product of spirilloxanthin (42) with variations of the biosynthetic pathway from intermediate compounds leading to other carotenoids. Five groups of carotenoids have been identified in photosynthetic bacteria (43,44); but, except for the green sulfur bacteria (Chlorobiaceae), there is little correlation between carotenoid composition and taxonomic categorization based on morphological aspects. Group 1 consists of the "normal" spirilloxanthin series of carotenoids produced by purple bacteria (Chromatiaceae and Rhodospirillaceae). In the case of the brown nonsulfur bacteria (Rhodospirillaceae), the final product is an earlier member of the series such as lycopene or rhodopene. Some facultatively aerobic purple nonsulfur bacteria make Group 2 carotenoids by a divergence of the "normal" synthetic pathway from the intermediate compound neurosporene. Under aerobic conditions these carotenoids are converted to the corresponding keto-carotenoids. Group 3 carotenoids are keto-carotenoids produced by anaerobic purple sulfur bacteria, the main carotenoid being okenone. Group

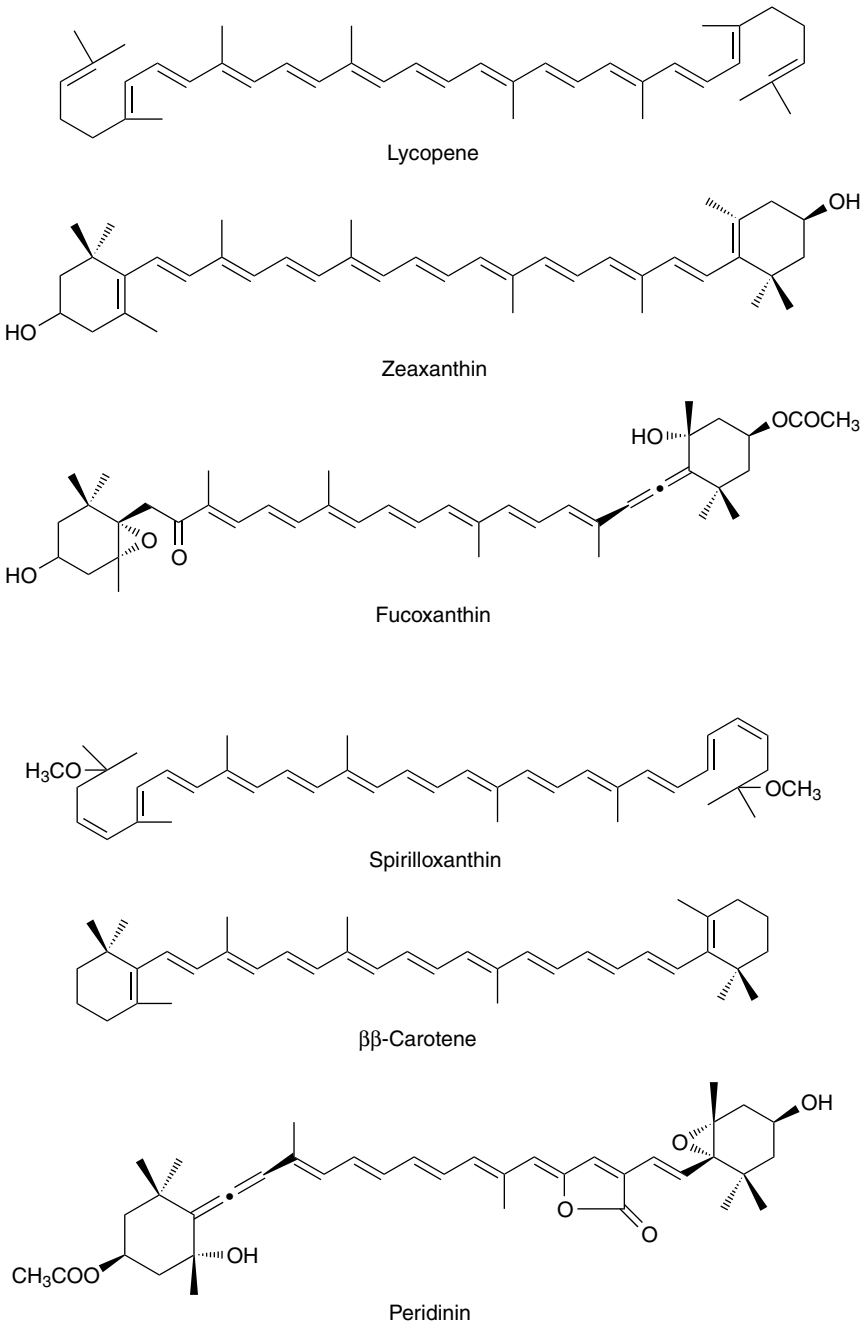

Figure 4. Chemical structures of some representative cartenoids.

4 carotenoids are produced by all purple sulfur bacteria and belong to the Warmingone-series, aliphatic carotenoids, which do not contain methoxyl groups. Rhodopene may be a precursor of these carotenoids. Group 5 carotenoids, chlorobactene and its hydroxy derivatives, are the major carotenoids in the green sulfur bacteria (Chlorobiaceae).

Algae contain more than 30 major ecologically relevant carotenoids (45). The biosynthesis of carotenes in algae is mediated by membrane-bound enzymes in the chloroplast (46). Whether the entire biosynthesis, from carbon fixation, through the production of acetyl-CoA and the subsequent production of *iso*pentenyl disphosphate, to the final carotenoid, occurs in the chloroplast is still in doubt. Some experimental evidence suggests that *iso*pentenyl disphosphate is formed in the cytoplasm and subsequently transported into the chloroplast for carotenoid synthesis (46). The enzymes for the desaturation of phytoene to create lycopene have been shown to reside primarily on the thylakoid membranes within the chloroplast (47). The epoxidation reactions converting Zeax to Viol also occur on the thylakoid membranes (48,49). Britton (50) reviewed the major biosynthetic pathways for carotenoid biosynthesis in algae. The xanthophylls Zeax and Lutein are formed by the enzymatically mediated hydroxylation of β-Car and α-Car, respectively (33).

The majority of carotenoids are noncovalently bound and highly ordered within the pigment-protein light

harvesting complex outside the photosynthetic reaction center. The pigments in this complex absorb light energy, often at wavelengths, that Chl cannot efficiently absorb, producing an excited state of the carotenoid (33). The transfer of energy to the reaction center Chl occurs by a resonant transfer of the energy from the excited state of one pigment to the ground state of another, requiring a spectral overlap between the pigments. Since the excited state of the carotenoids is extremely short-lived, highly ordered arrangements of the pigments are required within the protein matrix of the light harvesting complex. The pigments in the light harvesting complex consist of other Chls, carotenoids, or phycobiliproteins. It is the composition of this pool of pigments, that varies between taxonomic groups and can be used to identify groups of algae present in a mixed algal community.

Certain carotenoids do not act as accessory pigments to provide light energy for the reaction center Chl *a* molecule. Membrane-bound protein-carotenoid complexes found in cyanobacteria and prochlorophytes may play a role in ion-uptake processes (51). In eukaryotic algae, carotenoids are also involved in phototropic responses or as photoprotective agents in high-light environments to absorb and dissipate excess photons entering the cell (52,53). These carotenoids can exist free in the cellular cytoplasm, bound to protein complexes separate from the light harvesting complex, or bound as part of the light harvesting complex (33). In high-light conditions excited singlet state oxygen ($^1O_2$), a highly damaging molecule, can form from an energy transfer from excited state Chl. Carotenoids can reduce the formation of $^1O_2$ by quenching the excited state Chl or by directly deactivating $^1O_2$. After accepting the energy from the excited state molecule, carotenoids can dissipate the energy and return to ground state (33).

Xanthophyll Cycling

Protection against photoinhibition can also be achieved by the epoxidation/de-epoxidation reactions of xanthophyll cycling (54). In the dark-adapted state the xanthophylls exist in the epoxide form. In the presence of light and two H atoms, oxygen is removed to form the de-epoxide form and water. In phaeophytes, chlorophytes, and higher plants Viol is de-epoxidized to Anth, which is further de-epoxidized to Zeax (55). In chromophytic algae Diad is de-epoxidized to Diat in the light. The de-epoxidase enzyme has a pH optimum of about 5 (25) and is active in vivo only at low pH (<5.8) (56). Under high-light conditions the production of extra protons by photosynthesis could trigger the de-epoxidation reaction (25). Experimental results confirm that irradiance levels change the amount of Diad, as Diad is de-epoxidized to Diat (57). In addition, light intensity will affect the Diad + Diat pool size with larger Diad + Diat/Chl *a* pool sizes observed at higher irradiances (58). In nonchromophytic algae such as marine cyanobacteria, Zeax may serve a photoprotective function under conditions of high-light (59). Xanthophyll cycling, however, has not been documented in species of cyanobacteria, prochlorophytes, cryptophytes, or rhodophytes (60).

Phycobiliproteins

Phycobiliproteins are water-soluble photosynthetic antenna pigments found in cyanobacteria, rhodophytes, and cryptophytes (Fig. 5). These brilliantly colored (phycocyanins are blue and phycoerythrins are red) pigments were named after the organisms in which they were initially found. For instance, R-phycoerythrin (R-PE) and R-phycocyanin (R-PC) were first found in rhodophytes and C-PE and C-PC were first observed in cyanobacteria (61). The rationale for these designations is tenuous. For instance, C-PC occurs in both cyanobacteria and rhodophytes, but this nomenclature has persisted because the names relate to pigments with unique spectral characteristics. Most analytical determinations of oceanic phycobiliprotein concentrations have used either flow cytometric (62) or fluorescence spectrophotometric techniques (63), some of which utilize the in vivo glycerol decoupling method (64).

Phycobiliproteins harvest solar energy in regions where low chl *a* absorption occurs (500–650 nm) and function to transfer this energy directly to the reaction center Chl *a* molecule (Fig. 6). In addition, these pigments may also serve as cellular nitrogen storage compounds (65,66), although this function is somewhat controversial (67). Phycobilins are open-chained tetrapyrrole chromophores that are covalently attached to the biliproteins; the structure would be approximately similar to a Chl molecule that had lost its magnesium atom, been clipped, and been linearized (Fig. 5). There are five major phycobilin types, each with a unique spectral absorption curve (Fig. 2); phycocyanobilin (PCB), phycoerythrobilin (PEB), phycourobilin (PUB), phycobiliviolin (PXB), and cryptoviolin (CV). A few other minor phycobilin compounds have also been identified (68). In contrast to the Chl molecules, the phycobilins contain no metal ions.

Phycoerythrins carry one or two chromophore types; PEB and/or PUB. Some marine cyanobacteria species (e.g., WH 7803) have high ratios (ca. 4) of PEB:PUB (63,69)

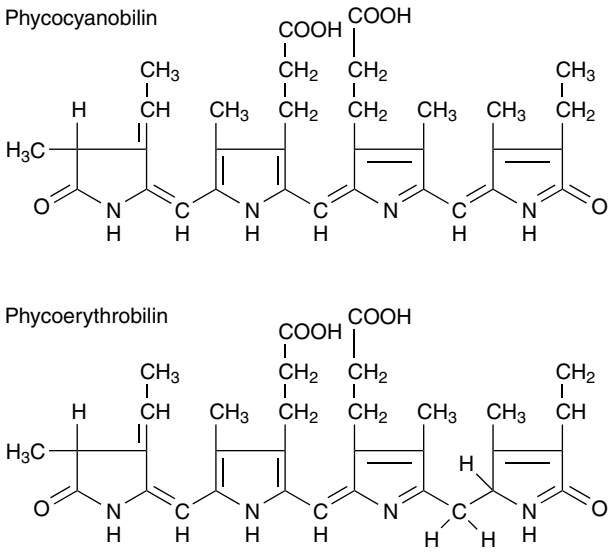

Figure 5. Chemical structures of some representative phycobilins.

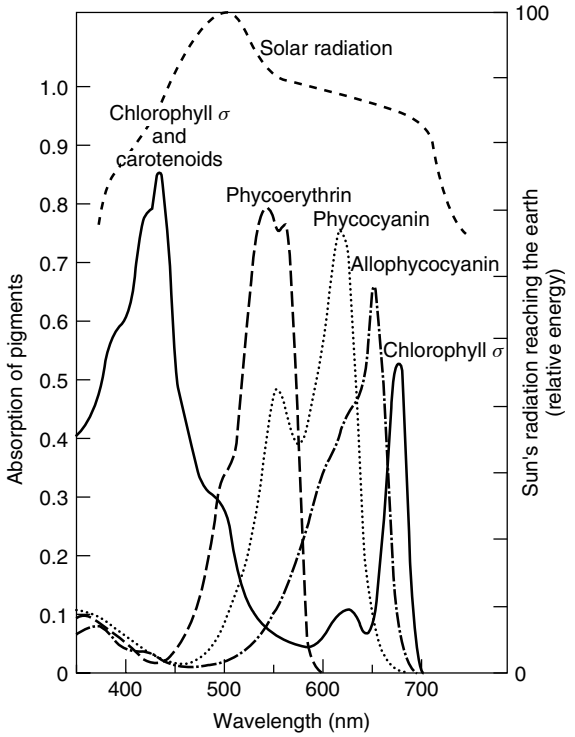

Figure 6. Absorption spectra of pigments and phycobiliproteins (From Gantt, 1990).

while other oceanic strains of *Synechococcus* spp. (e.g., WH 8103) have higher quantities of PUB with PEB:PUB ratios that are less than 1 (70). Both immunofluorescence techniques (71) and flow cytometric data (62) have revealed that oceanic *Synechococcus* spp. have very low ratios of PEB:PUB. Distinct PE spectral signatures were noted in oceanic and coastal species of *Synechococcus* in the Gulf of Maine and the North Atlantic Ocean (63). Open ocean species of *Synechococcus* in the North Atlantic were characterized as having a Type I PE spectral signature (fluorescence emission value of 555–565 nm) composed of both PEB and PUB (63). In contrast, the coastal *Synechococcus* had a Type II PE signature composed solely of PEB (determined from the 570 to 580 nm emission fluorescence). In the tropical and subtropical Pacific Ocean, PEB:PUB ratios of 0.50 to 0.67 were observed in *Synechococcus* dominated waters (72). A high PEB containing species was also observed in the Equatorial Pacific Ocean suggesting that PE compounds in oceanic waters may be more diverse than currently believed (72).

The idea that PE is only found in marine cyanobacteria, cryptophytes, and rhodophytes is no longer valid. A recent finding indicated that some marine dinoflagellate species (*Dinophysis* spp.) contained a unique PEB with a spectral signature, including a 545-nm maximum absorption peak (73). There was no evidence that endosymbionts were present and responsible for this spectral signature. It was also recently observed that the α- and β-subunits of PE were present in the genome of some species of marine *Prochlorococcus marinus* (74–76). The presence of PE is apparently associated with low-light acclimated strains of *P. marinus*, which reside at the bottom of the photic zone (76).

The biosynthesis of phycobilins follows the same pathway as Chls and BChls and branches off at the Protoporphyrin IX point. Ferrochelatase (protoheme ferrolyase, EC 4.99.1.1) catalyzes the last step of protoheme formation; the insertion of Fe^{+2} into protoporphyrin IX (68). Phycobilins are synthesized from protoheme via the synthesis of the intermediate compound, Biliverdin IXα (68). Heme oxygenase (EC 1.14.99.3) is the enzyme responsible for catalyzing the opening of the heme macrocycle to form biliverdin (68). Virtually all of the experimental work on phycobilin biosynthesis has been done using the rhodophyte *Cyanidium caldarium*.

Phycobilisomes

The phycobilisome is a supramolecular subcellular complex, which appears as tiny balls attached to the stromal side of the thylakoid membrane. The phycobilisome consists of chromophores, which are covalently bound to the apoprotein (via a thioether linkage) forming the phycobiliprotein unit. These proteins represent approximately 85% of the total protein in phycobilisomes. The phycobiliproteins are bound together by colorless linker polypeptides, which function to bind and stabilize the phycobiliproteins (77). The linker polypeptides are basic (with a pI of 6.0 to 8.5), whereas the phycobiliproteins are more acidic (with a pI of 4.3 to 6.3) (78). Phycobilisomes are either hemi-discoidal or hemi-ellipsoidal in shape (78). Most phycobilisomes are of the hemi-discoidal type (78) although, some are as broad as they are high (77). The actual size and shape of the phycobilisome is species dependent (79). Phycobilisomes are composed of two main structural elements; peripheral rods, and a core substructure (Fig. 7). The rods are entirely made up of phycoerythrin and phycocyanin. The core region consists of allophycocyanin (APC) perpendicularly attached to the terminal pigment, which transfers light energy from the phycobilisome to the photosystem II reaction center Chl *a* molecule.

The transfer of energy occurs via the anchor polypeptides progressively from the high-energy (500 nm) absorbing PE at the periphery to PC (620 nm) to APC (650 nm) and finally to the Chl *a* antenna in the PS II reaction center (Fig. 6) (also known as the terminal pigment). The energy transfer from the phycobilisomes to Chl *a* occurs rapidly,

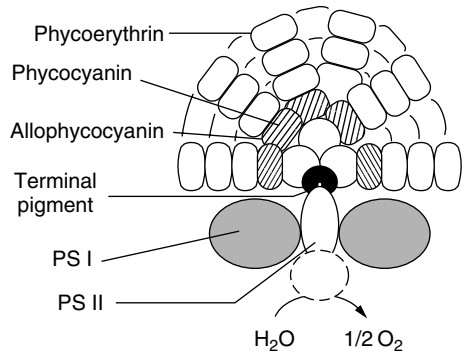

Figure 7. Arrangement of phycobilins, pigments, and photosystems in a phycobilisome (From Gantt, 1990).

on the order of nanoseconds (80). The radiation-less excitation energy transfer occurs with an efficiency greater than 95% (81). The excitation energy reaching the antenna Chl *a* in the PSII reaction center can then follow one of the two paths: the energy can be transferred to the PS II reaction center Chl *a* leading to the electron transport chain and PS I, or the energy can be transferred directly to the PS I antenna Chl *a*. The transfer of energy does not occur by emission of a photon followed by energy absorption by a neighboring molecule but rather by radiation-less, dipole-induced, dipole resonance energy transfer (82). In this process the energy is localized in a cluster of Chl molecules. The energy is then distributed throughout the Chl supermolecule and is not contained within any one individual Chl molecule. This process is similar to the system of localized electrons within a benzene ring.

The photosynthetic apparati of rhodophytes and cyanobacteria are unique here that they contain phycobilisomes as light-harvesting antenna and do not contain stacked or fused thylakoids. Cryptophytes, although containing phycobiliproteins, do not contain phycobilisomes.

Purified PE, PC, and APC are composed of at least two polypeptide subunits as revealed by sodium docecyl sulfate (SDS) gel electrophoresis (83). The lower molecular weight subunit is designated as α and the larger one as β, both having a size range of 15 to 22 kD (78). APC is regarded as the simplest phycobiliprotein containing one PCB per α and β-polypeptide. PC molecules generally consist of one PCB per α-polypeptide and two per β-polypeptide with a combined heteromere size (α_6, β_6) of ca. 220 kD (78). PE molecules have a larger number of chromophores than the other phycobiliproteins. In addition, some PE molecules also contain other subunits, although much less is known regarding these other subunits compared to the α- and β-subunits (83).

METHODS FOR IDENTIFICATION AND QUANTIFICATION OF PIGMENTS

Concentration and Extraction of Pigments

Algae samples collected from culture or a natural phytoplankton community are typically filtered onto GF/F filters. Cells collected on the filter are disrupted by grinding, sonication, or freezing, and the pigments are extracted by soaking in an organic solvent (e.g., methanol or acetone) at a low temperature ($<0\,^{\circ}$C) for up to 24 hours. While in solution, pigments are very susceptible to degradation, so care must be taken to keep the pigment extracts cold and away from bright light. For long-term storage of pigment extracts, placement in a $-80\,^{\circ}$C freezer or in liquid nitrogen is highly recommended. The sample should be centrifuged and/or filtered to remove particulate matter from the pigment extract solution.

Spectrophotometric Methods

The concentration of a purified pigment extract can be determined using a spectrophotometer. Purified pigments can be obtained from a number of commercial sources or by HPLC extraction, separation, and collection of the pigment as it elutes from the system. Since absorption spectra for each pigment vary considerably depending on the solvent the extinction coefficient (α) used for determining concentration (C) must be specific to the solvent and wavelength (λ). Table 2 lists extinction coefficients for a wide variety of pigments. To maintain the linearity of concentration versus absorption (A_λ), the measured absorption should not exceed 1.5. The equation for concentration (mg l^{-1}) using a 1 cm pathlength cell is:

$$C = 1,000^{*}\ A_{\lambda}{}^{*}\alpha^{-1} \tag{1}$$

The concentration of Chls and carotenoids in a sample extracted in 90% acetone containing a mixture of pigments can be determined using the equations of Jeffrey and Humphrey (15) and Parsons and coworkers (84). The absorption of the solution is measured at 480, 510, 630, 647, 664, and 750 nm. The absorbance readings at 630, 647, and 664 nm are then corrected by subtracting the absorption at 750 (known as the turbidity blank), which should be close to zero. For the absorptions at 510 and 480 nm, 2x and 3x, the 750 nm absorbance is subtracted, respectively. The concentrations (mg l^{-1}) of each of the Chls (*a*, *b*, and *c*) and the total carotenoids are determined from the following equations:

$$\text{Chl } a : (C_a) = 11.85\ A_{664} - 1.54\ A_{647} - 0.08\ A_{630} \tag{2}$$

$$\text{Chl } b : (C_b) = 21.03\ A_{647} - 5.43\ A_{664} - 2.66\ A_{630} \tag{3}$$

$$\text{Chl } c : (C_c) = 24.52\ A_{630} - 1.67\ A_{664} - 7.60\ A_{647} \tag{4}$$

Total Carotenoids:

$$(C_{Car}) = 7.6(A_{480} - 1.49\ A_{510}) \tag{5}$$

The concentration of Chl *c* is the sum of Chl c_1 + Chl c_2 + Chl c_3, and concentration for total carotenoids is only an estimate because of the wide variations in extinction coefficients among carotenoids. The pigment concentration (mg l^{-1}) in the initial sample can be calculated using the following equations incorporating the concentration determined above (C), the extract volume (V_e) and the filtered volume (V_f), both in ml:

$$\text{Conc} = C^{*}V_{e}{}^{*}V_{f}^{-1} \tag{6}$$

Fluorometric Methods

Chl *a*, in 90% acetone, fluoresces with a peak excitation about 435 nm and peak emission about 667 nm. The fluorometric method uses a Turner Designs fluorometer to measure Chl *a* concentration. Earlier models of the Turner Designs fluorometer required a two-step process to measure Chl *a* in a sample because of the additional fluorescence generated by Chl degradation products such as Ph-tin *a*. The fluorescence of the sample was measured (F_0), the sample was acidified with a couple drops of 10% HCl, and the fluorescence was measured again (F_a). The Chl *a* concentration (C_a) (μg l^{-1}) in the extracted sample is calculated:

$$C_a = K\frac{(F_0 - F_a)}{\text{Sens}} \tag{7}$$

Table 3. Measured Concentration and Fluorescence of Fluorescing Compounds (in 90% Acetone) Using a Turner Designs 10-AU Fluorometer

Pigment	Spec Conc. (μg l^{-1})	Fluor Conc. (μg l^{-1})	Percent Fluor:Spec
Chl *a*	366	372	102
Chl *b*	1,386	149	10
Chl $c_1 + c_2$	710	156	22
Chl c_3	58	8	14
Ph-ide	1,094	171	16
Ph-tin	1,103	138	13
Chl-ide	183	166	90

K is the calibration factor for the instrument and Sens is the sensitivity setting used for the measurement. Calibration of the instrument involves using successive dilutions of purified Chl *a* to establish a linear regression of $(F_0 - F_a)$ versus C_a, over the sensitivity range of the instrument.

The Turner Designs 10-AU does not require acidification of the sample because of the different light source and the narrow-band excitation and emission filters used (85). After a simple blank determination and one-point calibration using purified Chl *a*, the instrument reports Chl *a* concentration directly. Even in this setup, however, the concentration of Chl *a* can be overestimated due to the presence of secondary fluorescing compounds such as Chl *b*, Chl *c*, Chl-ide, Ph-tin, or Ph-ide. Table 3 gives the spectrophotometrically determined pigment concentration of pure standards, the fluorometric concentration reported as Chl *a* by the Turner 10-AU fluorometer, and the percent ratio of the two.

For other Chls, Ph-ide, and Ph-tin about 10 to 20% of the concentration will be reported as Chl *a*; but for Chl-ide, 90% will be reported as Chl *a*. In regions where these compounds contribute significantly to the total pigment present, the fluorometric method will greatly overestimate the concentration of Chl *a*.

HPLC Methods

The primary means to separate and identify specific pigments from cultures and natural communities involves concentrating cells by filtering the sample, extracting the pigments in an organic solvent, and separating the pigments using High Performance Liquid Chromatography (HPLC; 86). In order to reduce the solvent strength of the extract solution it is typically mixed with water or buffer solution before injection into an HPLC reverse phase system for separation and identification of the pigments.

Three main HPLC methods are generally employed to separate and identify pigments. All employ reverse phase (C_8 or C_{18}) columns and gradients containing mobile phases of aqueous and organic solvents. More polar pigments, such as Chl *c*, Mg DVP, and the Chl degradation compounds Chl-ide and Ph-ide, elute early in the gradient, followed by a series of xanthophylls, and finally the most nonpolar pigments such as Chl *b*, Chl *a*, and the carotenes. The first method (#1) (26) uses a gradient of methanol, acetone, and an aqueous solution containing the buffer ammonium acetate with or without the ion-pairing reagent tetrabutyl-ammonium acetate. A widely used method (#2) (87) uses a gradient of methanol, acetonitrile, ethyl acetate, and an aqueous buffer solution containing only ammonium acetate. The third method (#3) (88) uses a gradient of methanol, acetone, acetonitrile, and an aqueous solution containing pyridine as an ion-pairing reagent. The gradient profiles and mobile phase compositions for these methods are summarized in Table 4.

An in-line detector, such as a photodiode array or an ultraviolet/visible spectrophotometer, measures the absorption by pigments at a specific wavelength (typically about 440 nm) as well as recording the absorption across a spectrum at regular time intervals. A pigment can be identified based on its characteristic absorption spectrum and quantified on the basis of the detector response (peak area) at a specific wavelength. An in-line fluorescence detector can be very useful to measure fluorescing pigments, especially if present in very small amounts. If optimized for Chl *a* (i.e., excitation wavelength about 436 nm and emission wavelength about 666 nm) then a fluorescence detector is much more sensitive and accurate for the detection and quantification of most Chls and Chl degradation products (e.g., Chl-ide, Ph-ide, or Ph-tin).

The HPLC system is calibrated by repeated injections of pigment standards to establish a regression of detector response (peak area) to pigment amount (ng). A typical limit of detection for Chl *a* and other pigments is about 1 to 5 ng, and calibration amounts typically range from 1 to 200 ng. The exact amount will vary depending on the type of instrument. Coefficient of variation from replicate injections of standard pigments should be less than 3% on most HPLC systems.

For comparison, HPLC chromatograms of a pigment mixture that are separated by two different methods (#1 and #3) are presented in Figure 8. Elution order varies slightly for pigments 6 and 14. Method #3 provides near baseline separation between pigments 1 and 2 (Chl c_1 and c_2), provides for a better separation between xanthophylls 4 through 15, and even resolves pigments 18 and 19 (DV Chl *a* and Chl *a*). Separation between pigments 13 and 14 (Lutein and Zeax) is poor in both methods, but better in Method #3. Neither method separates pigments 16 and 17 (DV Chl *b* and Chl *b*). Method #3 does a better job of separating Chl-ide and Mg DVP from Chl c_1 and c_2 than Method #1 (not shown).

ECOLOGICAL DISTRIBUTIONS OF ALGAL AND BACTERIAL PIGMENTS

BChls are typically in very low abundance in marine oxygenated waters. Recent evidence, however, documents the prevalence of aerobic anoxygenic photoheterotrophs in surface ocean waters (89,90). These obligate aerobes that are closely related to purple photosynthetic bacteria have unusually high concentrations of carotenoids but low ratios of BChl *a*: cell (90). These facultative photoheterotrophs can metabolize organic carbon compounds when present but are also capable of photosynthetic light utilization when organic carbon sources are scarce (90).

Table 4. Summary of Buffer Solutions, Mobile Phases, and Gradient Profiles for the Three Main HPLC Methods

	Method #1 (26)				Method #2 (87)				Method #3 (88)		
HPLC Column	25 × 0.46 cm C_{18} 5 μm				25 × 0.46 cm C_{18} 5 μm				15 × 0.46 cm C_8 3.5 μm		
Aqueous Buffer Solution	0.5 M Ammonium Acetate Acetate pH 7.6				0.5 M Ammonium Acetate pH 7.2				0.25 M Pyridine (20 ml/L) Acetic Acid (10 ml/L) pH 5.0		
Mobile Phase A	85 : 15 Methanol: Buffer				80 : 20 Methanol: Buffer				50 : 25 : 25 Methanol: Acetonitrile: Buffer		
Mobile Phase B	Methanol				90 : 10 Acetonitrile: Water				20 : 60 : 20 Methanol: Acetonitrile: Acetone		
Mobile Phase C	Acetone				Ethyl Acetate				N/A		
Gradient Profile	Time	%A	%B	%C	Time	%A	%B	%C	Time	%A	%B
Time in minutes	0	100	0	0	0	100	0	0	0	100	0
Flow rate:	5	100	0	0	4	0	100	0	22	60	40
1 ml/min	10	7	93	0	18	0	20	80	28	5	95
	20	7	93	0	21	0	100	0	38	5	95
	28	0	100	0	24	100	0	0	40	100	0
	30	0	75	25	29	100	0	0			
	32	0	0	100							
	34	0	0	100							
	35	100	0	0							
	40	100	0	0							

Preliminary evidence suggests that these organisms are prevalent in the upper ocean and represent at least 11% of the total microbial community (90).

Bacteriorhodopsin, a retinal containing membrane protein that was recently discovered in the ocean, utilizes the in situ light energy in the marine photic zone to produce conformational changes in the pigment proteorhodopsin leading to light-driven proton pumping (via H^+-ATPase) (1,2). This pathway was formerly thought to exist only in halophilic Archaea but has recently been discovered in γ-proteobacterium in the marine environment and may represent a globally significant oceanic pathway for bacterially mediated light-driven energy production (1,2). Our understanding of the importance of bacterial photosynthesis in the ocean will undoubtedly undergo some major changes in the near future because of these recent discoveries.

In anoxic waters, such as, at the chemocline of the Black Sea, integral BChls in the anoxygenic zone can exceed total Chl *a* in the overlying oxygenated portion of the photic zone (91). Since the discovery of cyanobacteria (*Synechococcus* spp.; 92,93) and prochlorophytes (*P. marinus*; 94) in the open ocean, pigments have been used as diagnostic indicators for the presence of prokaryotic photoautotrophs. The abundance and distribution of marine prokaryotic algae are usually measured using flow cytometric techniques that utilize the presence of photosynthetic pigments (95). In the tropical and subtropical oceanic regimes of the world's oceans, the prokaryotic pigments, Zeax and DV Chl *a*, typically represent a significant fraction (20–60%) of the total algal pigments measured in surface waters (96–98).

Another recent technological development that has enabled researchers to utilize photosynthetic pigments to estimate the abundance of algal populations in the open ocean involves satellite remote sensing (99). Satellite imagery is being used not only to measure algal abundance but also to estimate productivity in the open ocean based on pigment concentrations in surface waters (100). New satellites such as Sea-viewing Wide Field-of-view Sensors (SeaWiFS) are now being used to assess phytoplankton Chl distributions and primary productivity in various remote oceanic realms (101). Other applications for pigment-based remote-sensing applications are also being explored. For instance, fourth derivative pigment analyses in conjunction with other optical measurements may prove useful in forecasting harmful algal blooms in coastal waters (102).

Macroalgae effectively absorb photosynthetically active radiation (400 to 750 nm) by producing various pigments to harness light energy in their specific ecological niche in the intertidal coastal zone. The rapid attenuation of red light in surface waters results in a vertical zonation of algal pigments observed among macroalgal species. The vertical distribution of seaweeds typically encountered are: the green algae residing in shallow water, the brown algae in the intertidal, and the red algae in the deeper subtidal portion of the water column.

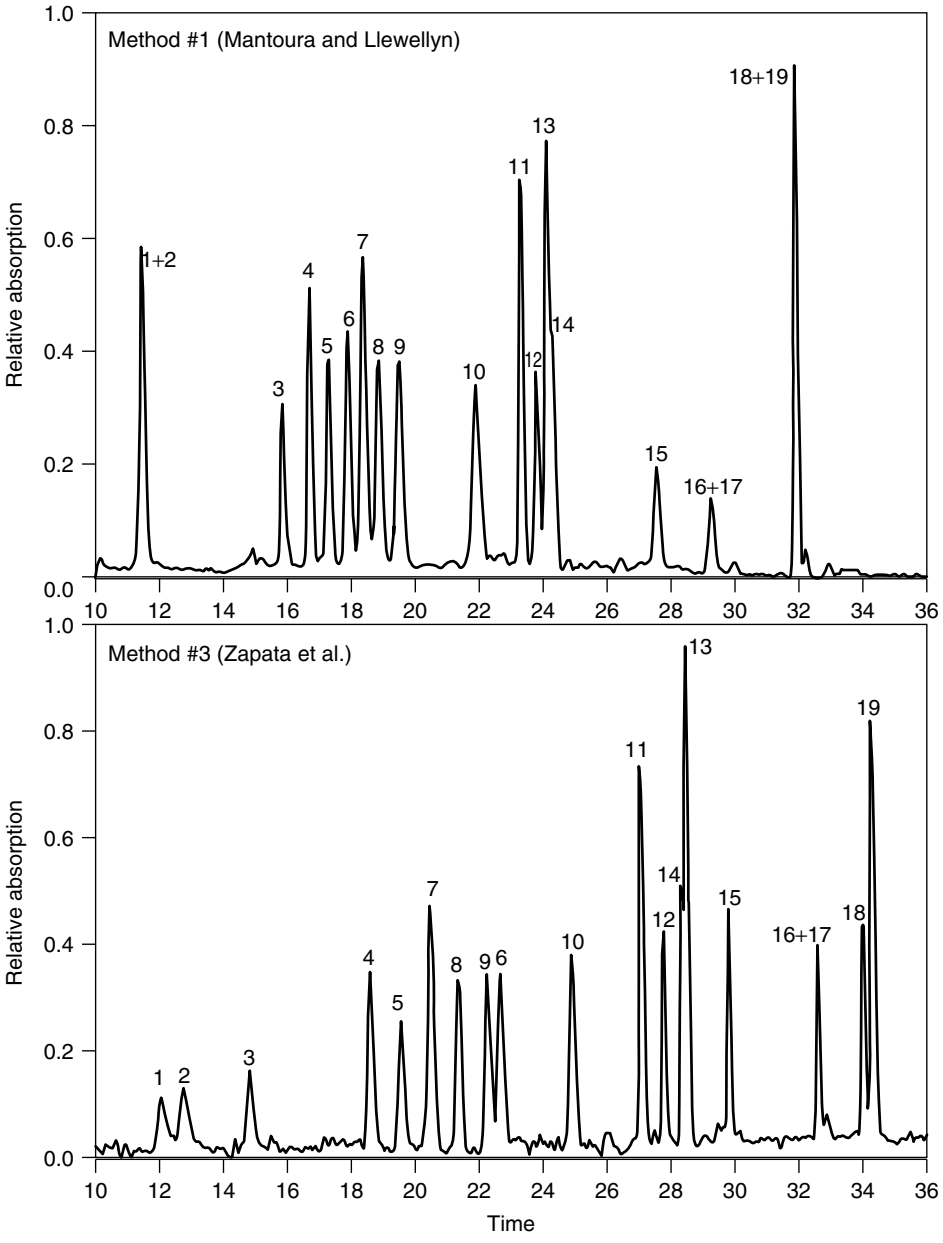

Figure 8. Comparison of HPLC chromatograms from Methods #1 and #3. Refer to Table 2 for identification of the numbered peaks.

PIGMENTS AND TAXONOMY

Photosynthetic pigments are increasingly used to identify the taxonomic composition of a sample collected from a community containing a mixture of taxa. Certain pigments are specific to single classes or a small number of classes, while other pigments are present across a wide variety of classes (Table 5). Distributions of pigments within the groups of photosynthetic bacteria have not been investigated as thoroughly as the distributions in algal groups. Within the eukaryotic algae, all classes that contain Chl *a*. Chl *b* are present in the Plantae algal classes (except the rhodophytes), the Euglenozoa, and the enigmatic protistan phylum Chlorarachniophyta. The remainders of the protistan and protozoan classes all contain one version or another of Chl *c*.

Photosynthetic Bacteria

While photosynthetic bacteria are classified on the basis of morphological and physiological aspects, rather than by pigment composition, some generalizations can be made. The two classes of purple bacteria (Rhodospirillaceae and Chromatiaceae) both contain BChl *a* as their primary photosynthetic pigment and BChl *b* as a secondary pigment. The suite of carotenoids produced by these classes varies widely within each group. The green sulfur bacteria (Chlorobiaceae) contain only minor amounts of BChl *a* in the reaction centers, and have BChl *c*, BChl *d*, and Bchl *e* as accessory pigments. The major carotenoids found in this class include chlorobactene and its hydroxy derivatives. The carotenoids (xanthophylls and carotenes) present in eukaryotic algae are the more diagnostic pigments, with some xanthophylls present in only one,

Table 5. Representative Groups of Photosynthetic Bacteria and Algae and Typical Pigment Compositions. Pigments in Bold Are Considered Diagnostic: Pigments in Parentheses Occur Only in Some Species or in Trace Amounts

Algal Group	Pigments	Refs
Prokaryotes		
Rhodospirillaceae	BChl *a* (BChl *b*) Lycopene, Neurosporene, Rhodopene, Spirilloxanthin	8,43
Chromatiaceae	BChl *a* (BChl *b*) Okenone, Spirilloxanthin, Warmingone — series	8,43
Chlorobiaceae	(BChl *a*) BChl *c*, BChl *d*, BChl *e*, Chlorobactene	8,43
Cyanobacteria	Chl *a*, **Zeax**, β-Car, **Phycobiliproteins**	14
Prochlorophyceae 1	**DV Chl *a***, **Zeax,** α-Car	14
Prochlorophyceae 2	**DV Chl *a***, **Mg DVP** (Zeax) **Para**, α-Car	14
Protozoa		
Euglenozoa	Chl *a*, Chl *b*, Diad (Diat) (Neox) β-Car	14
Dinoflagellatea	Chl *a*, Chl c_2, **Perid**, Diad, (β-Car)	14
Protista		
Chlorarachniophyta	Chl *a*, Chl *b*	103
Cryptophyta	Chl *a*, (Chl c_1) Chl c_2, **Allo**, Monad, α-Car, **Phycobiliproteins**	14,27
Diatomae	Chl *a*, Chl c_1, Chl c_2, **Fuco**, Diad (Diat) (β-Car)	14,104
Dictyochae	Chl *a*, Others?	
Haptophyta 1	Chl *a*, Chl c_1, Chl c_2, Fuco, Diad (Diat) (α-Car) (β-Car)	8
Haptophyta 2	Chl *a*, Chl c_1, Chl c_2, **Chl c_3**, Fuco, Diad (Diat) (α-Car) (β-Car)	8
Haptophyta 3	Chl *a*, Chl c_1, Chl c_2, **Chl c_3**, **19Hex**, Fuco, Diad (Diat) (α-Car) (β-Car)	8
Haptophyta 4	Chl *a*, Chl c_1, Chl c_2, **Chl c_3**, 19But, Fuco, **19Hex**, Diad (α-Car) (β-Car)	8
Raphidophyta	Chl *a*, Chl c_1, Chl c_2, Diad (Diat) Fuco, Zeax, β-Car	14,105
Phaeophyta		
Phaeophyceae	Chl *a*, Chl c_1, Chl c_2, **Fuco**, β-Car (α-Car)	31,106
Chrysophyceae	Chl *a*, (Chl c_1) Chl c_2, Fuco (Viol) (Neox) (Zeax) Diad (Diat) (β-Car)	14
Synurophyceae	Chl *a*, Chl c_1 (Viol) Fuco, (β-Car)	104,105,107
Eustigmatophyceae	Chl *a*, **Viol, Vauch** (Zeax) β-Car	14,108
Pelagophyceae	Chl *a*, Chl c_2, Chl c_3, **19But**, Fuco, (19Hex) Diad, (β-Car)	107
Phaeothamniophyceae	Chl *a*, Chl *c*, Hetero, Fuco, Diad, Diat, β-Car	109
Xanthophyceae	Chl *a*, Chl c_1, Chl c_2, Hetero, Diad (Diat)**Vauch**, β-Car	104,108
Plantae		
Chlorophyta	Chl *a*, **Chl *b***, Neox, Viol (Zeax) **Lut**, (α-Car) β-Car	14,106
Prasinophyta 1	Chl *a*, **Chl *b***, Neox, Viol (Zeax) **Lut**, (α-Car) β-Car	14,110
Prasinophyta 2	Chl *a*, **Chl *b***, **Mg DVP**, Neox, **Pras** (Zeax) **Lut**, (α-Car) β-Car	14,110
Prasinophyta 3	Chl *a*, Chl *c*, 19But, Fuco, (β-Car)	14,110
Rhodophyta	Chl *a* (Chl *d*) (Anth) (Lut) **Zeax**, β-Car, **Phycobiliproteins**	78,106

or a very few, classes. Some xanthophylls, such as Fuco and Diad, occur in many, if not most, classes.

Cyanobacteria (Cyanophyceae, Blue-Green Algae)

In addition to Chl *a*, cyanobacteria contain a suite of carotenoids, primarily Zeax, echinenone, myxoxanthophyll, and β-Car, but many species contain minor carotenoids such as Canth (111). Strains of *Synechococcus* contain Chl *a*, Zeax, and β-Car only (112,113).

Prochlorophyceae

Prochlorococcus contains the pigments DV Chl *a* and DV Chl *b*, which distinguish prochlorophytes from all other photosynthetic organisms (97,114,115). In addition, prochlorophytes contain Zeax and α-Car (116), and some strains contain phycoerythrin (74). Recently, a novel strain of *P. marinus* has been described from low-light, suboxic environments in the Arabian Sea and the Eastern Tropical Pacific (117). This strain, in addition to the normal prochlorophyte pigments, also contains Mg DVP and Parasiloxanthin. At higher light levels one strain of *P. marinus* also contained Chl *b* in small quantities (113).

Euglenozoa

Since euglenophytes contain Chl *a*, Chl *b*, Neox, Zeax, Siphonein, and β-Car they have been generally classified with the chlorophytes. However, they contain Diad as their major xanthophyll as well as Diat and Hetero, which are all characteristic of the Protistan algae. Combined with the consideration of ultrastructural characteristics there is sufficient cause to classify the euglenophytes as Protozoan algae (31,118).

Dinoflagellatea (Pyrrhophyta, Dinophyceae)

Dinoflagellates typically contain the pigments Chl *a*, Chl c_2, Diad, Diat, and β-Car, as well as Perid, which is uniquely associated with the dinoflagellates (119,120). The presence of endosymbionts can complicate the suite of pigments associated with dinoflagellates (121), with the addition of pigments typical of the endosymbiont. Some strains of *Gyrodinium* have been shown to contain Fuco or 19Hex, instead of Perid, as the main xanthophyll (122,123). Some dinoflagellates are reported to contain Chl c_1, in addition to Chl c_2 (124).

Chlorarachniophyta

Containing both Chl *a* and Chl *b*, the enigmatic alga *Chlorarachnion reptans* shows affinities to the Chlorophyceae; however, its ultrastructural characteristics more closely resemble the Cryptophyta (103). Ludwig and Gibbs (103) theorize that the chloroplasts in these species evolved from a chlorophyte endosymbiont, and, while they do not specify the other pigments present in these species, they are presumably the same as the Chlorophyceae.

Cryptophyta (Cryptomonada)

The primary Chl *c* pigment in cryptophytes is Chl c_2 (107); however, Chl c_1 and traces of Mg DVP have also been identified in the cryptophyte *Chroomonas* sp. (104). Alloxanthin is the primary carotenoid associated with cryptophytes (27,120,125), while crocoxanthin and monadoxanthin occur in most species but at lower concentrations (27,125). Cryptophytes are the one protistan algal group, that contains phycobiliproteins: phycocyanins and phycoerythrins.

Diatomae (Bacillariophyceae)

The amount of Fucoxanthin in a sample is usually correlated with the abundance of diatoms even though Fuco also occurs in other taxa, but in much smaller amounts (120).

Dictyochae (Silicoflagellates and Pedinellales)

No studies of the pigment composition of these algae have been reported to our knowledge.

Haptophyta (Prymnesiophyceae)

Some researchers have considered 19Hex as the diagnostic pigment for prymnesiophytes (126); however, in a survey of 29 species (50 strains) (127) the haptophytes were divided into four types based on their pigment composition. All 50 strains contained Chl *a*, Chl c_1 and/or c_2, Fuco, Diad, Diat, and β-Car. Type 1 contained no additional pigments; Type 2 contained Chl c_3; Type 3 contained Chl c_3 and 19Hex; and Type 4 contained Chl c_3, 19But, and 19Hex. Some strains also contained α-Car. Others (128) agree that 19Hex is not present in all haptophytes. This algal group has a diverse pigment composition and there is no clear correlation between pigment type and traditional Order or Familial classification.

Raphidophyta

Withers (105) report finding Fuco as the dominant pigment in raphidophytes, with lesser amounts of Zeax and trace amounts of β-Car in two strains of *Olisthodiscus luteus*. Fiksdahl and coworkers (129) report finding Fuco, Fucoxanthinol, and β-Car as the major pigments in two marine species (*Chattonella japonica* and *Fibrocapsa japonica*). Viol was a minor pigment (1 to 2%) of the total carotenoids and Zeax was also detected in one species. The pattern of pigment composition differed significantly from the freshwater species examined.

Phaeophyceae (Brown Algae)

In addition to Chl *a*, the phaeophytes contain chl c_1 and c_2, Fuco, and β-Car, with α-Car present in some species (106).

Chrysophyceae

Chrysophyte algae contain both Chl c_2 and c_1 (107). In an examination of the carotenoids contained in chrysophytes Withers and coworkers (105) found Fuco to be the major carotenoid in all species and β-Car was always present. A variety of other pigments, including Zeax, Diad, Diat, Neox, and Viol, have been found in some, but not all, species examined (105).

Synurophyceae

The Synurophyceae have recently been separated from the Crysophyceae, based on the absence of Chl c_2 and the presence of Chl c_1 in *Synura* and *Mallomonas* (107,130). Schimek and coworkers (104) also reported only Chl c_1 from *Synura petersenii*. Fuco is the predominant carotenoid in *Synura* with only trace amounts of Viol and β-Car (105).

Eustigmatophyceae

Eustigmatophytes contain Vauch and are differentiated from the xanthophytes by the absence of Chl *c* and the presence of Viol (108).

Pelagophyceae

The pelagophytes have been separated from the chrysophytes on the basis of a number of morphological, ultrastructural, and pigmentation features (131). *Pelagococcus subviridus* contains Chl c_3 and Chl c_2, but not Chl c_1 (107,132). Fuco and 19But are the major carotenoids, and Diad, Diat, and β-Car are minor carotenoids (133). The diagnostic pigment for Pelagophytes is 19But (120,132,134). Trace amounts of 19Hex have been found in another strain of *P. subviridus* (135).

Phaeothamniophyceae

Based partially on photosynthetic pigments, Bailey and coworkers (109) defined a new class of protistan algae containing genera formerly classified as Chrysophyceae or Xanthophyceae. The presence of both Hetero and Fuco is unique to this class.

Xanthophyceae (Tribophyceae)

In their survey of xanthophytes, Sullivan and coworkers (108) report finding that all of them have Chl *a*, Chl *c*, Diad, Diat, and β-Car. Most species also contained Hetero and Vauch, while none contained Mg DVP or Viol. *Pseudopleurochloris antarctica*, a new species described from Antarctic pack ice, contained Chl *a*, Chl c_2, Hetero, Diad, Diat, Vauch, and β-Car, but no Fuco or Chl c_1 (18).

Chlorophyta (Green Algae)

Chlorophytes contain the general suite of pigments as do the higher plants (42): Chl *a*, Chl *b*, Neox, Zeax, Lut, and

carotenes. Additional carotenoids found in some species of macroalgae include siphonaxanthin, siphonein, and astaxanthin (106).

Prasinophyta

On the basis of pigment composition, prasinophytes have been divided into three types (110). Type I exhibited the normal chlorophyte pigment suite (Chl *a*, Chl *b*, Neox, Viol, Zeax, Lut, and carotenes). Type II contained all of these pigments plus Prasinoxanthin, considered to be the diagnostic pigment for prasinophytes (21). Type III lacked both Pras and Chl *b*, and contained other carotenoids, which are present in chrysophytes (19Hex, Fuco, and Diad). Mg DVP has been reported in several species, including *Mantoneilla squamata* and *Pycnococcus provasolii*, Type II prasinophytes (104,110,136).

Rhodophyta (Red Algae)

In addition to Chl *a*, and the major carotenoids Zeax and β-Car, rhodophytes contain the phycobiliproteins: APC, PC, and PE (106). Some species contain the minor carotenoids Lutein or Anth (78,137). While Chl *d* has been identified, whether it plays a role in photosynthesis or is merely a degradation product remains to be determined (78).

CHEMTAX ANALYSIS OF PHYTOPLANKTON COMMUNITY COMPOSITION

CHEMTAX is a matrix software routine developed to determine the percentage of Chl *a* in a collection of samples allocated to different algal groups (138–143). CHEMTAX works within the MATLAB computing system to determine the class composition of a phytoplankton assemblage based on the photosynthetic pigments measured using HPLC separation techniques. CHEMTAX begins with an initial pigment ratio matrix containing the relative pigment content for each of the identified pigments within each taxonomic group. A second matrix is prepared with the pigment concentration for each sample in the study. CHEMTAX factors together the two matrices to produce a final matrix of the percent contribution of each taxonomic group to the total Chl *a* concentration in each sample. The preparation of an appropriate initial pigment ratio matrix is key to the proper analysis of pigments contained in an extracted phytoplankton sample. Mackey and coworkers (140) stressed the importance of calibrating CHEMTAX using major phytoplankton species native to the area where the data samples were obtained. Different regions will require different initial pigment matrices as a result of the different suites of phytoplankton present. Currently, researchers around the world are developing appropriate initial pigment ratio matrices for various oceanographic regimes, and then using these matrices to describe phytoplankton community assemblages and their impacts on biogeochemical cycles. It is important that future laboratory calibrations of the CHEMTAX method utilize ecologically relevant algal species and that oceanic studies corroborate the pigment-based algal distributions with microscopic identifications.

PHOTOTROPHIC PURPLE AND GREEN BACTERIA IN MARINE AND HYPERSALINE ENVIRONMENTS

JOHANNES F. IMHOFF
Institut für Meereskunde an der Universität Kiel
Kiel, Germany

The ability to transform light energy into biochemical energy is found in all major phylogenetic branches of life, the archaea, the eubacteria, and the eukarya. Two basically different biochemical mechanisms are known that transform light energy into biochemical forms of energy that can be used in metabolic processes, namely, retinal-containing rhodopsins and chlorophyll-containing protein complexes.

Retinal-containing proteins, the rhodopsins are well known as characteristic components of extremely halophilic archaea, the halobacteria. Rhodopsins have been intensively studied in these archaea in which they function in transmembrane proton transport (bacteriorhodopsins), in chloride transport (halorhodopsins), and as photosensory receptors (sensory rhodopsins) (1). A retinal-containing protein with characteristic features typical of archaeal rhodopsins was recently also found in γ-Proteobacteria of the SAR86 group (2), which is

widely distributed in marine environments. The proton export from intact cells by this protein, called *proteorhodopsin*, could be demonstrated (2). Although both bacteriorhodopsins and proteorhodopsins function as proton pumps and establish a light-driven transmembrane proton gradient, archaea and γ-Proteobacteria containing these proteins are basically chemoheterotrophic bacteria and depend on respiratory energy transformation for growth. They gain selective advantage in illuminated environments by their ability to use light-driven membrane energetization in addition. However, a phototrophic way of life based on light-driven energy transformation, as the principal source of metabolic energy, is not possible by these bacteria.

The chlorophyll-mediated energy transformation is widely distributed among eubacteria, but is not known to occur in archaea. On the basis of fundamental physiological differences, we distinguish among oxygenic phototrophic bacteria that use water as photosynthetic electron donors and produce molecular oxygen (cyanobacteria), anoxygenic phototrophic bacteria that use reduced substrates such as sulfide, hydrogen, ferrous iron, and a number of simple organic substrates as photosynthetic electron donors but do not produce oxygen during photosynthesis, and aerobic bacteriochlorophyll-containing bacteria ("ABC-bacteria"), which represent chemoheterotrophic bacteria with the potential to produce photosynthetic pigment-protein complexes and to perform light-mediated photosynthetic electron transport processes.

The aerobic bacteriochlorophyll-containing bacteria ("ABC-bacteria") are represented by a number of α-Proteobacteria, and at present by a single β-Proteobacterium. Although light-mediated energy-transfer apparently contributes to their energy budget (3,4), the principal process of their energy transformation is the oxidation of organic substrates by aerobic respiration. Photopigment biosynthesis and formation of the photosynthetic apparatus in these bacteria, in contrast to anoxygenic phototrophic bacteria, is not inhibited but depends on the presence of oxygen (5). These bacteria are widely distributed in the oxic marine environment (6). Indeed, fluorescence kinetic measurements demonstrated the widespread presence of bacterial photosynthesis, presumably by ABC-bacteria, in tropical surface waters of the eastern Pacific Ocean and also in coastal waters of the northwestern Atlantic Ocean (7). Phototrophy has not been demonstrated in these bacteria and their potential advantage in natural habitats, due to their photosynthetic potential, has not been unequivocally demonstrated. [Note that the distinction is made between *photosynthesis* (and *photosynthetic*) as the ability to perform light-mediated energy transduction and *phototrophy* (and *phototrophic*) as the ability to grow on the basis of light-mediated energy transformation as the principal source of energy.] From what is known about these bacteria, it is reasonable to assume that they grow just as other chemotrophic bacteria under oxic conditions in the dark (including the deep sea in general and — contradicting Yurkov and Beatty (8) — also in the vicinity of hot vent locations), but make use of their photosynthetic apparatus in illuminated oxic environments to gain additional metabolic energy (7).

Phototrophic bacteria are found in major eubacterial branches and have characteristic differences in the structure and function of the photosynthetic apparatus, in the pigment content and in important physiological properties. Characteristic properties to distinguish these major branches of phototrophic bacteria including *Chloroflexus* and relatives, Chlorobiaceae, cyanobacteria, *Heliobacterium* and relatives, and phototrophic purple bacteria (α-, β- and γ-Proteobacteria) are summarized in Table 1.

The Cyanobacteria (including those known as *prochlorophytes*, such as *Prochloron*, *Prochlorococcus*, and *Prochlorothrix* species) are phototrophic bacteria performing an oxygenic type of photosynthesis. In addition, some representatives are able to use reduced sulfur compounds as photosynthetic electron donors and under these conditions use only one photosystem in an anoxygenic type of photosynthesis. The most abundant phototrophic organism in the global ocean environment, most likely, is a very small oxygenic phototrophic prokaryote, *Prochlorococcus marinus* (9).

The Heliobacteria are anoxygenic phototrophic bacteria that contain bacteriochlorophyll *g* and carotenoids. They are highly sensitive to oxygen and some species form heat-resistant endospores. They are phylogenetically related to gram-positive bacteria and grow photoheterotrophically. Marine forms of these bacteria are so far not known.

The green nonsulfur bacteria (Chloroflexaceae), also known as *filamentous and gliding green bacteria* are anoxygenic phototrophic bacteria that contain bacteriochlorophyll *c* or *d* in light-harvesting complexes located in special light-harvesting organelles, the chlorosomes. They move by gliding, are tolerant to oxygen, and grow preferably as photoheterotrophs. These bacteria are adapted to hot freshwater environments. Although they have been observed microscopically in marine habitats, pure cultures of marine representative do not exist.

The green sulfur bacteria (Chlorobiaceae) are anoxygenic phototrophic bacteria that contain bacteriochlorophyll *c*, *d*, or *e* in light-harvesting complexes located in special light-harvesting organelles, the chlorosomes. They are obligately phototrophic, require strictly anoxic growth conditions, and have a low capacity to assimilate organic compounds. Depending on the pigment content, a number of green-colored and corresponding brown-colored species are known. Several species have been found in marine and also hypersaline environments, in which under appropriate conditions intensively colored, visible mass developments are formed.

The purple sulfur bacteria (Chromatiaceae and Ectothiorhodospiraceae) and the purple nonsulfur bacteria are anoxygenic phototrophic bacteria that contain bacteriochlorophyll *a* or *b* in the light-harvesting complexes located in the cytoplasmic membrane and various kinds of invaginations of it. Bacteria of this group are the most prominent and abundant anoxygenic of phototrophic bacteria in marine and hypersaline environments.

1. The *Chromatiaceae* are γ-Proteobacteria and grow well under photoautotrophic conditions and use

Table 1. Diagnostic Properties of Major Groups of Phototrophic Prokaryotes

	Chlorobiaceae	Chloroflexaceae	Purple bacteria	Heliobacteria	Cyanobacteria (including prochlorophytes)
Photosynthesis	anoxygenic	anoxygenic	anoxygenic	anoxygenic	oxygenic
Type of (bacterio) chlorophyll	bchl c, d, e (+ bchl a)	bchl c, d (+ bchl a)	bchl a, b	bchl g	chl a, chl b*
Phycobilins present	−	−	−	−	+/−
Type of reaction center	I	II	II	I	I + II
Reduction of NAD^+ by primary photosynthetic electron acceptor	+	−	−	+	+
Location of antenna	chlorosomes	chlorosomes	ICM	CM	ICM phycobilisomes**
Pathway of autotrophic CO_2-fixation	reductive TCA cycle	Hydroxypropionate-pathway	Calvin cycle	−	Calvin cycle
Preferred electron donor	H_2S, H_2	organic compounds (H_2S)	H_2S, H_2 organic compounds	organic compounds	H_2O
Chemotrophic growth	−	−	+/−	−	−/(+)

*present in prochlorophytes;
**absent in prochlorophytes; CM cytoplasmic membrane; ICM internal membranes.

sulfide as photosynthetic electron donors, which are oxidized to sulfate via intermediate accumulation of elemental sulfur inside the cells. Photoheterotrophic, chemoautotrophic, and chemoheterotrophic growth has been demonstrated in several species.

2. The *Ectothiorhodospiraceae* are γ-Proteobacteria and can be distinguished from the *Chromatiaceae* by deposition of elemental sulfur outside or in the peripheral part of the cells, and their preference for alkaline and saline growth conditions. Some species may also grow chemotrophically under aerobic dark conditions.
3. The purple nonsulfur bacteria are α- and β-Proteobacteria and preferentially grow under photoheterotrophic conditions, though most of them also have the ability to grow photoautotrophically with either hydrogen or reduced sulfur compounds as electron donors. Some species can use sulfide as photosynthetic electron donors, but only a few are able to completely oxidize sulfide to sulfate.

Among those bacteria that perform a phototrophic way of life, as defined earlier, the most significant physiological and ecological differences are between oxygenic and anoxygenic phototrophic bacteria. Both of these groups have representatives living in the marine and also the hypersaline environment. Although individual species of phototrophic bacteria are well adapted to a particular habitat and mineral salts composition, qualitatively and quantitatively, as a group, phototrophic bacteria have adapted to the whole spectrum of salt concentrations from freshwater to saturated brines.

Depending on their different responses to oxygen, the oxygenic phototrophic bacteria and the anoxygenic phototrophic bacteria are found in different ecological niches. Cyanobacteria usually inhabit the upper part of the photic zone in lakes, on hard substrates and in the sea. Those cyanobacteria that can perform anoxygenic photosynthesis are found in the lower anoxic part of stratified environments such as the Solar Lake (10). The anoxygenic phototrophic bacteria inhabit the lower anoxic part of the photic zone. In addition to their ability to perform anoxygenic photosynthesis, many of them have the capacity to grow chemotrophically under microoxic to oxic conditions in the dark and have adapted to niches in the oxic environment and to unstable, not permanently anoxic habitats. In the marine intertidal zone, both oxygen-producing cyanobacteria and anoxygenic purple and green phototrophic bacteria often occur close together and may form colored blooms and microbial mats. This article deals with the biology of anoxygenic phototrophic green and purple bacteria that live in marine and hypersaline environments, but excludes the oxygenic phototrophic cyanobacteria. An overview on the biology of marine and halophilic cyanobacteria was given earlier (11).

GENERAL ECOLOGY OF PHOTOTROPHIC BACTERIA IN SALINE HABITATS

Anoxygenic phototrophic bacteria are widely distributed in shallow marine sediments and water and regularly form visible mass developments in marine environments of the coastal zone and at the chemocline of marine waters. Already Warming (12) reported on such massive developments of phototrophic purple bacteria at the coast of Denmark. Since then, similar observations have been made around the world's coastlines. Phototrophic bacteria occur at all kinds of shorelines and geographic regions and numerous examples have been described in the literature of colored blooms and mass accumulations of

phototrophic bacteria in the coastal zone (for reviews see 11,13–15). Environments suitable for the development of phototrophic bacteria include sand beaches, tidal flats, estuaries, salt marshes, closed bays, and coastal lagoons, but also stratified water bodies such as fjords, deeper bays, and saline lakes and salterns, and salt and soda lakes. They prefer the anoxic zones, but some of these bacteria live in anoxic niches of the bulk oxic marine environment, which is generally regarded as being devoid of anoxygenic phototrophic bacteria.

The intertidal environments range from permanently dry sediments (which receive water by capillary movements from the ground), over sediments falling dry during low tides, to sediments that are permanently covered with water, which is either partly exchanged with the tides or exchanged only occasionally with unusually high tides. The smaller the water exchange with the tides, the better the conditions for the establishment of an anoxic water body, by rise of sulfide into the water, and the better the conditions for the development of conspicuous blooms of phototrophic bacteria.

Environmental Conditions in Favor of Phototrophic Bacteria

The most important properties that determine the development and distribution of phototrophic bacteria in nature are the concentrations of sulfide and oxygen and the light intensity, which form countercurrent gradients. The depth at which phototrophic sulfur bacteria develop is largely restricted to the concomitant presence of light and sulfide. Some of the microbial activities that determine slope and position of these gradients, such as oxygen production by algae and cyanobacteria and sulfide oxidation by phototrophic bacteria, show diurnal, light-dependent fluctuations. Others, such as sulfide production by sulfate-reducing bacteria and oxygen consumption by respiratory bacteria, do not. As a result of these processes, the sulfide horizon rises during the night and goes down again during the day. The motile phototrophic purple bacteria are able to follow the moving sulfide horizon. Under favorable conditions, separate layers of green sulfur bacteria are formed underneath layers of phototrophic purple bacteria and of algae and cyanobacteria. Frequently, however, mixed communities (not well-separated layers) of purple and green sulfur bacteria are observed, and purple nonsulfur bacteria regularly accompany the mass development of phototrophic sulfur bacteria.

The Role of Hydrogen Sulfide. The ability of phototrophic sulfur bacteria to oxidize sulfide and other reduced sulfur compounds under anoxic conditions is one of their most characteristic and ecologically important properties. Sulfide is not only used as the electron donor and sulfur source, but also serves to maintain anoxic conditions. One of the possible final stages of anaerobic decomposition of organic matter is performed by sulfate-reducing bacteria. Whenever the activity of sulfate-reducing bacteria in sediments is high enough to raise the sulfide horizon into the photic zone, development of purple and green sulfur bacteria is possible.

Concentrations of sulfide and elemental sulfur and the relations of the different phototrophic bacteria to these compounds are significant factors in determining patterns of natural dominance and successful competition. Of particular importance are the affinities to these two sulfur compounds, their oxidation rates, the ability to use external elemental sulfur, and the ability to store elemental sulfur inside or outside the cells. The intracellular storage of elemental sulfur by Chromatiaceae gives these bacteria an additional advantage over those bacteria that store elemental sulfur outside the cells (green sulfur bacteria and purple nonsulfur bacteria). All elemental sulfur formed by Chromatiaceae is inaccessible to other bacteria, whereas the elemental sulfur formed by green sulfur bacteria is also available to Chromatiaceae. Therefore, intracellular stored elemental sulfur is of inestimable value for these bacteria: (*1*) under conditions of external sulfide depletion in the light, it serves as a reservoir of photosynthetic electron donors; (*2*) under dark conditions and in the presence of oxygen, it may support endogenous respiration (16,17); (*3*) under anoxic conditions in the dark, it may serve as an electron acceptor during endogenous fermentation of stored carbohydrates (18,19).

The Role of Light. Not only the quantity, but also the quality of light is of major importance for the development of phototrophic bacteria, and because of different pigment contents of the various phototrophic bacteria, light is also a selective environmental factor. The light quality required by a phototrophic bacterium is reflected in the absorption spectra of the photosynthetic pigment-protein complexes and is a characteristic property for a particular species and group of phototrophic bacteria.

Great variation exists with respect to the chemical structures and the light-absorbing properties of bacteriochlorophylls and carotenoids in different species. The light-harvesting organelles of the phototrophic green bacteria, the chlorosomes, contain either bacteriochlorophyll *c*, *d*, or *e*, all of which have their long-wavelength absorption maximum between 700 and 760 nm. Heliobacteria have a major absorption maximum of bacteriochlorophyll *g* at 770 to 790 nm. Most of the phototrophic purple bacteria have bacteriochlorophyll *a*, with long-wavelength absorption maximum between 800 and 900 nm. Quite a few species have bacteriochlorophyll *b*, with an absorption maximum at 1,015 to 1,035 nm, exceptionally also below 1,000 nm (e.g., at 986 nm in *Rhodospira trueperi*, 20). These spectral properties demonstrate that on the basis of (bacterio)chlorophyll absorption there is no competition among green bacteria, purple bacteria, and oxygenic phototrophic organisms. (The chlorophyll *a* of cyanobacteria and eukaryotic algae absorbs below 700 nm).

Within sediments, the availability of light severely limits the development of phototrophic bacteria. Light is strongly absorbed by sand. In fine sand containing 5% mud, about 10% of the surface light penetrates 1.5 mm, and only 1% is present in a 3-mm depth of sediment (21). In addition, sand acts as an infrared filter and allows longer wavelengths, a deeper penetration (22). As a consequence, only steep countercurrent gradients

of sulfide and oxygen below an oxic sediment surface will form suitable conditions for the development of phototrophic bacteria. Their development is therefore restricted to the uppermost few millimeters of the sediment, where they often form thin layers below a surface layer of cyanobacteria. Bacteriochlorophyll absorption is of major importance in sediments, because infrared radiation penetrates particularly deep into sandy sediments (22). In deeper layers of water, however, the use of bacteriochlorophylls for light harvesting is limited by the stronger absorption of infrared radiation by water, in particular above 800 nm. Therefore, bacteria with bacteriochlorophyll *b* are the least suited to develop in deeper layers of lakes. They appear to be well-adapted to shallow water and in particular to sediment habitats not permanently covered by water.

In aquatic marine habitats, where sulfide-containing layers receive only low light intensities, *Chlorobiaceae* have a general advantage over the phototrophic purple bacteria because of their more efficient light-harvesting machinery, the chlorosomes. This efficiency allows growth at very low light intensities (below 50 lux), not enabling phototrophic purple bacteria to grow. The phototrophic green sulfur bacterium, *Prosthecochloris aestuarii*, was grown at light intensities as low as 5 to 10 lux, if cocultured with the sulfur reducer, *Desulfuromonas acetoxidans* (23). In those cases in which detailed studies of the colored water layers have been undertaken, and in which these layers received only low light intensities, brown-colored *Chlorobiaceae* such as *Chlorobium phaeobacteroides* and *Prosthecochloris phaeoasteroidea* have been found as the dominant phototrophic bacteria. Light absorption by carotenoids is of major ecological significance in deeper layers of aquatic habitats, because radiation between 450 to 470 nm penetrates deepest into water (24,25). Light penetration of seawater parallels the absorption properties of the carotenoids of the brown-colored *Chlorobiaceae* (26), which thereby have a selective advantage. This has been taken as an explanation for their dominance in lakes, where the anoxic hypolimnia occupy deeper layers (26–28). By mixing pure cultures of *Thiocystis violacea*, *Chlorobium limicola*, and *C. phaeobacteroides* and incubation of these mixtures at various depths (down to 30 m) in marine coastal waters, it could be shown that, with increasing depth, sunlight selects the brown *C. phaeobacteroides* (29).

The Relations to Oxygen. Oxic parts of nature in principal are not considered to be environments for anaerobic bacteria, and the open ocean is generally regarded as being devoid of anoxygenic phototrophic sulfur bacteria. However, there are at least two strategies that enable growth, reproduction, and even successful competition of phototrophic purple bacteria under oxic conditions and are of importance in the marine environment: (*1*) true adaptation by metabolic flexibility in energy conservation, that is, the ability to readily use both photosynthetic and respiratory mechanisms and (*2*) the development in and effective use of anoxic niches in an apparently oxic environment.

The first strategy enables the facultative respiring phototrophic bacteria to develop under diurnal oscillating conditions as part time phototrophs and part time chemotrophs at the oxic/anoxic chemocline, in natural gradient systems. Respiration is common among purple nonsulfur bacteria, and also many purple sulfur bacteria are able to respire (30). In particular, *Thiocapsa roseopersicina* is of high metabolic flexibility, and this species is well equipped to take advantage of changing conditions from oxic/dark to anoxic/light conditions and even simultaneously drives respiration and photosynthesis (31–33). Several observations indicate that respiration is of selective advantage for this species in nature: (*1*) Elegant competitive experiments demonstrate the advantage of *T. roseopersicina* under dynamic changes of oxic to anoxic conditions and under diurnal changes of illumination (33). (*2*) It has been isolated from environmental samples by the agar dilution series kept in darkness over several transfers as a chemotrophic sulfur oxidizer (Imhoff, unpublished). (*3*) It has been found, though in low numbers, at the chemocline of the Gotland deep in the Baltic Sea (which was at 120 m depth in darkness) where light was absent or its availability critical. Chemolithotrophic growth is their likely way of life at such places. In conclusion, respiratory capabilities not only are of advantage in environments with steep chemical and physical gradients, in which during diurnal cycles changes of the light regime and of oxic to anoxic conditions occur and these bacteria may use both phototrophic and respiratory systems, but also in situations of prolonged darkness in which only respiration is possible.

An interesting example of the second strategy also is found among Chromatiaceae. Apparently, the strictly phototrophic *Marichromatium purpuratum* has adapted to anoxic niches in the bulk oxic environment and even succeeded to conquer niches in the open ocean. Originally, it was isolated from a strictly oxygen demanding marine sponge, which contained massive cell densities (34,35). Later, a *Didemnum* species revealed similar mass accumulations of this species (11), and more recently it was isolated from the stomach of marine copepods that have a translucent chitin mantle (36).

Habitats

Marine Shorelines and Sediments. The shorelines of marine environments with their numerous niches can be considered as the most important places for the development of phototrophic sulfur bacteria in recent times, although they are unstable and in a continuous change. Habitats of anoxygenic phototrophic bacteria at the shorelines occur at different geographic regions all over the world, from the polar regions and the sea ice to the equator, and are the most obvious and visible documentation of the presence of anoxygenic phototrophic bacteria in the marine environment. Most of our knowledge is from the moderate northern hemisphere, in particular the European and the American coast. Conditions that favor the development of anoxygenic phototrophic bacteria can be found wherever quiet water is present, for example, in small splash water ponds at rocky shores, in small puddles and large lagoons, and in various types of sediments. They develop in the sediments of sandy beaches, of salt marshes and tidal

flats, and in muddy masses of decaying biomass of algae or seaweeds (11,13,14,37).

It appears that artificial changes at the shorelines, in particular the removal of quiet-water zones and places of sedimentation due to the construction of dikes, have a serious impact on natural habitats of anoxygenic phototrophic bacteria. Certainly, such activities have destroyed or disabled many locations for the development of these bacteria. This is apparently the case at the German coasts of the Baltic Sea, where places for the mass development of phototrophic bacteria are not common. However, when new natural shorelines are formed outside the constructed dikes and situations are established leading to quiet water and accumulation of dead organic matter, massive blooms of phototrophic bacteria may develop. Interestingly, such locations often are found in natural reserves, although the development of anoxygenic phototrophic bacteria certainly was not a reason to preserve these areas. Examples from the German Baltic Sea shore are the "Bottsand" close to Kiel, the "Geltinger Birk" in northern Schleswig-Holstein, and the northern part of the island of Hiddensee.

The Wide Distribution of Phototrophic Bacteria in Marine Habitats. The obvious and massive developments that already can be seen with the naked eye naturally have attracted scientists and such places were selected for investigations and used as sources to isolate phototrophic bacteria. From these descriptions, the impression may result that phototrophic bacteria occur at a few restricted sites. However, their occurrence, distribution, and development in nature must be much wider. Much more frequently the number of phototrophic bacteria is expected to be below the level that causes colored spots and layers in sediments or in coastal waters. Obviously, the blooms form the tip of an iceberg and the invisible development is the much more widely occurring situation.

Anoxygenic phototrophic have been found, for example, in many coastal sediments, even if these appeared to be oxic at the surface and not provide conditions suitable for anaerobic phototrophic bacteria. It could be demonstrated, for instance, that purple sulfur bacteria are widely distributed in sediments of the Baltic Sea. Not only at the shoreline, but also in most of the sediment samples even below 20 m in water depth, purple sulfur bacteria were found in numbers from a few hundred to a few thousand per mL from the deepest to the lower sites. Numbers at selected sites of the shoreline were significantly higher. The numbers in sediments of the open Baltic Sea are far too high to be explained by introduction from shoreline regions where places of massive development are not common and numbers in total are not sufficiently high (Imhoff, unpublished results). Most common at these places were strains genetically related to *T. roseopersicina*. Also, green sulfur bacteria occur regularly in coastal sediments of the Baltic Sea, where viable counts were found approximately two orders of magnitude below those of purple sulfur bacteria (i.e., 10^3 to 10^4 cells /mL in a sediment at a pre-blooming state of purple bacteria with 10^5 to 10^6 cells /mL). This is a level that clearly escapes detection by the naked eye.

Obligately phototrophic green sulfur bacteria have even been found, though in very low numbers, in sediments of the subtidal zone from the German Waddensea, which were characterized by high bacterial activity, decomposition and sulfate reduction, and anoxic/sulfidic conditions close to the surface. However, because of the tidal movement of the water at these places, the sediments were dry and in contact with the air during the low water situation, and oxic water was introduced during high tides; therefore, the top layer always received oxygen and remained oxic or at least microoxic through most of the time. Anoxic niches could prevail or be established for a short period during low tides at the sediment surface of mud puddles when strong sulfate reduction occurred at the top layer of the sediment. Unlike places having microbial mats with a prominent contribution of phototrophic microorganisms that stabilize the sediment surface and a steep chemical gradient system, these locations were without surface stabilization and visible signs of phototrophic microorganisms (Imhoff, unpublished results). It is certainly difficult to consider these places as habitats of strictly anaerobic and obligately phototrophic green sulfur bacteria. However, anoxic microniches receiving some illumination may be sufficient to maintain small populations of these anoxygenic phototrophic bacteria. If the movement of the water is stopped and sulfide production causes prolonged anoxic and sulfidic conditions of sediment and water phase, in nature or artificially in the lab, green sulfur bacteria may develop and eventually bloom rapidly.

Great Sippewissett Salt Marsh. An outstanding example of a marine coastal habitat is found in the microbial mats of the Great Sippewissett Salt Marsh (Cape Cod, Massachusetts). A number of phototrophic bacteria were isolated and several new species were described from this habitat (20,37–39). Laminated microbial mats of unusual thickness regularly occur during summer at Great Sippewissett Salt Marsh, and Nicholson and coworkers (40) described one very well-developed mat. In sandy intertidal sediments of the marsh, the mats were about 10 mm thick and comprised four to five distinctly colored layers. Phototrophic purple sulfur bacteria of the central pink layer and the directly underlying peach-colored layer were identified by using both pigment analysis and fine structure as revealed in thin sections by transmission electron microscopy. The bacteria of the peach layer were recognized as *Thiococcus pfennigii* on the basis of the presence of bacteriochlorophyll *b* and the bundles of tubular intracellular membranes in the coccoid cells. Another bacterium with bacteriochlorophyll *b* was isolated from this habitat, which resembles *T. pfennigii* in many properties but is a motile coccus. It was described as *Thioflavicoccus mobilis* (39). In the peach-colored layer of mats from the same locality, also, small spirilloid cells were detected by scanning electron microscopy (about 1% of total cells). This bacterium was isolated and found to have bacteriochlorophyll *b* and to exhibit a number of unusual characteristics. It was described as a new species *R. trueperi* (20). Also, *Roseospirillum parvum* was isolated from this habitat (38).

Coastal Waters, Lagoons, Fjords. There are a number of reports on the development of phototrophic bacteria in shallow coastal waters, such as lagoons, but also in saline lakes and anoxic fjords (11,13,14,37). In the more stable estuarine habitats, such as closed bays and lagoons, besides purple sulfur bacteria, green-colored species of the *Chlorobiaceae* are frequently found in massive blooms. In these shallow waters, they may have an advantage over their brown-colored counterparts. Both green- and brown-colored *Chlorobiaceae* may, however, occur together in such environments as have been found in the Bietri Bay of Ebrie Lagoon (Ivory Coast) (41). In this shallow water, the layers of phototrophic purple bacteria and *Chlorobiaceae* were not clearly separated as, for example, in Solar Lake (10). A similar pattern, however, was found with the highest number of phototrophic purple bacteria in the uppermost part of the layer and the maximum cell density of *Chlorobiaceae* below. The brown-colored Chlorobiaceae became more dominant in the deepest part of the layer in this lagoon (41) and are considered to generally gain importance with the decline of the chemocline to deeper water layers as in lakes and fjords.

The Black Sea. A special case of a stratified marine habitat is the Black Sea. Although its anoxic layer did not reach the photic zone, and development of phototrophic bacteria seemed to be impossible, such bacteria have been isolated from the dark anoxic layers. Hashwa and Trüper (42) observed in enrichment and pure cultures from Black Sea bottom sediments at 600 and 2,240 m depth, respectively, *T. roseopersicina*, *Allochromatium warmingii*, and *C. phaeobacteroides*. These authors assumed survival of the phototrophic bacteria that may be washed away from their estuarine environment in the dark layers of the Black Sea, but excluded active growth. At about the same time of their study, there was a report on mass mortality of phototrophic bacteria in the Black Sea (43). These authors had only scanning-electron microscopic information of particle form, size, and number and therefore could not prove the existence of phototrophic sulfur bacteria, but claimed the mass mortality of bacteria such as *Thiocapsa*, that is, spherical purple sulfur bacteria. At the time of their investigation, there was no light at the chemocline, and phototrophic life was not possible. If the particles observed by Dickmann and Artuz (43) were bacteria, the development of a chemolithotrophically growing purple sulfur bacterium such as *T. roseopersicina* at the dark chemocline could be one possible explanation. The chemocline in the Black Sea had risen during the following years and the situation was much different approximately 10 years later, when it reached horizons receiving light of minor intensities and large amounts of bacteriochlorophyll *e* and brown-colored green sulfur bacteria were detected (44–46).

Sea Ice. A habitat generally regarded to be oxic but not anticipated to have anoxic niches is sea ice. In sea ice of the western Baltic Sea that formed a layer of 1 to 2 m thickness over several weeks in the late winter of 1996 (February/March), purple sulfur bacteria were found in significant proportions by using genetic approaches (47). Genetic sequence information obtained after PCR and DGGE separation gave evidence of a marine purple sulfur bacterium (three related sequences) together with other anaerobic bacteria in the interior of the ice cover (47). These data are the first strong hints on the possible existence of anoxic niches within the complex system of small brine channels within sea ice. Again, the oxygen tolerance, the potential of respiratory energy conservation, and the ability to grow both photo- and chemoorganotrophically are considered to be excellent prerequisites for an anoxygenic phototrophic bacterium to live in this habitat.

Salt and Soda Lakes. Although many habitats of phototrophic bacteria in the coastal zones contain brackish waters, others are more concentrated than seawater. Shallow waters in splash water ponds, coastal lagoons, closed basins, etc., of the coastal zone receiving intensive illumination from the sun are subject to evaporation. As a consequence, not only inorganic salts but also organic matter accumulates and chances for the occurrence of anoxic conditions and the development of anoxygenic phototrophic bacteria increase dramatically. These waters have higher fluctuations in salt concentrations and quite often the salinities are higher than in seawater. Phototrophic bacteria adapted to this type of habitat are expected to require or at least tolerate salt concentrations above seawater salinity. Many isolates from such places do so.

Hypersaline habitats show greatly varying ionic composition. Thalassohaline water occur as natural evaporation pools of marine water or as artificial evaporation ponds of marine salterns. A different type of hypersaline environments is found in various athallassohaline water of inland saltwater lakes. A few prominent examples of such lakes are the Great Salt Lake (Utah), the Dead Sea (Israel), and the soda lakes of the Wadi Natrun in Egypt. Halophilic phototrophic bacteria occur in visible masses and were isolated from marine salterns (48–50), alkaline soda lakes in the Egyptian Wadi Natrun (51–54), Russian soda lakes in Siberia and Mongolia (55,56), and the Solar Lake (10,57,58).

PHOTOTROPHIC BACTERIA ISOLATED FROM MARINE AND HYPERSALINE HABITATS

The most prominent groups of anoxygenic phototrophic bacteria in marine habitats are the purple and green sulfur bacteria. From the early literature, the impression is given that marine forms of purple and green sulfur bacteria are not well differentiated from their counterparts living in freshwater environments. Many of the isolates from marine habitats were identified or tentatively classified as species known from freshwater sources. Because, for many of the early isolates from marine environments, salt response has not been determined, it remains unclear whether they are true marine bacteria or not. Historically, the establishment of media and culture conditions for green and purple sulfur bacteria (59,60) stimulated the isolation and study of phototrophic sulfur bacteria mainly from freshwater sources. In the early 1970s, the majority of

known anoxygenic phototrophic bacteria was represented by isolates from freshwater sources, and only a few salt-dependent phototrophic purple sulfur bacteria had been described. The first salt-dependent and sulfide-tolerant marine purple nonsulfur bacterium described was *Rhodovulum sulfidophilum* (61). In particular, during the past two decades, the consequent application of salt concentrations relevant to marine and hypersaline environments, respectively, led to the isolation of a larger number of new, truly marine and halophilic, phototrophic bacteria specifically adapted to the salt concentrations of their habitats (Tables 2–4).

Chromatiaceae

Chromatiaceae are the most obvious and numerous phototrophic bacteria in many estuarine habitats. Purple sulfur bacteria, most frequently observed and also isolated from marine sediments and shallow waters, were assigned to *T. roseopersicina*, *T. violacea*, and

Allochromatium vinosum. Also, *A. warmingii*, *Thiocystis violascens*, *Allochromatium minutissimum*, *Thiocystis minor*, *Thiocapsa rosea*, *Marichromatium gracile*, and *Isochromatium buderi* were common (11,13,14,37). Of these bacteria, only *I. buderi* has been described as a marine and salt-dependent bacterium (62) and only this species and *M. gracile* belong to the phylogenetic branch of the truly marine and halophilic Chromatiaceae (63; Table 2). Other truly marine Chromatiaceae were described more recently and include *M. purpuratum*, *Rhabdochromatium marinum*, *Thiorhodococcus minor*, *Thiorhodovibrio winogradskyi*, and *Thioalkalicoccus limnaeus* (Table 2). Also, three genetically related species (*T. pfennigii*, *T. mobilis*, and *T. limnaeus*) that have spherical cells, containing bacteriochlorophyll *b* and tubular internal membrane systems, appear to be well-adapted to the lower salinity range of brackish and marine habitats. *Thioalkalicoccus limnaeus* lives in low salinity alkaline soda lakes at pH 9.0 (56).

Great metabolic versatility is an important selective advantage in particular in unstable marine coastal habitats. Interestingly, the most versatile phototrophic purple bacteria frequently are among the dominant species in highly dynamic coastal habitats (11,37,79–81). In particular, *A. vinosum*, *M. gracile*, *T. roseopersicina*, and *R. sulfidophilum* have frequently been observed and isolated from marine coastal habitats. The physiological versatility of these species is reflected (*1*) in the ability to use different possibilities of energy conservation and different photosynthetic electron donors, in particular sulfide and thiosulfate, (*2*) in the high potential of photoheterotrophic growth together with the ability to assimilate sulfate as sole sulfur source, and (*3*) in the ability to grow chemotrophically under oxic conditions in the dark, either autotrophically or heterotrophically.

The occurrence and dominance of *T. roseopersicina* in coastal marine environments deserves special attention. *Thiocapsa roseopersicina* is found in the phylogenetic branch of the freshwater Chromatiaceae (discussed later), and therefore part of the following discussion may be representative also for other species of this branch that live in the marine environment, but are not true marine bacteria. There are several reasons for *T. roseopersicina* to be very common in marine coastal habitats and among the most frequently isolated phototrophic purple sulfur bacteria. One of the most important reasons is its very high metabolic flexibility. This bacterium not only is tolerant to oxygen, but readily makes use of it by growing

by aerobic respiration; chemoorganotrophic and also chemolithotrophic growth in the dark is possible. As far as can be delineated from the ecological evidence and from preliminary experiments under enrichment conditions, *T. roseopersicina* can compete with chemolithotrophic sulfur bacteria and grow chemolithotrophically at the chemocline of sediments and marine waters. This versatility can be responsible for the wide distribution in marine environments, if these bacteria are able to cope with the prevailing salt concentrations. The salt relations of *T. roseopersicina* reveal no salt requirement but a tolerance and an indifferent response to the low concentrations found in brackish and marine habitats (37,82,83). The nature of osmotica accumulated by these bacteria upon salt stress, sucrose as sole component, reveal that they have limited capacity to adapt to saline conditions and are not fit for life at elevated salt concentrations. Sucrose is found in bacteria that are the least adapted to saline environments (84).

Halophilic Chromatiaceae species that optimally thrive at elevated salt concentrations beyond those of seawater are represented by a few specialized species such as *H. salexigens* (65), *H. glycolicum* (57) and *T. halophila* (66).

Ectothiorhodospiraceae

Most probably, early observations indicate the presence of bacteria that could be *Ectothiorhodospira* or *Halorhodospira* species in hypersaline environments long before the systematic position of these bacteria became known. Baas-Becking reported on a red halophilic spirillum from the Owens Lake, California (85), which apparently formed extracellular elemental sulfur, similar to the spiral and halophilic phototrophic bacteria found by Van Niel in some hypersaline lakes (86). Butlin and Postgate (87), during their work on the Ain-en- Zauia (Libya), observed many spiral bodies that might have been *Halorhodospira* cells. An isolate from the Owens Lake (California) was first described as a *Chromatium*, but fitted well with the properties of halophilic *Halorhodospira* species (88). It was recognized later as such (89,90). Post (91) in his work on the Great Salt Lake (Utah), did not mention the presence of phototrophic bacteria, but Brock observed a bacterium resembling *Hlr. halophila* in the more saline northern part of this lake and reported on the isolation of this bacterium (92). Jannasch (51) observed a red coloration in some alkaline salt lakes in the Wadi Natrun (Egypt), and attributed this coloration to the development of phototrophic bacteria. Microscopical observation showed that spiral forms were dominant, but attempts to isolate these bacteria were not successful. During our studies on these lakes, we found mass developments of both green- and red-colored species of the genus *Halorhodospira* that developed separately, but close together at some locations (54). Also, some representatives of *Ectothiorhodospira* species were found. A larger number of pure cultures were obtained from these lakes (11,52,53,93).

Ectothiorhodospira and *Halorhodospira* species are characterized by their distinct and obligate requirement for salt and alkaline pH (94), and by their deposition of elemental sulfur outside the cells, if grown with sulfide as photosynthetic electron donors (94–96). Species of these genera have been isolated from marine and hypersaline habitats, but not from freshwater sources. The two genera can be distinguished on the basis of their salt requirement. *Ectothiorhodospira* species have growth optima of 1 to 7% total salinity (tolerances up to 15% by *Ect. haloalkaliphila* and down to 0% of *Ect. shaposhnikovii*) and were isolated from marine environments and from hypersaline lakes. They include the slightly halophilic species *Ect. mobilis* (74), *Ect. vacuolata* (78), *Ect. shaposhnikovii* (77), and *Ect. marismortui* (75), as well as *Ect. marina* (76,82) and *Ect. haloalkaliphila* (76). Only strains of *Ect. haloalkaliphila* tolerate and grow up to 15% total salts, although their salt optima are much lower.

Ectothiorhodospira species are quite common in marine habitats typical for other purple bacteria (11,34,37,82,97), although never as numerous and dominant as representatives of the Chromatiaceae.

Halorhodospira species require very high salt concentrations and do not grow below 10% total salts. The extremely halophilic *Hlr. halophila*, *Hlr. halochloris*, and *Hlr. abdelmalekii* bloom in concentrated brines of alkaline salt and soda lakes at various places around the world (51,54,88,95,96), are well adapted to the high temperature, high pH levels, high light intensity, and high salinity of these environments and have not been isolated from marine habitats. *Halorhodospira halophila* is the most common of the extremely halophilic species and has been isolated from many hypersaline environments (11). *Halorhodospira halophila* strains show optimum growth at equal or even higher salinities than representatives of the known archaeobacterial "extreme halophiles." They develop in saturated brines of alkaline soda lakes.

The recently described *T. sibirica* is specifically adapted to low saline, alkaline soda lakes and phylogenetically belongs to the Ectothiorhodospiraceae (55).

Purple Nonsulfur Bacteria

Purple nonsulfur bacteria are regularly found together with purple and green sulfur bacteria in sediments and aquatic habitats, sometimes even in high numbers (11,79,98). Compared with the *Chromatiaceae*, which are easily recognized by elemental sulfur globules stored inside their cells, the purple nonsulfur bacteria are morphologically much less conspicuous. Most of the purple nonsulfur bacteria have been isolated from freshwater habitats and are very sensitive to even low concentrations of sulfide. For a long time, purple nonsulfur bacteria have been considered typically to inhabit freshwater habitats and to be unable to use sulfide as a photosynthetic electron donor (24,79,86). In marine environments, in which anoxic conditions normally correlate with the presence of sulfide, they would not find conditions for their development.

The first, truly marine purple nonsulfur bacterium isolated in pure culture was *R. sulfidophilum* (61), a bacterium that requires salt for optimum growth and is quite tolerant even to high sulfide concentrations (6 mM) and readily uses sulfide as a photosynthetic electron donor. Although *R. sulfidophilum* can grow at low salt concentrations, it has an optimum at 2.5% NaCl and apparently is restricted to the development in marine

waters. This habitat restriction is demonstrated by the fact that *R. sulfidophilum* has not been isolated from freshwater habitats and by the following observation. From two small puddles, a splash water puddle at the rocky Adriatic shoreline and a freshwater puddle not more than 10 m apart from the other but outside the splash water zone, the dominant purple nonsulfur bacteria were isolated. The isolates from the salty puddle yielded strains of *R. sulfidophilum*, whereas those from the freshwater yielded *Rhodobacter capsulatus* strains (11). *Rhodovulum sulfidophilum* is the most common marine purple nonsulfur bacterium and is even found in hypersaline environments. It has been found, sometimes in high numbers, in marine mud flats of the Dutch Waddensea, in marine sponges, in sandy sediments of the German Island Mellum, in salt swamps at Al-Azraq (Jordan), in various splash water pools, in marine lagoons and lakes (11). *Rhodovulum sulfidophilum* is well adapted to rapidly changing environmental conditions in marine tidal areas by its great metabolic versatility. The latter is reflected in the ability to grow photoheterotrophically with organic electron donors, photoautotrophically with hydrogen, sulfide, and thiosulfate as electron donors, and also chemotrophically under oxic conditions in the dark (61,99). In particular, its high tolerance toward sulfide and its ability to readily oxidize sulfide and thiosulfate to sulfate are prerequisites for a successful competition with purple sulfur bacteria in the natural environment. Such a successful competition could be demonstrated in enrichment cultures from tidal pools, where both *Marichromatium* and *Allochromatium* species together with *R. sulfidophilum* were present, and where the *Rhodovulum* rapidly outgrew the purple sulfur bacteria (11). All attempts to isolate *R. sulfidophilum* from freshwater sources were unsuccessful (11,61). The salt responses are slightly different, depending on the natural habitat of the isolate. Some strains did grow in the absence of salt; others were strictly salt dependent. Optimum growth of all strains was between 1 and 5% NaCl, and good growth of some strains was observed even at 10% salts (11).

Most of the purple nonsulfur bacteria from marine habitats known to date are typical marine bacteria that require NaCl and are not found in freshwater habitats (11, Table 3). These marine forms include the species of the genera *Rhodovulum* and *Rhodobium*. Another true marine bacterium from marine salt marshes is *R. trueperi* (20). Also, *R. parvum* is well adapted to marine salt concentrations (38). *Rhodobaca borogenensis* is a new isolate from an alkaline soda lake with low salt concentrations and adapted in its salt response to this habitat (100). True marine purple nonsulfur bacteria and some of their properties are shown in Table 3.

In addition, several halophilic purple nonsulfur α-Proteobacteria that live in hypersaline habitats are known. *Rhodothalassium salexigens* and *R. salinarum* are common to evaporated seawater pools and marine salterns (48,101,102), and *R. sodomensis* is well adapted to hypersaline environments (103). *Roseospira mediosalina*, although growing optimally between 5 to 7% NaCl, was isolated from a salty hot spring containing not more than 2% salts (104).

Chlorobiaceae

Chlorobiaceae are obligately phototrophic, strictly depend on anoxic conditions and on reduced sulfur compounds, do not grow under photoheterotrophic conditions, and can assimilate only a limited number of organic carbon sources while growing photolithotrophically (110,111). Therefore, they depend on quite stable environmental conditions to compete with the more versatile phototrophic purple bacteria. Nevertheless, Chlorobiaceae are common in marine habitats. Most obvious is their development in the more stable brackish and marine lagoons and ponds (37,78,112–114) and in the lower anoxic part of deeper aquatic marine habitats. In marine sediments, they occur in lower numbers and below the red layers of phototrophic purple bacteria (115).

Green sulfur bacteria that occur in brackish and marine water tolerate or require NaCl for growth and have a salt optimum between 2 to 5% (Table 4). Among these are the vibrioid green sulfur bacteria that were cultivated routinely at 1% NaCl (Pfennig, pers. comm.). *Prosthecochloris aestuarii* and *Chlorobium vibrioforme* are frequently observed in marine coastal habitats (37,82,115), but also *Pelodictyon luteolum* and *Chlorobium chlorovibrioides* were regularly found (115,116).

The most halophilic and also halo-tolerant species of the green sulfur bacteria is *P. aestuarii*. This species is widely distributed in estuarine environments and has been found in various lagoons and estuarine ponds (10,82,115,122,123). It does not grow in the absence of salt, has a salt optimum between 2 and 6% NaCl, and can tolerate more than 10% NaCl (82,115).

PHYLOGENY OF MARINE AND HALOPHILIC PHOTOTROPHIC BACTERIA

Many observations give rise to the assumption that the salt relations of phototrophic bacteria are an important selective environmental factor and that salt concentrations of natural habitats have determined in an exclusive way the development and evolution of a selected range of phototrophic bacteria. On the basis of 16S rDNA sequences, a detailed analysis of the genetic relationship of anoxygenic phototrophic bacteria has been made (63,76,83,124,125). These phylogenetic studies gave considerable support to the existence of truly marine and halophilic phototrophic bacteria and demonstrated evolutionary lines of these bacteria separate from their freshwater relatives (63,76).

Chromatiaceae

Major phylogenetic branches within the Chromatiaceae can be distinguished on the basis of their salt requirement, one exclusively containing marine and halophilic species, the other primarily freshwater bacteria (63). The marine branch includes the genera *Marichromatium*, *Halochromatium*, *Rhabdochromatium*, *Thiococcus*, *Thioflavicoccus*, *Thioalkalicoccus*, *Thiorhodovibrio*, *Thiohalocapsa*,

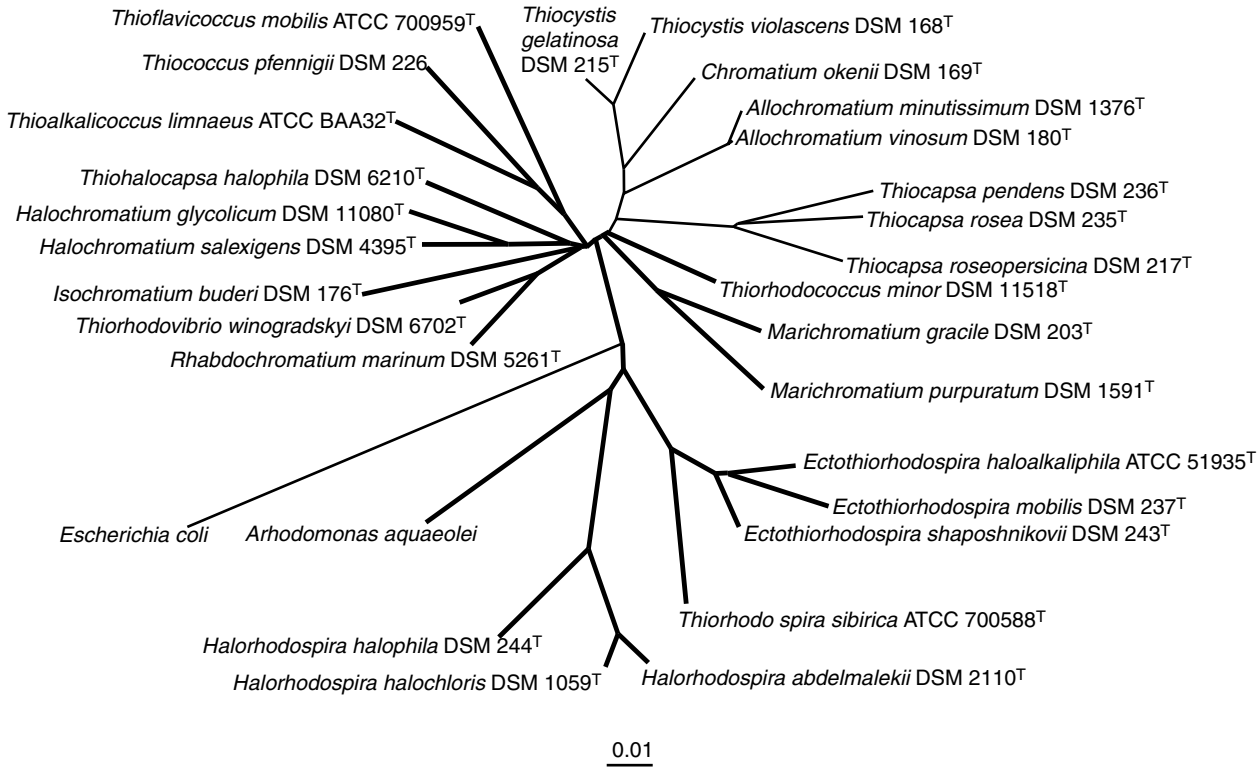

Figure 1. Phylogenetic tree of representative species of purple sulfur bacteria based on 16S rDNA sequence similarities and showing the phylogenetic lines of marine and halophilic species in comparison with those of freshwater species. Bold lines connect marine and halophilic strains. Sequence data used were published previously (63). In addition, 16S rDNA sequences of *Arhodomonas aquaeolei* (M26631), *T. sibirica* (AJ006530), *T. limnaeus* (AJ277023), and *T. mobilis* (AJ010125) were used. The distance bar indicates 1% sequence difference.

Thiorhodococcus, and *Isochromatium* (Fig. 1). Three of the marine species (*T. pfennigii*, *Thioalkalicoccus sibiricus*, and *T. mobilis*) that are adapted to the low range of salt concentrations of brackish and marine habitats contain bacteriochlorophyll *b*, have tubular internal membranes and are genetically related (20,39). Both the genetic relationship and the salt responses enable one to distinguish the halophilic *H. salexigens* and *H. glycolicum* and the marine *M. gracile* and *M. purpuratum* from each other and from freshwater species such as *A. vinosum* and relatives.

Another major branch of the purple sulfur bacteria represents the freshwater species (63). Several of these bacteria that do not have a specific requirement for salt and are routinely grown in freshwater media were frequently observed and also isolated from marine coastal habitats. Because they are tolerant to salt concentrations of brackish and marine waters and physiologically among the most versatile purple sulfur bacteria, they may well compete with the marine species of purple sulfur bacteria, in particular at low salt concentrations. Thus, although they do not require salt, their tolerance is sufficient to enable development and competition in numerous coastal habitats. Individual species of this group, such as *Thiocapsa litoralis* (126), even may grow better at minor salt concentrations than in its complete absence.

Ectothiorhodospiraceae

Two main phylogenetic subbranches of Ectothiorhodospiraceae represent the marine and moderately halophilic *Ectothiorhodospira* species on one and the extremely halophilic *Halorhodospira* species on the other hand (Fig. 1). Of particular importance in this context is the finding of phylogenetic relatedness of strictly chemotrophic halophilic bacteria without photosynthetic pigments, such as *Arhodomonas* and related species (127), which form a phylogenetic line of distant relationship to *Halorhodospira*. This is taken as support of the strong phylogenetic relevance of salt adaptation. Also, *T. sibirica* belongs to this group as a separate phylogenetic line related to *Ectothiorhodospira* (55).

Purple Nonsulfur Bacteria

The phototrophic purple nonsulfur bacteria have representatives in the α- and in the β-Proteobacteria. All known phototrophic β-Proteobacteria are freshwater bacteria, whereas a number of phototrophic α-Proteobacteria are represented by marine and halophilic species. According to the 16S rDNA sequence comparison, *Rhodobacter* species form two branches of marine and freshwater species. The marine species of *Rhodobacter* were removed from this genus and are now recognized as *Rhodovulum* species (128). Both genera represent closely related,

though phylogenetically separated, species of the α-3 Proteobacteria. *Rhodobium* species are genetically clearly distinct from all other α-2 Proteobacteria. Also, *R. trueperi*, *R. mediosalina*, and *R. parvum*, although related to *Rhodospirillum* species, form distinct phylogenetic lines of α-3 Proteobacteria. Not clearly affiliated to any of the other phototrophic α-Proteobacteria are the halophilic representatives, *R. salexigens*, and the two species of *Rhodovibrio*, *R. salinarum*, and *R. sodomensis* (Fig. 2).

Chlorobiaceae

Among the green sulfur bacteria, phylogenetic branches of bacteria having a salt requirement can be distinct from those of freshwater bacteria (Fig. 3). Those strains of green sulfur bacteria with 16S rDNA sequences similar to *P. aestuarii* have a definite salt requirement and are truly marine bacteria. This branch contains *P. aestuarii*, *C. vibrioforme* DSM 260, and *C. phaeovibrioides* DSM 1678 and is most distant to the other green sulfur bacteria (124,129, Alexander and Imhoff, unpublished). Genetically related to this group, though at a greater distance, is the marine *C. thalassium* (121). A second branch of salt-dependent green sulfur bacteria is formed by those strains known as *C. vibrioforme*, *C. phaeovibrioides*, and *P. luteolum*, all routinely grown at 1% NaCl (Pfennig, pers. comm.). *Chlorobium chlorovibrioides* together with two strains isolated by Lascelles represent a salt-dependent line within a further group of species (130, Alexander and Imhoff, unpublished). Salt-dependent green sulfur bacteria have the greatest phylogenetic distance among this group of bacteria and represent the deepest branching points. This gives support to the conclusion that the green sulfur bacteria have originated in the marine environment.

It should be noted here that the taxonomy of green sulfur bacteria is not reflecting the genetic relationship of these bacteria on the basis of 16S rDNA sequences, which strongly deviates from the current taxonomic system based on morphological and physiological properties (124,129).

SALT REQUIREMENT AND OSMOTIC ADAPTION

Common to typical marine species is a distinct salt requirement for optimum growth, which clearly distinguishes them from freshwater species growing best almost in the absence of salt. Although many of the marine and halophilic phototrophic bacteria can grow over a broad range of salt concentrations, most of them are strictly marine bacteria and have a lower limit below which no growth is possible. Physiological properties that define

Figure 2. The distance bar indicates 1% sequence difference.

the specific adaptation of bacteria to the marine environment are the requirement for salt and/or inorganic ions and are manifested in the accumulation of elevated concentrations of compatible solutes for osmotic adaptation (84).

How to Define Marine and Halophilic Bacteria?

The true marine nature of bacteria needs clear specification, but certainly cannot be defined as "growth in the presence of salt," because that could reflect a tolerance toward salt only, which is found to a different degree in a great number of freshwater bacteria. Freshwater species that do not require but are tolerant to salt concentrations in brackish and even marine habitats may develop there and even successfully compete with marine strains. An outstanding example of this last group of bacteria is *T. roseopersicina* (82,83).

The marine nature also cannot be defined as "no growth in the absence of salt" or inorganic ions below a threshold limit, because bacteria optimally adapted to the marine salt concentrations could be tolerant to low salt concentrations and grow in the absence of significant concentrations as, for example, *Ect. shaposhnikovii*. Although this does not appear to be common among true marine bacteria, those specifically adapted to the brackish water environment are also likely to grow in the absence of salt.

The only way to clearly define the need for and the degree of this requirement is the indication of the salt concentrations that define the growth optimum (84,131). Growth limits may be defined in addition. It should be noted that reliable results are obtained only if the growth response is tested over at least three consecutive subcultures at the same salt concentration.

Suggestions to define the ranges of the demand (132,133), and in addition the tolerances (84,131) have been made. Common natural environments to which bacteria have to be adapted represent freshwater, brackish water, marine habitats, slightly hypersaline water, and highly saline water including all possible transition stages. According to these natural situations and their growth optima, it has been proposed to classify bacteria as freshwater species (below 0.5%), brackish water species (0.5 to 2.0%), marine or slightly halophilic species (2.0

to 7%), moderately halophilic species (7 to 15%), and extremely halophilic species (more than 15%). Those bacteria that behave indifferent to salt concentrations from 0 to 3% NaCl or more, as *T. roseopersicina*, should be classified as slightly halo-tolerant freshwater bacteria.

Specific Sodium Requirement

Studies with halophilic *Halorhodospira* and *Ectothiorhodospira* strains indicate a distinct requirement for the sodium ion (134,135). Potassium ions were not required at elevated concentrations for growth of *Ect. haloalkaliphila* and could not effectively replace the high concentrations of sodium ions. The chloride ion could be replaced almost completely by sulfate and carbonate anions, and also elevated concentrations of sulfate were not required. Sodium and also chloride ions were actively excluded from the cytoplasm (134).

The question of a specific sodium requirement for *Ect. haloalkaliphila*, apart from any dependence on a specific external osmolarity, was approached by stepwise replacing NaCl in the medium by KCl or LiCl (11). A requirement of about 0.25 M NaCl was found. Below this concentration the growth rate decreased sharply (11). In similar experiments with *Hlr. halophila* and *Hlr. halochloris* by replacing NaCl with sucrose, a definite requirement for NaCl could also be shown for these species. NaCl could be substituted only partly by sucrose, indicating a specific requirement for NaCl by *Ectothiorhodospira* and *Halorhodospira* cells, which is, however, lower than the concentrations needed for optimum growth.

The structural and physiological basis for the increased dependence on NaCl in *Halorhodospira* cells is largely unknown. NaCl could be necessary for the integrity of the cell envelope or for some sodium-dependent processes within the membranes. It is, however, unlikely that variation in salt dependency of *Halorhodospira* species reflects the requirement for cell integrity. Cells of even the most halophilic strains do not lyse at 0.5 M NaCl. Sodium-dependent transport of glutamate and some other carboxylic acids has been found in *Hlr. halophila* and *Ect. shaposhnikovii* (136–138). Sodium-dependent transport systems per se do not, however, explain the high requirement for this ion. Maximal uptake rates of glutamate in *Hlr. halophila* were found well below the minimum growth-supporting concentration of NaCl (136).

Significant differences have been observed with regard to the requirement and growth responses toward various concentrations of the bivalent cations, magnesium and calcium. A specific cation requirement may be explained by the specific binding of cations to cell-surface structures. Isolates from alkaline soda lakes that almost are devoid of these cations demonstrate a requirement for minimum concentrations of these ions, whereas bacteria from thalassohaline salt lakes and from the Dead Sea with much higher concentrations of bivalent cations also have an increased requirement thereof (see 11,69,114). Thus, the concentrations of bivalent ions that favor optimum growth reflect the environmental concentrations and demonstrate that these bacteria are adapted to this aspect of their environment.

Osmotic Adaptation

To cope with elevated salt concentrations, transport systems for inorganic ions and uptake, respectively, synthesis of organic solutes to achieve osmotic adaptation is required. Whether or not it is the specific ionic requirement or the osmotic demand or both, osmotic adaptation is required in direct response to the actual external osmolarity (84).

It was the application of carbon-13 NMR spectroscopy that led to the recognition of organic solutes involved in osmotic adaptation of halophilic eubacteria. The biosynthesis of various organic compatible solutes was first demonstrated in a number of cyanobacteria. In a marine isolate of *Synechococcus*, O-a-D-glucopyranosyl-(1-2)-glycerol was found as principal osmoticum by application of NMR measurements (139). Later, a greater number of cyanobacteria have been analyzed and a correlation was found between the chemical nature of accumulated osmotica and the salt tolerance (140–142). It was demonstrated that the kind of accumulated solutes correlated well with the tolerated salt concentration. Typical freshwater cyanobacteria with a maximum salt tolerance of approximately 1 M NaCl accumulated sugars (sucrose, glucose, fructose, trehalose). Cyanobacteria from marine environments with maximum tolerance below 2 M NaCl accumulated glucosylglycerol, and more tolerant isolates from hypersaline environments accumulated glycine betaine or glutamate betaine (140). These findings suggested that a correlation exists between the upper limit of tolerated salt concentration and the solutes accumulated inside the cells, that is, the more compatible the accumulated solute the higher the salt or osmotic tolerance. The low compatibility of reducing sugars and the high compatibility of glycerol and glycine betaine have been demonstrated in many investigations (84,143–145). Structure, solubility, and accumulation in marine cyanobacteria indicate an intermediate compatibility of glucosylglycerol (142). In consequence, one of the reasons for the lack of salt or osmotic tolerance can be the inability to accumulate suitable compatible solutes by uptake or biosynthesis.

The situation is quite similar with anoxygenic phototrophic purple bacteria (84,146,147). Sucrose as the sole compatible solute is found only in species with low salt tolerance, including species frequently found in brackish and marine coastal waters including *T. roseopersicina*, *A. vinosum*, *T. violacea*, and *T. rosea* (147). Two green sulfur bacteria accumulated trehalose as the sole compound (147). Those species that are well adapted even to hypersaline salt concentrations accumulate a combination of glycine betaine, ectoine, N-acetyl-glutaminylglutamine amide (or other glutamine amide derivatives) with the one or the other sugar (trehalose or sucrose) in addition (Tables 2 to 4).

More elaborate studies have been made with *Hlr. halochloris*. The major compatible solute of this bacterium is glycine betaine, which is synthesized from acetate and carbonate in response to the external salinity and accumulated to more than 2 M inside the cells (148). Also, significant concentrations of ectoine and trehalose were found under certain growth conditions (149). The relative proportions of the three compatible solutes vary with the

growth conditions and the growth phase. Under nitrogen starvation, trehalose concentration increases up to 0.5 M in *Hlr. halochloris* and replaces, in particular, ectoine, which contains two nitrogen atoms per molecule. A trehalase has been characterized from this bacterium, which is specific for trehalose, has a high K_m of 0.5 M for trehalose, is activated by glycine betaine and inhibited by salts, most strongly by NaCl (150). These properties, in particular the inhibition by NaCl and the low K_m, are characteristic for an enzyme that degrades a compatible solute. Activation by betaine is suited to increase trehalose degradation if glycine betaine is accumulated, and under suitable conditions enables a rapid replacement of trehalose by glycine betaine. Also, the biosynthesis of glycine betaine and ectoine in *Hlr. halochloris* have been elucidated (151,152). All available evidence points to a comparatively low content of inorganic ions in the cytoplasm of *Halorhodospira* species. In agreement with a low ionic cell interior, is the strong inhibition by NaCl and KCl of several enzymes (isocitrate dehydrogenase, malate dehydrogenase, glutamate dehydrogenase, ribulose bisphosphate carboxylase, and ATPase) in *Hlr. halophila* and *Hlr. halochloris* (11,153,154). Light-dependent release of sodium and uptake of potassium ions indicates an energy-dependent maintenance of high-concentration gradients of these ions across the membranes.

Although ion transport and accumulation of compatible solutes in the cells is a necessary prerequisite to cope with increased osmotic pressures in the saline environment and to adapt to elevated salt concentrations, it appears that this ability defines the upper limit, that is, the tolerance rather than the requirement of a particular bacterium. The increase of internal concentrations is directly related to the external solute concentrations, respectively osmolarity, and not dependent on the optimum salt concentrations. A higher requirement for salt, however, in most cases also implicates a higher tolerance. Therefore, the kind and concentration of accumulated solutes is of importance for successful adaptation to the marine and hypersaline environment.

CONCLUSION

All available evidence from the ecological, physiological, and phylogenetic line is indicative of the existence of truly marine and halophilic phototrophic bacteria in the groups of green sulfur bacteria, purple sulfur bacteria, and also purple nonsulfur bacteria. Evidence for the heliobacteria and the green nonsulfur bacteria (*Chloroflexus* and relatives) is lacking or insufficient to draw clear conclusions. Major phylogenetic lines of purple and green sulfur bacteria represent branches of bacteria adapted to the saline and hypersaline environment. In addition, separate lines of evolution of the purple nonsulfur α-Proteobacteria are marine or halophilic bacteria. The phototrophic purple nonsulfur β-Proteobacteria are true freshwater species and no representative is known to occur in marine habitats.

Although the whole spectrum of salt concentrations is inhabited by phototrophic bacteria, individual species are adapted to a selected range according to the definitions given for freshwater, brackish water, marine, moderately halophilic, and extremely halophilic bacteria. Although the dependence on even low concentrations of salt prevents growth of strictly marine and halophilic species in freshwater habitats, the salt tolerance of several freshwater species gives a chance to these bacteria to develop in brackish and marine habitats. Similarly, salt responses of extremely halophilic species exclude their development in marine and brackish waters, whereas some of the marine species are tolerant to concentrations of the hypersaline range. The salt relations of the bacteria determine possible natural habitats and exclude others. If the environmental salt concentration is an exclusive factor for the development of bacterial species, habitat restriction for certain species should result and over evolutionary timescales give rise to different phylogenetic lines of bacteria. Thus, salt responses should, to the degree they are exclusive, show up in phylogenetic relationships of the (phototrophic) bacteria. Over evolutionary timescales this has resulted in a separation of species from freshwater habitats and saltwater habitats, allowing an overlap between freshwater and brackish water as far as common species in both kinds of habitats exist. This is exactly the picture that emerges from phylogenetic data, salt responses, and the growing knowledge on habitat ranges of the species.

Present day knowledge on the natural diversity is based on pure culture studies and depends on the success of our isolation and cultivation skills. New techniques of molecular genetic analysis that allow us the identification of bacteria in the natural environment without cultivation will enable us to determine the species composition of specific habitats and ecological niches. These methods will allow to prove the concept of habitat restriction and to determine the role of physicochemical factors for habitat selection and distribution of phototrophic bacteria. Quite interesting, the application of such molecular genetic approaches to determine the natural diversity of green sulfur bacteria in marine coastal habitats of geographically very distant places so far only yielded sequences belonging to the marine branches of the phylogenetic tree of the green sulfur bacteria (Alexander and Imhoff, unpublished results). These results not only proved the success of available culture techniques to isolate and cultivate representatives of important phylogenetic lines found in nature but also demonstrated the role of salt in habitat restriction.

PHYLOGENETICALLY BASED METHODS IN MICROBIAL ECOLOGY

BARBARA J. MACGREGOR
Max Planck Institute for Marine Microbiology
Bremen, Germany

Molecular biological methods in microbial ecology are used to describe the composition and activity of complex communities by characterizing biomarker molecules, rather than by isolating and culturing microbial species in the laboratory. Commonly used biomarkers include pigments (1), lipids (2), quinones (3), proteins (4,5), and the nucleic acids, DNA and RNA, which are the focus of this chapter.

A serious limitation of traditional culture-based methods of studying natural microbial populations is that only species able to grow and outcompete other species, under particular growth conditions, will be detected (6–8). Traits conducive to growth in laboratory media do not necessarily confer competitiveness in the frequently harsher and more variable natural environment; it is generally impractical to test all possible permutations of temperature, carbon source, oxygen concentration, and so on. It may also be difficult to differentiate among closely related species on the basis of assayable phenotypic traits.

The limitations of molecular biological methods, on the other hand, include questions of extraction efficiency (9,10), differential molecular preservation (11), environmental heterogeneity and sampling scale, sample handling and contamination (12), and database completeness. Microbial activities in the environment are often best explored by a combination of traditional and molecular methods — time and money permitting.

A sometimes confusing proliferation of nucleic acid–based techniques has been developed in the past decade or so; many of them designated by acronyms (RT-PCR, T-RFLP, DGGE, etc.) that can seem quite mysterious to the uninitiated. Several currently popular methods are introduced here and have also been recently reviewed elsewhere (13–16). Further descriptions of RNA, DNA, and the enzymes that act on them can be found in microbiology, biochemistry, and molecular biology textbooks such as the excellent ones by Madigan (17), Stryer (18), and Alberts (19). An introduction to detailed experimental methods can be found in Sambrook and coworkers (20), and in the catalogs or on the World Wide Web sites of companies that supply oligonucleotide probes and primers.

BACKGROUND

Transcription and Translation: A Review

In the "central dogma" of biochemistry (21; for a historical perspective, 22), RNA polymerase transcribes DNA-encoded genes to RNA, and ribosomes then translate messenger RNA (mRNA) to protein (Fig. 1). DNA is a double-stranded polynucleic acid, with complementary "sense" and "nonsense" strands joined by adenine-thymine (A·T) and guanine-cytosine (G·C) base pairs. RNA is a single-stranded polynucleotide, transcribed from the "sense" strand, with uracil (U) replacing thymine. Proteins consist of amino acids joined by peptide bonds. Each of the 20 amino acids found in proteins is encoded by specific 3-nucleotide RNA sequences (codons). Transcription, translation, RNA and protein stability, and the enzymatic activity of proteins may all be regulated in response to environmental conditions. One goal of molecular microbial ecology is to measure the expression of specific genes in mixed populations, which might include

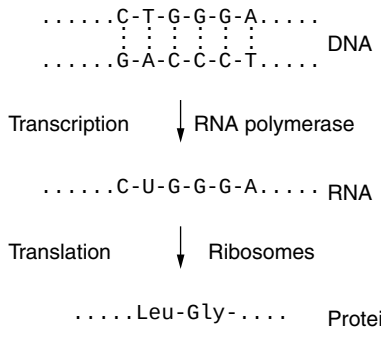

Figure 1. Transcription and translation: an overview.

thousands of species, and this, clearly, is an ambitious undertaking.

A more detailed view of transcription and translation is shown in Figure 2. RNA polymerase binds to specific DNA sequences (promoters) that precede genes or groups of genes (operons). Promoter recognition can be modulated by polymerase subunits (sigma factors) and regulatory proteins that may be produced or activated in response to environmental conditions such as heat shock or iron limitation. The polymerase moves along the DNA and produces an RNA molecule complementary to the coding strand. Transcription continues until the polymerase reaches a terminator sequence, at which point it dissociates from the DNA.

There are three major classes of RNA: ribosomal RNA (rRNA), transfer RNA (tRNA), and messenger RNA (mRNA). rRNA is a constituent of ribosomes, which are two-subunit rRNA/protein complexes. In prokaryotes (bacteria and archaea), the small subunit includes a 16S (SSU) rRNA, and the large subunit includes 23S and 5S rRNAs. Eukaryotes have 18S (SSU), 28S, 5S, and 5.8S rRNAs. Production and assembly of ribosomal components is tightly regulated (23–25). Several recent studies have given a detailed three-dimensional view of the complicated ribosome structure (26–28) showing how these components fit together.

tRNAs are small RNA molecules that carry specific amino acids on one end and have a 3-nucleotide RNA sequence (anticodon) complementary to the corresponding 3-nucleotide mRNA codon on the other end.

Ribosomes bind to specific ribosome-binding sequences in mRNA, complementary to a sequence in SSU rRNA, and begin translation at an initiation codon (most often AUG) encoding the amino acid methionine. The ribosome matches mRNA codons to tRNA anticodons and forms peptide bonds between sequential amino acids.

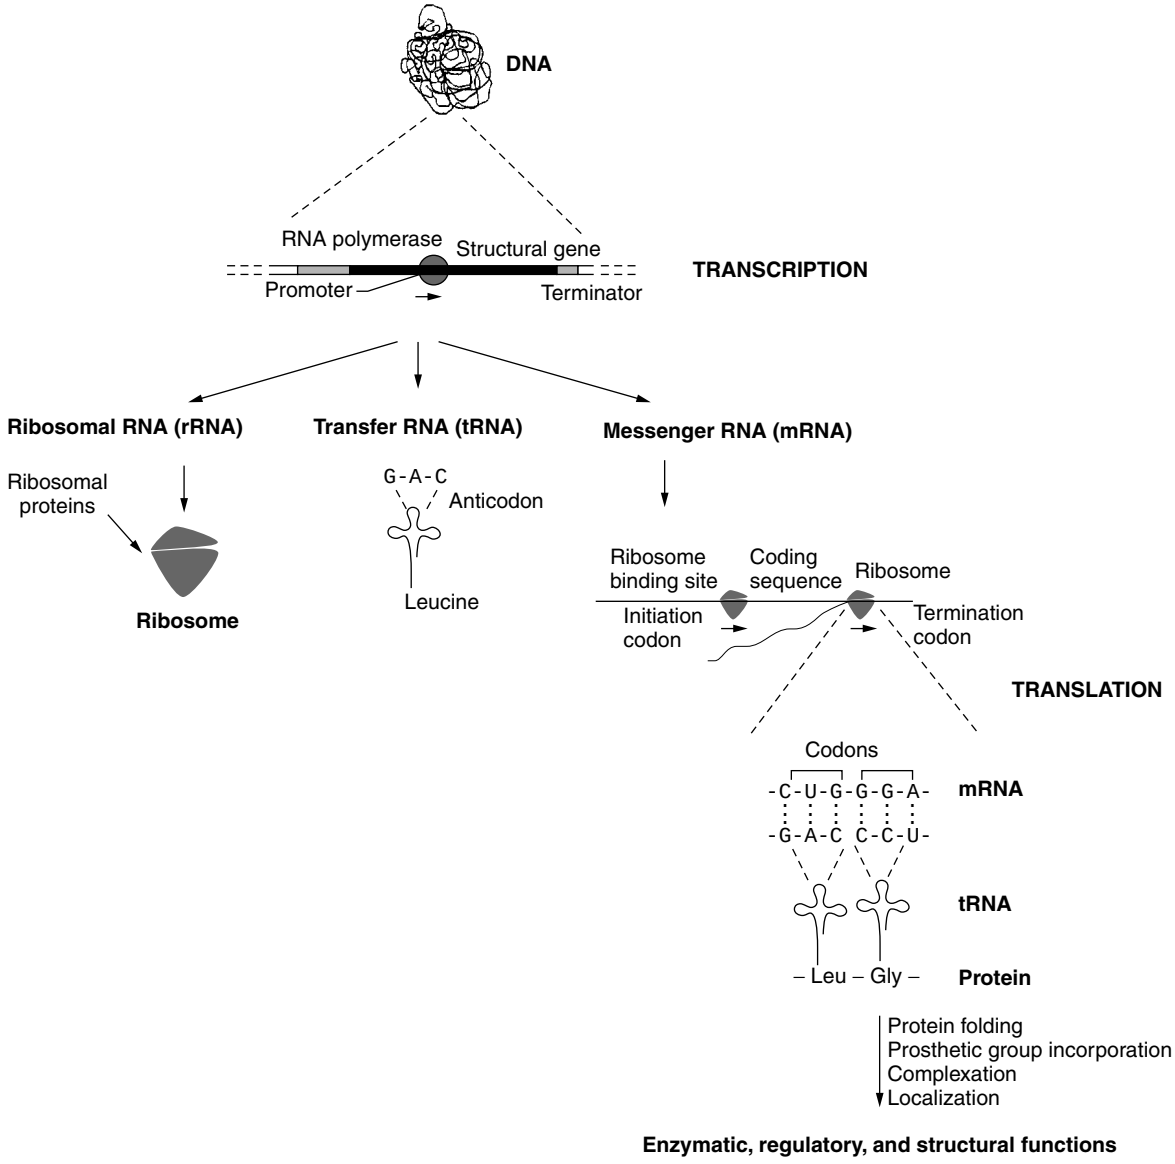

Figure 2. Transcription and translation: some details. See color insert.

Translation continues until the termination codon (UAG, UAA, or UGA) is reached. Newly produced proteins must then fold into their active configuration, and may require additional processing, cofactors, or localization to become functional.

From this brief overview, it can be seen that DNA-, RNA-, and protein-based methods measure different aspects of community activity. Transcription, translation, and protein maturation, as well as RNA and protein stability, may be regulated in response to environmental conditions. mRNA and protein stability may differ for a given gene (29), and proteins may have both active and inactive forms (e.g., 30). Both active and inactive microbes contain DNA, but active ones contain proportionally more RNA. To further complicate environmental studies, DNA can be stable extracellularly (31–33), whereas RNA is quickly degraded (a notorious problem in the laboratory), so amplified DNA sequences may not necessarily derive from the current population.

Phylogenetic Inference from Nucleic Acid Sequences

Nucleic acid sequences can be used to infer phylogenetic relationships and to identify unknown microbes by database comparisons. Steps in the construction of a phylogenetic tree are outlined in Figure 3. A collection of DNA sequences (in this case rDNA) is aligned. The dashes indicate positions in which other species (not shown) have additional bases. Mutations tend to occur less frequently in sequences encoding essential inter- or intramolecular interactions, such as substrate binding or secondary structure formation, so alignments generally reveal more- and less-conserved regions.

From the alignment, the number of base changes that would be required to change one sequence to another is computed for all pairs of species. Allowance is made for the presumed rate of back mutation. The resulting distance matrix is commonly shown as a tree, here in two different formats. In the radial tree, the evolutionary distance between species is represented as the sum of the lengths of the line segments connecting them. In the linear representation, distances are shown by the horizontal segments only. In both types of trees, nodes between branches represent inferred common ancestors.

The distance between two species is related to the time elapsed since divergence, but cannot be considered a direct measure of time. Mutation rates may vary among species, and between genes in the same species. For eukaryotic organisms, the molecular "clock" can be calibrated by comparison with the fossil record. For prokaryotes, with only a limited fossil record, calibration relies on evidence such as microbial molecules preserved in geologic formations.

Phylogenetic reconstruction is complicated by the possibility of gene transfer laterally between individuals (34,35) as well as vertically from an individual to its descendants (Fig. 4). This example shows the evolution of two genes in two species derived from a common ancestor. Gene A has been transmitted only vertically, whereas gene B was at some point transmitted horizontally from species 1 to species 2. Comparing the sequences of the genes in the present-day species, more differences will likely be seen between 1A and 2A than 1B and 2B. If only B were sequenced, a more recent common ancestor would be inferred.

As a result of gene transfers, therefore, different genes may yield different phylogenetic trees (36). It has been suggested that evolution might better be considered a network than a tree, with a combination of vertical and lateral exchanges, such that different genes in the same organism may have quite different histories (37). The relative importance of these two modes of inheritance should become clearer as the whole-genome sequences now being collected are interpreted (38).

The trees shown here were constructed with the neighbor-joining algorithm in the Arb sequence database program (*http://www.mikro.biologie.tumuenchen.de/pub/ARB*). A detailed discussion of the different algorithms available for phylogenetic analysis is beyond the scope of this article; an introduction may be found in Hillis and coworkers (39), and on-line resources have been collected by Felsenstein (*http://evolution.genetics.washington.edu/phylip/software.html*). DNA sequences obtained by researchers around the world are collected in a database maintained by the National Center for Biotechnology Information (*http://www.ncbi.nlm.nih.gov/*). For the most recent information on genome sequencing projects, The Institute for Genomic Research web site (*http://www.tigr.org*) is a good starting point.

Ribosomal RNA-Based Phylogeny

The SSU rRNA gene (the *rrn* operon or rDNA) is frequently used to construct evolutionary trees (40,41). It is an essential gene found in all known organisms, as well as in mitochondria and chloroplasts. It includes both quickly- and slowly-evolving regions, so that comparisons across both long and short evolutionary distances are possible. An extensive database of SSU rDNA sequences has accumulated, so newly acquired sequences may quickly be identified (see e.g., the Ribosomal Database Project web site, *http://www.cme.msu.edu/RDP/*). For determining the phylogeny of very closely related species or strains, however, longer or more quickly evolving sequences such as the 16S/23S spacer region (42) or the gyrase gene (43) may give better resolution than the SSU rRNA gene.

One complication for rRNA-based phylogeny is that many organisms have multiple *rrn* operons. Their sequences tend to be nearly identical, perhaps because of the requirement for interaction with ribosomal proteins (41,44), but some exceptions are known (e.g., 45,46).

It is generally considered that horizontal transfer of rDNA is unlikely, so that trees constructed using SSU rDNA sequences are predicted to accurately reflect the evolution of species. Ribosomes composed of a mixture of introduced and host-cell components might not work efficiently, so that cells containing them would grow slowly and be outcompeted in environments with limited resources. There is some recent evidence that this may not be entirely true. For example, an *Escherichia coli* strain with all seven of its chromosomal *rrn* operons deleted grew at near-normal rates when supplied with *rrn* operons from two of the three other bacterial species tried (47).

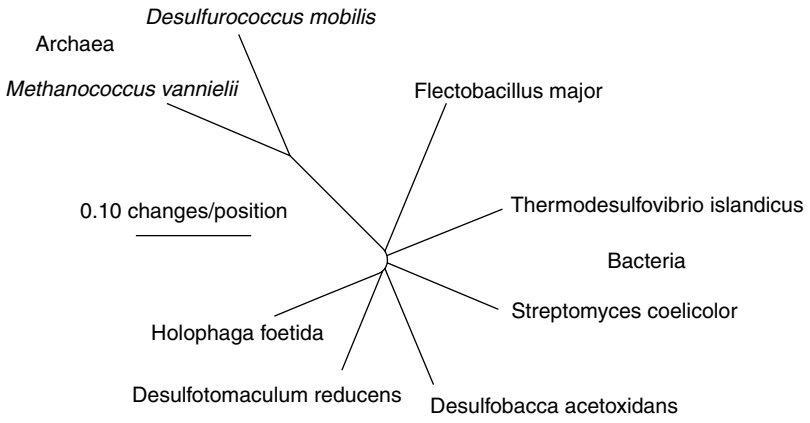
Radial tree



Linear tree

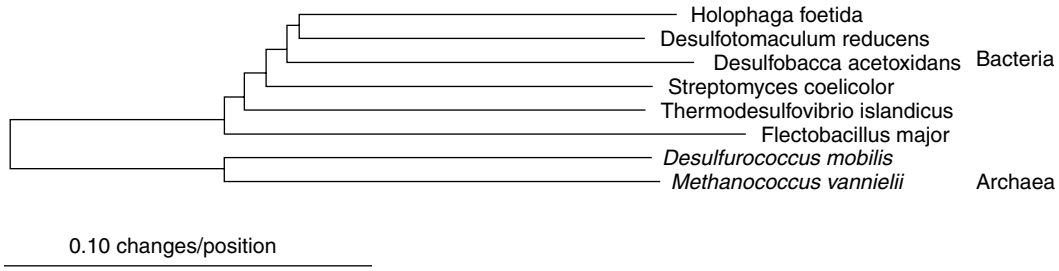


Figure 3. Construction of phylogenetic trees.

Many antibiotics kill cells or retard growth by interfering with ribosome function, and resistance can be conferred by ribosomal mutations. Gupta (48) has suggested that in environments in which antibiotic-producing bacteria are present, there might be a selection for acquisition of genes encoding antibiotic-resistant ribosomes, despite the possibly slower resultant growth rates. Evidence so far suggests that although such exchanges of rDNA may have occurred (49), they have been rare.

DNA-BASED METHODS

DNA can be considered the genetic potential of an individual or population. DNA isolated from environmental samples may be studied by direct hybridization with labeled probes that are cloned into plasmids or amplified by the polymerase chain reaction (PCR), with or without subsequent cloning.

Cloning and PCR increase rare sequences to assayable concentrations, but may introduce biases. Not all cloned

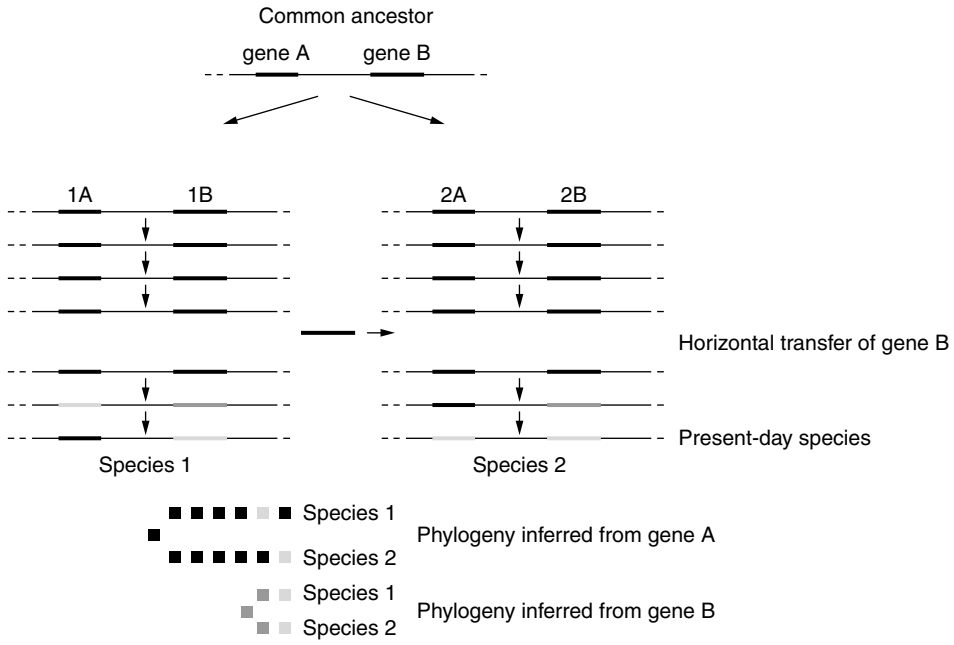

Figure 4. Lateral gene transfer. See color insert.

DNA sequences are stably maintained in host cells — for example, they may encode proteins that retard growth by competing for essential cofactors. Some DNA sequences are more readily amplified than others, for reasons not yet completely understood (50,51), hence not all sequences are necessarily amplified in direct proportion to their original abundance. It is also difficult to be sure that DNA (or any other biomarker) is being extracted with equal efficiency from all species in a sample. These caveats must be considered when designing experiments and interpreting results.

The Polymerase Chain Reaction (PCR)

PCR employs oligonucleotide primers and thermostable DNA polymerase to amplify target DNA sequences by temperature-controlled cycles of strand separation, primer annealing, and primer extension (Fig. 5). DNA isolated from an environmental sample is mixed with heat-stable DNA polymerase (e.g., Taq polymerase, isolated from the hyperthermophile *Thermus aquaticus*), dideoxy nucleotide triphosphates (dNTPs), and oligonucleotides complementary to the upstream and downstream ends of the gene to be amplified (primers). Reactions are performed in small volumes (typically 10–50 μL) in a thermal cycler capable of rapid cycles of heating and cooling. The reaction mixture is heated to separate it into single strands and then cooled to a temperature that allows stable but specific binding of the primers to their target sequences. DNA polymerase binds the resulting short double-stranded regions and elongates them. Repeated cycles result in numerous copies of the target sequence.

The primers used for PCR can be designed to target phylogenetic groups from the "universal" to the subspecies level. Annealing temperature, buffer composition, and number of cycles can be adjusted to control specificity. Optimum conditions must be determined empirically for each primer pair. This has become easier with the development of temperature-gradient PCR machines.

PCR amplification is prone to several types of artifacts. PCR bias was mentioned above. Chimeric sequences may be also produced, joining partial sequences amplified from two different templates (52,53), especially if short elongation times or too numerous cycles allow partially amplified sequences to accumulate (54). Computer algorithms are available to help detect these mixed sequences (55) by comparing different segments of amplified products to the database separately. If the two ends of a sequence have different closest relatives, the sequence is probably chimeric. Insertions, deletions, and base changes may also be introduced during elongation, but with a high-fidelity DNA polymerase, these should be found in only a very small proportion of product molecules and so are not likely to be detected by sequencing.

Cloning

Cloning is a method of separating the mixture of fragments obtained by PCR amplification, restriction enzyme digestion, or physical fragmentation (56,57) of a DNA sample (Fig. 6). The fragments are ligated with a plasmid, a small circular DNA molecule that can be maintained by bacteria as an extrachromosomal element. In the example shown, the plasmid encodes an antibiotic resistance enzyme and a lethal gene. The plasmid is linearized with a restriction enzyme that cuts it once, within the lethal gene, and ligated with PCR amplification products. Ligated molecules are introduced into *E. coli* cells made competent for direct DNA uptake by (for example) calcium chloride treatment (58–60), and the cells spread on antibiotic-containing agar plates. Only cells carrying active antibiotic resistance genes, but not expressing the lethal gene, will divide and give rise to colonies; the majority of such cells should contain plasmids with a lethal gene interrupted by a

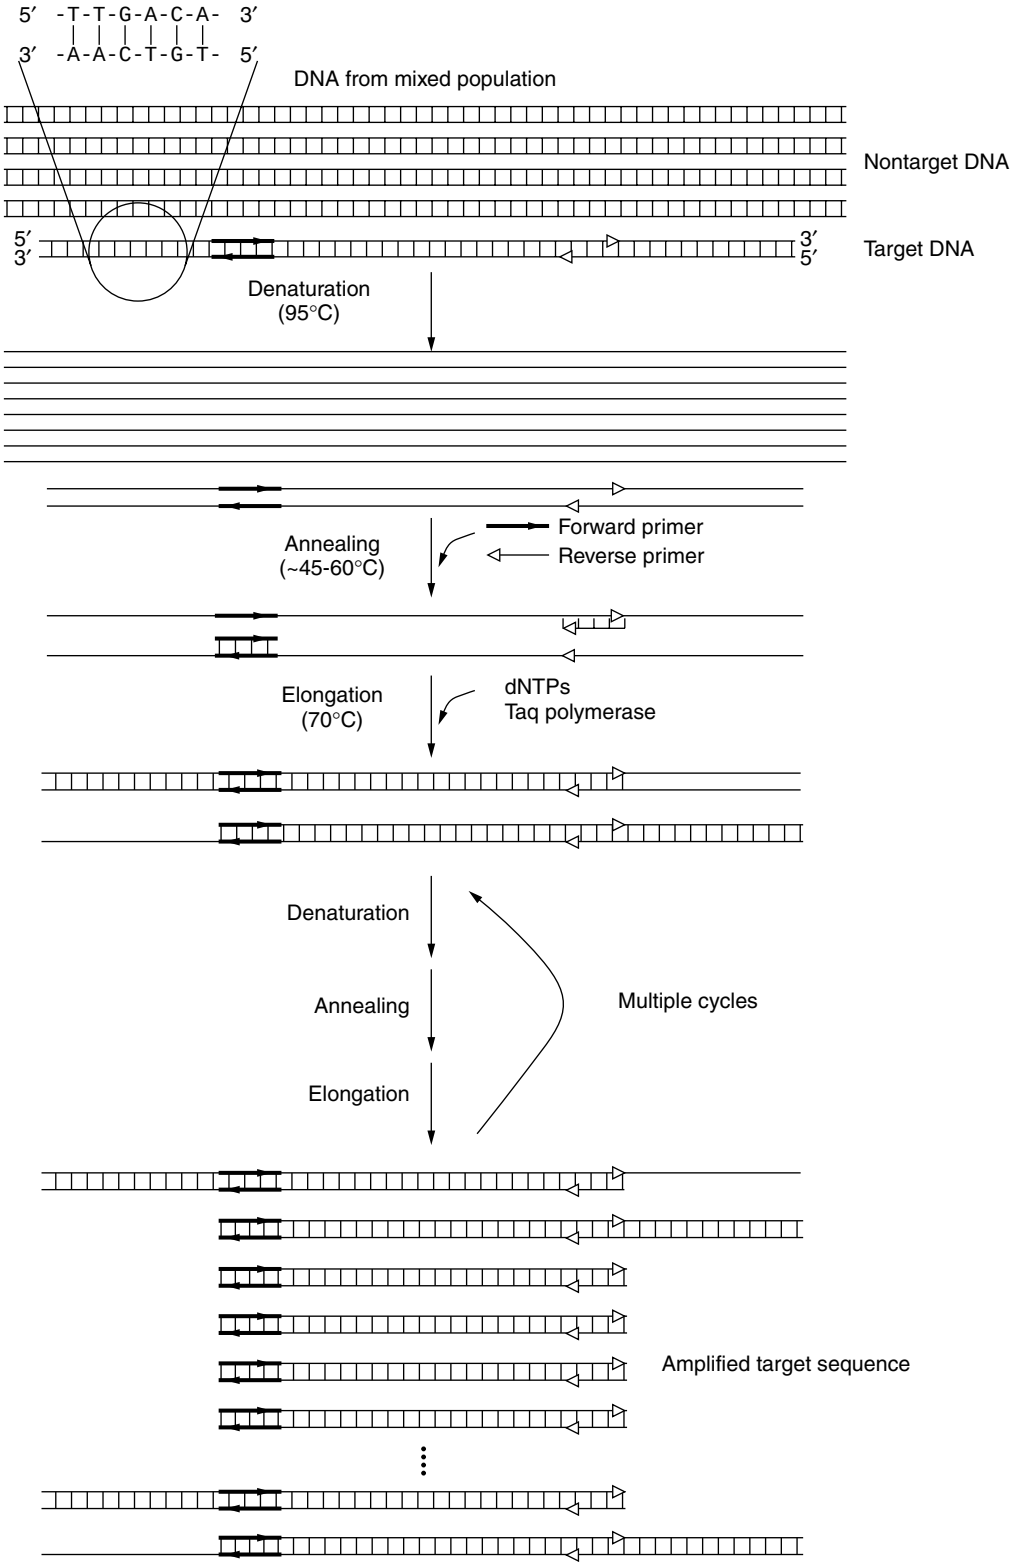

Figure 5. Polymerase chain reaction.

fragment of environmental DNA. Individual colonies are purified by repeated streaking on antibiotic-containing agar plates, and the cloned fragments are identified by DNA sequencing.

Denaturing Gradient Gel Electrophoresis (DGGE)

PCR products (amplificates) of similar length can be screened for sequence heterogeneity before sequencing by

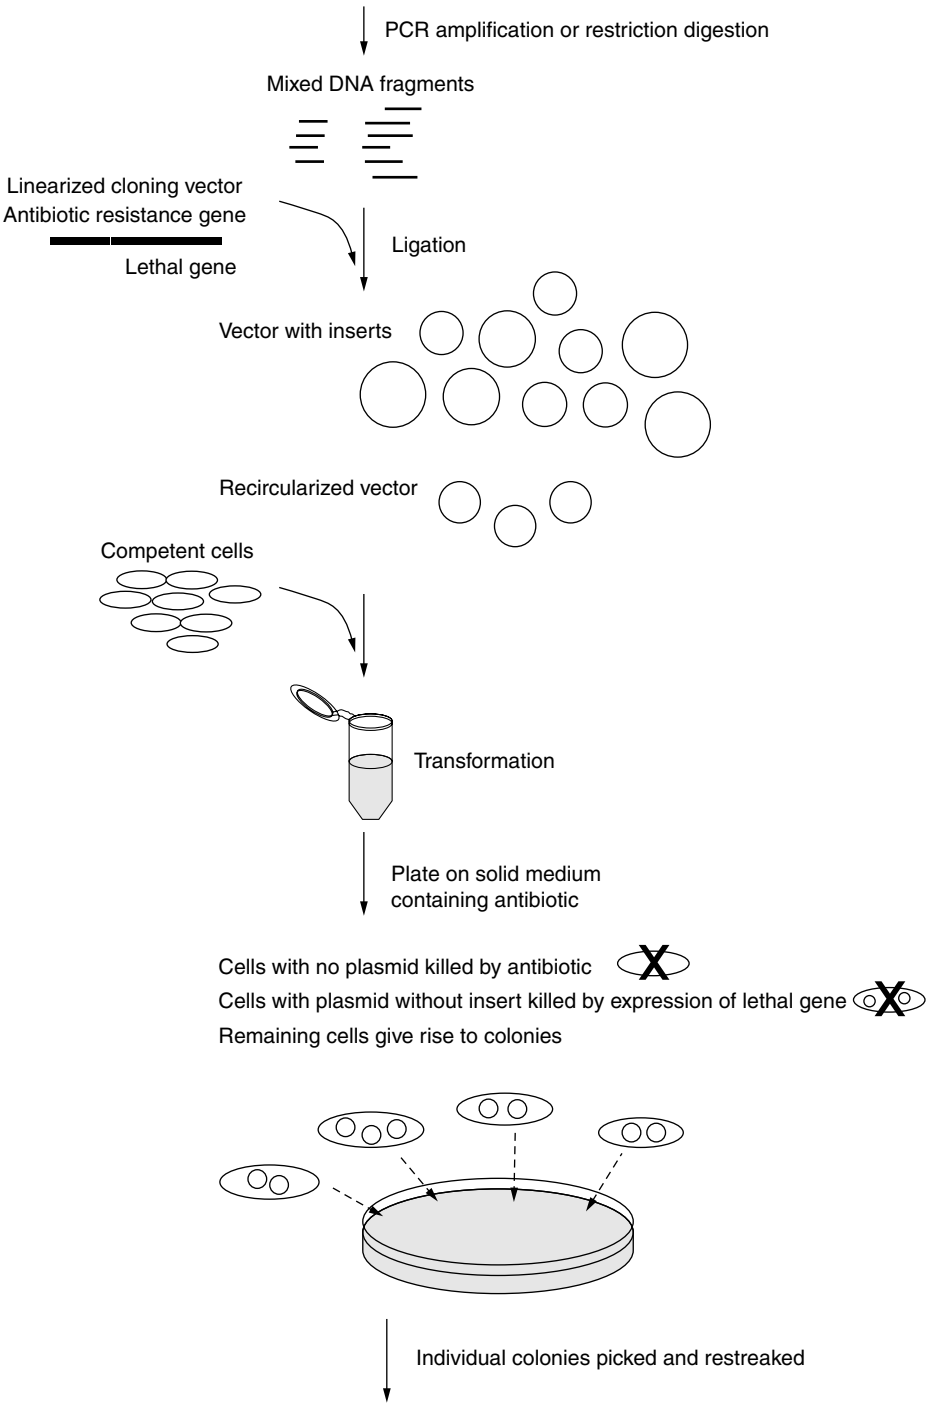

Figure 6. DNA cloning. See color insert.

several methods. Denaturing gradient gel electrophoresis (DGGE, Fig. 7) exploits the sequence dependence of DNA duplex denaturation (61) to separate molecules of similar length but different nucleotide composition. DNA from a mixed population is PCR-amplified with primers targeting the gene of interest (e.g., bacterial SSU rRNA). One of the primers has a GC-rich "tail," which is amplified as one end of the PCR product molecules. The mixture of product molecules is then electrophoresed on an acrylamide gel prepared with an increasing gradient of denaturant. DNA is negatively charged, because of the phosphate groups in its sugar backbone, and will move toward the positive electrode. The double-stranded molecules run through the gel until they reach a denaturant concentration that separates all but the high-GC clamp into single strands. The resulting Y-shaped molecule essentially stops migrating, forming a band that can later be visualized by staining with DNA-binding dyes such as ethidium

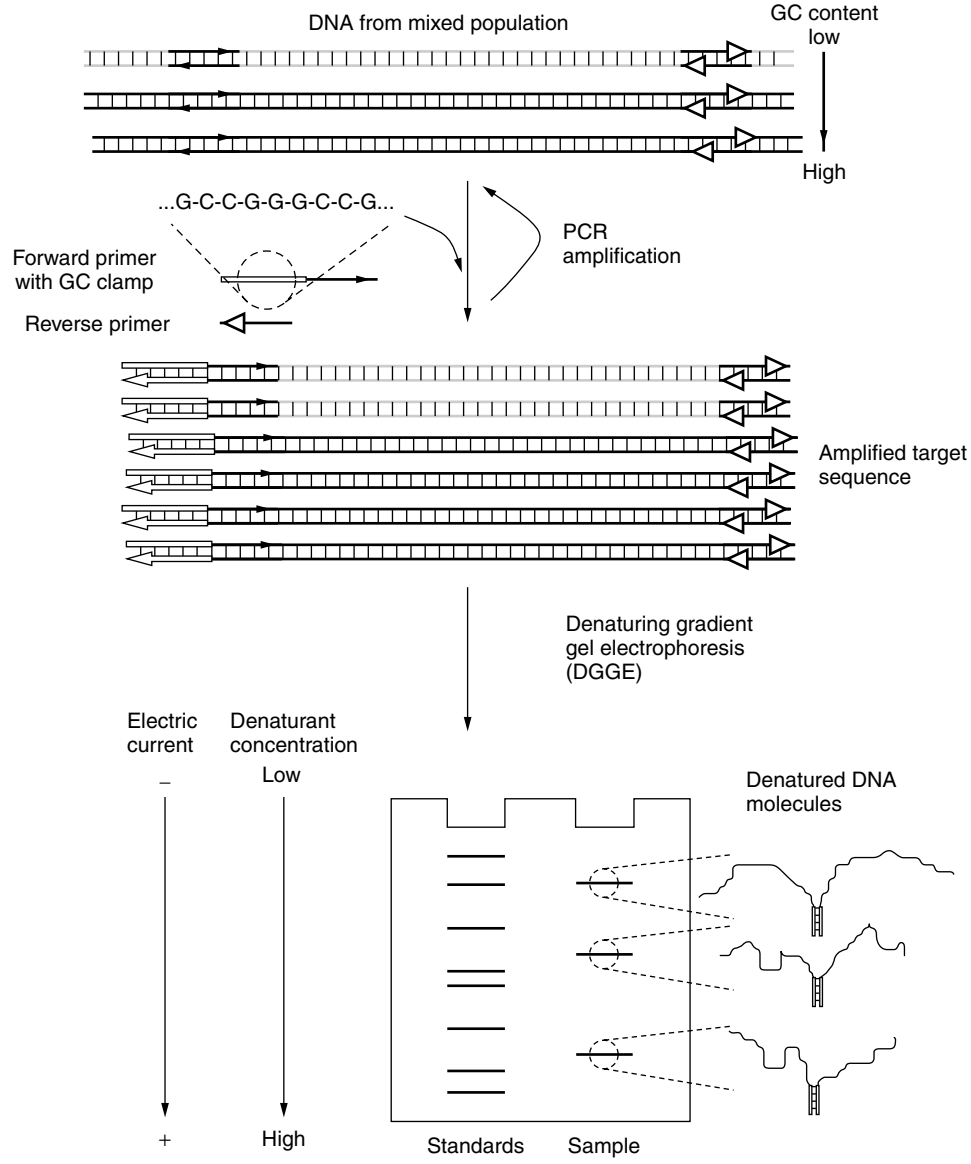

Figure 7. Denaturing gradient gel electrophoresis (DGGE).

bromide. Bands may be identified by comparison with known standards; hybridization to labeled oligonucleotide probes specific for particular groups; or DNA sequencing. The patterns of amplificates obtained from different environments, or from the same environment at different times, can be compared to detect changes in microbial community composition.

A variation of DGGE, TGGE, uses a heat gradient to separate molecules with different melting temperatures (62).

Terminal Restriction Fragment Length Polymorphism (T-RFLP)

T-RFLP is a method for estimating the number of different sequences in a mixture of PCR products (63). One of the two PCR primers is fluorescently labeled (Fig. 8). After amplification, the PCR products are digested with a restriction enzyme chosen to cut at different positions in different product sequences. This assumes that the sequences of all molecules likely to be in the sample are already known — this may not be the case for all samples. The digested DNA is then separated by gel electrophoresis on a DNA sequencing machine that can detect the fluorescent label. Fragment lengths are determined by comparison with fragments of known length. Because only the terminal fragments of each PCR product molecule are labeled, a unique band is ideally detected for each type of sequence. Bands may be identified by comparison with known sequences.

RNA-BASED METHODS

The advantage of RNA over DNA for community studies is that RNA reflects the active population more closely. Environmental studies have been based on both ribosomal

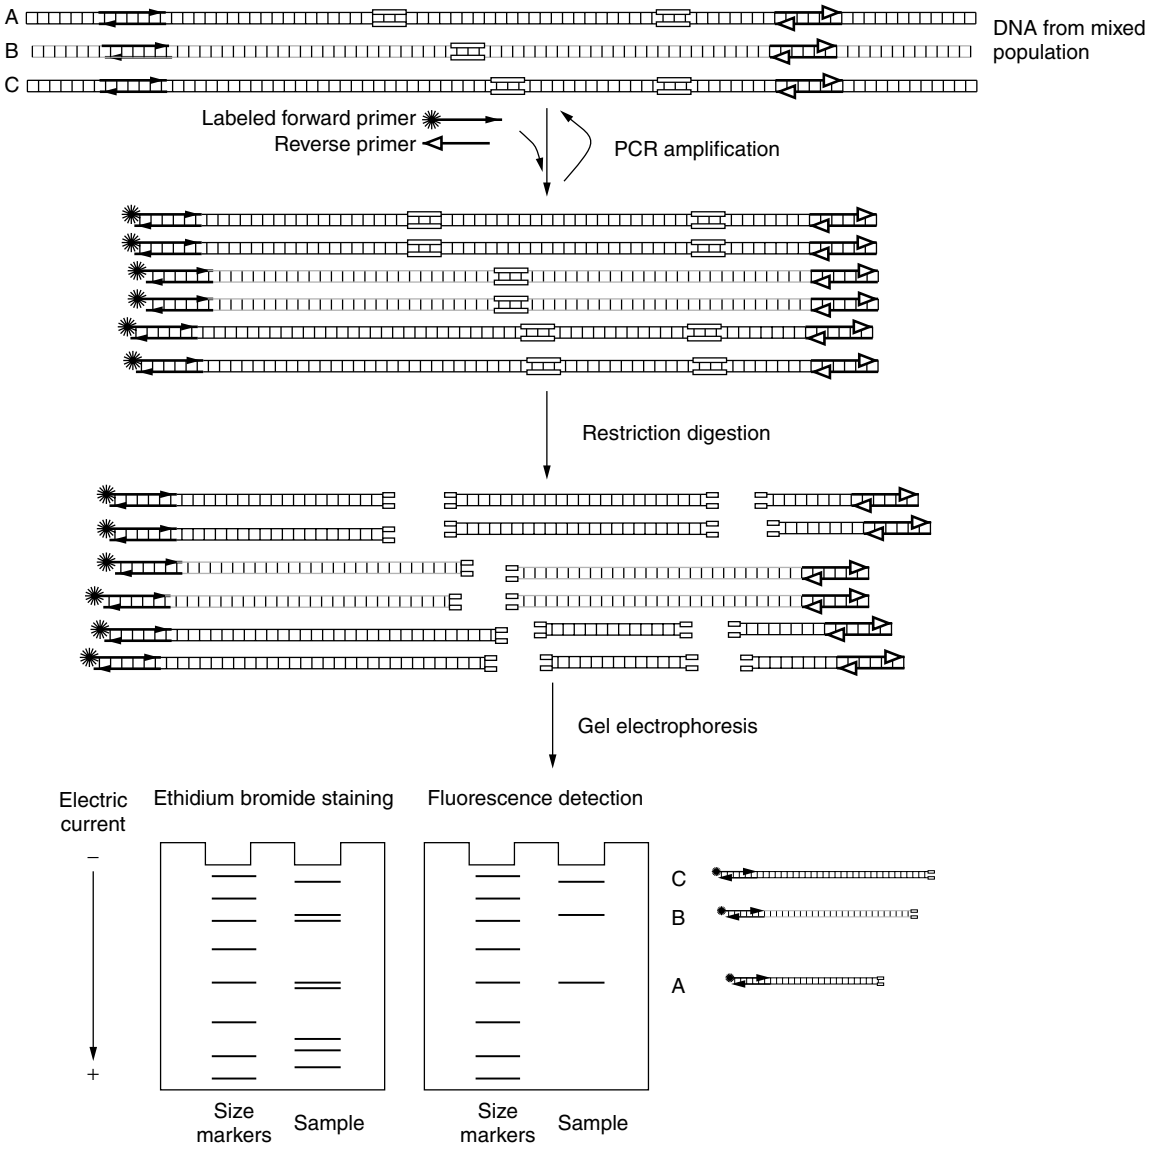

Figure 8. Terminal restriction fragment length polymorphism (T-RFLP).

and messenger RNA detection: rRNA as a measure of general metabolic activity and mRNA as a measure of specific functions.

SSU rRNA content generally increases with growth rate, so rRNA levels reflect population activity. Oligonucleotide probes can be designed to target the RNA of specific microbial groups, from the subspecies to the domain level, so that changes in their relative activities can be followed over time or compared between sites. It should be borne in mind, however, that the relationship between rRNA content and growth rate is not necessarily linear (64) and may differ among species and strains (65). Some microbial species may maintain a ribosomal reserve at very low growth rates, perhaps to allow quick response to improved conditions (66). Thus, the precise relationship between rRNA concentration and metabolic activity in a mixed population depends on community composition.

Ribosome production is regulated in macroscopic organisms as well as microbes. For example, RNA/DNA ratios are used as a measure of the condition of larval fish populations on the assumption that faster-growing individuals will posses more ribosomes and therefore more rRNA (67).

mRNA provides a more direct link to function than does rRNA. Ecologically important microbial activities such as nitrogen fixation are often scattered among distantly related species owing to independent evolution or interspecific gene transfer. This makes studying them by SSU rRNA sequences laborious, at best. However, the relatively low copy number per cell of mRNAs makes detection difficult. Some methods of signal amplification are discussed below.

Oligonucleotide Probe Hybridization

The rRNA contributed by different microbial populations may be measured following RNA extraction, by methods such as membrane hybridization, or within fixed

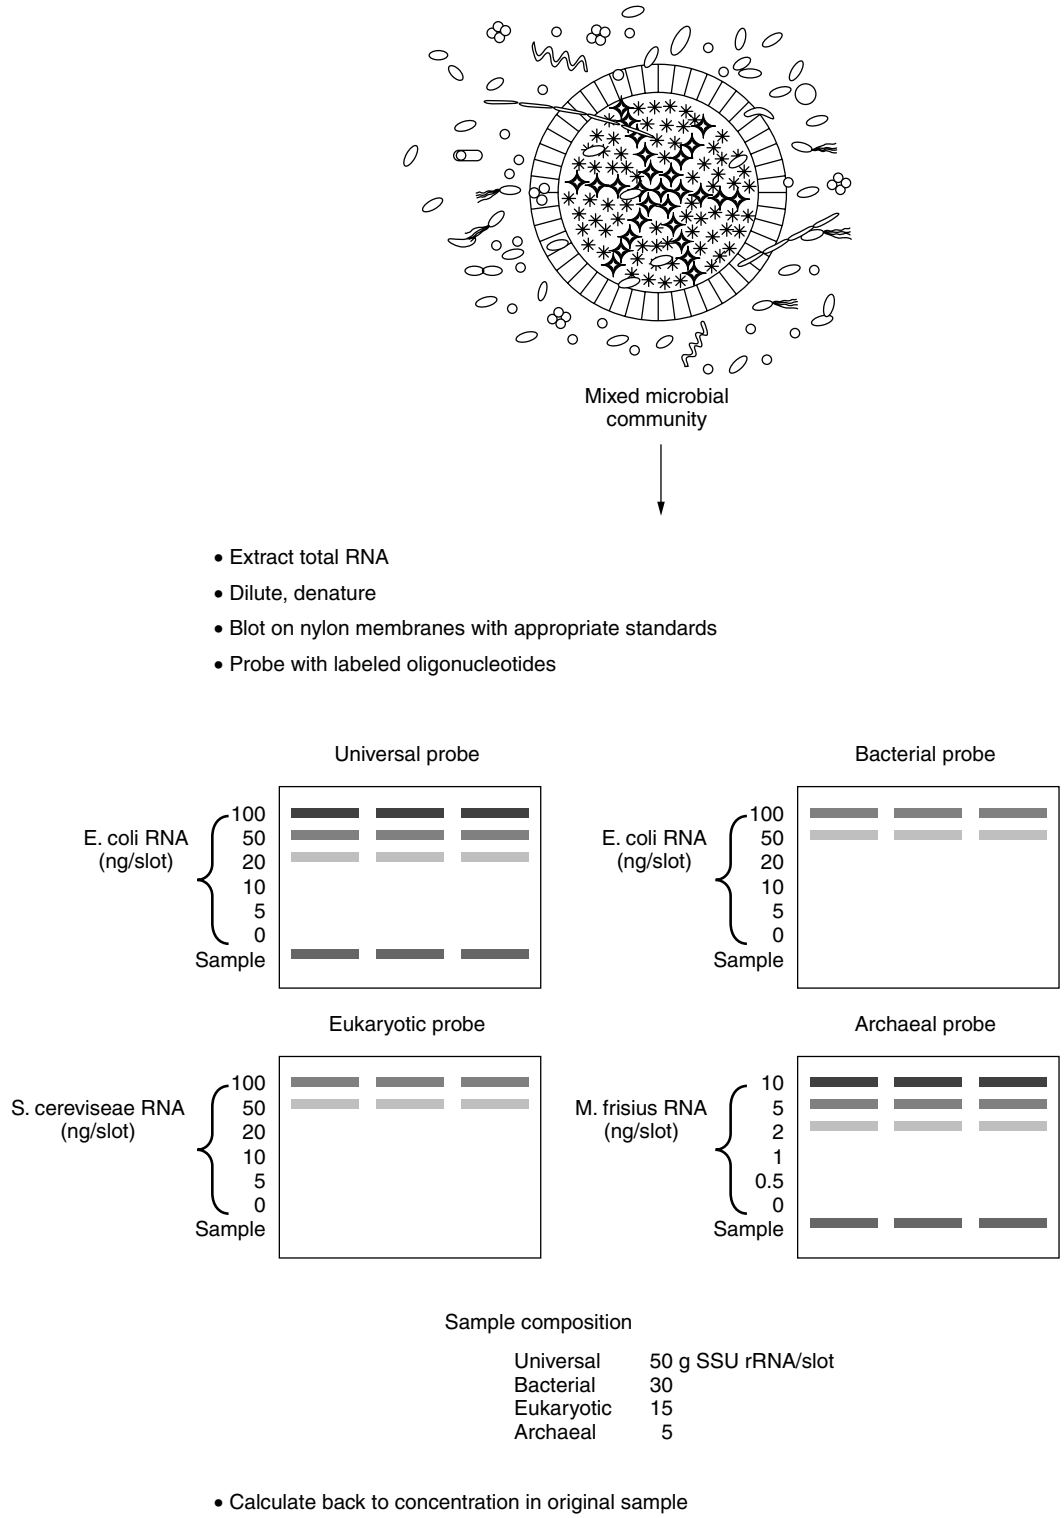

Figure 9. Membrane hybridization. See color insert.

cells, by in situ methods. Membrane hybridization, illustrated here for SSU rRNA (Fig. 9), is an example of an in vitro method. Total RNA is extracted and blotted in triplicate onto a positively-charged nylon membrane (RNA is negatively charged), along with a range of concentrations of a reference RNA. The membranes are hybridized with oligonucleotides targeting particular phylogenetic groups (68) — for example, archaeal or bacterial SSU rRNA. The concentration of target RNA in the samples is calculated by comparison with the reference RNA. To control for cross-hybridization, nested sets of probes are recommended — for example,

universal probe hybridization should ideally equal the sum of bacterial, archaeal, and eukaryotic probe hybridization.

In fluorescent in situ hybridization (FISH), fluorescently labeled oligonucleotides are hybridized to fixed microbial cells (69). SSU rRNA-targeted probes can be used for phylogenetic identification of organisms not yet obtained in pure culture, and multiple probes with different fluorescent labels can be used to visualize several species at once.

Laser confocal microscopy can give a three-dimensional picture of microbial associations (70,71). The development of automated image analysis systems for FISH should dramatically increase the quantitative information that can be extracted from a sample by this method.

mRNA Detection

There are exceptions to the central dogma: of particular relevance to this article, genetic information in retroviruses is carried by RNA rather than DNA, and transcribed to DNA by the viral enzyme reverse transcriptase. This enzyme has proven useful in molecular biological studies for the detection of mRNA, which is present at a much lower copy number per cell than is rRNA.

mRNA detection methods include in situ reverse transcription (RT) and in situ or in vitro RT-PCR (Fig. 10). RT-PCR is a method for detecting genes that are being actively transcribed, by amplifying RNA as DNA. It can be done either in vitro, which allows the amplified products to be identified by sequencing; or in situ, so that the spatial distribution of the expressed genes can be seen. In either case, RNA is hybridized with a specific oligonucleotide primer. Reverse transcriptase binds to the RNA/oligonucleotide hybrid and transcribes the RNA to DNA. The DNA may then be PCR-amplified, using labeled nucleotides to allow detection. Methods of mRNA detection in eukaryotic systems have recently been reviewed (72). Applications to microbial populations have been limited to data owing to the technical difficulty of specific detection of very low-abundance molecules.

FUTURE DIRECTIONS

Phylogenetically based molecular microbiological methods have greatly increased the number of detected microbial species; the next challenge will be to assign ecological roles to these many players. Several methods are currently being worked out in controlled environments for directly linking identifiable biomarkers to physiology.

For example, rRNA-targeted probes have been used to follow populations of sulfate-reducing bacteria in sediment slurries after addition of different carbon substrates to elucidate possible pathways of carbon flow in mixed populations (73). Fluorescent in situ hybridization has been combined with microautoradiography to directly identify cells incorporating radiolabeled substrates (74,75).

Isotopically heavy DNA was isolated from soil samples incubated with ^{13}C-labeled methanol (76), suggesting that the isotopic composition of nucleic acids might help directly identify natural populations using isotopically distinctive carbon or perhaps nitrogen sources such as biogenic methane or atmospheric N_2. However, this will depend in part on the degree to which cellular nucleic acids are synthesized de novo by a given species.

Judging from the rate at which new methods (and new acronyms) are appearing in environmental microbiology literature, the molecular approach is still in its early days. It will be interesting to see what new developments appear in the second edition of this Encyclopedia.

PLANKTONIC ALGAE IN THE MARINE ENVIRONMENT

Larry E. Brand
University of Miami
Miami, Florida

Planktonic algae (phytoplankton) are the base of the food web in the ocean, absorbing sunlight with chlorophyll *a* and accessory pigments for photosynthesis and providing most of the primary production of organic matter that ultimately feeds the rest of the organisms in the ocean. Only a small proportion of the ocean (<5%) is shallow enough for light to reach the bottom, allowing benthic plants such as macroalgae, seagrasses, and symbiotic algae inside animals such as corals to grow. Intertidal plants, such as marsh grasses and mangroves, also occupy a very small area of the ocean. Because benthic plants live in such a small area of the ocean, they contribute relatively little photosynthesis to the marine ecosystem, and planktonic algae provide over 95% of the primary productivity, upon which the entire ecosystem is dependent. An overview of the role of phytoplankton in the ocean can be found in references 1 and 2.

Among these planktonic algae, approximately half are prokaryotic cyanobacteria, which are discussed in another article. The other half is eukaryotic algae, belonging to around 10 different phyla within the kingdom of Protists. Table 1 lists these phyla, according to several different systematic schemes that have been proposed (3–6). The systematics of algae continue to be in a state of flux and will certainly change as molecular genetic data accumulate and replace the traditional systematic characteristics of pigments, chloroplast structure, types of flagella, cell wall structure, ultrastructure, storage products, modes of reproduction, and life cycles.

The distinction between algae and protozoa within the Protist kingdom is largely physiological–algae being autotrophic and protozoa being heterotrophic. Phylogenetically and morphologically, there is considerable overlap between algae and protozoa. For example, approximately half of all dinoflagellates are primarily or exclusively heterotrophic and the other half is primarily or exclusively autotrophic. Some species can be both autotrophic and heterotrophic (and both osmotrophic and phagotrophic) at the same time or at different times. Dinoflagellates such as *Pfiesteria* spp. can be photosynthetic in part of their life cycle, providing primary productivity at the base of the food web, and parasitic on fish at other times, essentially appearing as a predator near the top of the food web. A large number of euglenophytes and cryptophytes are also partially or totally heterotrophic.

The term *algae* is then used to characterize protists that are primarily photosynthetic. Although phylogenetically prokaryotic cyanobacteria are very different from the eukaryotic algae, physiologically and ecologically they are very similar in many ways, as they are both photosynthetic and live in essentially the same habitat. Therefore, they can be considered as prokaryotic algae. This article will focus on the eukaryotic algae.

HABITAT CHARACTERISTICS

A general discussion of the marine environment in which phytoplankton live can be found in references 1,7, and 8. Planktonic microalgae can be found everywhere in the ocean where there is enough light for photosynthesis, which typically requires at least 1% of full sunlight for growth. Generally, light intensity declines exponentially with depth and around 1% is left at around 100 m in clear open ocean water. The water column where there is enough light for photosynthesis in known as the photic zone. As one moves from the open ocean to coastal waters, the higher concentrations of particles and dissolved organic matter absorb more light and reduce the depth of the photic zone. All wavelengths of light are not absorbed equally. Infrared, red, and ultraviolet light are the most strongly absorbed (most within a few meters). In the open ocean, blue light (around 480 nm) travels the furthest, whereas in many coastal waters, the absorbance spectrum is shifted so that green light travels the furthest.

Because around 99% of the light is absorbed and converted to heat in the photic zone, the photic zone is often warmer, thus less dense than the water below. This often leads to a sharp temperature gradient (known as a thermocline) at some depth near the bottom of the photic zone. Near the coastline where large amounts of freshwater runoff occurs and near melting ice, the salinity of the surface water can be lowered, generating a halocline in which lighter, low-salinity water rests above denser, high-salinity water. Temperature and salinity are the two major factors that control the density of seawater, so their vertical gradients can generate a large vertical gradient in density, known as a pycnocline. This pycnocline greatly inhibits vertical movement and mixing of the warm surface waters with cold deep waters. There is a net flux of organisms and detritus from the surface through the

pycnocline. Therefore, most nutrients in the photic zone tend to be taken up by phytoplankton and eventually end up as particles that sink through the pycnocline into deep water. As a result, nutrients generated from the decomposition of these materials tend to accumulate in the deep waters. Because the pycnocline inhibits the upwelling of this dense, nutrient-rich water, a strong vertical gradient in nutrient concentrations, known as a nutricline, develops with low concentrations of nutrients in the photic zone and high concentrations below. This results in the fundamental dilemma that phytoplankton face in the ocean–the spatial separation of the two main resources they need: light and nutrients. In much of the photic zone, there is plenty of light for photosynthesis, but not enough nutrients to sustain much growth. Below the photic zone, there are plenty of nutrients but not enough light. Phytoplankton have many adaptations for dealing with this dilemma (to be discussed later). Phytoplankton grow best and tend to be most abundant where this spatial separation of light and nutrients is reduced. The pycnocline is strongest in the tropical open ocean and weakest in the polar and coastal regions. As a result, there are strong latitudinal and inshore-offshore gradients in nutrient concentrations and phytoplankton abundance, with the lowest levels in the tropics and central ocean. This accounts for the very clear water in the tropics and open ocean.

Most of the nutrients that support phytoplankton growth in the photic zone come from nutrient-rich upwelled water below. Near the coastline, land runoff can be a major source of nutrients. Atmospheric inputs may be of significance in some circumstances as well. Because of the insolubility of iron in seawater, upwelled water in the open ocean is depleted of iron relative to the other nutrients. As a result, atmospheric dust input appears to be an important source, leaving places far from land influences (such as the central Pacific and Southern oceans) iron limited. Agricultural activities and fossil fuel burning has increased the amount of bioavailable nitrogen in the atmosphere and it appears that the deposition of the atmospheric nitrogen could be of significance in some situations.

Close to 10% of the ocean area is over the continental shelves. This coastal ocean (regarded as the neritic habitat) has an average depth of around 100 m. Close to 90% of the ocean is around 4,000 m deep and is regarded as the open ocean or oceanic habitat. There is a relatively sharp transition from the continental shelf to the deep sea, so only a relatively small portion of the ocean is in this transitional zone. This neritic-oceanic boundary is also a relatively strong boundary between two very different ecosystems with very different environmental parameters and biological communities. For example, there are a great many more mechanisms that force nutrient-rich deep water up into the surface photic zone in the coastal ocean than in the open ocean. As a result, nutrient concentrations and phytoplankton abundance are typically much higher in coastal waters. Because of the large habitat differences, very few phytoplankton species live in both the coastal and the open oceans.

Because of the high specific heat content of seawater and the transparency of the water, which disperses the solar energy over many tens of meters, temperature does not fluctuate very much in the ocean compared with the land. The largest variation is seasonal in temperate regions. Ultimately, temperature is not a very important ecological factor compared to light and nutrients. Phytoplankton growth and biomass do show a negative correlation with temperature, however, because it reflects the strength of the pycnocline. Deep water, even in the tropics, is very cold. Therefore, in the tropics, warm surface water overlies cold water, generating a strong pycnocline that greatly reduces the upwelling of nutrients. In polar regions, both the surface and bottom waters are cold. In this case, the pycnocline is weak.

Most of the ocean has a salt content of around 3.5% (referred to as 35 parts per thousand by oceanographers). Because the major salts (sodium, chloride, sulfate, magnesium, calcium, and potassium) have residence times in the ocean of over a million years, they are well mixed and occur in very constant ratios relative to each other, allowing one to use total salt content (salinity) without referring to individual ions. Because the salinity of the ocean does not change much, it is not a major factor affecting phytoplankton in the ocean. Large changes occur only near areas of land runoff, shallow lagoons greatly influenced by rain and evaporation, and freezing and melting ice.

PHYLOGENETIC RELATIONSHIPS

There are two major phylogenetic lineages of algae: the chlorophytes, which have chlorophyll *b* as an accessory pigment, and the chromophytes, which have chlorophyll *c* as an accessory pigment (3–6) (Table 1). It is thought that each of these eukaryotic lineages evolved by endosymbiosis, with a prokaryotic cyanobacteria becoming the eukaryotic chloroplast. Some cyanobacteria have been found to be very similar to the chloroplast of chlorophyte algae. The chlorophyte lineage includes the phyla chlorophytes, euglenophytes, and prasinophytes. The green macroalgae appear to have evolved from the chlorophyte microalgae, and all higher plants (charophytes, bryophytes, and tracheophytes) ultimately evolved from them. Chlorophytes and euglenophytes tend to be quite abundant in freshwater ecosystems but rather sparse in the ocean. In marine ecosystems, they tend to be more important in brackish water ecosystems. Prasinophytes, on the other hand, appear to be in moderate abundance in the ocean. The chromophyte lineage includes dinoflagellates, diatoms, prymnesiophytes, chrysophytes, xanthophytes, and raphidophytes. Many of these phyla are predominately marine, although they can also be found in freshwater. As a broad generalization, however, the chlorophyte lineage tends to dominate freshwater ecosystems and the chromophyte lineage tends to dominate marine ecosystems. The evolution of the chlorophyte lineage ultimately led to the higher plants found on land. The evolution of the chromophyte lineage ultimately led to the macroalgal phaeophytes (brown algae). Some of the large kelps in the phaeophyte phylum begin to approach the morphological complexity of higher

plants, with their stems (capable of nutrient translocation), distinct leaves, and specialized sex organs. As the chromophytes tend to have high concentrations of accessory pigments such as the carotenoids fucoxanthin and peridinin, they tend to be yellow-brown in color, not green. In general then, terrestrial and freshwater plants tend to be green, whereas marine plants tend to be yellow-brown.

In addition to the two main lineages of algae, a few other phyla of algae exist with more obscure phylogenetic relationships to the rest of the algae. The rhodophytes (red algae) are mostly macroalgae, but some unicellular rhodophytes are found in the ocean, generally in low concentrations in brackish waters. They are different from the chlorophyte and chromophytes lineages by having phycoerythrin as an accessory pigment and not chlorophyll *b* or *c*. Cryptophytes are a phyla of microalgae that also have phycoerythrin and not chlorophyll *b* or *c* and tend to be found in relatively low concentrations in mostly brackish water.

At the present time, it is estimated that there are perhaps around 5,000 species of phytoplankton in the ocean, although the estimate could change substantially as new techniques are used to detect more species.

SYSTEMATICS

The identification of species of the large phytoplankton, such as many diatoms and dinoflagellates, is based primarily upon overall cell morphology and can be conducted by light microscopy. For species with hard parts (silica frustules of diatoms, calcium carbonate coccoliths of coccolithophores, cellulose plates of dinoflagellates) the detailed patterns on these structures, using scanning electron microscopy, can be used to distinguish species. For small cells with no hard parts, examination of ultrastructure is about the only way to distinguish species, and is undoubtedly not distinguishing many species because of the morphological similarities of species. New developments in molecular biology can be expected to provide better techniques for distinguishing species in the future.

The term species is often used in a somewhat arbitrary manner. Various morphological characteristics are used to define species; yet biologically and ecologically, one thinks of a species as a group of organisms with similar genetic composition (as a result of gene flow) and similar ecological requirements. In fact, there is considerable genetic variation within phytoplankton species, even among groups that clearly have significant gene flow (9). Cells of a species, all found within 1 L of water, can be shown to be genetically different. Populations of cells of the same species in different water masses can be genetically quite different from each other and have different ecological requirements. There is also evidence that because of the considerable genetic variability within populations, genetic changes occur in the timescale of seasonal changes, indicating how rapidly natural selection can occur on these organisms with a generation time on the order of a day or less.

EVOLUTIONARY HISTORY AND FOSSIL RECORD

An overview of the evolutionary history and fossil record of algae can be found in references 10–14. The first oxygenic photosynthesizers, the prokaryotic cyanobacteria, first appeared in the fossil record around 3.5 billion years ago. The eukaryotic algae did not appear in the fossil record until around a billion years ago, about when free molecular oxygen begins to appear on the earth. The earliest phylogenetic groups were probably the dinoflagellates and chlorophytes. As with any fossil record, there is a strong bias toward organisms with hard parts. In the

case of marine phytoplankton, the best preserved are the silica frustules of diatoms and calcium carbonate coccoliths of coccolithophores. Indeed, the fossil record of coccolithophores and diatoms is so good that their species distributions in cores taken around the world are used by paleoceanographers to estimate paleotemperatures, paleoclimate, paleocirculation, and so on. The ^{18}O and ^{13}C isotopic ratios in coccoliths are particularly important in paleoceanography. The fossil record of other groups is based primarily on the cellulose cell walls, with a bias in favor of the particularly thick and resistant cellulose walls of cysts.

Because of differential preservation, a complete evolutionary history of phytoplankton is impossible to discern, but the fossil record does show some interesting patterns. For example, coccolithophores first appear in the fossil record in large numbers in the Jurassic (145 to 210 million years ago), about the same time that calcareous foraminifera become planktonic. Diatoms first appear in the Cretaceous (65 to 145 million years ago), about the same time as a large increase in siliceous radiolarians appears. This leads to questions about the possible relationship between the changing biogeochemistry of the ocean and the evolution of phytoplankton with mineral hard parts.

By the end of the Cretaceous, coccolithophores were extremely diverse and cosmopolitan in distribution. Diatoms were still relatively sparse. At the time of the Cretaceous extinction around 65 million years ago, calcareous organisms were particularly hard hit by the extinction event (suggesting a drop in the pH of the surface ocean) and coccolithophores went almost completely extinct. The diatoms (and siliceous radiolarians) were affected very little by the Cretaceous extinction. As a result of the Cretaceous extinction event, diatoms appear to have been able to exploit the large decline in coccolithophores and occupy their resulting empty niches. Today diatoms, not coccolithophores dominate coastal and polar waters. Coccolithophores remain relatively important only in the temperate and tropical open ocean today.

MORPHOLOGICAL CHARACTERISTICS

Because all the different phyla of microalgae are subjected to similar selective environmental forces, there has been considerable convergent evolution in their sizes, shapes, and other morphological characteristics (15–17). Some of these can be seen in Figures 1, 2, and 3.

Cell Size

The eukaryotic phytoplankton range from around 2 to 2,000 μm in diameter. This translates to approximately a billion-fold range in cell volume. A common terminology for different size phytoplankton is shown in Table 2. Because phytoplankton are microscopic and thus outside the perception range of normal human experience, there is a tendency to think of phytoplankton as "little round green things" and to lump them all together. Translating that billion-fold size range to the human perceptual scales leads one to realize that this would be the same as lumping small weeds and redwood trees together as plants. In some situations this is appropriate, but in others, it is highly misleading. On this spatial scale, particles have Reynold's numbers well below 1 (generally 10^{-6} to 10^{-2}), resulting in viscous forces being much greater than inertial forces. As a result, the uptake of nutrients can be diffusion limited and the sinking rate increases with cell size. Both are important factors that influence the evolution of cell size in phytoplankton.

Phytoplankton are essentially surrounded by a sheath of stagnant water. Therefore, the transport of nutrients from the water to the surface of the algal cell is restricted by the rate of diffusion. In broad terms, the rate at which nutrients can diffuse to the cell surface is approximately proportional to the surface area, and the amount of nutrients needed for growth is approximately proportional to the volume of the cell. Therefore, the rate at which cells can accumulate nutrients and replicate their biomass is proportional to r^2/r^3 or $1/r$ (r is the cell radius). Small cells with a small radius clearly have an advantage over large cells with low Reynold's numbers where nutrients are a limiting factor (to be discussed in detail later).

Because planktonic algae are forced to drift with the water and thus are surrounded by stagnant water, the selective pressure of nutrient limitation leads to small cells. For this reason, the vast majority of phytoplankton in the ocean is only a few microns in diameter. Many are at the lower limits that are possible for a eukaryote, having only one chloroplast and one mitochondrion. An excellent discussion on the constraints and implications of minimum cell size in phytoplankton is given in reference 18. Phytoplankton are smallest in the subtropical waters of the open ocean in which nutrient concentrations are lowest, and are largest in upwelling areas in which nutrient concentrations are highest and sinking out of the photic zone is not a problem.

As there is enough light for photosynthesis in only the top 100 m or less of the ocean, it is important that phytoplankton have the ability to avoid excessive sinking. At such small Reynold's numbers, Stokes' law should predict the sinking rate of such particles in seawater (19,20). It would predict a sinking rate approximately proportional to the square of the radius. Actual experimental observations indicate a more linear relationship between cell size and sinking rate (19). In areas with strong thermoclines and fairly stagnant surface waters, such as the subtropical open ocean, sinking is potentially a major problem, so small cell size is advantageous. In upwelling areas, small cells drifting with the water will eventually be transported out of the nutrient-rich upwelling area. Upwelling tends to select for larger cells that sink at the same rate as the water

Table 2. Terminology for Cell Sizes (in μm)

Picoplankton	<2
Nanoplankton	2 to 20
Microplankton	20 to 200
Mesoplankton	200 to 2,000

upwells, leaving the cells in the nutrient-rich upwelling plume.

As a broad generalization then, phytoplankton communities are dominated by small species in areas with strong pycnoclines and low nutrient concentrations and by large species in turbulent water with high nutrient concentrations. As with most any generalization, there are significant exceptions. One can find very large diatoms and dinoflagellates in the open ocean and picoplankton in estuaries and upwelling areas. Their adaptations for surviving in these habitats despite their size will be discussed later. In most habitats, the entire range of phytoplankton cell sizes can be found, but there is a large shift toward a predominance of small cells in the nutrient-limited oceanic waters and toward a predominance of large cells in coastal waters and upwelling areas.

Cell Shape

Most phytoplankton are spherical or slightly oblong, particularly the smaller species. Species with flagella tend to be more oblong. A greater variety of shapes is observed in species with larger cell sizes, particularly diatoms and dinoflagellates. Diatoms can be shaped like petri dishes, cylinders, long rods, or rectangular plates. Many also have long spines protruding from them, which increase the surface/volume ratio and reduce the sinking rate. Dinoflagellates tend to have a variety of rather globular shapes, some with protuberances. Most are asymmetrical. Being the fastest swimming of the phytoplankton, they often have shapes that enhance swimming in one orientation and reduce sinking when in another orientation–thus the advantage of their asymmetrical shapes.

Colonies

Most phytoplankton exist as single cells, but some form colonies of various sizes. Among the smaller species, they often consist of typically two to eight cells, sometimes embedded in a gelatinous matrix, although in some cases, hundreds of cells can occur in one colony. Colonial diatoms and dinoflagellates tend to form linear chains.

Ultimately, it is thought that the sizes and shapes of various phytoplankton species have evolved primarily to solve the problems of diffusion-limited nutrient uptake, sinking, effective swimming, and grazing.

Cell Wall

Whereas some of the smallest phytoplankton have only a cell membrane and no cell wall, most have some type of cell wall. Most are made of various types of carbohydrates, particularly cellulose. It is usually a complex matrix of microfibrils. In some, such as dinoflagellates, it is composed of distinct plates of cellulose, the shapes of which can be used for taxonomic purposes. Many microalgae also surround themselves with a layer of gelatinous mucilage, the production of which often varies with environmental circumstances and physiological state. In the case of diatoms, the wall is heavily impregnated with silica, effectively providing a glass shell around the cell. The glass shell (known as a frustule) is in two halves that fit together somewhat like a petri dish (21). Upon cell division, each daughter cell gets half the frustule and synthesizes the other half. The distinctive patterns in these glass shells can be used for taxonomic purposes. Because these silica frustules preserve reasonably well in the fossil record, they have been very useful in paleoceanography for examining how the marine environment has changed over the history of the Earth. In the case of coccolithophores (a calcifying subgroup of prymnesiophytes), organic plates are covered with crystals of calcium carbonate in distinct patterns (called *coccoliths*). The distinctive patterns can be used to identify species, both in the water and in the fossil record. During cell division, each daughter cell gets approximately half the coccoliths. A number of different hypotheses have been proposed for the function of the coccoliths (22,23). Euglenophytes differ from most microalgae by having a very flexible cell wall composed of strips of protein. This allows them to constantly change shape.

A number of species, particularly dinoflagellates, chrysophytes, and raphidophytes, have structures called *trichocysts* embedded within their cell walls. They are used to inject mucus, "darts," or toxins into the environment or other organisms (15).

Flagella

Diatoms and rhodophytes do not have flagella (except the gametes of diatoms), but all the other phyla of microalgae have at least some species that have flagella. As a crude generalization, perhaps half of the microalgae in the ocean are capable of swimming, using flagella. Most have one or two flagella, but some can have more. When there are two or more, they usually emerge from the same part of the cell. A major exception to this is that many dinoflagellates have two flagella at right angles to each other. In many cases, one propels the cell through the water, while the other causes the cell to rotate. Most flagella are typically one to two cell diameters in length, but a wide range is found. Some flagella are simple and smooth, whereas others are covered with microfibrils called *mastigonemes*. These can be extended out from the flagella to increase surface area greatly (and thus friction and stickiness between the flagella and the water) or collapsed onto the surface of the flagella to reduce surface area. At the low Reynold's numbers of microalgae, friction between the cell surface and the water is the dominant factor, so complex interactions between mastigoneme movements and flagella movements are needed to move through the viscous media.

In addition to flagella, some prymnesiophytes have a flagellum-like structure called a *haptonema*, which can be very short or very long. It emerges from the cell between the two flagella. Long haptonema can form tight coils. In some species they are used for attaching to surfaces. In other cases, it is thought that the haptonema is used to capture particles for food.

Eyespot

A number of flagellates have an accumulation of pigments, often near the base of the flagella, known as an eyespot. Some can be quite complex in structure. It appears that the eyespot is used to determine the intensity and direction of light and then control phototactic behavior.

Vacuoles

The smallest phytoplankton may have only one small vacuole or even none at all. On the other hand, the largest diatoms usually have one very large central vacuole that occupies over 50% of the volume of the cell. Essentially, these diatoms have a thin layer of cytoplasm suspended on the inside of the glass shell, with the central core of the cell being one large vacuole. As a result, the ratio of surface area to cytoplasm volume is larger than in a cell without such a large central vacuole, thereby reducing the nutrient diffusion problem. In addition, these cells actively exclude heavy ions and accumulate light ions, so the vacuole ends up less dense than seawater. Because of the large volume of this less-dense vacuole relative to the whole cell, these large diatoms do not sink as fast as one might expect from Stokes' law and can even end up neutrally buoyant or even positively buoyant in seawater. High concentrations of nutrients can also be stored in the vacuoles, allowing cells to continue to grow and divide at times when external nutrients are not available.

Chloroplasts

Microalgal chloroplasts are found in a wide variety of sizes and shapes. Many of the smallest phytoplankton have only one chloroplast. Some large diatoms can have up to 50 or more chloroplasts spread throughout the cytoplasm on the inside of the frustule. Some large phytoplankton cells will have only two very large chloroplasts. Chloroplasts can be shaped as spheres, discs, bands, and stars. In many species, the chloroplasts change size and shape and can

migrate within the cells, depending on the light conditions. The pattern appears to expose more pigments under low-light conditions and expose less pigment under high-light conditions. Some diatoms even have chloroplasts that extend out into the their spines to avoid self-shading.

Storage Products

Distinct deposits of various carbohydrates, proteins, or oils can be found in many microalgae. These appear to be storage products that accumulate during unbalanced growth when there is a surplus of one resource and a deficit of another. These storage products can then be used at a later time when environmental conditions change.

Nucleus

In most cases, the nucleus of microalgae is similar to that of other eukaryotic cells. The euglenophytes and dinoflagellates differ in having their DNA organized in a rather primitive way. Because of the poor organization of the DNA in dinoflagellates, up to 50% of the volume of the cell can be occupied by the nucleus.

PHYSIOLOGICAL ADAPTATIONS

A large literature (24–27) on the physiology of marine phytoplankton exists.

Reproduction

Most of the time, microalgae reproduce by simple asexual binary fission. A wide range of division rates can be observed. As a broad generalization, dinoflagellates are the slowest, almost always doubling at less than once a day, and diatoms are the fastest with up to six divisions a day (a 64-fold increase in biomass in 1 day). Within a phylum, small cells, with their higher S/V ratio, tend to grow faster than larger cells.

A shift from asexual binary fission to sexual reproduction generally occurs when environmental conditions become unfavorable for growth. In general, it appears that the vegetative cells of diatoms are diploid, whereas most other phyla are haploid. In diatoms, meiosis precedes the production of gametes, whereas in the other microalgae, meiosis occurs after the fusion of two gametes have produced a diploid zygote. Some species are heterothallic, meaning that the gametes must come from different genotypes for the production of viable zygotes. Homothallic species have gametes that can fuse with gametes of the same genotype. Some species have isogametes, which appear identical to each other. Other species have anisogametes, the beginnings of the distinction between male and female gametes. In some cases, the anisogametes are of different sizes. Sometimes the male gamete has flagella and the female gamete does not.

Many species, particularly coastal species, have the ability to form resting stages, such as cysts. In some cases this simply involves the thickening of the cell wall and reduction of metabolism. In other cases, cyst formation is intimately involved in the life cycle and sexual reproduction. Germination of the cysts often requires quite specific environmental cues such as photoperiod or temperature changes. Because of the thick cell walls, cysts preserve better than vegetative cells and are better represented in the fossil record.

Control of Sinking

Typical sinking speeds of phytoplankton range from 0.1 to 100 m/day (19). Sinking is a double-edged sword for phytoplankton. Neutral buoyancy keeps phytoplankton in the photic zone indefinitely, and slow sinking rates keep them in the photic zone for long periods of time. Reduced or no cell movement relative to water, however, results in diffusion being the only mechanism for the transport of nutrients to the cell surface. If a cell sinks rapidly through the water, the diffusion boundary layer is reduced, enhancing nutrient uptake, but the cell is in danger of sinking out of the photic zone relatively quickly. Some species with large cells reduce this problem by having cell or colony shapes and orientations that cause them to spiral or zigzag horizontally through the water as they sink. This effectively diverts the inertial motion from vertical to more horizontal, thereby maintaining speed relative to the water and reducing diffusion limitation, but also reducing the net downward sinking out of the photic zone.

Sinking is not a major problem in upwelling areas in which the upwelling rate is greater than the sinking rate. Indeed, sinking can be advantageous, as it keeps the cells from being swept away as the upwelling waters reaching the surface then move out of the upwelling area and nutrients are depleted. Upwelling areas select for cells that sink at the same rates as the water moves upward and against neutrally buoyant cells that then get transported downstream. On a smaller scale, Langmuir circulation cells can also support and select for algae cells that sink rapidly. These vertical circulation cells are generated when persistent winds from one direction reach 3 to 6 m/seconds (28,29). Because cells spend more time in the upwelling plumes of Langmuir circulation cells than in downwelling plumes, large, rapidly sinking cells can be maintained in the photic zone indefinitely. In this situation, rapidly sinking cells are less affected by nutrient diffusion limitation than neutrally buoyant cells and end up with a competitive advantage. In these situations in which sinking is advantageous, the heavy silica frustules of diatoms and calcium carbonate coccoliths of coccolithophores are useful adaptations. When the winds die down or change direction, however, the Langmuir circulation cells collapse and large heavy cells begin sinking through the photic zone. As a result, competitive advantage shifts from rapidly sinking cells to neutrally buoyant cells. Therefore, variability in wind speed and direction can explain the relatively rapid changes in phytoplankton community composition and the wide distribution of cell sizes and sinking speeds in the ocean.

Phytoplankton cells do not sink at the rates predicted by Stokes' law. Large cells tend to have large vacuoles, which have a chemical composition different from that of seawater. Many large cells use energy to actually pump out heavy ions and accumulate light ions, resulting in a

cell vacuole in osmotic balance with seawater but having a lower density. Many large diatoms and dinoflagellates that would be expected to sink rapidly, based on Stokes' law, in fact can be neutrally buoyant or even positively buoyant as a result of this ion discrimination (30,31). It appears that some species use ion discrimination to change their density from positive to negative on a diel basis, allowing them to float up into the photic zone during the day for photosynthesis and sink down below the nutricline to take up nutrients at night.

Swimming

Many phytoplankton have flagella, which allow them to swim upward to counteract the results of sinking (32). Typical swimming speeds range from 0.01 to 3 cm/minute. They are able to detect the intensity and direction of light, resulting in phototactic behavior that appears to generate vertical distributions that, to some extent, optimize the ratio of light from above and nutrients from below (33,34). This phototactic behavior is thought to be one of the major reasons for the particularly high concentrations of phytoplankton near the bottom of the photic zone. Above this deep chlorophyll maximum, nutrients are limiting and light is in excess, whereas below, light is limiting and nutrients are in excess. This spatial separation of light and nutrients is a fundamental dilemma faced by phytoplankton in many parts of the ocean because the pycnocline tends to hold the colder, nutrient-rich water below the photic zone. Some large dinoflagellates solve this dilemma by swimming up into the photic zone during the day for photosynthesis and then down at night to take up nutrients. Some diatoms may use their vacuole to alter their buoyancy in the same way.

Adaptation to Temperature

Different species of algae can be found over the entire range of temperatures found in the surface ocean. Many polar species can grow at $-2\,^{\circ}C$, the lowest temperature at which seawater remains liquid. Eukaryotic algae have been found in hot springs up to $70\,^{\circ}C$ and are found in tidal pools that heat up considerably. Temperature affects which species live in various parts of the ocean, but does not restrict them from any parts of the photic zone (35–37).

Whereas the light reactions of photosynthesis are largely temperature independent, the dark reactions and most other biochemical processes are influenced by temperature. As a result, the enzyme and protein contents of algal cells tend to increase at lower temperatures to allow the biochemical processes to keep up with light harvesting. Conversely, the pigment contents of the cells tend to be greater at higher temperatures to be able to supply the higher demand of the dark reactions.

Overall growth of phytoplankton in response to temperature is similar to that of many organisms–a linear or exponential increase with increasing temperature up to an optimum, and then a dramatic decline with only a small further increase in temperature. Death often occurs only a few degrees above the temperature optimum. Most marine phytoplankton species do not survive above about $30\,^{\circ}C$. In polar waters, where the water never gets above around $2\,^{\circ}C$, many phytoplankton species die of excessive heat above $5\,^{\circ}C$. Conversely, many species survive quite well at temperatures far below their temperature optima.

Temperature and salinity determine the density of water, which in turn determines much of its movements in the ocean. Much of the ocean is characterized by fairly distinct water masses (with rather uniform temperature and salinity regimes within) with fairly sharp transitions at the boundaries between water masses. These boundaries tend to also be the major biogeographic (phytohydrographic) boundaries for phytoplankton species distributions, although primarily as a result of transport restrictions, not actual temperature restrictions.

Although phytoplankton grow faster at higher temperatures, on a global basis there is a negative correlation between temperature and phytoplankton photosynthesis and standing biomass. Phytoplankton biomass and productivity are lowest in the tropics and highest in polar regions, in general. The reason for this is that when surface temperatures are low, the thermocline separating nutrient-rich deep water and the photic zone is weak, allowing a large flux of nutrients into the photic zone to support high photosynthetic rates and algal biomass. In the tropics where surface temperatures are high, the thermocline is strong, thus restricting the flux of nutrients into the photic zone and greatly reducing photosynthesis and phytoplankton biomass.

Osmoregulation

Most of the surface ocean has a salinity between 33 and 37 parts per thousand (ppt), and local rainfall and evaporation does not cause it to fluctuate much. As a result, most marine phytoplankton tolerate only a relatively narrow range of salinities (are stenohaline), as they do not need adaptations to tolerate large changes in salinity. Close to the coastline, however, land runoff can cause a large decline in salinity, particularly in embayments. In estuaries, one can find the entire range from freshwater up to full strength seawater. In isolated or semi-isolated basins in arid areas, evaporation can generate hypersaline conditions. The most rapid changes in salinity can occur in shallow tidal pools. Obviously phytoplankton species that live in such habitats have to tolerate a wide range of salinities (are euryhaline) (38,39). The main method they use to maintain osmotic balance with seawater of varying salinity is to polymerize and depolymerize various polyol compounds such as glycerol, mannitol, sorbitol, or a number of other similar compounds (40,41).

Marine phytoplankton species that live in low salinity water generally are not stenohaline for low salinity, but rather are euryhaline and thus can tolerate high salinity as well. Down to around 5 ppt, the freshwater dilution of the seawater does not significantly change the ratios of ions found in seawater. Because the ratios of ions in freshwater are so different from those in seawater, the resulting ratios in water less than 5 ppt tend to be different from seawater and this apparently causes problems for most marine phytoplankton. Whereas a few species can grow as well in freshwater as in seawater, most grow very poorly or not at all in water less than around 5 ppt.

Adaptations to Light

A good overview of photosynthesis and phytoplankton adaptations to light can be found in references 2,42–48. Typically, the chlorophyll *a* content of phytoplankton cells is around 1% of the biomass of the cell, although this varies widely, depending on species and environmental conditions. Within the chloroplasts, photosystem II typically contains 200 to 300 chlorophyll molecules, along with various carotenoids (both carotenes and xanthophylls). It is here that photons are used to drive electrons off water, thereby generating molecular oxygen. The electrons are then transported to photosystem I, where photons are absorbed to boost the energy level of the electrons. Ultimately, these electrons are used to generate reduced nicotinamide adenine dinucleotide phosphate (NADPH) and adenosine triphosphate, which are then used in the dark reactions of photosynthesis to convert carbon dioxide to organic molecules. In addition to the standard C3 photosynthetic pathway, which starts with the carboxylating enzyme ribulose bisphosphate carboxylase, many algae use additional biochemical pathways for the conversion of inorganic carbon into organic compounds (49–51). For example, many phytoplankton have the enzyme phosphoenolpyruvate carboxylase, which uses the bicarbonate ion as its substrate. This pathway leads to the production of amino acids. Overall, the quantum yield of photosynthesis in phytoplankton is around 0.08 moles of carbon per mole of photons. This, of course, varies with species and environmental circumstances.

The relationship between photosynthetic rates and light intensity is typically shown as a "P versus I curve." As a broad generalization, net photosynthesis (total or gross photosynthesis minus respiration losses) is positive at light levels above approximately 1% of full sunlight. This of course varies with species and environmental conditions, and some polar microalgae have been found to grow at 0.01% of full sunlight. From this compensation point (where gross photosynthesis just compensates for respiratory losses), up to about 10 to 20% of full sunlight, the relationship between light intensity and photosynthetic rate is roughly linear, indicating light limitation. The slope of this line (designated as $\alpha = P/I$) is an index of photosynthetic efficiency. From 10 to 20% up to perhaps 50% of full sunlight, the P versus I curve is flat–increasing light does not increase the photosynthetic rate. At these light intensities, the biochemical reactions generating organic carbon (the dark reactions of photosynthesis) are the limiting step and photosynthesis is light saturated. Often above 50% of full sunlight, photosynthetic rates decline as a result of photochemical damage from UV radiation and the intense visible light (known as photoinhibition). The shape of the P versus I curves changes considerably among species as well as in response to other environmental factors such as nutrients and temperature.

Phytoplankton respond to changing light intensity with a variety of adaptations on various timescales. Some morphological and biochemical responses occur within seconds. The structure of the thylakoids can change within seconds. The size and shape of chloroplasts can change in minutes to maximize or minimize light absorption in dim or bright light (52). In many species, chloroplasts can migrate within the cell, dispersing in dim light to reduce self-shading and aggregating in bright light to increase shading (53,54). On longer timescales (hours), the amount of pigment changes and in some species the number of chloroplasts can change (55,56). In response to dim light, many algae increase the size of the photosynthetic unit, but some increase the number of photosynthetic units. Some carotenoids, such as violoxanthin and diadinoxanthin, are used to absorb light to protect against excessive light. Carotenoids and mycosporine-like amino acids are produced to protect against UV radiation.

Most algae have a variety of carotenoids (such as fucoxanthin or peridinin) which absorb light in the green and yellow region of the light spectrum, between the blue and red absorption peaks of chlorophyll *a* (57–59). These carotenoids absorb wavelengths of light that chlorophyll absorbs very poorly and transfer the energy to chlorophyll *a*. Chlorophylls *b* and *c* also absorb wavelengths longer than what chlorophyll *a* absorbs. These accessory pigments allow algae to absorb more light than they would with chlorophyll *a* alone. This is particularly important in dim light and at depth where, as a result of differential absorption of different wavelengths by water, the remaining light is of wavelengths that carotenoids and chlorophylls *b* and *c* can absorb better than chlorophyll *a*. As a result, the ratios of chlorophyll *b*/chlorophyll *a*, chlorophyll *c*/chlorophyll *a*, and carotenoid/chlorophyll *a* tend to be higher in dimmer light.

Many of the changes in algae in response to changes in light intensity are also observed on a diel basis (60). Chlorophyll content and capacity for photosynthesis are lower at night than during the day. This is not just a simple response to light intensity. Many of the photoadaptive responses are under the control of a biological clock (61). Because some of the adaptations take hours, this allows algae to prepare their photosynthetic apparatus ahead of time rather than simply responding to changes in light intensity and losing hours of light availability while adapting. This also keeps algae from responding to short-term fluctuations in light intensity. For example, it would not be advantageous to begin shutting down the photosynthetic apparatus in response to a brief drop in light intensity caused by a passing cloud or vertical mixing.

Nutrient Acquisition

As a broad generalization, the concentration of nutrients inside phytoplankton cells are typically about a million times greater than in the water in which they live. This indicates the volume of water out of which they must obtain nutrients to double their biomass for binary fission.

As nutrients are usually at very low concentrations in the ocean (62–65), most phytoplankton have uptake enzymes with very high affinities for the various nutrients (66–69). They have the capacity to store ten to a hundred times more nutrients in the cells than what they need for one cell division, a process known as luxury uptake (70,71). It is suspected that phytoplankton

experience a patchy environment on a microscopic scale, so excess stored nutrients from luxury uptake allows them to continue growing during times of limited access to external nutrients. For dinoflagellates that undergo daily vertical migration through the nutricline, luxury uptake allows them to take up and store nutrients while below the photic zone to utilize later after they have swum up into the photic zone. Growth rate has been found to then be related to the amount of stored nutrients in the cell.

Because bicarbonate is a major ion in seawater, marine phytoplankton are generally thought to not be carbon limited, although there is some evidence that carbon uptake could be diffusion limited (72). The two major nutrients that phytoplankton need that are usually in very low limiting concentrations are nitrogen (N) and phosphorus (P). Generally, phytoplankton have a molar elemental C/N/P composition of around 106 : 16 : 1, known as the Redfield Ratio (73). Upwelled deep water typically has inorganic C/N/P in ratios of around $1,100 : 15 : 1$ (74,75). A comparison of the two ratios indicates that the phytoplankton will run out of nitrogen first, and phosphorus soon after, but there is plenty of carbon. The conclusion is that nitrogen is the most important limiting nutrient in most parts of the ocean, with phosphate almost as limiting, and only about 10% of the carbon is taken up.

Upwelled water contains considerable amounts of nitrate but very little ammonia (64). Surface waters are depleted of nitrate by phytoplankton, causing a shift over to reliance upon ammonia as a nitrogen source. This ammonia comes from the decomposition of organic matter and excretion by animals, and is thus recycled nutrients within the photic zone. The organic matter that is produced by phytoplankton utilizing upwelled nutrients (primarily nitrate) is called *new production* because it is supported by nutrients new to the photic zone ecosystem (76,77). As these new nutrients come from outside the ecosystem, they lead to a net increase in biomass. The organic matter produced by phytoplankton using nutrients (mostly ammonia) recycled from heterotrophic activity in the photic zone is called *old production*, as it is supported by old nutrients that have already been in the photic zone ecosystem for awhile. This old production does not lead to an increase in biomass in the ecosystem because it relies upon old recycled nutrients that are derived from the decomposition of old biomass. Because phytoplankton must use NADPH to reduce nitrate to the redox level of ammonia for incorporation into amino acids, they preferentially take up ammonia until it is depleted before using nitrate. Whereas some phytoplankton can take up amino acids and other organic nitrogen compounds, it appears they are not very good at outcompeting heterotrophic bacteria for organic compounds at the low concentrations found in most seawater. The direct C–N bond in most complex organic molecules generally makes them unavailable to most phytoplankton as a nitrogen source.

Whereas eukaryotic algae are not capable of nitrogen fixation, some oceanic diatoms and dinoflagellates with large vacuoles have cyanobacteria inside. It is suspected that these cyanobacteria fix nitrogen and transfer some of the fixed nitrogen to the host diatom or dinoflagellate to help maintain a symbiotic relationship.

Both old (recycled) and new phosphorus are in the same redox state, PO_4^{-3}. In addition to inorganic phosphorus, however, many phytoplankton have phosphatase enzymes that can cleave the ester bond of organic phosphorus compounds (78,79). It appears that phytoplankton are capable of utilizing a large percentage of the organic phosphorus found in water.

Diatoms need as much silica (for their frustule) as nitrogen, whereas other groups of phytoplankton need little or no silica (80). This puts diatoms at a competitive disadvantage relative to other phytoplankton in areas that are low in silica. Silica is different from other nutrients in that it cannot be stored at high concentrations inside the cell to any great extent like the other nutrients because of autopolymerization problems. This forces diatoms to take up silica only at the time of frustule formation, which takes place primarily around the time of cell division.

Quantitatively, the next most important nutrient is iron, which is used in a wide variety of enzymes, particularly those involved in energy transfer and redox reactions (81,82). The amount (by moles) needed is around 1/100 to 1/10,000 that of phosphorus (83). It appears that iron is a primary limiting nutrient in some parts of the ocean. Other trace elements such as manganese, zinc, cobalt, copper, and selenium are needed in smaller amounts and may be limiting is some circumstances (84,85). In many situations, phytoplankton are faced with multiple nutrient limitation, as the ratios of nutrient requirements appear to be similar to availability ratios, as seen in the N/P ratios. It is less clear with trace metals, however, because many trace metals appear to be strongly complexed by organic molecules, making them unavailable to phytoplankton. At the same time, it appears that some trace metals can substitute for each other. It appears that in many parts of the ocean, a number of nutrients may be approximately equally limiting.

Coastal phytoplankton have higher requirements for NO_3, NH_4, PO_4, Si, Fe, Zn, and Mn than oceanic species, which corresponds to the higher concentrations of these nutrients found in coastal waters (84,86,87). This indicates that oceanic species have adapted to their low nutrient environment by increasing their efficiency of utilizing nutrients at low levels.

Approximately half of the marine phytoplankton species appear to need at least one vitamin (88). The one needed by the most species is vitamin B_{12}, although a number of species need thiamine or biotin. These vitamins are produced and excreted by various biota in the ocean, but it is not clear if their concentrations are low enough to limit the growth rate of some species. As many species do not require any vitamins, low vitamin concentrations in the ocean could only alter species competition and community structure, not overall primary productivity.

Paradox of the Plankton

One interesting aspect of marine phytoplankton communities is their high diversity (89). Unlike animal species, which have different diets, and terrestrial plants, which obtain nutrients from different patches of soil, millions

of phytoplankton cells representing hundreds of species can be found living in 1 L of water in the open ocean. Because all the species have essentially the same nutritional requirements and they are competing for the same nutrients in that liter of water, the question arises why does one species not eventually grow faster and outcompete all the other species for those nutrients. Considering the competitive exclusion hypothesis and the concept of niche partitioning, it is difficult to understand how so many species can all exist in a small, well-mixed parcel of water. This question is known as "The Paradox of the Plankton." Some hypotheses emphasize the variability of the environment as a mechanism for maintaining coexistence (90), but the highest diversity of marine phytoplankton is found in the tropical open ocean where environmental variability is lowest and the nutrients they are competing for are at their lowest concentrations. Phytoplankton species diversity is lowest in estuaries where nutrient concentrations are high and the environment is highly variable. This paradox of the plankton illustrates how much we probably do not know about the subtle relationships among marine phytoplankton species.

Avoidance of Grazing and Microbial Attack

Herbivores (insects, crustaceans, etc.) on large plants on land or macroalgae in the ocean generally are considerably smaller than their prey and take only small parts of the plant away. Because the plant survives to be able to propagate its genes in the future, there is a selective advantage for large plants to produce toxins or other noxious compounds that reduce grazing and thus biomass loss. In the case of microscopic unicellular algae, their grazers are much larger than them and actively consume large numbers of phytoplankton cells of a variety of species at a time. Any noxious or toxic compounds produced by one cell can hardly have much effect on a large herbivore. If it does have an effect, it will reduce grazing (on all the species, not just the toxic species) only after that toxin-producing cell has already been consumed and thus unable to propagate its genes. Therefore, there is no selective advantage for microalgae to produce toxins. Most of the toxins known to be produced by phytoplankton are toxic to fish, mammals or other organisms, not their herbivores. Those toxins appear to be produced for some other reason. The end result is that phytoplankton have relatively few options for deterring grazing. Their main strategy appears to be to outgrow their grazers.

Cell size can help avoid being grazed by some animals but not others (91,92). Crustaceans can typically filter cells larger than 5 to 10 μm, so smaller cells can avoid those grazers (93). Large cells can avoid being eaten by the small abundant protozoans. Any size cell may be able to avoid some groups of grazers but is vulnerable to another group.

Spines and long chains of cells may block the feeding mechanisms of some grazers. Some species, particularly those covered with mucilage may be able to survive gut passage, indeed profiting from being in such a nutrient-rich environment.

Some species of dinoflagellates are capable of producing flashes of bioluminescent light when disturbed. There is evidence that these flashes reduce predation (94,95).

Bacteria are known to attack and consume phytoplankton, but it is not known if they can attack healthy cells or only weakened or dying cells. Large numbers of viruses are found in seawater and some are known to be able to lyse algal cells. At the present time, however, not much is known about the quantitative role bacteria and viruses play in phytoplankton population dynamics. Bacteria and viruses can be found on the surface of cells, in their vacuoles, and in the cytoplasm, but their roles as symbionts, commensals, or parasites are not well known (96,97).

Toxins

Whereas the vast majority of marine phytoplankton are not toxic, a few species, primarily dinoflagellates, are known to produce toxins (98). Under certain circumstances, these species can produce large dense blooms, which can lead to the death of fish and others organisms in the food chain. In some cases, the toxin ends up in seafood, leading to human sickness and/or death (see RED TIDES AND OTHER HARMFUL ALGAL BLOOMS, this Encyclopedia).

ECOLOGICAL DISTRIBUTIONS

Biogeography

There is a large literature on the distribution of phytoplankton species, but references 99 to 104 provide an overview. Because the plankton are constantly being moved around by surface currents, and environmental conditions are reasonably uniform over large areas of the ocean, most marine phytoplankton have rather cosmopolitan distributions, much more so than benthic or terrestrial organisms. The four major biogeographic (or more properly, phytohydrographic) boundaries in the ocean that separate different phytoplankton communities are the coastal-oceanic boundary, the Antarctic Convergence, the latitudinal thermal gradients, and the north-south–trending continents.

The strongest and oldest phytohydrographic boundary is the coastal-oceanic one at approximately the shelf break where the continental shelf (typically around 100 m deep) ends and the bottom drops rapidly to the deep sea (typically around 4,000 m deep). This boundary is geologically formed, thus quite ancient. Very few phytoplankton species live in both coastal and oceanic waters. The oceanic habitat is characterized by a strong pycnocline, thus low nutrient concentrations in the photic zone. The water is also quite transparent, leading to a deep photic zone. A large number of mechanisms help weaken any pycnocline that develops in coastal waters, so they tend to have much higher concentrations of nutrients. Coastal waters also tend to have higher concentrations of dissolved organic matter, detritus, resuspended sediments, and planktonic biomass, leading to a much shallower photic zone. The much shallower water column and proximity to terrestrial weather systems also lead to environmental conditions in coastal waters changing much more rapidly. On a longer timescale, one has to consider that the continental shelves alternate between terrestrial and shallow marine ecosystems as sea level changes over time. Our present continental shelves have been flooded only for

the past 5,000 to 15,000 years. Species that populate the continental shelves have to be adapted to survive in other refuges when sea level is low and the shelves are dry land. Apparently, estuaries and not the oceanic habitat serve as refuges for coastal phytoplankton during times of low sea level. Many coastal species also live in estuaries but not in the open ocean.

The Antarctic Convergence is the second strongest phytohydrographic boundary separating phytoplankton communities. It developed around 30 million years ago as the Antarctic continent separated from the other continents and drifted to the South Pole. This allowed the Circumpolar Current to develop, which effectively isolates the Southern Ocean from the rest of the world. Over 50% of the species in the Southern Ocean are endemic. Relatively few species are found in both the Antarctic and Arctic because the two ecosystems are in fact quite different from each other in many ways.

Also important are the latitudinal thermal gradients found in the ocean today. The ocean today is divided into equatorial regions, subtropical gyres, subpolar gyres, and polar regions, each with their own distinctive phytoplankton communities. These latitudinal thermal gradients have been strengthening over the last few million years, making them even more important phytohydrographic boundaries.

Of lesser importance are the continents that separate the Atlantic from the Pacific and Indian oceans. In the past, a Tethyan Seaway connected all three oceans near the equator and phytoplankton species lived in all three. About 3 million years ago, tectonic activity generated the Isthmus of Panama, separating the Atlantic from the Pacific. Most phytoplankton species still live in all three oceans, but genetic divergence is developing as a result of the spatial separation today.

Invasions

Species distributions observed today cannot be regarded as being completely natural. Phytoplankton are transported around the world in the ballast tanks of ships. In a few cases, it has been documented that phytoplankton species had apparently never lived in a certain part of the world and then suddenly appeared and proliferated (105). It is suspected that transport in ballast tanks is the cause (106).

Seasonal Succession

One observes quite strong seasonal succession of species in temperate and polar waters (107). In polar waters, this is primarily the result of the large seasonal change in light availability–light intensity, day length, and winter winds and lack of a pycnocline causing mixing of the phytoplankton below the photic zone. In temperate regions, there are dramatic changes in species composition as the environment shifts between the winter and summer. In the winter, the pycnocline is weak or gone, thus nutrient concentrations are high, but the phytoplankton are getting mixed to great depths. In the summer, the pycnocline is strong, so nutrient concentrations are low, but the phytoplankton remain in the photic zone and light intensity is high and day length is long. This strong seasonal gradient between light limitation in the winter and nutrient limitation in the summer generates quite strong successional sequences of phytoplankton species.

EFFECTS ON BIOGEOCHEMISTRY

As marine phytoplankton are responsible for over 95% of the photosynthesis in the ocean as a whole, they are a major component of the biogeochemical cycles in the ocean and indeed the planet. They take up carbon dioxide, turn it into particulate carbon, which then sinks below the pycnocline into the deep sea, where it decomposes back into carbon dioxide (108). The residence time of this carbon dioxide–rich deep water is around a 1,000 years before it upwells back to the surface, releasing the excess carbon dioxide that has accumulated over this time span back to the atmosphere. The net effect of this biological pump (109,110) is to transfer large amounts of carbon dioxide from the atmosphere into the deep ocean, where it is stored for around 1,000 years. If this biological pump and resulting carbon dioxide disequilibrium, driven by phytoplankton, was stopped, atmospheric carbon dioxide would be around three times higher. As carbon dioxide is a greenhouse gas, the pumping of carbon dioxide out of the atmosphere by phytoplankton and storing it in the deep sea effectively cools off the Earth's climate.

Phytoplankton may also be affecting the Earth's climate in another way. Many species, particularly prymnesiophytes and dinoflagellates, produce dimethylsulfonium propionate, which through one of several mechanisms ends up as the gas dimethyl sulfide (111). This gas emerges from the ocean to ultimately form aerosol particles that enhance cloud formation over the ocean (112). Thus it appears that phytoplankton enhance the production of clouds, which reflect sunlight back out into space, thus cooling the earth's climate. Phytoplankton also produce a number of other gases that emerge from the ocean and affect the atmosphere's chemistry.

Phytoplankton modify their environment in other ways as well. Many phytoplankton produce organic compounds that specifically bind various trace metals, completely changing their chemical behavior (81,82). As one example, without this biological complexation by phytoplankton exudates, copper concentrations in the ocean would be high enough to be quite toxic to most phytoplankton. By producing specific compounds that tightly bind up this copper in the photic zone, phytoplankton have effectively detoxified their environment (113,114).

Phytoplankton take up not only carbon dioxide and nutrients, but also inadvertently many metals and other elements, along with pollutants. The same biological pump that transports carbon dioxide and nutrients into the deep ocean also transports these other materials as well (65). As a result, marine phytoplankton play a major role in most biogeochemical cycles in the ocean.

The production of silica frustules by diatoms and calcarious coccoliths by coccolithophores and the subsequent

sinking of the mineral hard parts and burial of a fraction of these materials in the sediments are important components of the biogeochemistry of these elements.

Eutrophication

As a result of the large increase in the human population and the associated runoff of sewage and agricultural fertilizer into coastal waters and atmospheric input of nitrogen from the combustion of fossil fuels, nutrient concentrations have increased in many coastal waters, particularly in the past century (115–117). This has led to increases in overall phytoplankton biomass and significant changes in phytoplankton species composition. In some cases, this also results in oxygen depletion, harmful algal blooms (including toxic species), alteration of the entire food web, and widespread death of fish and other animals. It is widely recognized that this problem is increasing over time.

PRODUCTS FROM MARINE MICROALGAE

One of the most widespread uses of marine microalgae is as food for animals in the aquaculture industry. Large amounts are fed to the larval stages of shrimp, clams, oysters, and other species in hatcheries (118,119). Wide variation exists among phytoplankton species as to which species are suitable for food. The industry has settled upon relatively few species that are widely used by many hatcheries. More research would surely identify more species that are suitable or perhaps even better foods.

Although marine microalgae produce quite a few useful biochemical compounds, they are not exploited much because of the difficulty and expense of harvesting microbes from water (120,121). One product from marine microalgae that is commercially viable is beta-carotene, which is produced in large quantities by certain green algae, and is used as a food coloring. Because of their long evolutionary history, phylogenetic diversity, and divergent biochemistry, one might expect microalgae to be a good source of antibiotics and other pharmaceuticals. This possibility remains relatively unexplored.

METHODS

Biomass

For the estimation of overall phytoplankton biomass in the ocean, the most widely used technique is to filter the water and measure the amount of chlorophyll *a* on the filter (122). Chlorophyll *a* concentrations are measured by extracting the pigment with a solvent (usually acetone or methanol) and measuring chlorophyll fluorescence with a fluorometer (the most sensitive method) or absorbance at a number of wavelengths using a spectrophotometer. The advantage of this method is that chlorophyll *a* is specific to algae (prokaryotic and eukaryotic). The disadvantage is that the ratio of phytoplankton biomass to chlorophyll *a* is variable, typically 25 to 150. Another approach is to actually count individual cells under a microscope and estimate the biomass from cell size. Not only is this laborious, but many cells cannot be easily seen by light microscopy and many cannot be easily distinguished as being either autotrophic (containing chlorophyll *a*) or heterotrophic. The presence of chlorophyll *a* readily and specifically identifies organisms as being photosynthetic. Low levels of chlorophyll cannot be easily detected microscopically, but can be measured fluorometrically.

Primary Productivity

The primary method of measuring primary productivity (rate of photosynthesis) in the ocean is to incubate a parcel of water with ^{14}C-labeled bicarbonate added (122). Because the concentration of bicarbonate in seawater is high, the added radioactive bicarbonate does not change the concentration or perturb the system or alter uptake kinetics. After a period of time, the water is filtered and the radioactivity remaining on the filter (presumed to be inside the phytoplankton cells as organic carbon, whereas unused bicarbonate has passed through the filter) is measured with a scintillation counter. An alternative, less-sensitive method of estimating photosynthetic rates is to compare oxygen concentration changes in incubated illuminated and dark bottles and/or observed diel changes in oxygen (see PRIMARY PRODUCTIVITY IN THE MARINE ENVIRONMENT).

Phytoplankton Cultures

Many phytoplankton species can be isolated from the ocean and grown in culture media as pure cultures (123). Because most reproduction by phytoplankton is by asexual binary fission, one can pick up a single cell in a micropipette and inoculate it into sterile culture media, and it will develop into a genetically pure clonal culture. This allows researchers to study the ecological requirements of individual species under controlled conditions as well as generate specific products produced by individual species. Cultures of many species can be obtained from various culture collections around the world.

CONCLUSIONS

Planktonic algae are found virtually everywhere in the surface layer of the ocean where at least 1% of sunlight reaches. Despite having similar (autotrophic) nutritional requirements, the planktonic algae are extremely diverse phylogenetically, distributed among ten or more different phyla. They also have diverse morphologies, with diameters ranging from one to a thousand microns. Phytoplankton provide almost all the organic carbon produced by photosynthesis in the ocean and thus provide the base of the entire marine food web. Being the dominant producers of oxygen and consumers of carbon dioxide and nutrients, planktonic algae have a major influence on the biogeochemical cycles of the earth and even the climate. Despite being the dominant autotrophs in the ocean, their standing biomass is low. The major factor limiting phytoplankton growth in the ocean is nutrients, primarily nitrogen and phosphorus, but also sometimes

iron. The combination of their growth being limited by sparse nutrients and strong grazing pressure by heterotrophs keeps the standing biomass of plankton algae low in the ocean, which is why most of the ocean is blue, not green. Despite this low biomass, planktonic algae harvest a large fraction of the solar energy used in the earth's ecosystems and they play a major role in the biogeochemical cycles and energy budget of the planet.

PLANKTONIC MICROORGANISMS: BACTERIOPLANKTON

CLIFFORD A. OCHS
University of Mississippi
University, Mississippi

Bacterioplankton are microscopic prokaryotic organisms occurring in the water column of aquatic ecosystems, including rivers, lakes, and the ocean. They are modern representatives of the oldest forms of life on Earth, dating back to as much as 3.5 billion years ago (1–3). As one of the most abundant types of organism on Earth (4–6), bacterioplankton occur wherever water exists, from geothermal springs to the polar ocean, in abundances that often exceed one billion cells per liter. As a group they are highly diverse in species, modes of energy acquisition, tolerance of oxygen and other chemicals, substrates consumed, and chemical compounds they make and release into the environment. The high abundance and ubiquity of bacterioplankton, combined with their metabolic diversity, make them critical to the movement and transformation of naturally occurring and anthropogenic materials, including many pollutants, on local, regional, and global scales. Their activities in the cycles of carbon, nitrogen, phosphorus, sulfur, and other elements directly influence the chemistry and water quality of oceans and lakes, and has a profound effect on the chemistry of the atmosphere, the temperature of the planet, and ultimately the overall state of the biosphere (7).

Especially in the last two decades, enormous progress has been made in understanding bacterioplankton, but there remain many questions regarding their phylogenetic diversity, population dynamics, adaptability to environmental change, interactions with each other and other organisms, orientation in microspace, physiological activities in nature, and how they structure the physical and chemical environment of aquatic ecosystems through their behavior and activities. With the imaginative application of a variety of new tools to measure bacterioplankton community composition and activities in natural environments, complemented by traditional approaches of studying microorganisms under controlled conditions, understanding of the nature of the bacterioplankton will surely continue to expand in the coming decade (8,9).

This article begins with a general description of bacterioplankton, followed by a discussion of their nutritional modes, and an overview of recent research regarding the taxonomic diversity of the bacterioplankton community. Next, the ecology of bacterioplankton is discussed in detail with an emphasis on factors controlling abundance, growth rates, and biomass production. Examples are provided from both marine and freshwater environments. After that, roles of the bacterioplankton in the cycles of carbon, nitrogen, and phosphorus are explained. The article concludes with a listing of current major research questions regarding bacterioplankton. Recent texts providing excellent overviews of various aspects of bacterioplankton biology include Ford (10), Fenchel and coworkers (11), Cooksey (12), Kirchman (13), and Wetzel (14).

PLANKTON

Plankton comprises a diverse group of organisms common to almost all surface-water ecosystems. Organisms are defined as being plankton according to their size and where they live, rather than taxonomically. Planktonic organisms generally are less than a few millimeters in length and live in open water. Although many species of plankton are capable of self-propelled mobility, because of their small size planktonic organisms are dispersed principally by water movement. Depending on the environment, the plankton community of an aquatic ecosystem may include phytoplankton (microscopic photosynthetic organisms, both prokaryotic and eukaryotic), zooplankton (animal plankton), protozooplankton (protozoan plankton), bacterioplankton (prokaryotic plankton), and viruses. In the photic region of most aquatic ecosystems, these types of organisms occur together.

In addition to a classification based on taxonomy, planktonic organisms may also be categorized according to size (15). Organisms larger than about 200 μm (1 μm is a millionth of a meter) in longest dimension belong to the macroplankton. Macroplankton are primarily zooplankton, and may be visible to the naked eye. But the vast majority of planktonic organisms are microscopic. Microplankton are organisms between 20 and 200 μm in length and consist of some animals, unicellular and colonial phytoplankton, and some protozoa. Nanoplankton are between 2 and 20 μm in length and consist mostly of small phytoplankton and protozoa. Organisms between 0.2 and 2 μm in length are called picoplankton, and consist mostly of bacterioplankton.

BACTERIOPLANKTON

The three main lineages, or domains, in which life is classified are Archaea, Bacteria, and Eukarya. Organisms are assigned to one of these three domains on the basis of gene sequences, cell structure, and in some cases, physiological properties. The Eukarya consist of organisms having a complex cell structure including a membrane-bound nucleus containing DNA in linear chromosomes, and other membrane-bound organelles such as mitochondria and chloroplasts. Archaea and Bacteria consist solely of prokaryotic organisms. Typical features of prokaryotes are a rigid cell wall, the absence of membrane-bound organelles, and a single unenclosed, usually circular, chromosome of DNA loosely bound in an aggregated mass called a *nucleoid*. Reproduction of prokaryotes is by *binary fission*, which is essentially the division of a single "parent" cell into two cells that are genetically copies of the parent cell. Besides having unique genetic properties, Archaea and Bacteria differ in the composition of cell membrane lipids, cell wall structure, and other features (3). The domain Bacteria consists of at least a dozen major divisions that, on an evolutionary basis, are more distant from each other than are animals and plants (3,16). The Archaea consist of fewer groups, although these are still widely distant.

The bacterioplankton consist of organisms in both the domains Archaea and Bacteria. They are the most

abundant organisms in the plankton (17). They occur wherever there is water, with abundances commonly between 0.5 and 5 billion cells per liter. Individual cells usually have the shape of straight or curved rods, spheres, or short filaments. Many bacterioplankton, perhaps most, are capable of motility by one or more flagella (18), allowing them directed movement toward or away from chemicals or other stimuli. They occur in the water column of aquatic environments as single free-living cells, attached to microscopic particles, or as colonies of attached cells. Most bacterioplankton are free-living, but where particulate material is in high concentration, as for example, following an algal bloom, bacterioplankton attached to small particles increase in number and their proportional contribution to the total bacterioplankton community (19). Individual free-living cells are typically less than 2 μm in diameter, with cell volumes between 0.02 to 0.1 μm^3. Attached cells can be as much as 10 times larger (11). Some colonies, especially those of the phototrophic cyanobacteria, may exceed a millimeter in the largest dimension. Many cells that appear to be "free-living" by microscopy may, in fact, be attached to a gel matrix of dissolved organic material, or to the cell surface mucous layers of other microbes (20).

Until the discovery that there are two distinct branches of prokaryotic life, all prokaryotes were referred to simply as *bacteria*. Often, the term *bacteria* is still used to refer prokaryotes as a group, but this usage can be confusing and will be avoided in this article. Instead, where prokaryotes are referred to generically, the term *prokaryote* will be used. Although it obviously is a holdover from prior usage, the term *bacterioplankton* makes no distinction between prokaryotes of the domains Bacteria and Archaea.

THE PHYSICOCHEMICAL ENVIRONMENT OF AQUATIC ECOSYSTEMS

The ecology, metabolic activity, and global significance of bacterioplankton must be considered in the context of their habitat. Bacterioplankton occur in all natural water bodies, including rivers, streams, lakes, and ocean. The ocean is by far their largest habitat, covering about 71% of the surface of the globe, and encompassing about 98% of all water in the biosphere (14). Inland water systems, including rivers, freshwater and saline lakes, comprise the other major habitats of bacterioplankton. Although they contain less than 0.01% of the water in the biosphere, these freshwater systems are major sources of water consumed by humans and other terrestrial animals, and their microbiology is of great interest.

As habitats for bacterioplankton, the ocean and inland water systems vary in substantial ways. The ocean has a salinity generally between 30 to 35 parts per thousand (ppt), and an average depth of 3,800 m, with a maximum depth of about 10,000 m. The surface mixed layer of ocean (the depth mixed by the wind) extends to perhaps 300 m, or about 2% of total ocean volume. At depths greater than about 1,000 m, the ocean is permanently cold, with a temperature between about −2 °C and 5 °C. This portion of the ocean, which is the deep ocean, is the largest habitat on earth. In the clearest parts of the ocean, light penetrates to about 100 m; below this depth it is aphotic (without light). At sea level, the pressure is 1 atmosphere (atm.), increasing by about 1 atm. for every 10 m depth. Because of deep mixing and downwelling currents, anoxic (without molecular oxygen) regions generally do not occur in most regions of the sea except in microenvironments such as within sedimenting particles or the guts of animals. However, in sediments, and in coastal environments receiving a high flux of organic matter, such as Chesapeake Bay or the Gulf of Mexico, hypoxia (low oxygen) or anoxia can develop in deeper portions of the water column. Most of the ocean away from coastal regions, that is, the "open ocean," is very low in dissolved organic matter, phosphorus, iron, and other nutrients, and considered oligotrophic (low production) in terms of biomass production. As discussed later, latitudinal variation in temperature, transparency, mixing depth, nutrient concentrations, and salinity may significantly influence spatial patterns in bacterioplankton community composition and activities in the sea.

There are many diverse inland water systems including freshwater lakes, saline lakes, temporary ponds, and running water systems of various kinds. Lakes and inland seas cover about 2% of the surface of the earth (14). Of these systems, approximately 45% of the inland surface waters of the world are saline, including the Black Sea and the Caspian Sea. On a volumetric basis, surface freshwater is concentrated in about 250 large lakes, which together contain about 75% of the volume of inland surface water; one of the most prominent of these large lakes is Lake Baikal of Siberian Russia, which alone contains approximately 20% of the worlds surface freshwater. However, the vast majority of lakes are small and relatively shallow, usually less than 20 m deep. Running water constitutes only about 0.1% of the land surface of the earth.

Across a latitudinal gradient, inland waters exhibit a wide range in temperature, mixing patterns, organic matter, nutrient concentrations, depth, and light penetration. Especially in temperate regions, seasonal changes in some of these physicochemical properties also occur. Depending on the geology of the watershed, and the hydrology of the basin, the salinity of freshwater lakes and running water ranges from very low (about 0.5 ppt) to higher than the ocean. Nutrient and dissolved organic matter concentrations also range widely, but because of the influence of the land, are generally higher than in the open ocean. Generally more turbid than the ocean, photosynthetically active radiation in lakes may penetrate to no more than about 10 to 20 m, sometimes much less, and thus a significant portion of the water column of many lakes is aphotic. Water temperatures of lakes vary with latitude, season, and depth from 0 °C, the temperature at which ice forms in freshwater, to higher than 40 °C in some areas. Because freshwater density decreases from 4 °C to 0°C, ice floats and, except where it is very shallow, lakes do not freeze to the bottom during winter. During summer, the water temperature of most lakes declines with depth, except in tropical and polar regions, where lake temperature may vary little with depth. This vertical temperature gradient,

Table 1. Terms to Describe Mechanisms of Energy Conservation and Carbon Metabolism of Living Things. As a Group, the Bacterioplankton Are Capable of All the Metabolic Modes Shown. Terms in Parentheses Are Widely Used Shorthand Versions of the More Cumbersome Full Descriptions

Metabolic Mode	Energy Source	Electron Source	C Source
Photolithoautotroph (Photoautotroph)	Light	Inorganic chemicals (e.g., H_2O, H_2S, S^o)	CO_2
Photoorganoheterotroph (Photoheterotroph)	Light	Organic chemicals	Organic C
Chemolithoautotroph (Chemoautotroph)	Chemicals	Inorganic chemicals (e.g., NH_4, H_2S, S^0, H_2)	CO_2
Chemoorganoheterotroph (Chemoheterotroph) (Heterotroph)	Chemicals	Organic chemicals	Organic C
Chemolithoheterotroph (Mixotroph)	Chemicals	Inorganic chemicals	Organic C

combined in some lakes with an increase in salinity with depth, may lead to at least temporary stratification of the lake into water layers that increase in density with depth. Consequently, depending on depth, surface area, salinity, and location, some lakes mix with the bottom continuously, some lakes mix for short periods only once or twice a year, and some lakes never fully mix to the bottom. In lakes that mix only occasionally or never mix fully with the bottom, a deep anoxic zone may occur, either permanently or transiently, where bacterioplankton having anaerobic modes of metabolism may flourish, but where few other organisms besides prokaryotes can survive. A prominent example is the Black Sea, where more than 87% of the volume is without molecular oxygen (14).

BACTERIOPLANKTON MODES OF ENERGY CONSERVATION AND CARBON METABOLISM

Metabolism refers to the sum of biochemical processes occurring in a cell. It is an indication of a common evolutionary link that prokaryotes share many properties of metabolism and cell structure with other life, for example, in assembling proteins and nucleic acids using essentially the same molecular building blocks as all other organisms on earth. Yet, prokaryotes as a group are remarkable for their metabolic diversity with respect to energy, carbon and other elements, and in other respects. This metabolic diversity, fully represented in the bacterioplankton, is the basis for much of the synthesis and degradation of organic matter, and patterns of nutrient cycling that occur on the planet. In this section, the metabolic diversity of the prokaryotes with respect to their mechanisms of energy conservation and carbon sources is outlined. Energy conservation refers to the mechanisms by which an organism obtains energy from the environment. Details of these nutritional modes can be found in most textbooks of microbiology.

All organisms must acquire from their environment, elements for biosynthesis (carbon, nitrogen, phosphorus, etc.), a source of electrons for construction of organic molecules and polymers, and a source of energy to build ATP molecules specifically (21,22). ATP (adenosine triphosphate) is the principal molecule used to drive energy-requiring chemical reactions in all cells. The terminology used to classify organisms nutritionally is based on their sources of energy, electrons, and carbon, and is summarized in Table 1. All terms used to describe these metabolic modes use the combining form troph as a suffix, derived from the Greek and meaning "to feed."

Organisms using organic molecules as carbon sources are called *heterotrophs*. Organisms that obtain carbon from carbon dioxide are called *autotrophs*. Autotrophs synthesize the organic biomolecules needed for maintenance or growth by first reducing carbon dioxide to sugar or other organic molecules, a process often referred to as *carbon fixation*. (Reduction is the addition of electrons or hydrogen atoms to a substance). As manufacturers of organic molecules from inorganic molecules, autotrophs provide the organic molecules on which heterotrophic organisms depend.

Autotrophs obtain the energy for synthesis of organic molecules and other purposes from either absorbed sunlight or by oxidation of consumed inorganic chemicals. Photoautotrophic organisms uses sunlight as an energy source, a process known as *photosynthesis*. Where a chemical is used by an autotroph, the organism is a *chemoautotrophi*. Chemicals used as energy sources by chemoautotrophs include reduced molecules of nitrogen (NH_4, NO_2^-), sulfur (H_2S or S^0), iron (Fe^{+2}), manganese (Mn^{+2}), or hydrogen (H_2), depending on the organism.

Most heterotrophic organisms are also chemotrophic, but unlike the chemoautotrophs, use consumed organic chemicals as sources of energy. There are two types of metabolic pathways used by heterotrophic organisms in catabolism (decomposition, with release of energy) of organic substrates, namely, respiration and fermentation. In respiration, an organic chemical substrate reacts chemically with an inorganic molecule such as O_2, NO_3, or SO_4 consumed from the environment. In this reaction, electrons stripped from the organic substrate (the electron donor) move, by a series of chemical intermediates, to the inorganic molecule (the electron acceptor). Energy released in this redox reaction (a chemical reaction involving the transfer of electrons from one molecule to another) can be harnessed by the cell to synthesize ATP. Respiration may be aerobic (using oxygen as an

electron acceptor) or anaerobic (using an inorganic electron acceptor other than oxygen). In either case, in respiration the organic substrate is catabolized fully to molecules of carbon dioxide and water.

Unlike respiration, which may be aerobic or anaerobic, fermentation is restricted to anaerobic environments. In fermentation, ATP is generated in the absence of an inorganic terminal electron acceptor. Instead, the same organic substrate is used as a source of energy, a source of electrons and, following partial decomposition, an electron acceptor. There are various kinds of fermentation pathways that differ in the type of substrate used, products formed, and number of ATP molecules made. In all fermentations, because catabolism of the substrate is incomplete, fewer molecules of ATP are synthesized per substrate molecule than in respiration. For this reason, fermentation is often described as a less efficient mode of energy metabolism than respiration. However, there are some organic molecules catabolized by fermentative organisms that cannot be used by at least some respiring organisms.

Finally, there is the requirement of electrons for the synthesis of organic molecules or polymers from more oxidized molecules. There are only two potential sources of electrons, namely, inorganic and organic chemicals. Lithotrophy refers to the use of electrons from inorganic molecules. Organotrophy refers to the use of electrons from organic molecules. Most autotrophs acquire electrons from inorganic chemicals. Aerobic photoautotrophs use water as the electron donor, whereas most anaerobic photoautotrophs use a reduced sulfur compound. For chemoautotrophic bacterioplankton, the same reduced inorganic chemicals described earlier as energy sources also serve as electron sources. Where water is used as an electron source in autotrophic metabolism, oxygen is generated, and the process is referred to as *oxygenic photoautotrophy*. Where one of the other reduced inorganic molecules is used, the process is anoxygenic. Unlike autotrophs, most heterotrophs acquire these electrons from the same organic chemicals used as a source of energy and carbon.

Putting the three prefixes of these italicized descriptors of metabolism together with the suffix troph (... troph), in the order, energy source-electron source-carbon source, the basic nutritional mode of any organism can be described (Table 1). For example, all plants and eukaryotic algae obtain energy from sunlight, electrons from water molecules, and carbon from carbon dioxide. This makes all plants and algae photolithoautotrophic (or photoautotrophic, for short). All animals and fungi obtain energy, electrons, and carbon from organic molecules, and are therefore chemoorganoheterotrophic (chemoheterotrophic, or simply heterotrophic, for short). Bacterioplankton, unlike animals and plants, as a group exhibit a highly varied array of nutritional modes.

Most bacterioplankton live in oxygenated water and are aerobic chemoheterotrophs (22). Modes of heterotrophic bacterioplankton respiratory metabolism in anoxic environments include nitrate reduction (denitrification), sulfate reduction, Fe^{+3} and Mn^{+4} reduction, and the reduction of carbon dioxide (a type of methanogenesis). There are also fermentative bacteria of various kinds in anoxic environments.

Autotrophic bacterioplankton also can be found in oxic and anoxic water. Aerobic photoautotrophic bacterioplankton primarily are in the division cyanobacteria. If there is sufficient sunlight, photoautotrophic bacterioplankton also may occur in anoxic water. Examples of photoautotrophic bacterioplankton in anoxic water include groups traditionally referred to as purple sulfur bacteria, purple nonsulfur bacteria, green sulfur bacteria, and green nonsulfur bacteria. Despite numerous genetic, morphological, and physiological differences among these groups (and between genera within these groups), they all have an anoxygenic, anaerobic photosynthetic metabolism, although some may be tolerant of oxygen. These organisms can be abundant in the water column of light-exposed anaerobic habitats having the appropriate electron donors such as clear, stratified sulfur-rich lakes (23), or as benthic bacteria in shallow sediments (24).

Chemolithoautotrophs (chemoautotrophs for short), use reduced inorganic chemicals as a source of both energy and electrons. There are numerous groups of chemolithoautotrophic bacterioplankton that vary in their sources of reduced inorganic compounds, but in most cases, the electron acceptor used by these organisms is oxygen. Examples of chemolithoautotrophy include the sulfur-oxidizing bacterioplankton (which use H_2S or S^o as energy/electron sources), nitrifying bacterioplankton (which use NH_3 or NO^-_2), and methanogenic bacterioplankton [which may use H_2 or acetate as energy/electron sources and produce methane (CH_4)]. Mixotrophic bacterioplankton are unusual in that they use an inorganic compound as an energy source and electron donor, but an organic compound as a carbon source.

Recently, it was discovered that cultivatable photoheterotrophic (actually photoorganoheterotrophic) bacterioplankton are active in the ocean (25). They metabolize dissolved organic matter (DOM) when available, using oxygen-dependent respiration. When DOM is in lower concentration, they are photosynthetic. In photosynthesis, they use DOM as an electron donor and so are anoxygenic, but in contrast to anoxygenic photoautotrophs, photoheterotrophic bacterioplankton live only in oxic environments. The photoheterotrophic genus *Erythrobacter* appears to be ubiquitous in the euphotic zone of the open ocean. In the northeastern Pacific Ocean, these anoxygenic photoheterotrophs may comprise at least 11% of the total bacterioplankton population in the upper 150 m of the water column, and it is possible that their contribution to the microbial community is even higher in more oligotrophic areas (25). Other species of photoheterotrophic bacteria occur in both marine (e.g., *Roseobacter*) and freshwater ecosystems (e.g., *Erythromicrobium*) (26), but little is known of their contribution to the productivity of these systems.

In summary, although a single species of bacterioplankton may be restricted in its metabolic mode, prokaryotes as a group exhibit a much broader range of capabilities in energy conservation and carbon metabolism than do plants and animals, which are either photoautotrophic or chemoheterotrophic, respectively. Prokaryotes, in contrast, are

capable of aerobic and anaerobic photoautotrophy, photoheterotrophy, multiple modes of chemolithoautotrophy, multiple modes of fermentation, and both aerobic and anaerobic chemoheterotrophy using a diverse array of organic substrates. The type of metabolism that is dominant at any one time or place depends on numerous environmental factors including salinity, oxygen concentration, availability of electron donors and acceptors, temperature, and organic matter concentration or composition. Their metabolic diversity, in combination with their abundance, make bacterioplankton extraordinarily important on a global scale for much of the cycling and transformation of materials that ultimately sustains all life on earth. Their role in global biogeochemical cycling is described in more detail in a later section.

BACTERIOPLANKTON TAXONOMIC DIVERSITY

A History of Methods

Until recently, identification of prokaryotes was based on phenotypic characters (morphological, biochemical, and physiological features) of cultivated isolates. From these methods, it was recognized that prokaryotic diversity is great, but as Stanier and coworkers (27) put it in a well-used text, "... the attempt to discern intergroup evolutionary relationships...seems doomed to failure." They go on to say, "The only attribute common to all these organisms is possession of the procaryotic cell as the unit of structure and function; although this certainly suggests a common primary evolutionary origin, the later divergences have been too great, and too remote, to permit reconstruction of evolutionary relationships on the basis of the properties of contemporary representatives." In other words, development of a trustworthy phylogeny of the prokaryotes that accurately represented evolutionary relationships seemed impossible in the late 1970s.

At about the same time, it became apparent that analysis of prokaryote diversity in the environment was deficient in another respect. Before the late 1970s, bacterioplankton were usually enumerated as colonies on nutrient-rich culture media. Typically, this technique involves spreading a small water sample of known volume across an agar plate enriched with nutrients. Cells reproducing in the medium form visible colonies that can be counted, each colony having descended from a single cell. A shortcoming of this approach is that some cell types may not grow in the culture medium used. This problem became most apparent with development of epifluorescence microscopy techniques, allowing direct counts of all bacterioplankton in a sample without cultivation (28). The method is straightforward. A dye that coats the bacterioplankton is added to a water sample, rendering them flourescent when illuminated with the appropriate wavelengths of light, and visible at 1000X.

Application of epifluorescence microscopy had two immediate consequences for our view of bacterioplankton ecology. First, it was discovered that most (more than 95%) bacterioplankton seen by this technique did not grow using traditional cultivation methods, and so estimates of bacterioplankton abundance and biomass went up dramatically, sometimes by two or three orders of magnitude. Secondly, microbiologists became increasingly concerned with the possibility that much naturally occurring bacterioplankton phylogenetic diversity was unknown. Obtaining organisms in culture has, until recently, been a prerequisite for taxonomic description. If only a small percentage of the bacterioplankton grew in commonly used culture media, perhaps many taxa of bacterioplankton had escaped detection. Without methods to analyze naturally occurring diversity, simple questions of bacterioplankton community ecology, for example, having to do with species composition or succession, could not be addressed (29).

In the early 1980s, the situation began to improve with the development of molecular methods of measuring microbial diversity. These approaches are based on sequencing of nucleotide or amino acid chains in nucleic acids and proteins, respectively. The molecule currently used most often as a phylogenetic marker in studies of the prokaryotes is the gene for the small subunit of prokaryotic ribosomes, the 16S rRNA gene. This gene is useful in the examination of diversity, and for the delineation of phylogenetic relationships, because it is contained by all organisms, is large enough to provide a sufficiently high amount of distinctive genetic information, and is highly conserved (unchanged over time) in some areas but less so in others. Furthermore, comparison between organisms of nucleotide sequences of genes allows a quantitative analysis of their relatedness by evolution (3).

Analysis and comparison of 16S rRNA genes of cultivated isolates, and other molecules, have been invaluable in constructing microbial phylogenetic relationships. In fact, the technique led to a revolution in the concept of evolutionary relationships of not just prokaryotes, but all life, and is the basis of the now widely adopted reorganization of life on earth into three main lineages, Bacteria, Archaea, and Eukarya (3).

Still, because many bacterioplankton taxa have not been isolated, the ability to examine natural microbial communities would remain poor if only cultivated bacterioplankton could be examined. Fortunately, a few years after molecular methods for phylogenetic analysis of cultivated isolates were introduced, a method was developed for the characterization of 16S rRNA genes of bacterioplankton from natural communities without cultivation (30). In the simplest variation of this approach, there are four main steps:

1. DNA is extracted from a natural bacterioplankton community. Contained in this DNA are a mixture of phylogenetically distinctive genes and gene fragments, such as the 16S rRNA genes, of specific organisms in the community.
2. Using the procedure *polymerase chain reaction* (PCR), the 16S rRNA genes of the community are preferentially amplified (repeatedly replicated), resulting in a mixture of DNA fragments, in which there are now large numbers of copies of each different 16S rRNA gene.
3. The mixture of different 16S rRNA genes are separated from each other by insertion into microbial

host organisms that easily can be kept as cultured isolates, such as the bacterium *Escherichia coli*. These foreign genes, carried by host organisms, are called *clones*. A collection of these genetically transformed host cells, containing cloned genes, is called a *clone library*. In the library, each host isolate contains a single type of 16S rRNA gene from the original plankton sample. Once the clone is inserted into the host, it can be further replicated within the host.

4. Following separation and cloning by insertion into host cells, the order of nucleotides of the different 16S rRNA genes can be sequenced. The diversity of the community can be evaluated on the basis of the different sequences obtained. Furthermore, by comparison of the different sequences, one can construct a phylogenetic tree illustrating the degree of relatedness of the organisms.

Using this approach, it is now possible to identify unique taxa of bacterioplankton on the basis of the genetic analysis of recovered genes, without the necessity of obtaining cultivated isolates (31,32). Furthermore, because comparisons of genes between organisms can be used to infer evolutionary relationships, it is now standard practice in studies of microbial communities to report not just the diversity present, but also a phylogenetic tree of the organisms found.

Another important recently developed tool for examination of taxonomic diversity of natural bacterioplankton communities are the nucleic acid hybridization probes (33). These probes consist of short nucleotide sequences (oligonucleotides) complementary to taxon-specific regions of RNA or DNA. They can be designed with various degrees of specificity, from universal probes that target bacterioplankton to probes that are group-specific or, in some cases, even species-specific. Where probes are marked with a fluorescent molecule, they can be used in a procedure called *fluorescent in situ hybridization* (FISH) (34). In this approach, a natural microbial community is exposed to one or more fluorescently labeled oligonucleotide probes. Hybridization of the probes to the targeted nucleic acids can be viewed by microscopy, and indicates the presence of particular taxa. These probes are now widely used to monitor spatial and temporal dynamics of particular groups of bacterioplankton in the natural environment (35).

Today, analyses of bacterioplankton community composition are based on molecular, combined with phenotypic, descriptions of cultivated isolates, sequencing of 16S rRNA (or other molecules) from natural communities, hybridization studies using targeted oligonucleotide probes, and other approaches (12,36). With this array of tools, there has been in the last decade a flood of new discoveries regarding the diversity, ecology, and evolutionary history of the prokaryotes.

A MODERN VIEW OF BACTERIOPLANKTON TAXONOMIC DIVERSITY

The systematic description of the prokaryotes is in progress, and will almost certainly undergo modification as additional information used in interpretation of phylogenetic relationships is obtained. Often, most of the organisms detected in modern studies of diversity, and included in phylogenetic reconstruction, have never been cultivated or even knowingly observed, and are known only from their genes, usually the 16S rRNA gene extracted from water. Terminology used for taxonomic classification in the following discussion of the bacterioplankton is partly from Garrity and coworkers (37) and Giovannoni and Rappé (26). There are several terms used in the following discussion that might be unfamiliar to the general reader. A distinct genetic sequence representing a phylogenetically identifiable taxon is referred to as a *phylotype*. A *clone*, as described earlier, is a number of copies of a gene (e.g., the 16S rRNA gene), or gene fragment, obtained by repeated replication starting with a single copy. Many phylotypes are known only from the distinctiveness of their cloned genes. A *gene cluster* is a group of DNA sequences from uncultivated organisms that are more closely related to each other than to any cultivated organism (38). A *clade* is a lineage of closely related (monophyletic) organisms, some of which may only be known from their genes.

BACTERIOPLANKTON OF THE DOMAIN BACTERIA

The domain Bacteria consists of at least 18 major lineages. Those having representatives regularly detected in aquatic environments include the *Proteobacteria*, green nonsulfur bacteria, Marine Group A, *Actinobacteria*, the *Cytophaga-Flavobacteria* group, and cyanobacteria.

The *Proteobacteria* are a diverse group of autotrophic and heterotrophic gram-negative bacteria that, according to gene cloning studies, are widespread and abundant in the ocean (26), and common in many lakes (39). They are separated into five subdivisions designated: α-*Proteobacteria*, β-*Proteobacteria*, δ-*Proteobacteria*, ε-*Proteobacteria*, and γ-*Proteobacteria*.

Important phylogenetically coherent groups within the α-*Proteobacteria* include the SAR11 gene cluster, the *Roseobacter* clade, and the SAR116 gene cluster. SAR11 is one of most commonly recovered gene clusters from the ocean and oligotrophic freshwater systems (26,40). Although not yet cultivated, on the basis of the use of flourescent probes for microscopic observation, members of this group are estimated to be about 0.25 to 0.7 μm in diameter. At present, little is known regarding its physiology or ecological role, but considering the ubiquity and abundance of SAR11, it is possible that these bacterioplankton are responsible for a high percentage of the nutrient cycling that occurs on Earth (26). Using a combination of oligonucleotide probes and radioactively labeled organic compounds to compare relative abundance of different taxonomic groups of bacterioplankton in coastal seawater samples with uptake of various substrates, it was found that α-*Proteobacteria* are particularly important in consumption of amino acids, but less so in the utilization of large biomolecules such as protein, chitin, and n-acetylglucosamine (41).

Bacterioplankton of the β-*Proteobacteria* subdivision have been detected in a wide variety of oxygenated

freshwater lakes (39,42), but are rare in open ocean marine systems (43). They do occur in coastal water, perhaps derived from freshwater runoff. It has been suggested that *β-Proteobacteria* have a low tolerance for marine salinity, but other selective factors may be at work in particular systems (44). For example, *β-Proteobacteria* were a minor proportion of the bacterioplankton community of oligotrophic freshwater Crater Lake, Oregon, perhaps because of limitation by trace metals, low dissolved organic carbon concentrations, high ultraviolet light exposure, an unusual phytoplankton community, or some combination of these factors (42).

SAR324 is a unique clade of the *δ-Proteobacteria*. It has been detected in the deep aphotic zone of both the Atlantic and Pacific Oceans, and is presumably adapted for life at high pressure, cold temperature, and the particular substrate content of the deep ocean.

Interestingly, among the cultivated isolates of the *Proteobacteria*, *γ-Proteobacteria* are most common. The implication is that the *α-*, *β-*, and *γ-Proteobacteria* differ in their nutritional requirements, with the *γ-Proteobacteria* favored where substrate concentrations are high (45,46). For example, in coastal marine waters, *γ-Proteobacteria* comprised approximately between 15 and 30% of the total bacterioplankton community and accounted for 19% and 29% of the cells consuming protein and amino acids, respectively (41). In deep water (1,200 m) of Lake Baikal, where sedimenting materials may accumulate, *γ-Proteobacteria* dominated the bacterioplankton (47). However, for reasons yet unknown, *γ-Proteobacteria* are generally uncommon in freshwater systems, perhaps because they are displaced by *β-Proteobacteria* (39,43).

In contrast to the organisms previously mentioned, which are all *Proteobacteria*, the SAR202 gene cluster has been classified with the green nonsulfur bacteria. SAR202 is intriguing in that it appears to be rare in marine surface water, but common in water of 200 m and deeper. The Marine Group A clade is a recently detected unique lineage of the bacteria. One of its uncultivated representatives, the SAR406 cluster, has been found in surface water and deep water of both the Atlantic and Pacific Oceans (26). Like most of the uncultivated bacterioplankton, little is known of the ecology of SAR324, SAR202, or SAR406, but through examination of their use of substrates, it should be possible to elucidate their roles in nutrient cycling (41).

Another important group of marine and freshwater bacterioplankton is the gram-positive *Actinobacteria* clade. In addition to a number of cultivated isolates, this group is represented by a cluster of closely related uncultivated gene clones. These bacterioplankton are commonly detected, especially in the photic zone, but do not appear to be as common as some of the other uncultivated bacterioplankton. Fewer studies have been conducted in freshwater environments, but at least in some lakes, the *Acintobacteria* can be abundant. In Lake Gossenköllesee, Austria, for example, they and the *β-Proteobacteria* were the dominant groups of bacterioplankton (48).

A broad group of bacterioplankton commonly encountered in plankton samples, and having both cultivated and uncultivated representatives, is the *Cytophaga-Flavobacteria* cluster. Members of this group are widespread and sometimes dominant in marine plankton, and common in many lakes (39,41,43,49). They are both free-living and attached to surfaces of detritus, algae, and animal bodies. In culture, representatives of these bacterioplankton produce hydrolytic exoenzymes that catalyze degradation of a variety of large biomolecules including chiton, agar, DNA, and cellulose; this suggests they are ecologically important in the degradation of particulate materials and dissolved biomacromolecules (41). For example, where protein was added experimentally to eutrophic seawater samples, bacterioplankton of the *Cytophaga-Flavobacteria* cluster dominated the community (41). In another study, their abundances increased with depth in the water column, suggesting that they may specialize in the degradation of recalcitrant macromolecules that might accumulate in deep water (43).

Cottrel and Kirchman (49) suggested that, perhaps because of poor PCR-amplification of *Cytophaga-Flavobacteria* genes, these bacteria have been severely underrepresented in diversity studies based on abundances of clones (i.e., clones of a particular type recovered from a sample). From the number of PCR-amplified cloned genes obtained in samples of coastal marine plankton, they found that representatives of the *Cytophaga-Flavobacteria* cluster comprised less than about 10% of the bacterioplankton community. However, using oligonucleotide probes (FISH) to measure their abundance in the same samples directly, they determined that the *Cytophaga-Flavobacteria* cluster were a numerically dominant component (up to 35%) of all bacterioplankton (49). As this study indicates, understanding of bacterioplankton community composition may need revision as limitations or possible biases of various molecular approaches for analysis of these communities are uncovered (50).

The most commonly recognized photoautotrophic bacterioplankton are of the cyanobacteria lineage (see CYANOBACTERIA, this Encyclopedia). The cyanobacteria are oxygenic photoautotrophs. They are common in both marine and freshwater systems, and consist of numerous species, many of which have distinct morphologies, are readily observable under the microscope, and have been studied for decades. The planktonic cyanobacteria occur as free-living single cells, or as colonies of cells in small bundles or filaments. Some species "fix" nitrogen, which means they are able to absorb and reduce molecular nitrogen (N_2) to ammonium, which is incorporated into proteins as an amino group. Nitrogen fixation requires the enzyme nitrogenase, which among the photoautotrophic plankton, is unique to cyanobacteria, and gives them an advantage in systems in which dissolved nitrogen compounds are in low concentration. The filamentous nitrogen-fixing cyanobacterium *Trichodesmium* spp. often forms visible aggregates in warm ocean water (51). Recently, it was discovered that abundant, single-celled, marine cyanobacteria in the size range of 3 to 10 μm express at least one of the genes for nitrogenase, which suggests that they may make a significant contribution to nitrogen fixation in the ocean (52).

In the late 1970s and 1980s, two new genera of cyanobacteria were identified in the ocean plankton, the genus *Synechococcus* and the prochlorophyte *Prochlorococcus* (53,54). Since then, *Synechococcus* has also been identified in many diverse freshwater environments, but *Prochlorococcus* may be restricted to marine environments (see PROCHLOROCOCCUS, this Encyclopedia). Organisms in both groups occur as single cells usually less than about 2 to 3 μm in diameter, and may be collectively referred to as *picocyanobacteria*. Besides their gene sequences, they are distinguished from each other by photosynthetic pigment composition. *Synechococcus* spp., like most cyanobacteria, have chlorophyll *a* and a group of accessory pigments called *phycobilisomes*. The prochlorophytes, in contrast, contain the unusual divinyl chlorophylls *a* and *b*, and lack phycobilisomes.

Depending on trophic conditions, *Synechococcus* and *Prochlorococcus* can occur in very high abundance, sometimes exceeding one million cells per milliliter, and in the vast oligotrophic areas of the oceans, these two genera dominate primary production (53,55). *Prochlorococcus* is probably the most abundant photosynthetic organism on earth (56). Nevertheless, until the development of the *flow cytometer*, these organisms were unknown because they could not be distinguished quantitatively from other bacterioplankton by microscopy. A flow cytometer can detect, and distinguish between, the fluorescence of various photosynthetic pigments at very low concentrations and thereby can be used to quantify individual phytoplanktons, including picocyanobacteria (57).

Remarkably, of the groups of bacterioplankton most often recovered from aquatic environments, only the cyanobacteria, the *Roseobacter* clade, and the *Cytophaga-Flavobacteria* cluster have representatives in culture collections (49,58). Various hypotheses have been suggested to explain the lack of success in cultivating many bacterioplankton phylotypes. One reason may be that it is difficult to reproduce precisely their nutritional or other growth requirements. A second possibility is that there is viral lysis of some bacterioplankton phylotypes on introduction to culture media. In any case, with additional effort, to successfully culture these presently "unculturable" species is likely (59).

BACTERIOPLANKTON OF THE DOMAIN ARCHAEA

(See ARCHAEA IN MARINE ENVIRONMENTS, this Encyclopedia)

The archaeal bacterioplankton consist of at least two major branches, or kingdoms, Crenarchaeota and Euryarchaeota. The Group I archaeal bacterioplankton are represented by a gene cluster of uncultivated organisms (but obtained as gene clones) in the Crenarchaeota. Group II archaeal bacterioplankton are a gene cluster of uncultivated clones in the Euryarchaeota. Recently, gene sequences recovered from marine deep-water plankton samples were classified as a distinct gene cluster of the Euryarchaeota, the Group III archaea (4).

Until recently, it was believed that archaea were restricted to "extreme" environments with very high salt content (such as the Great Salt Lake of Utah), high temperature, those that were very acidic (such as those that occur around some deep-ocean vents, and hot springs), or anoxic. Using molecular approaches to detect archaeal genes, it is now known that representatives of both the major archaeal branches are widely dispersed and common residents of the bacterioplankton communities of both freshwater and marine ecosystems (35,42,60–63). Compared with bacteria and eukarya, the genetic diversity of the archaeal bacterioplankton, at least in the ocean, appears to be low, with a few cosmopolitan phylotypes dominant in widely different ocean provinces (64). But archaea are abundant in the ocean; a recent estimate suggests that archaeal bacterioplankton are equivalent in number to bacterial bacterioplankton at ocean depths greater than 1,000 m, and constitute about 20% of the total marine picoplankton biomass worldwide (6).

The importance of archaea in bacterioplankton communities varies with depth, time, and trophic state. In a survey of eight different marine provinces, Massana and coworkers (64) found that while both Group I and Group II archaea occurred at the surface and below the photic zone in temperate regions of the ocean, Group I archaea predominated below the photic zone, and Group II archaea near the surface. In antarctic and subantarctic water, however, Group II archaea were practically absent (64). In the Gerlache Strait, a region west of the Antarctic Peninsula, archaea at all depths declined in relative abundance during repeated sampling over a two-week period of the austral spring (65). Similarly, Murray and coworkers (66) observed a marked decrease in archaeal rRNA from spring through the austral summer in Antarctic nearshore water. Archaea generally constituted a higher fraction (up to 50%) of the bacterioplankton community below the photic zone of both marine and freshwater systems (4,35,42,65). In the oligotrophic coastal water of California, archaea were less than 5% of the total bacterioplankton counted near the surface, but about 40% of the bacterioplankton at the 600 m depth (35). With increased algal biomass, archaea decline in their proportional representation in the bacterioplankton community (6,66). The latter observation suggested to Murray and coworkers (66) that bacteria may be competitively superior to archaea at times when nutrients are readily available, such as algal blooms.

The life histories and ecological roles of the archaeal bacterioplankton are still unknown. It has even been suggested that the Group II archaea, at least, may originate in the digestive tracts of zooplankton or fishes and not truly be metabolically active plankton (67). Further study of their population dynamics, growth rates, and metabolic activities is necessary for the elucidation of the ecological importance of the archaea in plankton environments. A similar statement could be made about much of the rest of the bacterioplankton.

SPATIAL AND TEMPORAL PATTERNS IN BACTERIOPLANKTON METABOLISM AND TAXONOMIC DIVERSITY

Spatial and temporal patterns in bacterioplankton communities can be described in terms of the metabolic properties of the communities, the taxonomic diversity of the communities, or, ideally, both. Here, general patterns

in space and time of dominant metabolic properties are described first. This is followed by a discussion of spatial and temporal patterns in taxonomic composition. Finally, there is a discussion of the link between metabolic properties and the taxonomic composition of bacterioplankton communities.

Spatial and Temporal Patterns in Bacterioplankton Community Metabolism

Spatial and temporal patterns in bacterioplankton metabolism occur in response to variation in environmental factors such as temperature, oxygen concentration, availability of electron donors and acceptors, light intensity and spectral composition, oxidation-reduction potential, and so on. Three examples illustrate how such patterns in bacterioplankton metabolic diversity can develop and be maintained.

The first example concerns spatial and temporal patterns in heterotrophic bacterioplankton metabolism in a system in which the availability of electron acceptors changes with time. The type of respiratory metabolism of heterotrophic bacterioplankton that dominates at any one time and place depends partly on the types of electron acceptors available in the environment. In general, the higher the reduction potential (tendency to be reduced) of an available electron acceptor, the more the energy that is released on oxidation of a particular substrate molecule, and the more ATP that can be synthesized. Because of its high reduction potential, more energy is acquired per substrate molecule with oxygen as an electron acceptor than with other electron acceptors. Thus, when oxygen is available, as in the ocean and the surface water of most lakes, aerobic heterotrophic bacterioplankton are usually the dominant prokaryotic heterotrophs. Depending on depth and mixing processes, however, oxygen may never be available or may seasonally become depleted in the deeper regions of the water column. Where oxygen is depleted, fermentative bacterioplankton and respiring bacterioplankton using other electron acceptors may thrive.

Consider a stratified lake in the temperate zone with depleted dissolved oxygen in the water at the bottom depleted. The order in which electron acceptors are used in anaerobic respiratory metabolism, and therefore the kinds of bacterioplankton that dominate at any one time and place, can be predicted by the energy yield for the reaction, and is typically (from high to lower energy yield) O_2, NO_3, MnO_2, FeOH, SO_4, and CO_2 (11,68). This sequence of electron acceptors suggests competition for organic substrates among bacterioplankton groups (69). In individual cases, however, energy yield alone does not explain the order in which microbial metabolic activities occur, and factors such as differential toxicity, substrate specificity, or growth rates may be important (70).

As a second example of spatial variation of bacterioplankton communities, consider the distribution of anaerobic phototrophic bacterioplankton in Mahoney Lake, British Columbia (23,71), maximum depth 14.5 m. Because of a pronounced vertical gradient in salinity, it is permanently anoxic below 6 m, and because of the geology of its watershed, it is high in sulfate. During the ice-free season, within a vertical 10-cm band located around 6.8 m, a very dense [up to 400 billion cells per liter (!)] population of the anaerobic phototrophic purple sulfur bacterioplankton *Amoebobacter purpureus* develops. In this narrow layer, oxygen is absent, but there is sufficient light and sulfide (used as an electron donor) to support anoxygenic photosynthesis by this sulfur-oxidizing organism. The sulfide that *A. purpureus* depends on is provided by the sulfate-respiring bacterioplankton within and below the layer.

Chemoautotrophic prokaryotes also exhibit distinct spatial patterns in abundance. In a stratified water column, these organisms may accumulate near the boundary between anoxic and oxic layers of the water column. Here they can catalyze energy-yielding oxidation-reduction reactions between upward-diffusing reduced inorganic compounds produced by anaerobic heterotrophic respiration in the anoxic zone and downward-diffusing molecular oxygen. This was documented in the water column of a Danish fjord, where chemoautotrophic bacteria using NH_4^+ (nitrification) and HS^- (sulfide oxidation) as energy sources were active just above the oxic–anoxic interface (72). Obviously, spatial patterns in microbial metabolism may be transient as conditions change with the season.

Spatial and Temporal Patterns in Bacterioplankton Community Taxonomic Composition

In samples of a particular water stratum from different oceans, there are bacterioplankton clones that are widespread, perhaps cosmopolitan and others that are less broadly distributed. Fuhrman and coworkers (73), for example, obtained identical clones in different marine samples, two pairs of which were between the Atlantic and Pacific Oceans. Nevertheless, they emphasized that marine bacterioplankton communities are diverse and not dominated by a particular clone sequence. In comparison, Mullins and coworkers (40) observed less diversity between the samples of bacterioplankton from the Atlantic and Pacific Oceans, a wider degree of overlap in composition between samples, and emphasized the similarity in bacterioplankton samples between the oceans. Similarly, DeLong (61) found identical archaea in both Pacific and Atlantic coastal water. Hagstrom and coworkers (59) obtained numerous isolates of bacterioplankton from the surface water of a wide range of marine areas. They observed that, although most genera of isolated bacterioplankton have closely related representatives in different oceans, the bacterioplankton community may be distinct, for example, in particular environments many of the isolates of bacterioplankton from the Baltic Sea were genera not obtained in other areas. They suggested that the low salinity of the Baltic Sea may select against many marine bacterioplankton.

Although some bacterioplankton may be cosmopolitan, at least within a particular water stratum, it is clear that along temporal and spatial gradients of some environmental factors, there are changes in the relative proportions of different components of the bacterioplankton community. Taxonomic variation in bacterioplankton communities occur along environmental gradients of salinity (74,75), oxygen (76), substrate composition (19,41,77),

depth (6,35), sunlight intensity and spectral composition (42), and grazing pressure (78). Discovery of these patterns in bacterioplankton community composition is essential for understanding bacterioplankton ecology, but at present the physiology of most components of the bacterioplankton has not provided a mechanistic explanation for them.

As an example, consider the importance of substrate composition on the taxonomic composition of the bacterioplankton community. In many aquatic ecosystems, the primary source of organic molecules used by heterotrophic bacterioplankton is phytoplankton production. At certain times of the year, usually because of an increase in inorganic nutrient availability, the phytoplankton population will temporarily increase dramatically in concentration, a phenomenon known as a *bloom*. Riemann and coworkers (19) followed the phylogenetic composition of a bacterioplankton community during and after an experimentally stimulated phytoplankton bloom. As the bloom progressed, there was a disappearance of three previously dominant, but uncharacterized, phylotypes of bacterioplankton, which they attributed to phylotype-specific grazing by protozoa or, possibly, viral mortality. Within a few days following the bloom, new phylotypes appeared, and bacterioplankton abundance, production, and enzyme activity became increasingly associated with small particles, suggesting microbial colonization of phytoplankton particulate debris. These presumably attached bacterioplankton had high growth rates and high cell-specific activities of protein, sugar, and lipid-degrading enzymes. Many of the attached bacterioplankton were from the *α-Proteobacteria* group, with some from the *Cytophaga-Flavobacterium* cluster (19). Other studies have found particle-associated bacterioplankton to be phylogenetically distinct from free-living cells (79,80).

The Link Between Diversity and Metabolism

It is evident from the discovery of previously unrecognized genes in samples of marine bacterioplankton that unrecognized metabolic activity of bacterioplankton of potentially great biogeochemical significance may exist. For instance, Zehr and coworkers (52,81) obtained the principal gene (and messenger RNA transcripts of the gene) for nitrogenase from apparently abundant, but in some cases uncultivated, unicellular, and filamentous, cyanobacteria, and *Proteobacteria*. These results suggest that nitrogen fixation probably occurs more broadly in the marine plankton than previously thought.

The tools of molecular biology also have been successful in discovering the potential for entirely novel modes of metabolism in bacterioplankton communities. For example, until recently, it was believed that most photosynthesis in the ocean was performed by cyanobacteria or eukaryotic algae. However, Béjè and coworkers (82) found genes for the protein bacteriorhodopsin in the uncultivated *γ-Proteobacterium* SAR 86. Bacteriorhodopsin enables a form of anoxygenic phototrophy in certain extremely halophilic archaea, but it had never been found in marine bacterioplankton. In another study, Kolber and coworkers (83) detected the presence of bacteriochlorophyll in marine bacterioplankton. This photosynthetic pigment of anoxygenic photoautotrophic bacteria had never been found in marine surface water samples. And, as mentioned earlier, recently discovered photoheterotrophic bacterioplankton may contribute substantially to the primary production in the ocean (25). These results suggest that in bacterioplankton communities, there are organisms with metabolic capabilities that are undiscovered, but have great biogeochemical significance.

Although it is now possible to describe bacterioplankton taxonomic diversity quantitatively, it remains a challenge for microbial ecologists to determine the relationship between diversity and community metabolic activity. Again, because few organisms commonly detected by molecular methods have been cultivated, relatively little is known of the metabolic activities of a substantial proportion of the bacterioplankton community. Increasingly, however, studies are being conducted to correlate phylogenetic and metabolic properties of the bacterioplankton community. For example, Ramsing and coworkers (84) examined relationships between the location and abundance of in situ sulfate-reducing bacteria quantified by oligonucleotide probes for sulfate-reducers, rates of sulfate reduction, and characteristics of the chemical environment along a vertical gradient in the water column of a stratified fjord in Denmark. Using fluorescent probes of varying specificity, from a general probe for all bacteria to genus-specific probes, they found pronounced spatial shifts in the bacterioplankton community within the water column associated with the chemical gradient.

Even small differences in genetic diversity (microdiversity) may be associated with significant differences in the metabolic activity or ecology. For example, Moore and coworkers (85) showed that co-occurring strains of the marine prochlorophyte *Prochlorococcus* had differences of only 3% in 16S rRNA sequence. These small genetic differences corresponded to ecologically significant differences in light-dependent physiology, with one population being able to grow at light intensities that inhibited growth of a co-occurring population. Similarly, Field and coworkers (86) hypothesized that genetic diversity of bacterioplankton within the SAR 11 cluster is related to niche partitioning along a depth gradient.

Clearly, there remains much to learn before predictive statements can be made regarding specific bacterioplankton abundance and distribution, the relationship of broad phylogenetic diversity (much less microdiversity) and the ecological function of naturally occurring microbial plankton. Experimental approaches using molecular techniques for the analysis of diversity can be used to address questions regarding the ecological determinants of bacterioplankton community composition and activity (19,41,77,87).

BACTERIOPLANKTON ABUNDANCE, BIOMASS, AND PRODUCTION

Total bacterioplankton abundance in aquatic ecosystems is generally between 0.05 and 5 billion per liter, although in particular systems, it can be less, or exceed this range,

by an order of magnitude (14). Spatial and seasonal variation in both heterotrophic bacterioplankton and picocyanobacteria are evident in some systems (88,89). In interecosystem comparisons, abundance tends to increase with algal biomass (90,91). In lakes, the lowest values are found in oligotrophic systems, and the highest values in eutrophic reservoirs and tropical alkaline saline lakes (14). In the ocean, bacterioplankton abundance averages about 0.5 billion per liter in continental shelf waters and above 200 m (including *Prochlorococcus* spp.), and about 0.05 billion per liter in the deep ocean (>200 m deep) (5). As a proportion of total microbial biomass, however, heterotrophic bacterioplankton biomass tends to increase with depth from approximately 55% of the total microbial biomass at 0 to 200 m, to virtually 100% of the microbial biomass from 200 to 1,000 m (92). Biddanda and Benner (93) estimated that approximately half of the bacterial biomass and metabolism of the open ocean occurs in the aphotic zone.

Bacterioplankton biomass in the ocean ranges approximately between 200 and 1,500 mg C m^{-2} (94). (The unit m^{-2} refer to the column of water under a squared meter of the surface). The lowest values reported by Ducklow (94) are from the Ross Sea, Antarctica. In nutrient-rich (eutrophic) coastal water, heterotrophic bacterioplankton biomass is generally much less than phytoplankton biomass, although exceptions exist where there are high concentrations of organic matter. In Chesapeake Bay, for example, where there are high levels of dissolved organic matter, heterotrophic bacterioplankton biomass is as much as 60% of the phytoplankton biomass (95). In a gradient from coastal areas to the nutrient-poor (oligotrophic) region of the ocean, phytoplankton abundance and biomass tends to decrease more than heterotrophic bacterioplankton abundance and biomass. As a consequence, in oligotrophic marine water, bacterioplankton biomass is commonly two to three times greater than photoautotrophic biomass (91,96).

As mentioned earlier, bacterioplankton consist of both free-living suspended cells and cells attached to particles in the water column. Although most of the bacterioplankton generally are free-living, size- and cell-specific metabolic activity are greater in the attached bacteria. The reason for these differences between free-living and attached bacteria is probably because of an increased concentration of substrates available at surfaces, possibly associated with reduced predation rates (79,97).

Besides the abundance and taxonomic composition, other important properties of a community are how fast and how much biomass is produced per unit of time. These properties are important both as fundamental measurements of the synthesis of organic matter, and because many other ecological processes are correlated with them. For example, the rate of biomass production of a microbial community is directly related to its consumption of carbon and other elements from the environment, its release of materials into the environment, and possibly the ways organisms in the community interact with each other (98).

With respect to bacterioplankton communities, there are several commonly used measurements that express amounts and rates of biomass production. The *production* of a bacterioplankton community is the amount of dry weight (or biomass, usually expressed in units of C) synthesized by the community per unit of volume (or per surface area) per unit of time. In bacterioplankton communities, biomass production could be due to increases in mean cell size with time, but is primarily because of reproduction of cells, in other words changes in population abundance. Production is, therefore, a product of both the biomass (or number) of organisms in the community and the instantaneous rate (specific growth rate) at which the biomass of the community is changing by reproduction. Theoretically, bacterioplankton production can be measured in either the absence (*gross production*) or presence (*net production*) of mortality (94). In the absence of mortality, bacterioplankton biomass will increase exponentially until there is a limitation by substrate shortage, space shortage, accumulation of toxic waste products, or other inhibiting factors. In natural environments, mortality of bacterioplankton generally keeps pace with bacterioplankton production such that bacterial biomass does not accumulate, and the net production is near zero. However, most techniques used to measure bacterioplankton production in nature are unaffected by mortality, and therefore measure gross production (98).

The *specific growth rate* of a bacterioplankton community is the rate of biomass production (e.g., in units: Cm^{-3} day^{-1}) divided by the mean amount of their biomass (in units: Cm^{-3}). Units for specific growth rate are inverse time (e.g., day^{-1}).

A final commonly used measurement of the rate of reproduction of a bacterioplankton community is *turnover time*, or *doubling time*. The turnover time of a community (or population) is the time required for the entire community to produce an equivalent amount of standing biomass, assuming no losses. It is calculated by dividing the mean biomass of a population by its rate of production; in other words, it is the inverse of specific growth rate.

According to Ducklow (94), gross bacterioplankton production in the ocean ranges approximately between 5 and 300 mg C m^{-2} day^{-1}, depending on the location and time of the year. Although rates of bacterial production by volume are typically higher in nutrient-rich water, as occurs along coastlines, oligotrophic regions of the ocean are generally much deeper. For this reason, oligotrophic regimes may have higher integrated (by surface area) bacterial production than coastal areas (94). In both marine and freshwater systems, rates of bacterioplankton community production by volume are often as large as the rate of zooplankton community production (99).

Mean specific growth rates of marine bacterioplankton range between 0.1 to 1 d^{-1} (94). Doubling times vary between 3.5 and 40 days, with the shorter time from the North Pacific during a bloom of phytoplankton, and the longest doubling time from the very cold Ross Sea (94). In most of the ocean, because rates of bacterioplankton production are extremely low but abundance is fairly

high, bacterioplankton growth rates are at the low of this range (100).

Commonly used techniques to measure each of the variables described earlier (production, specific growth rate, and doubling time) provide mean values for the bacterioplankton community. These may be of much use, but in a bacterioplankton community, individual organisms may vary widely in their rate of reproduction and metabolic activity. For example, under poor conditions, cells may stop growing and form resistant structures such as spores, or other quiescent states (101). Using epifluorescence microscopy alone, it can be difficult to distinguish between active, living cells and resting, or even dead cells. Clearly, interpretations regarding the community ecology of bacterioplankton would be very different if it were known that the population consisted of only a small fraction of actively growing cells, instead of consisting of cells growing at similar rates.

A variety of methods have been used to determine the percentage of actively growing cells in a bacterioplankton community. Some studies have suggested that most bacterioplankton are active and growing (102), but this may not always be the case (103). Small cells appear to be less active than large cells (104–106), and some bacterioplankton populations appear to consist of relatively few highly active cells in the presence of a greater number of dormant, or less-active, bacterioplankton (94,107). It is very likely that bacterioplankton constantly vary in metabolic activity, depending on nutrient availability or other factors, but the dynamics of bacterioplankton cell activity currently are poorly known.

THE FACTORS THAT CONTROL HOW FAST BACTERIOPLANKTON GROW

Depending on the composition of the community, rates of bacterioplankton production are affected by numerous environmental factors including organic substrate concentration, the concentration of inorganic nutrients, temperature, the presence of possibly inhibiting chemicals, sunlight intensity, oxygen concentration, pH, and so on. In this section, the influence of several important factors, such as mineral nutrient availability, substrate concentration, and temperature, is discussed.

Like other organisms, bacterioplankton biomass is mostly composed of the elements carbon, nitrogen, and phosphorus. Minor (or trace) elemental constituents include sulfur, iron, magnesium, and potassium. According to Liebig's law of the minimum (108), the element in the lowest concentration relative to the element ratios required by an organism for growth will limit, or regulate, that organism's growth rate. Probably, the element-limiting heterotrophic bacterioplankton growth rates varies geographically and temporally (109,110). For example, in coastal environments, heterotrophic bacterioplankton appear to be more often limited by organic carbon, whereas in offshore environments and many lakes, limitation of growth rate by mineral nutrients such as phosphorus or iron is more likely (110–113).

Heterotrophic bacterioplankton and phytoplankton (both prokaryotic and eukaryotic) depend largely on the same pool of dissolved nutrients. Their relative needs for these nutrients can be evaluated by their elemental biomass ratios (111). The C : N ratios of heterotrophic bacterioplankton and phytoplankton appear to be similar, between five and seven on a molar basis. In contrast, the C : P ratio of heterotrophic bacterioplankton is lower (average 53) than the C : P ratio of most phytoplankton (average 106) (114). In other words, relative to their requirement for carbon, most heterotrophic bacterioplankton have a higher demand for phosphorus than do phytoplankton. Consequently, where phosphorus is in low concentration, heterotrophic bacterioplankton growth may be limited by P availability, as demonstrated in numerous studies (109,115,116). Thus, there may be competition for this element between phytoplankton and heterotrophic bacterioplankton (111,116). The potential for such competition may be modified by the fact that phytoplankton, being autotrophic, are generally not limited by carbon, whereas heterotrophic bacterioplankton depend, at least partly, on phytoplankton production as a source of organic carbon. Little is known about the trace metal requirements for most naturally occurring bacterioplankton.

The mineral nutrients and organic substrates used by bacterioplankton have multiple sources. In small lakes or coastal environments, organic and inorganic molecules derived from aquatic plants or the watershed are important. In regions where there are high concentrations of animals (including humans) and in agricultural regions, organic and inorganic materials from these sources may stimulate vigorous growth of eukaryotic algae and bacterioplankton in adjacent aquatic ecosystems (117).

In the open ocean, and in pelagic areas of many large lakes, DOM and some mineral nutrients supporting bacterioplankton growth are in low concentration. In these environments, mineral nutrients may be derived largely from recycling processes occurring in the water column or, in some cases, from atmospheric dust. The primary source organic matter in these environments is production by autotrophic plankton, especially cyanobacteria and eukaryotic phytoplankton. The organic matter synthesized by these autotrophs is crucial to heterotrophic bacterioplankton production (118,119). In marine water, for example, about 50% of the primary production is processed daily by bacterioplankton (120).

There are several ways for the organic matter synthesized by phytoplankton to become utilizable by heterotrophic bacterioplankton. Phytoplankton produce both particulate cell structure and dissolved organic matter. The particulate matter becomes available for colonization and decomposition by bacterioplankton when the phytoplankton die, or as waste products of zooplankton that have consumed the phytoplankton. Upwards of 10% of the primary production leaches as dissolved organic molecules directly from the phytoplankton into the water (121). Although this source of DOM is important to bacterioplankton production, it is probably often insufficient to fulfill their demand. Perhaps more important ways that this photosynthetically derived DOM becomes available are in the waste products of protists and zooplankton, or by lysis of bacterioplankton cells by viral infection or other stresses (121,122). Nagata (121)

estimates that as much as 30% of the ingested organic matter of the prey is released as DOM by heterotrophic protozoa, and as much as 20% is released by zooplankton. Mechanisms of bacterioplankton mortality are discussed further in the following text.

In interecosystem comparisons, heterotrophic bacterial production is highly correlated with the production of phytoplankton biomass (net primary production), yielding a ratio of heterotrophic bacterial production to net primary production generally about 20 to 30% (99). Some exceptions to this relationship have been noted. For example, in the polar Gerlache Strait, Bird and Karl (123) reported a BP/PP ratio of 2 to 3%. They attributed the low bacterial production to the fact that bacterioplankton were kept in low numbers by protist grazers. Nevertheless, the correlation discovered by Cole and coworkers (99) suggests a dependency of heterotrophic bacterioplankton production on organic matter derived directly or indirectly from phytoplankton. This "coupling" is certainly the case in many systems, but in individual systems, especially where terrestrial sources of organic matter are significant, heterotrophic bacterioplankton growth may be less closely linked to phytoplankton production (124).

As it is for most organisms, temperature also is an important regulator of specific growth rates of bacterioplankton. Most cultivated bacterioplankton have a optimum range of temperature at which growth rate is at a maximum, growth rate declines with increasingly lower or higher temperature. The optimum temperature range varies between different isolates of bacterioplankton; some do better at cold temperatures, whereas others are best adapted to warmer, or even hot temperatures. In temperate ecosystems, bacterioplankton growth rates are positively correlated to temperature at least up to between 10 and 15 °C (88,125,126). But, as is evident from measurements of active bacterial metabolism in polar water, some bacterioplankton can grow at temperatures approaching the freezing point of seawater. These psychrotolerant (cold-tolerant) or psychrophilic (grow optimally at cold temperatures) bacterioplankton may play an important role in nutrient cycling both in polar water and the permanently cold deep sea (127).

Bacterioplankton are influenced by a multitude of interacting stimuli. Pomeroy and Wiebe (127), for instance, described how the relationship of the rate of bacterioplankton production and temperature can vary with substrate concentration. The basis of this interaction effect is probably that a reduction in temperature reduces substrate uptake and/or assimilation. Accordingly, an increase in substrate concentration, even at the low temperatures of polar water, can stimulate an increase in the rates of heterotrophic bacterioplankton activity. It is possible that the correlation observed between the temperature and bacterial productivity observed in some temperate lakes may be partly related to a reduction in substrate availability during colder months (128).

BACTERIOPLANKTON MORTALITY

Not long after the direct-count method of enumerating bacterioplankton was introduced, it was observed that their abundance does not vary more than about one order of magnitude. This is surprising because substrate concentrations, and bacterioplankton community production, can vary from one to several orders of magnitude between systems (129).

How can bacterioplankton exhibit turnover times as fast as a few days in eutrophic environments to as long as several weeks or more in oligotrophic environments while their, abundance is relatively uniform across trophic gradients? Most researchers now attribute this to density-dependent loss of bacterioplankton production. In other words, the faster bacterioplankton reproduce, the faster they die (129,130). This leads to the question of how bacterioplankton die.

Bacterioplankton die in various ways. One of the most important is by grazing of flagellated protists. In both the ocean and freshwater ecosystems, flagellated protists remove a large proportion of bacterioplankton production (131). These protists are mostly less than 20 μm in cell diameter and referred to as *nanoflagellates*. Depending on the species, they may be entirely heterotrophic, or combine photosynthesis with particle-feeding (132). Abundances of heterotrophic nanoflagellates may reach 10^6 cells per liter, or more (132). Other protist bacteriovores in the ocean include ciliates and sarcodines (foraminiferans and radiolarians) (133).

Ciliates can be significant consumers of bacterioplankton in freshwater and marine environments, but in most studies do not seem as important as nanoflagellates (134,135). For example, in a reservoir in South Bohemia, on an average about 70% of the bacterioplankton production was consumed by heterotrophic flagellates, and about 20% by ciliates (136). At least some protist grazers are selective in the bacterioplankton they eat based on prey size (137–139), activity (140), and species (141). They tend to remove more larger cells than smaller cells, and prefer motile over nonmotile bacterioplankton, although the latter effect could be a passive selection (142).

Animals also consume bacterioplankton. In marine environments, these include the larval and juvenile stages of some copepods, larvaceans, salps, and doliolods (131). In freshwater ecosystems, the major animal bacteriovores are cladoceran zooplankton, especially *Daphnia* spp., which when abundant can be even more significant as a source of bacterioplankton mortality than protist grazers (130,143,144).

Another important source of bacterioplankton mortality is lysis caused by viruses (bacteriophages) (145–147). Viruses are common in both freshwater and marine environments with abundances from 10^7 to more than 10^8 per liter, giving a ratio of viruses to bacteria of 2 to 50. Viral abundance, as is bacterioplankton abundance, is directly correlated with trophic conditions. Proctor and coworkers (148) observed that the percentage of visibly infected marine bacterioplankton ranged between 1 and 4%, but as infection is only visible in the last 10 to 20% of the infection cycle, they proposed that the actual percentage of infected bacterioplankton is probably closer to 5 to 40%. As viral infection rates increase with host abundance, it is likely that lysis by bacteriophages is a

more important cause of bacterioplankton mortality in eutrophic than oligotrophic environments (149,150).

Estimates of bacterial mortality due to bacteriophage infection range from less than 10 to more than 50% of the standing stock of bacterioplankton in the ocean (145,148,150,151). In Lake Constance, Germany, bacteriophage-induced mortality of bacterioplankton ranged between 1 and 24% of total mortality over the year (128). Seasonal patterns in bacteriophage activity have been examined in few other freshwater systems. In anoxic water, where nanoflagellates are not important, bacteriophage infection may be the primary cause of bacterioplankton mortality (151).

Theoretical analyses suggest that the taxonomic diversity of a bacterioplankton community will correspond both to the number of unique resources and the number of host-specific mechanisms of mortality (152). Both bacteriophages (151) and, as mentioned earlier, some protists show selectivity in bacterioplankton species they infect or consume. On the other hand, some bacteriophages may have a broad host range. For example, 7 of 85 bacteriophage isolates from the North Sea were capable of infecting 11 to 36 different hosts (153). At the same time, many bacterioplankton may be resistant to viral infection, as demonstrated for some strains of the cyanobacterium *Synechoccoccus* spp. (154). At present, the extent to which grazers and bacteriophages influence bacterioplankton community composition is still an open, fascinating question.

In addition to selective lysis of bacterioplankton, viruses may also influence microbial community structure via *transduction*. In transduction, segments of the host DNA incorporated by error into a bacteriophage during replication in one host cell are subsequently introduced into the genome of a second host cell on the movement of the phage from the first to the second host (155). In this way, transduction acts to transfer genetic information between similar or even distantly related hosts. Jiang and Paul (156) estimated transduction events in water off the coast of Florida at between 0 to 100 transductants per liter per day. It can also be an important mechanism of gene transfer in freshwater ecosystems (157,158). Although its ecological significance is not yet clear, transduction may act as a "genetic stabilizing mechanism" by reducing genetic differences between susceptible hosts in the community (147).

There remain many questions regarding the importance of lysis by bacteriophages compared with grazing with respect to bacterioplankton mortality in water of different trophic status. Especially in low productivity marine water, most studies show grazing rates by protists and zooplankton that exceed bacterioplankton production (131). But even in low productivity coastal water, bacteriophages can cause as much as 35% of bacterioplankton mortality (159,160). In more eutrophic water, in contrast, measured grazing rates are often less than measured rates of bacterioplankton production (129), suggesting a greater role for bacteriophages (131).

Grazers and bacteriophages can affect microbial community function as well as structure. By causing lysis of bacterioplankton and promoting nutrient release into the water, grazers and bacteriophages can stimulate cell-specific bacterioplankton and perhaps rates of phytoplankton production (161–165). Fuhrman (147) has hypothesized that lysis by viruses of bacterioplankton in the oligotrophic ocean may increase bacterioplankton production by about 30%; on a global scale, this could have important consequences for nutrient flux in the ocean.

Other mechanisms of bacterioplankton death have been considered, but their significance relative to grazing and viral lysis is not known. Some bacterioplankton may be lost from the water column by simply sinking; this is most probably true where cells are attached to a particle (92). Other potential sources of mortality are exposure to antibiotics produced by competing bacterioplankton (166), exposure to intense sunlight, or autolysis during times of nutrient starvation.

THE ECOLOGICAL SIGNIFICANCE OF THE BACTERIOPLANKTON

Significance in Nutrient Cycling

Bacterioplankton are critical to the cycling of carbon, nitrogen, phosphorus, sulfur, and numerous metals including iron, manganese, arsenic, antimony, mercury, copper, cobalt, selenium, cadmium, lead, and silver. Through their activities, bacterioplankton both respond to and help create the chemical environment of aquatic ecosystems, and even the atmosphere above aquatic ecosystems. Via consumption and/or regeneration of nutrients, heterotrophic bacterioplankton can both stimulate and inhibit the productivity of cyanobacteria and eukaryotic phytoplankton, depending on the environment. In this section, the activities of the bacterioplankton with respect to uptake, transformation, and regeneration of the macronutrients carbon, nitrogen, and phosphorus are discussed.

The role that bacterioplankton play in nutrient cycling depends on whether they are autotrophic or heterotrophic, whether they are in an environment with low nutrient and organic matter concentrations or a richer environment, whether they are attached or free-living, and on their species-specific ability to consume and/or metabolize a particular material. Like plants and eukaryotic algae, autotrophic bacterioplankton such as cyanobacteria and chemolithoautotrophs depend on inorganic compounds as sources of nutrients. Examples include CO_2, NH_4, NO_3, and PO_4. Heterotrophic bacterioplankton, on the other hand, can use either inorganic compounds or many types of small organic compounds as sources of nutrients. Decomposition of an organic compound, such as a peptide or carbohydrate, in addition to releasing energy, can make available various organic and inorganic components of the compound that subsequently may be assimilated into biomass or, if unrequired, released into the environment. Nutrient regeneration occurs when, in decomposition of an organic molecule, inorganic molecules are produced and released into the environment. The process in which inorganic compounds are produced by the decomposition of an organic compound is called *mineralization*. Inorganic molecules released into the environment by mineralization can be used by other microorganisms that depend on dissolved chemicals for nutrition.

Broadly speaking, bacterioplankton have dual roles in nutrient cycling through consumption and regeneration of dissolved nutrients (114). What determines whether a heterotrophic cell excretes or assimilates an element that it has consumed and is important in biomass synthesis? Where a consumed element is limiting bacterioplankton growth by being in short supply relative to the availability of other required elements, it is generally retained. Where it is in excess relative to the availability of other required elements, it is released or sometimes stored (11). For example, Tezuka (167,168) observed that above a freshwater algal substrate N : P ratio of 17 : 1, nitrogen was released during decomposition; below this ratio phosphorus was released. Similarly, Goldman and coworkers (169) found that nitrogen was released by a marine bacterioplankton assemblage only when the substrate C : N ratio was less than 10 : 1. In a study of three lakes in Ontario, Canada, Elser and coworkers (111) measured N : P biomass ratios in the bacterioplankton size fraction approximately between 8 and 35; the variance mostly was due to cell-specific phosphorus content rather than nitrogen content. At a N : P biomass ratio less than about 17 to 25 : 1, bacterioplankton retained the nitrogen. Above this ratio, where bacterioplankton presumably contained sufficient N to meet their needs, they released the nitrogen. These studies suggest that it is the stoichiometric relationship of substrate and the organism that has consumed the substrate that determines whether or not an element is released or not during decomposition (111).

Bacterioplankton and the Carbon Cycle

Bacterioplankton interact with the carbon cycle as both autotrophic synthesizers of organic molecules and heterotrophic consumers and decomposers of organic molecules. In the photic zone of the sea and lakes, cyanobacteria and eukaryotic phytoplankton provide much of the organic matter consumed by heterotrophic bacterioplankton and animals. In the absence of heterotrophic activity, organic matter would accumulate, and nutrients would not be regenerated in inorganic forms usable by primary producers. Where an environment has become polluted by sewage or even oil, consumption and degradation of these pollutants by heterotrophic bacterioplankton can be an important mechanism for the removal of these unwanted compounds. Wetzel (14) and Williams (170) provide comprehensive discussions of the various roles of bacterioplankton with respect to the decomposition of organic matter.

Rates of decomposition of organic matter depend, among other factors, on the temperature, availability of electron acceptors, and chemical structure of the substrate. As increased in temperature stimulates the rate of contact between enzyme and substrate, rates of decomposition tend to increase with a rise in temperature, at least up to the point at which the enzyme structure is disrupted (denatured). As discussed earlier, the higher the reduction potential of an electron acceptor, the more energy is released on oxidation of a substrate, and the faster the substrate will decompose. Finally, different kinds of organic matter decompose at various rates, depending on the state of the matter (dissolved or particulate), its molecular weight, and its accessibility to digestive enzymes. As is true for all cells, heterotrophic bacterioplankton can absorb only small dissolved organic molecules, such as amino acids, nucleotides, and simple carbohydrates. Larger dissolved molecules or particulate organic matter are first disassembled outside the cell by cell surface–attached hydrolytic enzymes (exoenzymes) (171). The small molecular subunits released by extracellular digestion can be subsequently consumed by the cell where they are used as an energy source by oxidation, or possibly directly incorporated into new cell biomass. The bacterioplankton-mediated turnover time for small organic compounds, such as simple sugars and amino acids, can be on the order of hours, whereas larger, polymeric organic compounds, such as complex polysaccharides (cellulose and hemicellulose) and lignin (complex structural polymer of wood), may persist in the environment for years.

In some circumstances, heterotrophic marine bacterioplankton, in addition of contributing to mineralization of organic matter, produce some dissolved organic compounds that are very slow to decompose, or refractory (172). The mechanism of how bacterioplankton produce refractory dissolved organic matter is unknown (172), but because these compounds degrade slowly, they can remain in the ocean for a long time. In this context, it is interesting to note that the mean age of dissolved organic matter in the ocean is greater than 2,000 years in surface water and 4,000 to 6,000 years in deep water (170).

Another important process in the cycling of carbon in aquatic environments is methanogenesis, the production of methane (CH_4). Methane is a product of metabolism by several different biochemical pathways, depending on the organism. All organisms producing methane are in the domain Archaea. They are obligate anaerobes and not likely to occur as free-living cells in the ocean, although they may occur in the guts of animals, anoxic bottom waters of lakes, and in sediments. The methane evolved may be used as an energy source by some bacterioplankton (methylotrophs), or may escape to the atmosphere where it acts as a greenhouse gas. Methanogenesis is more significant in freshwater environments than in the ocean both because freshwater environments are more likely to have an anoxic region of the water column and because methanogens are outcompeted for substrates by sulfate-reducing bacterioplankton in anoxic environments in which sulfate is abundant (173).

Bacterioplankton and the Nitrogen Cycle

Nitrogen, next to carbon, is the most quantitatively important constituent of microbial particulate biomass, and bacterioplankton are important in nitrogen cycling in a variety of ways. As mentioned earlier, many cyanobacteria fix nitrogen, which is a mechanism for the incorporation of inorganic molecular nitrogen into microbial biomass. In ammonification, bacterioplankton deaminate peptides with the liberation of NH_3. The NH_3 can be incorporated into cell biomass as, for example, an amino acid, or released from the cell into the environment. Some chemolithoautotrophic nitrifying bacteria use NH_3

as a source of energy for carbon fixation, oxidizing it ultimately to NO_3. In anoxic environments, denitrifying bacteria use NO_3 as an electron acceptor, reducing it to N_2. Finally, dissolved ammonium and nitrate are consumed directly from the water column by both autotrophic and heterotrophic bacterioplankton, and phytoplankton. Capone (174) provides a good overview of the marine microbial nitrogen cycle.

One way of quantifying the importance of bacterioplankton in nutrient flux is to calculate the percentage of an element consumed by heterotrophic bacteria relative to phytoplankton. Kirchman (114) notes that the uptake of ammonium by heterotrophic bacteria relative to the total uptake by the plankton varies from a low of 5% to as much as 78% in Georgia coastal waters. The overall median percentage is 40%. The energetic cost of nitrate uptake is higher than for ammonium; heterotrophic bacterioplankton account, on average, for about 16% of the nitrate uptake by the plankton, but this can be as much as 31% (114,175).

Bacterioplankton and the Phosphorus Cycle

Phosphorus is an essential element in nucleotides and nucleic acids (ATP, RNA, DNA) and phospholipid molecules, a major constituent of cell membranes. The primary source of phosphorus for bacterioplankton is dissolved orthophosphate (PO_4^{3-}), although dissolved organic phosphorus compounds may also be used, particularly at high substrate concentrations (14,176). Where an organic phosphorus-containing molecule is mineralized by an organism, and phosphorus in the molecule is in excess of the nutritional requirements of the organism, the phosphorus is released into the water column, primarily as PO_4^{3-}. In this way, heterotrophic bacterioplankton can regenerate phosphorus in a form that readily can be used by autotrophic organisms. However, because heterotrophic bacterioplankton growth is often limited by phosphorus, the bacterioplankton often can be more important as competitors with the phytoplankton for phosphorus, as opposed to providers (177–179). In these systems, the most important mechanisms for phosphorus regeneration may be death and lysis of bacterioplankton cells, or by the feeding and excretory activities of bacterivorous nanoflagellates and other grazers (180,181).

The median percentage of PO_4^{3-} uptake attributable to the size-fraction that is less than 1 μm when both freshwater and marine systems are considered is 60% (114). Where these measurements are corrected for uptake by cyanobacteria, between 24 and 46% of the PO_4^{3-} uptake is attributable to heterotrophic bacterioplankton.

The clear conclusion from these analyses is that bacterioplankton are exceedingly important in the turnover of growth-limiting elements in freshwater and marine systems. Their significance in plankton food webs is the subject of the next section.

IMPORTANCE IN THE FOOD WEB

The role of the bacterioplankton in the food webs of freshwater and marine systems is described by a conceptual model called the *microbial loop* (182,183). This model has been revised in various ways since it was first proposed, but remains useful as a means of illustrating the various roles that bacterioplankton have in the food web with respect to fluxes of energy and carbon. The essential features of the microbial loop are illustrated in Figure 1.

1. Solar energy captured by phytoplankton (cyanobacteria and eukaryotic phytoplankton) fuels primary production, the synthesis of new biomass from inorganic precursors including carbon dioxide.
2. By various mechanisms, much of this photosynthetically derived organic matter eventually enters the water in a dissolved state. Mechanisms cited as being important in this process include leaching directly from phytoplankton cells, lysis of bacterioplankton and phytoplankton by viruses or by other means, and excretion by heterotrophic protists and zooplankton.
3. Heterotrophic bacterioplankton consume this DOM from the water column, using it as an energy source and/or a source of new cell material, and respiring a portion of it as carbon dioxide.
4. Once converted into bacterioplankton biomass, this previously dissolved carbon is available to bacteriovores, and thereby enters (or reenters) the food web of particle-feeding organisms.

The model is referred to as a *loop* because DOM released from phytoplankton can, by incorporation into bacterial biomass, theoretically be returned to the food web (183). Following the discovery that bacterioplankton obtained much of their carbon from DOM, and that they had turnover times of as fast as a few days, it became of interest to know what proportion of DOM consumed by

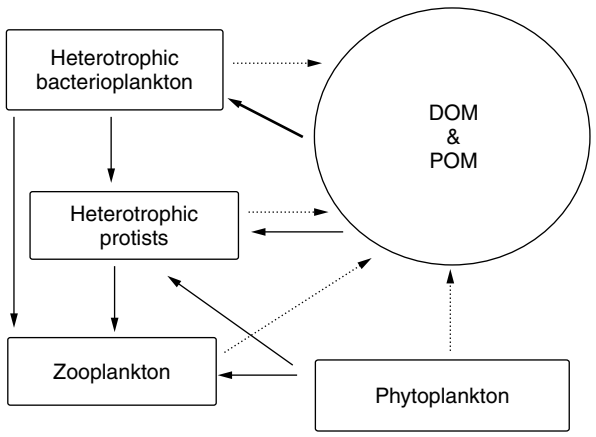

Figure 1. Main pathways of flux of organic matter through the microbial food web. Nonliving organic matter is represented by the compartment labeled DOM and POM (dissolved and particulate organic matter). All other compartments shown represent living organisms. Solid arrows show pathways of consumption of organic matter. Dashed arrows show pathways by which dissolved (DOM) and particulate (POM) organic matter is released from living organisms. This food web model is referred to as the *microbial loop* because DOM from all sources is partly channeled back into the food web by uptake by heterotrophic bacterioplankton, a pathway indicated by the large arrow.

bacterioplankton is ultimately realized in the secondary production of metazoan organisms, such as zooplankton and fish. The answer to the question depends on several factors. These include the number of links (i.e., the length of the food chain) between bacterioplankton and metazoan organisms, the growth efficiency at each step in the food chain (i.e., the proportion of consumed organic matter that is retained and converted to new biomass verses respired), and the extent that bacterioplankton are lysed by viruses as opposed to being grazed by protists or animals. By definition, the lower the growth efficiency at each trophic step, the higher the percentage of consumed organic carbon that is respired to carbon dioxide, and the less that is available for transfer to the next trophic link. Are bacterioplankton a link for the channeling of dissolved organic matter to metazoan consumers or are they a sink for this organic matter, such that most of the DOM they consume is never realized in metazoan production?

In an experiment to address this question directly, Ducklow and coworkers (184) introduced ^{14}C-labeled glucose into the plankton of an enclosed 300,000-L marine water column at Loch Ewe, Scotland. After 13 days, about 20% of the total label added was found in particulate matter, but only about 2% of the label ever passed into organisms greater than 1 μm in diameter. It was concluded that, at least in this environment, bacterioplankton acted primarily as a sink for organic carbon, such that it was mostly respired away by the microbial size fraction (184).

The link versus sink question was tested in a freshwater ecosystem by Wylie and Currie (185). Several of their conclusions are of interest. In agreement with Ducklow and coworkers (184), they found that bacterioplankton carbon is inefficiently transferred to zooplankton, but they also noted that algal carbon is transferred almost as inefficiently. For this reason, they suggested that it is misleading to single out the bacterioplankton as the only major sink for carbon in aquatic food webs; respiratory loss of carbon is high in both the autotrophic and heterotrophic components of the microbial food web. In terms of the total flux of carbon into zooplankton, however, they found that, depending on the types of zooplankton present, bacterioplankton could be important in their diet. Where copepods dominated the zooplankton community, insignificant amounts of carbon derived from bacterioplankton was measured in animal biomass. This can be explained by the fact that most copepods cannot feed on bacterioplankton directly. However, where the zooplankton community was dominated by cladocerans that can directly graze bacterioplankton, as much as 21% of the total flow of organic carbon to the zooplankton could be accounted for by bacterioplankton (including autotrophic picoplankton). They proposed that in systems in which cladocerans are abundant, and in which bacterioplankton biomass is high relative to algal biomass, as, for example, following the decline of an algal bloom or where terrestrial inputs of DOM are high, bacterioplankton can be important in directly supporting zooplankton productivity. As cladoceran zooplankton do not occur in the ocean, and as lake environments are more likely to receive loading of DOM from external sources than are marine environments, these results suggest a fundamental difference in the role of bacterioplankton as a food source in some freshwater plankton food webs compared with marine systems.

THE MAJOR QUESTIONS REGARDING BACTERIOPLANKTON

There are numerous questions regarding bacterioplankton that remain to be resolved. Some of these could not be adequately addressed until the recent development of molecular approaches for evaluating microbial diversity and in situ metabolic activity (8). As these questions have been at the heart of much of the ongoing research in microbial ecology in the last decade, and answers are beginning to emerge, the next decade promises to be an exciting and productive time for the study of aquatic microbial communities in general.

1. What is the taxonomic diversity of the bacterioplankton in different environments? What are the spatial and temporal patterns in taxonomic diversity?
2. What is the relationship between taxonomic composition and physiological function of bacterioplankton communities? How important is genetic microdiversity in niche partitioning of closely related organisms?
3. Are the newly discovered, many still uncultivated, organisms similar (or redundant) or distinct in physiological function? What is the significance of the physiological activities of the cultivated and uncultivated bacterioplankton to the patterns of energy and material flux through aquatic environments, in other words, ecosystem function?
4. What are the regulating factors that influence bacterioplankton population diversity and physiological activity? How are bacterioplankton community composition and function influenced by predators and parasites, or substrate composition, or light intensity or composition, or the interaction effects of these various environmental factors? Exactly what chemical compounds do bacterioplankton use, and in what ways?
5. Is there gene exchange between bacterioplankton, and to what degree? What are the mechanisms of gene exchange? What is the influence of gene exchange on bacterioplankton population composition, response to environmental change, and evolution?
6. What are bacterioplankton mortality factors? What is the relative importance of viruses, protozoa, and animal grazers in different environments? How does the kind of mortality bacterioplankton suffer shape the composition and metabolic activity of the bacterioplankton community?
7. What other kinds of interactions occur between different species of bacterioplankton, or between bacterioplankton and other organisms of the microbial community? Under what conditions do heterotrophic bacterioplankton and phytoplankton compete for nutrients, or support each other through excretion

of metabolites? What kinds of chemical communication, or chemical "warfare," symbioses or antagonisms, occur between microbial plankton and how do these behaviors influence nutrient cycling?

8. How might microbial biomass, or the physiological capabilities of the bacterioplankton, be used or modified for human application? What possibilities are there for bacterioplankton to be manipulated, perhaps engineered, to produce molecules of medical or industrial value, or as a source of food for humans or other animals, or in remediation of environmental damage?

Is microbiology entering a new golden age? Perhaps that question can only be answered in hindsight, but after many years of concerted effort, there is currently a strong feeling among microbiologists of finally being on the verge of a detailed understanding of the structure and function of natural bacterioplankton communities. Studies of bacterioplankton morphology, diversity, physiology, ecology, and genetic potential are certain to engage the interests of both basic and applied scientists from academia and industry for many years to come.

Acknowledgments
Thomas Chrzanowski and David Kirchman provided valuable, critical reviews of an early version of this article.

PLANT–MICROBE INTERACTIONS IN THE MARINE ENVIRONMENT

CHARLES R. LOVELL
University of South Carolina
Columbia, South Carolina

Intertidal and well-illuminated depths of subtidal zones support a wide variety of marine plant and algal species. The vascular plants are of particular importance because of their extensive growth in shallow marine environments and their great contributions to marine food webs and global element cycling. Marine vascular plants provide a variety of distinctive habitats for microorganisms and can greatly promote their growth and activity. Aboveground plant structures constitute the phyllosphere and typically support extensive growth of microorganisms. The phyllosphere is also a key location of plant biomass turnover for emergent plant species. Belowground plant structures and the sediments that they impact constitute the rhizosphere. The rhizosphere is heavily colonized by microorganisms and typically supports much higher levels of microbial biomass and activity than surrounding unvegetated sediments. Microorganisms can also be found within marine plant tissues and the endosphere constitutes a distinct and potentially important microbial habitat in marine vascular plants. Although the interactions between terrestrial plants and their microbiota have been intensively studied, those between microorganisms and marine plants have received substantially less attention. However, marine plant–microbe interactions are pervasive and have been shown to be extremely important to the productivity of marine ecosystems.

The major foci of this article are the microbiota associated with emergent and submerged marine grasses and the major interactions of the microbiota with their plant hosts. Much of the information available on marine plant–microbe interactions addresses nitrogen fixation (diazotrophy) and sulfate reduction. The information available on other microbial functional groups and their activities is also summarized.

PLANT-MICROBE INTERACTIONS OF EMERGENT MARINE PLANTS

Low energy intertidal zones in many parts of the world are dominated by emergent grasses, which occur in extensive and highly productive stands. Numerous species occur at various locations and one of the best studied is the smooth cordgrass, *Spartina alterniflora* (*Spartina* hereafter). *Spartina* is the dominant macrophyte in salt marshes along the temperate Atlantic coast of North America and the northern coast of the Gulf of Mexico. This plant grows extensively in the intertidal zone and can account for 75% of total primary production in some salt marsh systems (1). Because of its abundance and productivity and the extensive literature available on its microbiota, this species will be emphasized as an example emergent marine plant. Information on other plant species will be included as available and where appropriate.

Interactions in the Phyllosphere

The surfaces of the aboveground structures of *Spartina* are exposed to high levels of solar radiation and extremes of both temperature and desiccation, making them potentially hostile locations for many microorganisms. However, *Spartina* shoots and leaves become liberally coated with clays and other materials during tidal exchanges, particularly during spring tides. Epiphytic clay films are quite persistent and contain high levels of heterotrophic bacteria and *Cyanobacteria.* With the extremely high surface area of shoots in a *Spartina* marsh (as much as 6 m^2 of leaf surface for every m^2 of vegetated marsh), it is easy to see that this epiphytic microenvironment is potentially very important to microbially mediated nutrient dynamics and decomposition activities.

Most of the attention given to the epiphytic microenvironment of *Spartina* has focused on two key microbial activities, decomposition of standing dead plant biomass and diazotrophy. Both primary production (2,3) and decomposition (4,5) in many salt marshes are nitrogen-limited and diazotrophy is an important source of "new" nitrogen in these systems (6). In many instances heterotrophic diazotrophic bacteria are carbon- and energy-limited (7). Consequently, decomposition and diazotrophy in the phyllosphere can be viewed as somewhat interdependent. Standing dead biomass is abundant in *Spartina* marshes at all times of year and often occurs in about a 1 : 1 ratio with live plant shoots. The dead leaves and stalks are heavily colonized by fungi, particularly the ascomycetous fungus *Phaeosphaeria spartinicola* (8,9), which appear to be responsible for much of the decomposition activity. Decomposition rates for standing dead biomass are highly dependent on water availability, and when the stalks are wet the rates are comparable to those for submerged *Spartina* biomass and for other types of decaying vegetation (9,10). It is clear that initial decomposition of aboveground *Spartina* biomass begins in this standing dead phase before deposition of the dead leaves and stalks on the sediment surface or into tidal creeks.

Most of the diazotrophic activity in the *Spartina* phyllosphere is associated with standing dead shoots. Live shoots, even when heavily covered by epiphytic

clay layers, have only a fraction of the activity found in dead shoots (11). This virtual restriction of diazotrophy to standing dead shoots has been ascribed to a mutualistic interaction between the fungal decomposers and the diazotrophs although the specific organisms involved and the nature of the mutualism remain undetermined. The interactions of the various epiphytic and endophytic organisms in standing dead *Spartina* biomass support rates of diazotrophy equivalent to the highest rates reported for other decomposition processes (11). The key question of which organisms are responsible for diazotrophy in this phyllosphere system remains open.

Interactions in the Rhizosphere

The Rhizosphere Microenvironment. Emergent marine plants support extensive and highly active assemblages of microorganisms in close proximity to their roots. The rhizosphere can be defined to include the root surfaces (rhizoplane) and the surrounding sediments directly influenced by root products and their activities (12). In the case of some emergent marine plants, this zone of impact around roots and rhizomes can be fairly extensive and the rhizosphere sediment zones around different roots in dense root mats can overlap. This results in substantial microenvironmental heterogeneity within the root zone proper and makes precise delineation of where the zones of root impact begin or end difficult. The microbiota in this complex subsurface habitat include a substantial diversity of organisms having a broad range of growth requirements and physiological responses to plant-induced and edaphic (soil or sediment derived) variability in physicochemical conditions. Despite the substantial environmental variability that can occur over seasonal or shorter time frames, at least some of the residents of this habitat are persistent in that their signature nucleotide sequences can be recovered at different times of year (13).

Many of the organisms that can be isolated from root surfaces and surrounding soils utilize oxygen, which is provided in these otherwise anoxic soils and sediments through rhizosphere ventilation by the plants (Fig. 1). Marine plants grow in sediments that are typically water saturated and oxygen diffuses through water-filled pore spaces at only about 10^{-4} the rate in a similar unsaturated soil or sediment. The slow rates of oxygen diffusion and rapid consumption of oxygen by chemical and biological processes result in sediment anoxia at depths of only a few millimeters. In order to overcome the absence of oxygen and the presence of various phytotoxic compounds the plants ventilate their root systems (14–16). The importance of ventilation is clear because up to 60% of the biomass of salt marsh grasses such as *Spartina* is found below the sediment surface and this belowground biomass requires oxygen for respiration. A major adaptation of marine vascular plants is the development of a tissue containing interconnected intercellular gas-filled spaces called the aerenchyma, which can occupy as much as 70% of the plant tissue volume. Although the exact mechanisms of ventilation by many plants remain undetermined, diffusive and convective airflows through the aerenchyma of stems, rhizomes, and roots have been demonstrated for several species of emergent grasses (17), including *Spartina* (18). Most of these plants leak oxygen from root surfaces, thereby creating an oxidized rhizosphere (Fig. 2) that protects the plant from reduced toxins such as sulfides and reduced metal ions (19–21). This oxidized rhizosphere supports extensive populations of oxygen-utilizing bacteria. Anaerobic bacteria can also be found in reduced microzones around, on, and within the roots.

In addition to oxygen, emergent marine plants supply substantial amounts of labile carbon to the rhizosphere through exudation of soluble organic molecules, sloughing of mucigel, and decay of root tissues during senescence (12). Many rhizosphere microorganisms are intimately associated with the plant roots and their

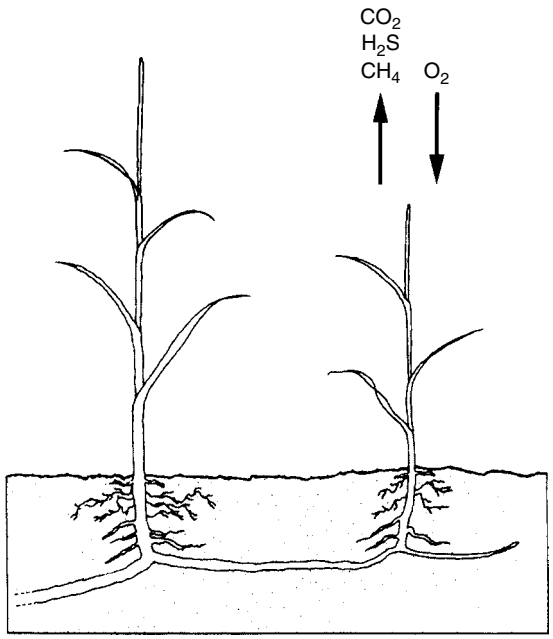

Figure 1. Mass transport of gases by the emergent marine grass, *S. alterniflora*. Gas exchange occurs through the aerenchyma and can result in substantial oxidation of sediments surrounding live roots. Modified from Dacey (14).

Figure 2. Sediment oxidation around live roots of the emergent marine grass, *S. alterniflora*. Note the dark strongly reduced sediments above the main root mass and the light-colored oxidized sediments associated with the root mass.

activities are strongly influenced by plant primary production (22–24). The activities of some rhizosphere microorganisms, particularly the diazotrophs, are strongly stimulated by soluble organic compounds from the plant tissues, including carbohydrates and carboxylic acids (24,25). The heterogeneity of the rhizosphere habitat in terms of organic carbon supply, provision of suitable terminal electron acceptors such as oxygen, and availability of presumed refugia from predation and/or chemical toxins provides niches for a great diversity of microorganisms.

Diazotrophic Bacteria and Diazotrophy in the *Spartina* Rhizosphere. Most of the nitrogen fixation activity in salt marshes is associated with plant roots (26,27). Consequently, the best-studied members of the rhizosphere microbiota of emergent salt marsh plants are the diazotrophic bacteria. Other rhizosphere bacterial groups that have received substantial study include the sulfate reducing bacteria (SRB) (28), some of which are also diazotrophs (29).

Numerous studies have employed pure culture isolation methods to recover diazotrophs from emergent grasses, including *Spartina* and the black needle rush *Juncus roemerianus* (*Juncus* hereafter). *Juncus* is an important plant found near the terrestrial fringe of many southeastern U.S. salt marshes and also occurs sporadically in small stands within the higher elevations of the *Spartina* zone. Other grasses, including other species of *Spartina* and *Juncus* are also found, but their rhizosphere microbiota have received less attention to date.

In addition to the distinct zonation in plant species observed in salt marshes (30), there is also a substantial gradation of plant morphology and productivity within the *Spartina* zone. Tall form plants ($\geq$1 m in height) grow along tidal creek banks. At higher elevations plant growth is stunted, resulting in short form plants ($\leq$30 cm in height). These differences in plant height and productivity are due to several pore water chemical parameters that form gradients from the tidal creeks to the upper marsh. The most important of these are soluble sulfide concentration, redox potential, and salinity (Fig. 3; 31). These edaphic factors, as well as temperature and ammonium concentration, also affect the activities of *Spartina* rhizosphere bacteria, particularly including the diazotrophs. Diazotrophic activity often differs between the tall and short form *Spartina* zones, with the tall form plants supporting higher levels of activity at most times of year (6,13,32).

A wide variety of diazotrophs have been recovered from the *Spartina* rhizosphere (Table 1). Obligately aerobic organisms including species belonging to the *Azotobacteriaceae* have been recovered from *Spartina*

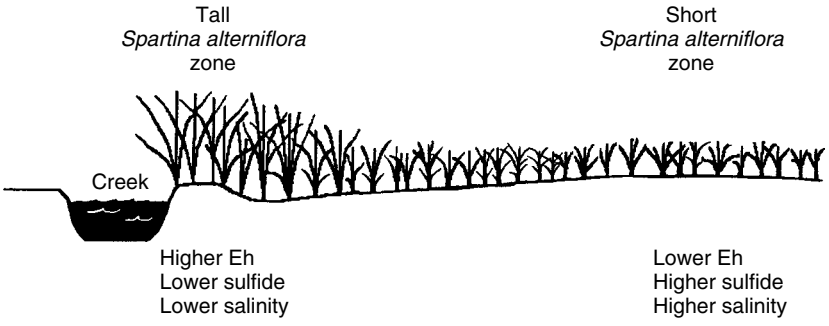

Figure 3. Diagram of the short and tall *S. alterniflora* growth zones showing key edaphic variables that influence plant height and productivity. Drawing by J. Pinckney.

Table 1. Examples of Diazotrophic Bacteria Isolated from the Rhizoplanes, Rhizospheres, or Vegetated Sediments Associated with the Emergent Marine Grass, *S. alterniflora*. These organisms reflect only a minor portion of rhizosphere diazotroph diversity, but provide examples of some key groups

Organism	Plant Source	Key Physiological Features	Reference
Arcobacter nitrofigilis	Rhizosphere	Microaerophilic, respiratory metabolism of organic and amino acids, anaerobic growth on aspartate and fumarate	38
Azotobacter sp.	Surface sediments Rhizoplane	Obligately aerobic, respiratory metabolism of carbohydrates, cyst formation	34 33
Clostridium sp.	Surface sediments	Obligately anaerobic, fermentative, endospore formation	34
Desulfovibrio sp.	Surface sediments	Obligately anaerobic, spiral shaped, sulfate reducing	34

rhizoplane (33) and from surface sediments in the *Spartina* growth zones (34). These are among the most abundant culturable diazotrophs in salt marsh vegetated soils and sediments, amounting to 10^7 cells (g dry wt)$^{-1}$ of sediments by most probable number (MPN) counts. It should be noted that the recovery of native bacteria from soils and sediments as well as other environments is subject to some important biases (35,36), including failure to recover species that are numerically significant and sometimes substantial underestimation of those species that are recovered. Numerical estimates based on laboratory cultivation should be viewed with caution, but cultivation does provide some insight into the types of organisms that can be recovered from natural samples and *Azotobacter*-like species are recovered frequently. Much lower numbers (around 10^3 cells g^{-1} sediment) of these organisms have also been recovered from unvegetated estuarine sediments (37). None of the 30 *Azotobacter*-like strains isolated by Herbert (37) would fix nitrogen in the presence of NaCl, which implies little participation by at least the isolated representatives of the *Azotobacteriaceae* in salt marsh nitrogen fixation.

Many microaerophilic and facultatively anaerobic organisms, mostly unidentified to date, have been recovered from *Spartina* rhizoplane (33) and from rhizosphere sediments (26). Approximately 10^5 heterotrophic diazotrophs per gram of rhizosphere sediment were recovered using semisolid media supplemented with glucose or malate (22,26). Microaerophiles were markedly enriched in the rhizosphere sediments relative to nearby nonvegetated sediments, demonstrating a pronounced "rhizosphere effect" for these organisms. Species likely belonging to the *Enterobacteriaceae* and the *Vibrionaceae* are among the microaerophilic and/or facultatively anaerobic organisms frequently isolated from *Spartina* rhizosphere (33) and from other estuarine sediment sources. Both *Klebsiella* spp. and *Enterobacter* spp. have been reported (37). Some *Klebsiella*- and *Enterobacter*-like isolates do not fix nitrogen in the presence of salt or seawater (37), whereas others are salt-tolerant (39). An obligately microaerophilic species, *A. nitrofigilis* (formerly *Campylobacter nitrofigilis*), has been isolated from *Spartina* roots and rhizosphere sediments from marshes as far apart as Georgia and Nova Scotia (38). This organism requires marine salinity for growth.

Obligately anaerobic diazotrophs, also mostly unidentified but apparently either fermentative (presumed *Clostridium* species) or sulfate reducing, have been amply demonstrated in the *Spartina* rhizosphere. MPN estimates of diazotrophic anaerobes were almost 10-fold higher than similar estimates of microaerophilic diazotrophs (26) and the majority of the organisms recovered seemed to be SRB. In contrast, nonrhizosphere surface sediments from a variety of salt marsh vegetation zones and from bare sediment locations, when inoculated into media suitable for *Clostridium* species or for *Desulfovibrio* species yielded only about 10^3 to 10^4 cells g^{-1} sediment for each group (34,37). Apparently there is a notable rhizosphere effect for at least some of these diazotrophic anaerobes. Studies employing sodium molybdate, a specific inhibitor of sulfate reduction, have demonstrated an important contribution of SRB to nitrogen fixation in shallow ($\leq$5 cm depth) short *Spartina* zone sediments (40). At greater depths, below the main mass of short *Spartina* roots and rhizomes, fermentative anaerobes contributed most of the diazotrophic activity (40). Both SRB and *Clostridia* isolated from estuarine sediments actively fixed nitrogen in the presence of NaCl and all 12 *Desulfovibrio*-like strains isolated by Herbert (37) required salt for diazotrophic activity. It is considered likely that diazotrophic SRB are significant contributors to rhizosphere diazotrophy in *Spartina* marshes although the specific organisms involved are not known (see following section).

In a recent study of oxygen-utilizing *Spartina* and *Juncus* rhizoplane diazotrophs, Bagwell and coworkers (33) inoculated fresh roots directly into semisolid media supplemented with different carbon or energy substrates but lacking combined nitrogen sources. Strains that grew out from the root surface and/or formed distinct bands of growth within the medium were recovered, isolated into pure culture, and characterized. A total of 339 strains were recovered; 67 from short *Spartina*, 103 from tall *Spartina*, and 169 from *Juncus*. All of these organisms were gram-negative and most were facultative anaerobes with a preference for microaerophilic growth conditions. The strains were grouped on the basis of physiological test results and tested for the presence of *nifH*, a key gene required for nitrogen fixation (see following section), yielding 54 groups of diazotroph strains (Table 2 and Fig. 4). Although nitrogen-efficient strains lacking detectable *nifH* were also isolated, 72% of the total strains recovered from *Spartina* and *Juncus* rhizoplanes were *nifH* positive. The majority of strain groups contained unidentified organisms probably belonging to the *Vibrionaceae* and *Enterobacteriaceae*. Some other strain groups contained unidentified organisms with characteristics similar to those of the *Rhizobiaceae*, *Spirillaceae*, *Azotobacteriaceae*, and *Pseudomonadaceae*. Although several strains were tentatively identified to genus or species level, the overwhelming majority of the isolates could not be easily identified on the basis of phenotypic traits. There is clearly an enormous diversity of oxygen-utilizing diazotrophs growing on the root surfaces of salt marsh grasses.

In addition to the great diversity of species and genera isolated from the rhizoplane of *Spartina*, there is a substantial range of physiological capabilities, such as substrate utilization, within many of the strain groups (41). This microdiversity is apparent even in strain groupings whose members are phylogenetically very closely related (i.e., strains within the same species), and probably contributes to physiological adaptation for the utilization of specific substrates or classes of substrates. Such specialization of ecotypes within closely related organism groups may reflect rhizosphere microenvironmental heterogeneity and a great variety of definable niches in the rhizoplane microenvironment. Extensive microenvironmental heterogeneity could contribute to the apparent stability of the rhizosphere microbial community (see following section), thereby preserving diversity. Microdiversity could also provide functional redundancy within the diazotroph assemblage, contributing to maintenance

Table 2. Key Physiological Features and Taxonomic Affiliations of Oxygen-Utilizing Diazotrophic Strains Isolated from the Rhizoplanes of Tall and Short Form *S. alterniflora* and *J. roemerianus*. Strains are designated by zone (S = Short Form *Spartina*, T = Tall Form *Spartina*, and J = *Juncus*), carbon source used for isolation (C = Citrate, M = Malate, G = Glucose, S = Sucrose), pH of the isolation medium (1 = pH 7.0, 2 = pH 7.5), and strain number. All listed strains were motile gram-negative rods. Physiological characteristics included in the table include oxygen requirements (A = Obligate Aerobe, M = Microaerophile, and F = Facultative Anaerobe), cytochrome oxidase production (OP = Oxidase Positive and ON = Oxidase Negative), and preferred substrate classes as determined from BIOLOG testing (C = Carbohydrates, CA = Carboxylic Acids, AA = Amino Acids, L = Low Utilization of all Substrate Classes, and B = Broad Substrate Range). The taxonomic groups closest in physiological characteristics to the unknown strains are provided, but these affiliations should be considered tentative. It should also be noted that the strains listed are representatives of strain groupings, some of which are not completely homogeneous. See Bagwell and Coworkers (33) for descriptions of isolation strategies and physiological and molecular biological testing methods. See Figure 4 for relationships among the various strains and to several known diazotroph species

Table 2. (*Continued*)

of ecological function (diazotrophy) across a broad range of variation in environmental conditions.

Other recent studies have employed molecular biological methods to recover diazotroph signature nucleotide sequences from *Spartina* rhizosphere samples (13). Several of the genes encoding proteins required for nitrogen fixation are somewhat conservative in nucleotide sequence. The most conservative of these is *nifH*, the structural gene encoding the nitrogenase iron protein, which is found only in diazotrophic *Bacteria* and *Archaea*. Several researchers have devised polymerase chain reaction primers specific for *nifH* that greatly facilitate recovery of these diazotroph-specific sequences. The translated peptide sequences from these are suitable for phylogenetic analysis and have been used to examine the diversity of diazotrophic bacteria in various environments (42,43, and references therein). It should be noted that although molecular biological approaches of this kind avoid the biases encountered in pure culture isolation from natural samples, they also introduce certain biases of their own, affecting which sequences can be recovered. For a more complete discussion of these biases see Ward and coworkers (44) and Zehr and Capone (42). However, these molecular approaches appear to sample natural assemblages of diazotrophic bacteria more accurately than pure culture methods and permit the recovery of *nifH* sequences from novel, unknown, and currently uncultivatable diazotrophic organisms (42).

Piceno and coworkers (13) recovered *nifH* sequences from DNA extracted directly from short and tall *Spartina* rhizosphere core samples. Samples were collected from both tall and short *Spartina* zones at several different times of year to encompass the annual cycle of plant ontogeny and the range of edaphic variability that occurs during the year. The *nifH* sequences were resolved using denaturing gradient gel electrophoresis (DGGE), which

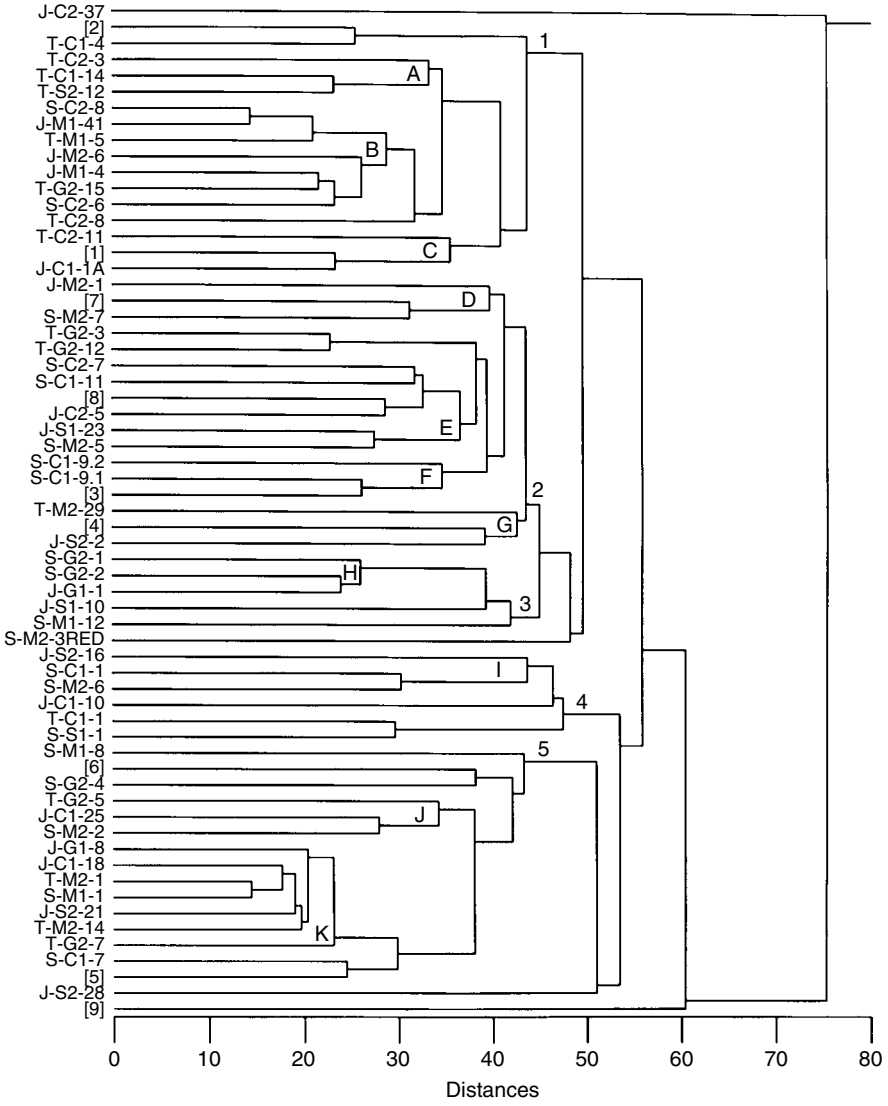

Figure 4. Dendrogram constructed from Euclidean distances of physiological test results for diazotroph strains from rhizoplanes of short and tall *S. alterniflora* and of *J. roemerianus*. Some selected known diazotroph species are included for comparison purposes. Strains designations are defined in the Table 2 caption. Known diazotrophs are as follows: [1] *Vibrio diazotrophicus*, [2] *Azospirillum brasilense*, [3] *Azotobacter chroococcum*, [4] *Klebsiella pneumoniae*, [5] *Azospirillum lipoferum*, [6] *Azotobacter diazotrophicus*, [7] *Rhizobium meliloti*, [8] *Rhizobium leguminosarum*, [9] *Azotobacter vinlandii*. Strain groupings and clusters are illustrated numerically and by letter at the appropriate node, respectively. See Bagwell and coworkers (33) for descriptions of isolation strategies and physiological and molecular testing methods.

separates different sequences on the basis of their melting temperatures (45). This approach yielded reproducible *nifH* sequence profiles that provided "fingerprints" for diazotroph diversity (Fig. 5). Quantitative comparison of band positions in these DGGE profiles revealed that the diazotroph assemblages associated with short and tall *Spartina* were quite similar in species composition, although diazotrophic activity was significantly higher and soluble sulfide levels were significantly lower in the tall *Spartina* zone. Also, the assemblages were quite stable, changing little during the year. Although methods involving PCR of a mixture of template sequences are inherently nonquantitative and no assessment of the quantitative representations of the different diazotroph species can be made from these data (i.e., band intensities do not reflect species abundances), it is clear that the diazotroph species composition in *Spartina* rhizosphere is quite stable (13).

The stability of the *Spartina* rhizosphere diazotroph assemblage was further tested through short-term manipulative experimentation. In some experiments, plots of short *Spartina* were fertilized with nitrogen, nitrogen plus phosphorus, or received no added nutrients (46). The intent of these experiments was to relieve nitrogen limitation. Diazotrophic bacteria have been considered to gain a significant competitive advantage in the rhizosphere through their unique capacity to fix nitrogen; and in salt marsh systems the diazotrophs appear to be carbon limited (32,47). Elimination of the advantage gained through diazotrophy was expected to result in the loss of species that competed poorly for available carbon (48). Fertilization treatments were maintained for eight weeks and rhizosphere core samples were collected after two weeks and eight weeks. Some additional samples were collected from plots that had been fertilized for over 12 years as part of a separate study. DGGE analysis of the rhizosphere diazotroph assemblage revealed that although short-term fertilization (up to eight weeks) increased nitrogen availability, it did not cause the loss of any detectable *nifH* sequences, and consequently, did not cause the loss of any detectable diazotroph species. One DGGE band was missing from the profiles from the long-term treatment

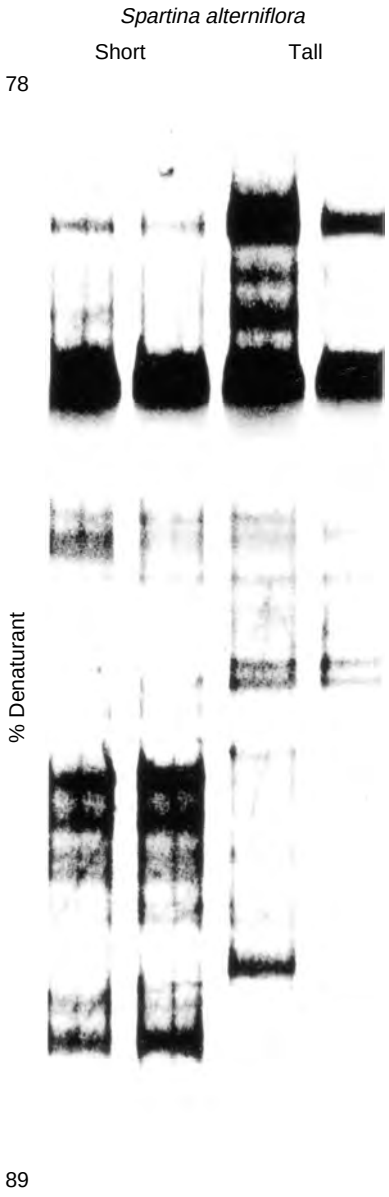

Figure 5. Denaturing gradient gel electrophoresis profiles of samples collected as part of a seasonal study of diazotroph species composition in the rhizosphere of short and tall form *S. alterniflora*. Note that only band positions are informative in defining diazotroph assemblages.

plots, indicating that species loss (or decrease in numbers to less than the detection limit of the method) is possible, but is certainly not rapid and seems to be restricted to a few taxa.

Other experiments altered carbon resource allocation by *Spartina* in order to limit carbon availability in the rhizosphere (49). The intent of these experiments was to further test the ability of the diazotrophs to compete for carbon against nondiazotrophic species. Plots in the short *Spartina* zone were either untreated or were shaded or clipped to cause the plants to reallocate resources away from the roots to compensate for reduced photosynthesis (50,51). Treatments were maintained for eight weeks and the diazotroph assemblage composition assessed as discussed earlier. The DGGE profiles were very similar across treatments, indicating that no detectable diazotroph species were displaced from the assemblage. These results imply that diazotrophs are able to compete successfully against nondiazotrophs for limiting carbon despite the high energy requirements of nitrogen fixation.

The outcomes of observational studies examining the *Spartina* diazotroph assemblage over an annual cycle (13) and experimental studies manipulating inorganic (46) and organic (49) resources indicate that this assemblage is very stable in species composition. This may be due in part to the very heterogeneous nature of the rhizosphere microenvironment, which may provide some "buffering effect" against short-term changes in host derived and edaphic environmental variables, and to the extensive microdiversity of diazotrophic organisms, which provides the capacity for interchange of strains having a high level of phylogenetic relatedness but substantial differences in physiological capabilities (41).

Although many different physiological types of diazotrophs have been isolated from the *Spartina* rhizoplane and rhizosphere, this approach provides an inadequate appraisal of diazotroph diversity. It is likely that only a fraction of the species present have been recovered and it is also entirely possible that many of the organisms that have been isolated, while able to grow rapidly on laboratory culture media, may be relatively unimportant in the rhizosphere environment (35). In order to obtain a more complete survey of the types of diazotrophs present in the *Spartina* rhizosphere, Lovell and coworkers (43) recovered the *nifH* DNA sequences from DGGE gels run by Piceno and coworkers (13) and Piceno and Lovell (46,49) and determined their nucleotide sequences. These were translated into amino acid (NifH) sequences and compared to NifH sequences from well-characterized diazotrophic organisms and to sequences recovered from other types of environments using *nifH* specific PCR primers. It should be noted that the diazotrophic bacteria are very diverse, covering a substantial range of genomic DNA mol% G + C contents. This results in a substantial bias in the mol% G + C content of the third nucleotide position in codons, which necessitates translation to amino acid sequences to facilitate meaningful sequence comparisons (52,53).

Phylogenetic trees constructed from the NifH sequences showed several large clusters representing important major groups of diazotrophs (Fig. 6). Three of these major sequence clusters contained *Spartina* rhizosphere NifH sequences. One major cluster contained numerous sequences from *Spartina* rhizosphere and sequences from known γ-*Proteobacteria* (and some β-*Proteobacteria*). This cluster was designated the γ-*Proteobacteria* cluster because of the prevalence of sequences deriving from known organisms in that group. Several of the *Spartina* sequences were very similar to those from *Pseudomonas stutzeri* and may represent species in the genus *Pseudomonas* or very closely related genera. Most of the *Spartina* sequences fell into distinct clades that contained no sequences from known species. One such sequence cluster had substantial similarity to the NifH sequence from

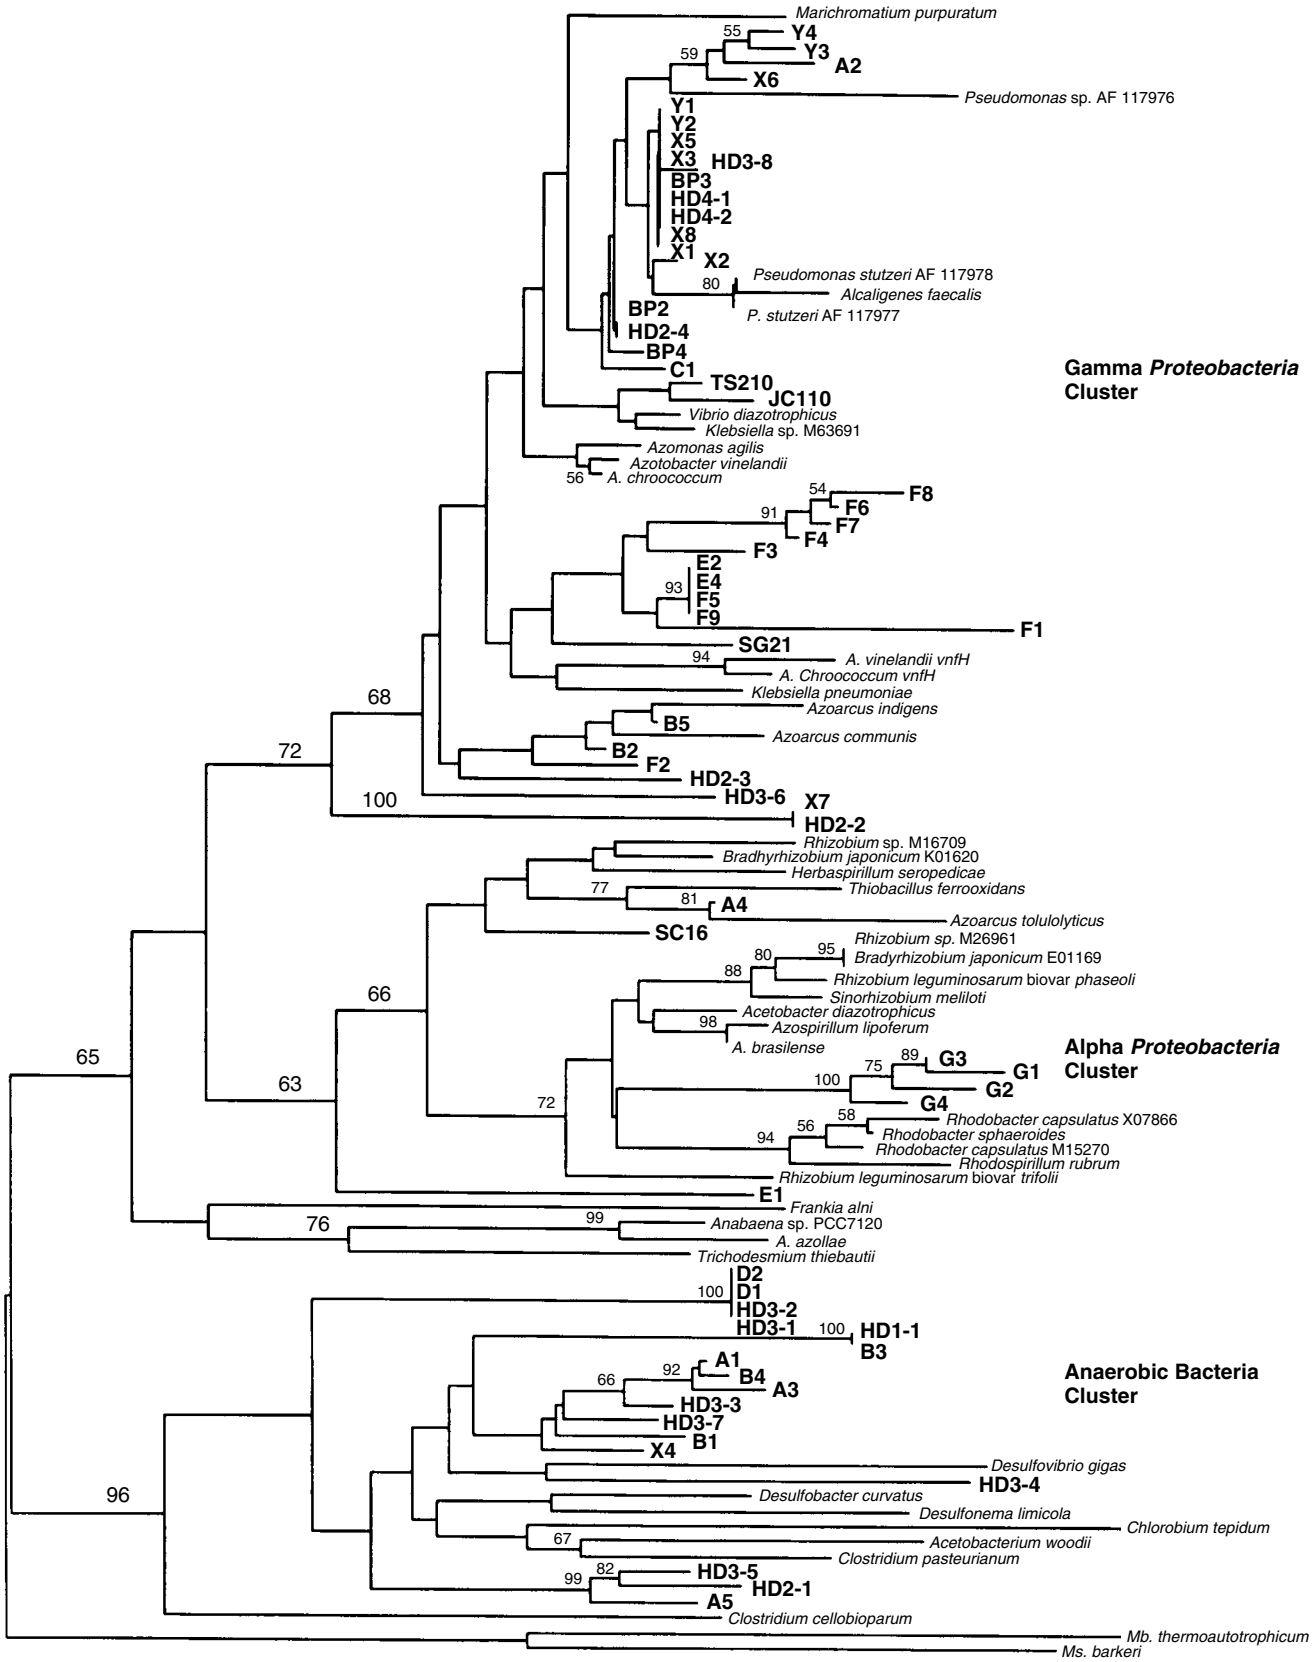

Figure 6. Phylogenetic analysis of *S. alterniflora* rhizosphere NifH amino acid sequences and sequences from selected known diazotrophs. The percentage of 1,000 bootstrap samples that supported each branch is shown. Capital letter designations in bold indicate the denaturing gradient gel bands from which the sequences were recovered (43). Bootstrap values below 50% are not shown.

a pure culture (SG21) isolated by Bagwell and coworkers (33) from the short form *Spartina* rhizoplane. Numerous NifH sequences from unknown bacteria inhabiting plant-associated and/or marine environments also fell into the *γ-Proteobacteria* cluster and a few showed significant similarities to *Spartina* rhizosphere sequences. However, none of the organisms from which these sequences were obtained have been characterized yet.

No *Spartina* rhizosphere sequences that were highly similar to NifH sequences from the *Azotobacteriaceae* or from *Klebsiella*-like organisms were recovered. It is possible that the biases inherent in PCR-based methods prevented recovery of such sequences; however, it is also possible that *Azotobacter*-like and *Klebsiella*-like organisms may not be as abundant in the *Spartina* rhizosphere as previously thought. The discrepancy between results of MPN counts using nonspecific media and the absence of NifH sequences from *Azotobacter*-like and *Klebsiella*-like organisms could also be due to misidentification of some of the organisms isolated from *Spartina* roots or associated sediments. Resolution of this issue will require quantitative determination of the abundance of authentic *Azotobacter* and *Klebsiella* species in the *Spartina* rhizosphere.

The second major cluster of NifH sequences includes those from the *α-Proteobacteria*. This cluster contains many familiar diazotrophs, including species of the *Rhizobiaceae* and the purple nonsulfur bacteria. Numerous sequences from unknown presumed *α-Proteobacteria* from various terrestrial and marine environments fall into this cluster, but few from the *Spartina* rhizosphere or other marine plant sources. It is noteworthy that NifH sequences from the rhizoplane of rice, a freshwater emergent grass that grows in anoxic sediments and significantly oxidizes its rhizosphere, also included few sequences belonging to the *α-Proteobacteria* cluster (54).

The third major cluster contained NifH sequences from known obligate anaerobes and many of the *Spartina* rhizosphere sequences. The reason(s) underlying the close association of NifH sequences from otherwise divergent anaerobes, such as the *Clostridia* and the SRB, is not known. However, anaerobe NifH sequences are more similar to each other than would be anticipated and the occurrence of unknown NifH sequences in this cluster provides good, although preliminary, evidence that these sequences are from anaerobic bacteria. Most of the *Spartina* rhizosphere anaerobe sequences formed well-supported monophyletic groups and none were closely related to any sequence from known diazotrophic anaerobes. Several sequences from rice rhizoplane and two from the rhizoplane of the sea grass *Halodule wrightii* (55) also fell into this cluster, but none were highly similar to sequences from the *Spartina* rhizosphere.

The finding of numerous NifH sequences from anaerobes is consistent with the known characteristics of the *Spartina* rhizosphere. Although the rhizosphere sediments in reasonably close proximity to live roots receive oxygen through the aerenchyma, sediments not impacted by plant inputs are likely to be anoxic (56). The rhizosphere core samples collected included live and dead roots and rhizomes, as well as surrounding sediment and organic matter (13,43). Results from inhibitor studies indicate a potentially significant role of diazotrophic SRB (40) and many of the sequences recovered from diazotrophic anaerobes show higher degrees of similarity to known diazotrophic SRB than to other anaerobic diazotrophs. The diazotrophic *Clostridia* appear to be poorly represented in the *Spartina* rhizosphere, consistent with the findings of Dicker and Smith (34) for surface sediments from various vegetated salt marsh zones. It is also possible that biases inherent in the molecular biological analyses prevented detection of *Clostridium*-like sequences. However, Ueda and coworkers (54) recovered few NifH sequences that were similar to clostridial sequences and they employed DNA extraction methods and PCR primers that were quite different from those of Piceno and coworkers (13). As was the case for the *Spartina* rhizosphere, NifH sequences from rice rhizoplane anaerobic diazotrophs that had substantial similarity to sulfate-reducer sequences were common. It should be noted that sequences within the anaerobe cluster are highly divergent, even within some well-defined clusters, and this might tend to obscure the membership of some *Spartina* anaerobe NifH sequences in those groups.

The exact identities of the *Spartina* rhizosphere diazotrophs are yet to be firmly established. NifH sequences are quite conservative, therefore similarity values for closely related species such as *A. chroococcum* and *A. vinelandii* (99.3%) or *A. brasilense* and *A. lipoferum* (99.3%) are very high. Consequently, the highest sequence similarity scores between *Spartina* rhizosphere NifH sequences and those from known diazotrophs are probably too low to reflect species-level relationships. In addition, many of the *Spartina* rhizosphere NifH sequences were found in distinct clades that were monophyletic with respect to known NifH sequences. This was also true when sequences from rhizoplanes of other wetlands plants were included in the analyses, with very few mixed clusters containing sequences from *Spartina* and rice or *H. wrightii* (43). At this time, the data available on diazotroph distributions and host affiliations in emergent marine grass systems are too sparse to allow firm conclusions regarding organism distributions or host specificity (or the lack of it) to be drawn. However, the prospect of host-specific diazotroph assemblages is certainly enticing and would have important implications for diazotroph diversity and interactions with emergent marine plants.

SRB and Sulfate Reduction in the *Spartina* Rhizosphere. As indicated by pure culture isolations, molecular biological analyses, and inhibitor experiments in the field, SRB constitute an important group of organisms in the *Spartina* rhizosphere. Numerous studies have measured rates of sulfate reduction in vegetated and unvegetated salt marsh sediments and their findings show the bulk of sulfate reducing activity and SRB to be located in shallow sediments and to be particularly associated with the roots of *Spartina*. Sulfate reduction rates in salt marsh sediments are extremely high (e.g., 57,58) and are strongly impacted by plant productivity (57). Sulfate reduction can be responsible for up to half of the total organic carbon turnover in these environments and SRB

are correspondingly numerous. SRB accounted for around 30% of bacterial rRNA in the *Spartina* rhizosphere and as much as 40% of bacterial rRNA in the *Spartina* rhizoplane (59). In contrast, only about 3% of bacterial rRNA from unvegetated marine sediments was from these organisms (60,61). Sulfate reduction and SRB are clearly responsive to the rhizosphere microenvironment and probably play an important role in the mineralization of *Spartina* biomass.

Pure culture isolation efforts have recovered SRB of the delta subdivision of the *Proteobacteria*, including species of *Desulfobacteriaceae* and *Desulfovibrionaceae* in the genera *Desulfoarculus, Desulfobacter, Desulfobacterium, Desulfobulbus*, and *Desulfovibrio* from *Spartina* rhizoplane or rhizosphere (62). Some of the isolates were somewhat divergent from representatives of known SRB genera and may represent new genera. PCR amplification of *Desulfobacteriaceae*-specific 16S rDNA sequences from *Spartina* rhizoplane material revealed abundant populations belonging to the genera *Desulfococcus* and *Desulfosarcina* (63). These organisms were not recovered as pure culture isolates (62) and were not especially abundant according to results from quantitative RNA-RNA hybridization (59), possibly indicating a PCR bias problem. The *Desulfococcus-Desulfosarcina*-like populations were responsive to plant growth dynamics, possibly because of alterations in organic carbon release at different stages in plant ontogeny, and are clearly quite tolerant of oxygen transported through the *Spartina* aerenchyma.

Other Microbial Activities and Associations Within the Rhizospheres of Emergent Plants. It is clear that the rhizospheres of aerenchymatous emergent plants, such as *Spartina*, are beneficial environments for the growth of many microorganisms. This oxic anoxic interface environment should favor the coupling of processes such as sulfate reduction and sulfide sulfur oxidation, denitrification, and nitrification, and iron manganese reduction and oxidation. In addition, chemoheterotrophic processes involved in organic matter turnover should be substantially enhanced in the *Spartina* rhizosphere. Unfortunately, few studies have been performed with regard to these processes, linkages among them, or the organisms involved in the *Spartina* rhizosphere. The information that is available from *Spartina* and some additional results from other systems are presented in brief here.

The aerenchymatous emergent freshwater macrophyte *Glyceria maxima* strongly stimulated activity and supported an abundance of nitrifying bacteria in the rhizosphere, particularly during periods of maximum growth and productivity (64,65). These oxygen-requiring bacteria were probably stimulated by oxygen introduction into the rhizosphere by the plant. The rhizosphere nitrifiers were also able to maintain both substantial numbers and their capacity to nitrify through periods of anoxia, which is often not the case for this group of organisms. There was also a positive relationship between *Glyceria* and denitrification activity in the rhizosphere. This relationship has been observed for other freshwater macrophytes, including *Littorella uniflora* (66), *Oryza sativa, Pontederia cordata*, and *Juncus effusus* (67). Under conditions of low nitrate availability, *Glyceria* strongly influenced the composition of the nitrate-reducing bacterial assemblage and shifted the predominant nitrate metabolism toward nitrate ammonification (68). When nitrate was abundant, the impact of *Glyceria* was negligible. *Spartina* also supports denitrification when grown under conditions of nitrate surplus, but competition between *Spartina* and the denitrifying bacteria for nitrate strongly restricts the extent of denitrification under nitrate-limited conditions (69). These effects of emergent macrophytes are viewed as significant because the flux of the gaseous products of denitrification from the rhizosphere through the aerenchyma to the overlying atmosphere can result in substantial nitrogen loss from vegetated sediments (67).

Roots of several emergent freshwater macrophytes including *Sparganium eurycarpum, Typha latifolia, P. cordata*, and *J. effusus* support dissimilatory reduction of ferric iron at quite high rates (70,71). This implies an important role of iron reduction in organic matter turnover in these mildly acidic, peat-rich freshwater systems. Roots of *Spartina* and of the sea grass *Zostera marina* also supported iron reduction, although at rates substantially lower than those of the freshwater plants (70). Iron reduction on roots of the latter two plants was not inhibited by molybdate implying that specialist iron-reducing bacteria, rather than sulfate-reducers, may be involved. Ferrous iron oxidation, through abiotic and/or biotic processes, is clearly feasible in the rhizospheres of plants that introduce significant levels of oxygen via aerenchymal transport. There is often visible evidence for this oxidation process in the form of iron plaque on the root surfaces (72). This material can include substantial levels of iron-oxidizing bacteria (73).

Rhizosphere ventilation also supports other oxygen requiring processes and organisms in the rhizospheres of aquatic plants. These include methane oxidation by methanotrophic bacteria growing on roots and rhizomes of various freshwater plants (74) and sulfur (thiosulfate) oxidation by various bacteria in the rhizosphere of rice (75). Although the specific organisms carrying out these activities have not been identified in most cases, it is clear that the coupling of various oxidative and reductive reactions in the carbon, nitrogen, iron, and sulfur cycles is supported in the rhizospheres of emergent marine plants. Such reactions could supply and regenerate oxidants essential for organic matter mineralization in anoxic vegetated marine soils and sediments.

Endosphere Microbiota

Although the majority of bacteria associated with emergent grasses are on the root and shoot surfaces, the interior intercellular spaces of many grasses are also well-known habitats for heterotrophic bacteria (76,77), including diazotrophic bacteria. *Spartina* is no exception (26,38) and unlike the roots of some terrestrial grasses (76), diazotrophy in *Spartina* roots is detectable immediately after excision, implying that this process occurs in roots of intact plants under natural conditions (78). Diazotrophic endophytes have also been found in rice (79,80), sugarcane (81), and Kallar grass (82). Endophytic bacteria appear to be

relatively common in grasses and although the nitrogen fixers have garnered the most attention, undoubtedly other types of organisms are also present (see (80)).

Bacteria have been observed intercellularly in the *Spartina* root outer cortex and also within visibly damaged root cortex cells (38). Most of these bacteria were in the lacunae and associated with cell walls. It is worthwhile to note that production of phytohormones by rhizosphere and endorhizosphere bacteria has been implicated in increased transport through roots, and altered patterns of root growth in some terrestrial grasses (83). However, until pure culture isolates are obtained and tested for phytohormone production, any discussion of the potential impacts of these bacteria on mass transport through the roots or on root development in *Spartina* must remain speculative.

PLANT-MICROBE INTERACTIONS OF SUBMERGED MARINE PLANTS

Shallow, well-illuminated subtidal locations can also support extensive stands of marine grasses. Sea grasses are quite diverse, with approximately 50 known species belonging to 12 genera (84). However, relatively few of these species have been examined for their interactions with microorganisms. As was the case for *Spartina* marshes, seagrass meadows are highly productive, often nitrogen-limited, and can support very high rates of diazotrophy relative to unvegetated sediments. In some seagrass flats as much as 50% of the plant nitrogen requirements can be met by diazotrophy in the rhizosphere sediments (85,86). Unlike the emergent grasses, living leaves of many seagrasses support extensive growth of complex and highly active epiphyte communities. Given the importance of diazotrophy in many seagrass systems it is no surprise that much of the information available on the interactions between the plants and their associated microbiota examines nitrogen fixation. Sulfate reduction rates are also elevated in seagrass meadow sediments and this process has been intensively studied.

Interactions in the Phyllosphere

Seagrass leaves are often heavily coated with epiphytic microorganisms including diatoms, *Cyanobacteria*, and heterotrophic bacteria and serve as both a solid support and a nutritional resource for these organisms. Bacterial numbers on surfaces of *Z. marina* leaves range from 10^6 to 2×10^7 cells cm^{-2} and increase with increasing distance from the leaf base (the youngest portion) toward the tip (87,88). In at least some cases, the mass of microbiota associated with leaf surfaces greatly exceeds that associated with root surfaces (89,90). The compositions and activities of these epiphytic communities are unknown for most seagrass species, but the epiphytes of a few species have undergone some study.

Culturable bacteria from leaves of *Halophila ovalis, Halophila stipulacea*, and *Halodule uninervis* collected at Aqaba (Jordan) showed highest densities in the summer months, when plant productivity was highest (90). Plate counts, averaged for the three species, ranged from 1.40×10^7 to 6.46×10^8 cells g^{-1} (wet wt). Numbers differed among the seagrass species and in general were higher on the *Halophila* species than on *H. uninervis*. Genera recovered from aboveground plant structures included *Arthrobacter, Actinomyces, Bacillus, Pseudomonas*, and *Vibrio*. Heterocystous *Cyanobacteria*, particularly *Calothrix* sp. are also common epiphytes on sea grasses, sometimes forming distinct colonies on mature leaves (89,91). These organisms can be significant contributors to phyllosphere diazotrophy (see following section).

The diversity of epiphytic bacteria associated with *H. stipulacea* was examined in detail using 16S rDNA sequence analysis (92). A total of 59 clones, belonging to 51 different amplified rDNA restriction analysis (ARDRA) groups, were sequenced. Most (62.6%) of the clone sequences belonged to the division *Proteobacteria*. The *γ-Proteobacteria* accounted for 27.3% of the clones and included sequences affiliated with the genera *Pseudomonas, Vibrio, Marinomonas, Oceanospirillum*, and other marine groups. Sequences affiliated with the *α-Proteobacteria* were also common, accounting for 24.2% of the total and including relatives of the genera *Hyphomonas, Roseobacter, Ruegeria*, and the family *Rhizobiaceae*. The remaining sequences included a small number affiliated with the *β-Proteobacteria*, several possibly belonging to the division *Proteobacteria*, but highly diverge from known sequences, and sequences affiliated with the *Verrucomicrobiales, Planctomycetales*, the high G + C *Firmicutes*, and the *Holophaga/Acidobacterium* division. In addition, sequences affiliated with diatom chloroplast rDNA sequences accounted for 20.2% of the total. Clearly, the diversity of seagrass phyllosphere bacteria, even on a single plant species, is very high and includes many organisms that are distantly related to any well-characterized bacterial species. This diversity likely encompasses numerous microbial activities, but the key functions of seagrass phyllosphere bacteria have received little study.

In addition to their high biomass and diversity, epiphytic bacteria inhabiting the phyllosphere of seagrasses are highly productive. Bacterial production rate estimates for the *Z. marina* phyllosphere are as high as 0.4 μg C h^{-1} cm^{-2} and largely due to increasing cell numbers, increase with increasing distance from the leaf base (87). The carbon and energy source supporting the extensive growth and productivity of epiphytic bacteria appears to be primarily exudation of organic carbon by intact *Z. marina* leaves. These exudates are efficiently assimilated by epiphytic bacteria (93), they amounted to about 10% of photosynthetically fixed carbon, and were sufficient to support most, if not all of the epiphytic bacterial production (87). Bacterial doubling times in the *Z. marina* phyllosphere are comparable to values estimated for water column bacteria, ranging from 1.5 to 17.6 hours (87,88).

Nitrogen fixation rates have been measured in the phyllospheres of several seagrasses and a broad range of values estimated. Tropical Australian seagrass meadows dominated by *Enhalis acoroides, Thalassia hemprichii*, and a mixture of *Syringodium isoetifolium* and *Cymodocea serrulata*, respectively, supported rates

of diazotrophy on aboveground plant surfaces of 4.2, 0.3, and 2.2 mg N m^{-2} d^{-1} (94). These values were about 13%, 5%, and 5% of total diazotrophy for seagrass meadows at the three sites. In a seasonal study of *Z. marina* in North Carolina, significant diazotrophy in phyllosphere portions of the plants was found only in the late fall through early winter (95). Phyllospheric diazotrophy was more significant than rhizospheric diazotrophy during this period and was ascribed to heavy colonization by heterocystous *Cyanobacteria*. Diazotrophy in the phyllosphere of subtropical *Thalassia testudinum* was also associated with heterocystous *Cyanobacteria* and amounted to 4 to 5 mg N m^{-2} d^{-1} at some sites during the summer (91). The varied microbiota of the seagrass phyllosphere are clearly capable of significant activities that can impact and contribute to seagrass success and productivity. The exact extent of such activities may be dependent on the seagrass species examined and the prevailing abiotic environmental parameters at the sites studied.

Interactions in the Rhizosphere

The Rhizosphere Microenvironment. Seagrasses grow in fully saturated, typically anoxic sediments and have the same potential problems with anoxia and accumulation of phytotoxins as the emergent plants (discussed earlier). The adaptations that help the seagrasses to solve these problems seem quite similar to those of the emergent plant species, namely, development of aerenchyma (96) and oxidation of the rhizosphere. Because seagrasses are completely submerged under most conditions and generally lack stomata, which limits transport of oxygen from outside the plants, photosynthesis appears to be the major source of oxygen (97). This oxygen can be transported through the aerenchyma from leaves to roots, with some leakage into the rhizosphere (20,98–100). Although measurement of the specific quantities of oxygen released is difficult and quantities vary substantially among seagrass species and meadow locations, free oxygen and detectable rhizosphere oxidation within a distance of a few millimeters from the roots has been demonstrated (99). Elevated oxygen levels were observed only when plants were illuminated and capable of supporting a favorable balance between photosynthetic oxygen production and root respiration. Rhizosphere oxygen concentrations declined exponentially when the plants were incubated in the dark. In addition, there was a pronounced seasonality of rhizosphere oxidation that differed between two seagrass species, *Potamogeton perfoliatus* and *Z. marina*, and also differed with depths of the sampling sites below the water surface for *Z. marina* (99). Oxygen release by the roots of seagrasses is clearly variable and a number of biotic and environmental factors control the degree of rhizosphere oxidation that can result. Oxidation of the seagrass rhizosphere should support growth of many oxygen-utilizing bacteria, as was seen for *Spartina*, but these organisms remain mostly uncharacterized at present.

In addition to oxygen, seagrasses are the primary source of organic carbon for their rhizosphere microbiota. The release of photosynthate from seagrass roots is substantial, approximately 10% of the carbon fixed in the case of tropical *H. wrightii* (101). A number of simple organic compounds have been tested for their stimulatory effect on diazotrophy in intact cores of *Zostera noltii* meadow sediments, with lactate and sucrose providing the greatest stimulation (84,102). Decomposition of belowground plant biomass and other sources of organic carbon must also be considered (103), but the tight coupling between bacterial activities and plant photosynthesis strongly implies that plant exudation is an important source of labile carbon for the rhizosphere microbiota.

The combination of carbon exudation and oxygen introduction has profound impacts on the rhizosphere microbiota, as illustrated by diel and seasonal variations in microbial biomass and activities (104,105). Seagrass rhizosphere bacterial growth rates, population sizes, and levels of activity are all closely coupled to plant primary productivity (84). The marked diel periodicity of bacterial activity and productivity in *Zostera capricorni* meadow sediments, with rates increasing from 5- to 10-fold during the morning hours, then declining in the afternoon (106), demonstrate this linkage. Direct microscopic counts of total bacterial cells in *Z. capricorni* rhizosphere sediments also increased by 50% during the summer months, when plant productivity was highest (105). However, it should be noted that different rhizosphere organisms can be affected differentially by plant productivity. The abundance of one *Z. capricorni* rhizosphere organism, *Alteromonas* sp., changed little with season (105). This may reflect nutritional versatility on the part of the *Alteromonas* species, or other adaptations (e.g., dormancy) that facilitate its persistence under resource limited conditions. Certainly plant productivity has major impacts on most rhizosphere species and on the gross activities of these organisms, though the dynamics of individual species are not well understood.

Diazotrophic Bacteria and Diazotrophy in Seagrass Rhizospheres. A few studies employing MPN and pure culture isolation methods have examined the numbers and types of culturable diazotrophs in sea grass meadow rhizospheres. Bulk rhizosphere sediments, sediments and bacteria tightly associated with roots, and root homogenates of *Z. marina* all showed quite high levels of diazotrophic bacteria (107). Under microaerobic incubation conditions cell numbers averaged 2.0×10^5, 4.5×10^6, and 3.4×10^5 cells g^{-1} (wet wt) for rhizosphere sediments, rhizoplane sediments, and root homogenates respectively. Anaerobic incubations yielded 1.4×10^5, 3.3×10^6, and 2.8×10^5 cells g^{-1} for the same sample types. A total of 127 strains of gram-negative, facultatively anaerobic, motile diazotrophs were isolated from these sources and their morphological and physiological features were consistent with their placement in the family *Vibrionaceae*. To date, molecular biological examinations of either the total rhizosphere microbiota or the diazotroph assemblage of seagrasses have been very limited. Kirshtein and coworkers (55) amplified *nifH* specific sequences from a salt-requiring *Klebsiella* strain originally isolated from *Ruppia maritima* roots and from DNA extracted from

H. wrightii root and rhizoplane material. The two *nifH* sequences from *Halodule* extracts were not very similar to those from known organisms, but fell into the anaerobe cluster and may represent SRB.

As is the case for other members of the rhizosphere microbiota, the diazotrophs are strongly influenced by plant primary productivity. Rates of diazotrophy, which range from 0.02 to 140 mg N m^{-2} d^{-1} (84), are clearly higher in seagrass rhizosphere sediments than in nearby unvegetated sediments (e.g., 85,108–110). The distribution of diazotrophic activity with depth in the sediments also corresponds to the distribution of belowground plant biomass (110), and the highest levels of activity are seen on the roots and rhizomes themselves (84). In meadows of *Z. nolti*, diazotrophic activity associated with belowground plant structures was up to 140-fold that recorded for rhizosphere sediments from which all roots and rhizomes were removed (84). Numbers of diazotrophic bacteria are also substantially higher in rhizosphere sediments than in unvegetated sediments (86) and microscopic examination has shown the roots of seagrasses to be heavily colonized by bacteria. In the case of the *Z. nolti*, rhizoplane bacterial assemblages have been estimated to be around 3×10^3 cells mm^{-2} (84,111).

Rapid transfer of nitrogen from rhizosphere diazotrophic bacteria to *Z. marina* and *Z. capricorni* has been demonstrated using ^{15}N labeling methods (7,85). In the case of tropical *Z. capricorni*, inputs from new nitrogen fixation into aboveground biomass alone were estimated to supply between 33 and 50% of plant nitrogen requirements. This tight association between rhizosphere diazotrophs and seagrasses can provide an important nitrogen source for the plants. However, it should be noted that the contribution of diazotrophy to plant nitrogen requirements varies among different seagrass species, geographic locations, and seasons, and is typically higher in tropical meadows than in temperate meadows.

SRB and Sulfate Reduction in Seagrass Rhizospheres. As seen in the emergent grasses, seagrass meadows support large populations of anaerobic bacteria, apparently dominated by the SRB. Very high rates of sulfate reduction that correlate strongly with plant distributions have been measured in several seagrass meadows (100,108,109,112–114) and the rates reported are often greatly in excess of those in unvegetated sediments. Sulfate reduction rates from isolated *Z. marina* roots were also much higher per gram dry weight than those in the meadow rhizosphere sediments (114,115). Rates of sulfate reduction (108,109,114) can be strongly influenced by plant photosynthetic activity, with substantially higher rates measured when the plants are incubated in the light versus in the dark. Very high numbers of SRB [10^7 to 10^9 cells (g dry wt)$^{-1}$] have also been estimated from the measured sulfate reduction rates and published cell-specific rates of sulfate reduction (114,115). These estimates are supported by results from a subtropical meadow of *H. wrightii*, where rhizosphere SRB numbers estimated by MPN and phospholipid fatty acid analyses were found to fall in the range of 10^7 to 10^8 cells (g dry wt)$^{-1}$ (116). Key SRB species in the *Halodule* rhizosphere appeared to belong to the genera *Desulfovibrio* and *Desulfobulbus*. In addition to their contributions to organic matter mineralization, inhibitor (molybdate) studies indicate that the SRB are an important group of heterotrophic diazotrophs in seagrass meadows. These organisms account for 25 to 95% of nitrogen fixation, with substantial variability between locations and seasons, even within the same seagrass species (109,110,117). Acetogenic anaerobes and acid fermenting *Clostridia*, although not as abundant as the SRB, were also detected in the *Halodule* rhizosphere (116). MPN estimates of acetogens were in the range of 10^5 cells g^{-1} of sediment, whereas butyrate-producing *Clostridia* amounted to about 10^4 cells g^{-1}. There was a notable rhizosphere effect for SRB and acetogens, but no significant enrichment of butyrate-producing *Clostridia* in the rhizosphere versus unvegetated sediments.

Other Microbial Activities and Associations in Seagrass Rhizospheres. Relatively few studies of other microbially mediated processes associated with seagrasses have been performed. Many of these have examined nitrogen cycle processes other than diazotrophy. Ammonia production (ammonification) from sediment organic matter occurs at high rates in seagrass meadow sediments relative to unvegetated sediments (118–122). This probably reflects higher levels of labile organic matter in seagrass meadow sediments. Nitrification and denitrification also tend to occur at high rates in these sediments. Sediments of a *Z. marina* meadow off western Alaska supported significant denitrification (98). Nitrate utilized in this process was proposed to arise from nitrification, an oxic process supported by oxygen transport to the rhizosphere by *Z. marina*. High rates of denitrification have also reported for a tropical *Halodule beaudetti* meadow (100).

Seasonal and other trends in nitrogen cycle processes vary among seagrass species and meadow locations. Ammonification and nitrification potentials tended to follow the annual cycle of productivity of temperate *P. perfoliatus*, peaking during periods of peak plant biomass, although denitrification potential did not (121). In contrast, although there were strong seasonal trends in ammonification, nitrification, and denitrification potentials in a temperate *Z. marina* meadow, all three processes displayed different trends (121). Given the small number of studies performed to date and the substantial differences in the methods employed, few broad conclusions regarding the interactions of seagrasses and the microbiota involved in nitrogen cycle processes other than nitrogen fixation can be drawn at present.

Sulfur cycle processes in seagrass meadows, with the exception of sulfate reduction, have also received relatively little attention. The chemocline microenvironment of the rhizoplane, with its overlapping gradients of oxygen (from the root) and hydrogen sulfide (from sulfate reduction) would certainly be expected to support sulfide- and sulfur-oxidizing bacteria. In addition, phototrophic green and purple sulfur bacteria are known to inhabit shallow marine sediments and could benefit from the organic enrichment of shallow seagrass meadow sediments. MPN estimates of the colorless sulfur bacteria

(CSB), phototrophic sulfur bacteria (PSB), and SRB in a temperate *Z. noltii* meadow showed that all three functional groups were present at fairly high abundances (123). The CSB were abundant from the sediment surface to depths of at least 5 cm, with highest numbers (around 10^9 cells mL^{-1}) in the upper 2 cm. PSB were much less common, with peak numbers less than 10^6 cells mL^{-1}, and were restricted to the upper 3 cm of the sediments. SRB were highly abundant at all depths examined, with more than 10^7 cells mL^{-1} in the upper two cm. As stated previously, MPN techniques can dramatically underestimate microbial numbers, so these functional groups are certainly abundant in seagrass meadow sediments and the sulfur cycle processes they catalyze are prominent features of seagrass meadow biogeochemistry. Tight coupling between sulfate reduction and sulfide oxidation processes has been invoked to explain the relatively low levels of sulfides found in some seagrass meadow sediments (123).

Endosphere Microbiota

Seagrasses contain a surprising abundance and diversity of bacteria within their root and rhizome structures. One endospheric *Klebsiella* strain has been identified in *H. wrightii* using classical cultivation and immunofluorescence methods (124). Using radioactively labeled probes specific for the clostridia, some species of acetogens, the low G + C content *Firmicutes*, species of *Desulfovibrio*, *α-Proteobacteria*, *Archaea*, and sulfate-reducing bacteria, Küsel and coworkers (116) observed high levels of colonization of the root epidermis and the intercellular root spaces of *H. wrightii*. *Bacteria* and *Archaea* hybridizing with all of the probes used were observed on the rhizoplane. Rhizoplane *Desulfovibrio* occurred primarily as single cells, whereas the acetogens formed large clusters. Clostridial, acetogen, and archaeal colonization extended into the root cortex and *Desulfovibrio* cells were seen deep in the root cortex, where 61% of the deepest cortical cells were colonized by these organisms. The identities and physiological properties of the cells hybridizing with the probes specific to *Archaea* are not known, but they may be methanogens. The prevalence of so many anaerobic bacterial groups within tissues that are oxygenated during periods of active photosynthesis is particularly interesting. Tolerance to oxygen exposure would seem to be a required trait for these organisms, many of which are typically regarded as completely oxygen intolerant. The extent and nature of the activities carried out by these endospheric anaerobes are not known, but it seems likely that they would be most active at night, when photosynthetic oxygen production cannot occur.

In addition to the endospheric bacterial flora, some seagrasses contain symbiotic fungi. *Thalassia testudinum* contains a common rhizomycelial chytrid, described as a *Nowakowskiella* or *Cladochytrium* species that occurs in living leaves (125). However, such fungal symbioses are not universal among seagrasses because no such symbionts were reported for *Z. marina* (126).

CONCLUSION

The similarities in the types of plant-microbe interactions observed in emergent and submerged marine plant systems are quite striking. In both types of systems, the plant clearly supplies important carbon resources to the bacteria in all of the plant-associated microenvironments. In the rhizospheres of both plant types, oxygen introduction by the plant roots is also of paramount importance and substantially impacts both the nature and the activities of the associated microbiota. Thus, some key processes, such as diazotrophy and sulfate reduction, and the regulation of these processes by photosynthetic carbon and oxygen supply to the rhizosphere have been identified. However, some key differences between emergent and submerged grasses are also apparent, particularly the prevalence of epiphytic bacteria on living leaves of the submerged plants. It is clear that these organisms are highly significant to some seagrass species, but their contributions and the constraints limiting their growth and activity are not well understood. The marine vascular plants are enormously productive and although under substantial pressure from development and anthropogenic pollution, provide significant carbon and nitrogen inputs to marine food webs. The interactions of these plants with their associated microbiota provide the foundation for this productivity and a better understanding of these interactions will be required to successfully manage these vital biotic resources.

Trondheim, Norway

All life on earth is dependent on the ability of plants to use energy from solar radiation for the reduction of CO_2 and the synthesis of diverse organic compounds that support all animal life. Such primary production in the marine environment is accomplished primarily by unicellular phytoplankton, with relatively small contributions by multicellular algae that grow attached to the ocean bottom in shallow coastal regions, and is believed to exceed the magnitude of primary production occurring in all terrestrial environments. Oceanic phytoplankton are thus of vital importance in regard to global production of food materials in the marine environment as well as playing an

integral role in the sequestering of atmospheric CO_2 and the subsequent transport of organic particles to the deep sea. This assimilation of atmospheric CO_2 and subsequent transport of reduced carbon to the deep sea plays a vital role in the global carbon cycle and thus helps to minimize possible harmful consequences of the increase of CO_2 in the atmosphere (the "greenhouse effect"). The distribution of phytoplankton in the marine environment, however, is extremely variable because the biomass of phytoplankton that can be supported in the upper water column is dependent primarily on an adequate inorganic nutrient supply and sufficient solar radiation, and also on suitable physical factors such as water salinity and temperature. The availability of inorganic nutrients in surface waters is influenced mostly by the profile of water column stability and the physical upwelling of nutrient-rich deep water into the euphotic zone. Upwelling processes are found predominantly in the Southern Ocean and in subarctic Pacific waters, and to a lesser extent along the western coasts of Africa and the Americas (1), whereas vertical mixing is predominant in the Atlantic Arctic. Consequences of biological activity by phytoplankton in the polar regions thus must be viewed in the context of global processes, because both the world's atmosphere and ocean waters are in constant circulation, with mixing between the Northern and Southern Hemispheres (2–4). Because the biomass and rates of primary production by phytoplankton are limited by chemical, optical, and physical factors that are strongly influenced by dynamic physical processes and topographical characteristics of the sea floor and land masses, these latter aspects are briefly discussed later.

GENERAL CHARACTERISTICS OF PHYTOPLANKTON

The "phyto" prefix means that the cells have the physiological characteristics of green plants, whereas the "plankton" suffix signifies that the cells are freely suspended in the water column. Like all green plants, phytoplankton require only sunlight, CO_2, water, inorganic nutrients, and suitable physical conditions for growth (see section Major Factors Affecting Growth Rates of Phytoplankton). However, many types of phytoplankton have flagella or some gliding mechanism that gives them limited ability to move toward or away from external stimuli such as a change in light intensity or various chemicals. Such movements although are sufficiently slow that the distribution of cells in the water column is largely dependent on physical mixing processes. One exception to this although involves phytoplankton cells that grow either within the ice or attached to the underside of the ice in both polar regions. When the ice melts during spring and summer, these ice algae are liberated to the water column and are believed to initiate the growth of phytoplankton blooms commonly found near the receding ice edge. A brief description of the cellular appearance and major taxonomic groups of polar phytoplankton is given below.

Cellular Characteristics

Most phytoplankton occur as single cells, but in some species the cells may aggregate to form chains, clumps, or colonies. Single cells, which are microscopic and too small to be seen with the naked eye, are commonly categorized as picoplankton (<2.0 μm in size), nanoplankton (>2.0 μm but <20 μm), and microplankton (>20 μm, but usually <100 μm). The cellular structure and organelles of phytoplankton found in polar waters are eukaryotic (i.e., the nucleus and various plastids are enclosed within membranes) and basically similar to phytoplankton found in temperate or tropical waters. The gross chemical composition (i.e., cellular concentrations of protein, lipid, carbohydrates, nucleic acids, etc.) of polar phytoplankton does not differ appreciably from the composition of phytoplankton found in other waters. Some taxonomic groups of phytoplankton have thick cell walls that may be elaboratively sculptured and possess spines or appendages (e.g., the siliceous cell walls of diatoms and the cellulosic plates of dinoflagellates), while other groups may have no firm outer cell wall. Photoautotrophic procaryotic cells (nucleus and other organelles not membrane-bound), which include Cyanobacteria (also called blue-green algae in the division Cyanophyta), may be dominant components of the phytoplankton in tropical or temperate waters, but are found only occasionally in cold polar waters. Similarly, no filamentous nitrogen-fixing blue-green algae have been described in marine polar waters. Endosymbiotic associations among an autotrophic alga living within a protozoan are not common in polar waters, but occasionally such cells have been found to be a dominant component of the phytoplankton (5). Discussion in the following sections is restricted only to the dominant eukaryotic phytoplankton.

Adaptations to High Latitudes

The major environmental differences between polar waters and temperate or tropical waters that are important with regard to survival of phytoplankton are the low water temperatures and the seasonal cycle of solar radiation, which ranges from months of long summer days with high light to months of darkness during winter. Water temperatures in the polar regions generally range from $-1.8\,^{\circ}C$ (the freezing point of seawater) to approximately $+5\,^{\circ}C$, although water temperatures may approach $10\,^{\circ}C$ in some areas of the Bering Sea. Polar phytoplankton are physiologically adapted to grow at these low temperatures (see Section Major factors affecting growth rates of phytoplankton) and generally do not survive at temperatures exceeding approximately $10\,^{\circ}C$. The seasonal variation in solar radiation poses two problems for survival of phytoplankton: (*1*) during the winter months solar radiation is so low (there is no direct sunlight between the polar circle and the geographic pole at the time of the winter solstice) that most cells in the water column must survive by respiration of stored cellular substrates such as lipids or carbohydrates and (*2*) the combination of cooling of surface water and storm activity results in deep mixing of the upper water column in winter, so that phytoplankton cells are lost to deep waters and to the sediments. To survive such winter conditions, polar phytoplankton thus must have the ability to minimize respiratory requirements during periods of darkness and also to develop spores or other

reproductive cells that remain viable for many months or years. This ability to maintain cell viability during the long winter period requires physiological acclimation by the cells in response to slowly changing environmental conditions–sudden darkness would not result in a similar adaptive state.

Dominant Taxonomic Groups

Species from the following taxonomic divisions of phytoplankton are generally found in both polar regions. Although representatives from these groups are also represented in temperate and tropical waters, many of the species found in cold polar waters generally are not found in warmer waters. Similar species are often described from both the Arctic and the Antarctic, but because phytoplankton classification is still based largely on morphological characteristics and not on analysis of the genetic material deoxyribonucleic acid (DNA), it is not possible to say if these species are truly identical with regard to genetic constitution or if they merely have similar morphological appearance. Further information on phytoplankton taxonomy may be found in references (6–8).

Bacillariophyta. Diatoms are usually the dominant component of the phytoplankton in both polar regions. The cell wall consists of two overlapping siliceous frustrules, which are generally highly sculptured and often with spines. Cells may be single or connected to form long chains. Diatoms are a major food item for most zooplankton and krill.

Pyrrophyta. Dinoflagellates generally have two flagella for motility and may be either armored with thick, sculptured cellulosic plates (theca) or naked, without any theca.

Cryptophyta. Cyptophytes are naked, flagellated cells that have accessory photosynthetic blue (phycocyanin) and red (phycoerythrin) pigments in addition to chlorophylls *a* and *c*.

Haptophyta. Flagellated forms that may or may not have organic or elaborately sculptured outer plates of calcium carbonate (the Coccolithophorids). This group also includes *Phaeocystis* species, which are found either as solitary cells or organized into spherical colonies and at times is a dominant component of the phytoplankton in both the Arctic and the Antarctic. *Phaeocystis* species are known to produce the antibiotic acrylic acid. Bactericidal effects, however,m appear to be restricted to extremely acid environments such as penguin guts. Phaeocystis species also release demethylsulfide, which may, when released into the atmosphere, produce sulfuric acid droplets that act as condensation nuclei for cloud formation.

Chrysophyta. This varied group, also called golden brown algae, are flagellated and may have scales and needles composed of silica (the silicoflagellates). Other forms include *Dinobryon* and its close relatives, which are important in the sea ice flora.

Chlorophyta. This group of green algae, which contains chlorophyll *b* in addition to chlorophyll *a*, are represented in polar waters by small, unicellular *Chlorella*-like cells. Their biomass though, is generally small relative to that of other phytoplankton groups.

Cyanophyta. Small procaryotic unicells (also referred to as Cyanobacteria) are often dominant in tropical waters, but are rarely seen in cold polar waters. When they are found in the polar regions, it is usually in coastal habitats or in places where water temperature is greater than 5.0 °C.

PHYSICAL AND CHEMICAL ASPECTS OF THE ARCTIC AND THE ANTARCTIC

Although some environmental conditions in the Arctic and the Antarctic are similar (e.g., low water temperatures, seasonal cycle of solar radiation, and annual formation of sea ice), the two polar regions are also very different in regard to some factors that are important for the survival and growth of phytoplankton (9). The geographic areas to be included in the terms "Arctic" and "Antarctic" depend to a large extent on whether or not a strict, geographic criterion (e.g., the Polar Circles, which are located at approximately 66.5 °N and 66.5 °S) is most relevant, or if primary consideration should be given to the area where certain environmental conditions are found. In the latter case, the term "Arctic" is often delineated by the southernmost boundary where the air temperature isotherm during July approximates 10 °C. Such a boundary would be far south of the Arctic Circle over portions of northern Canada and would include portions of the Bering Sea, but it would be to the north of the Arctic Circle in the waters to the west of Norway as a result of the relatively warm northward-flowing Gulf Stream with the North Atlantic current. For simplicity, the discussion below will consider the Arctic marine ecosystem to include the High Arctic (the Arctic Ocean) as well as peripheral Low Arctic (also called sub-Arctic) waters, which include the Bering Seam Hudson Bay, Baffin Bay, Barents Sea, Greenland Sea, and the Norwegian Sea (Fig. 1a). The situation is far simpler in the Antarctic, where oceanographic conditions are fairly uniform from the coastal waters surrounding the continent northward to the Polar Front (formerly referred to as the Antarctic Convergence), which lies to the north of the Antarctic Circle (Fig. 1b). The accepted definition of the Southern Ocean thus is the oceanic area lying to the south of the Antarctic Polar Front, which lies between 47 and 60 °S and where the water temperature ranges from 4 to 5 °C. The major differences between the two polar regions are briefly discussed in the following sections.

Arctic

The geographic north pole (90 °N) is located in the relatively small Arctic Ocean, which is surrounded by the large land masses of North America, Europe, and Asia (Fig. 1a). As can be seen from the 1,000 meter depth isopleth, deep waters in the Arctic Ocean are limited primarily to the central deep basins; the relatively shallow (<300 m) continental shelf waters account for a large

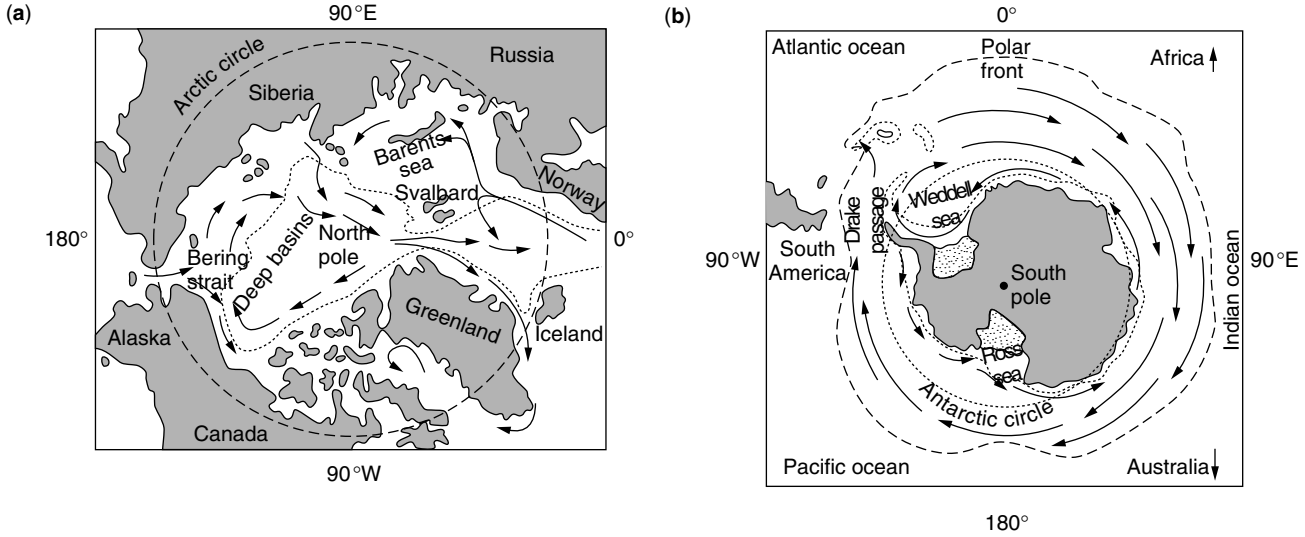

Figure 1. Maps of the Arctic (**a**) and Antarctic (**b**) to illustrate major differences in these two polar regions. Location of the Polar Circles are shown in addition to the 1,000 meter bottom contour (dotted lines). Note that different scaling factors have been used, as evidenced by the larger size of the polar circle in the Arctic as compared with that in the Antarctic. Arrows indicate directional flow of surface waters. See text for comments.

portion of the Arctic Ocean. Although the waters over the shelf areas occupy 37% of the Arctic Ocean area, they comprise only 2% of its volume. The permanent ice pack covers much of the area of the deep basins, where depths can exceed 4,000 m. Being largely enclosed by land masses, water flow into the Arctic basin is limited and is predominantly from the northeast Atlantic and subsequent flow to the northeast across the shelf region adjoining Siberia (10). There is also a substantial amount of fresh water flowing into the Arctic basin from northward flowing rivers, and also some periodic transport of water north through the Bering Strait. The river flow, however, is small compared to the flow from the Atlantic, but entrainment caused by the river waters helps create the transpolar flow. There is no large-scale upwelling on the Atlantic side; the area is known for downwelling or deep-water production. The extent and duration of sea ice in the Arctic is of much importance for the phytoplankton because sea ice scatters and absorbs solar radiation, resulting in light-limiting conditions in the underlying water column. Of the total ocean area of the Arctic Seas ($\sim 20 \times 10^6 km^2$), approximately 80% is generally covered with sea ice in winter and approximately 50% in summer (see also section Interannual Variability: Importance of Global Cyclic Climatic Events). Inorganic nutrient concentrations in Arctic waters are much lower than in the Antarctic. During spring-summer following the first bloom in ice-free waters, the concentrations of nitrate, phosphate, and silicic acid in surface waters are often close to zero, resulting in nutrient limitation of phytoplankton biomass and rates of primary production. During this low-nutrient summer period, nutrients derived from biological activity (e.g., ammonia, urea, dissolved organic nitrogen compounds) can be significant. The profiles of salinity, temperature, and water density during the summer growing season also differ appreciably between the two polar regions as indicated by representative data shown in Figure 2. It is seen that the upper water column of Arctic waters (Fig. 2a) is generally less saline, warmer, of lower water density, and with a much more stable upper mixed layer when compared with Antarctic waters.

Antarctic

In contrast to the Arctic, the South Pole (90 °S) is located on the high plateau of the Antarctic continent, which is a large land mass with mountains exceeding 5,000 m

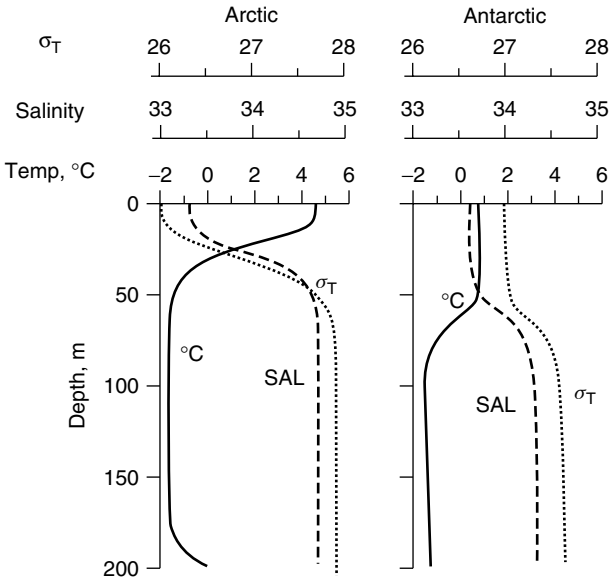

Figure 2. Typical mid-summer profiles of temperature, salinity, and water density in the upper water column of both polar regions. (**a**), data from the Barents Sea in the Arctic in July and August; (**b**), data from the Scotia Sea, Antarctica, in February.

in elevation. The continent is an isolated land mass, being surrounded by the Southern Ocean, which flows unimpeded through the southern regions of the Atlantic, Pacific, and Indian Oceans (Fig. 1b). As a result of its isolation and the vast ocean surrounding the continent, it is much colder in the Antarctic than in the Arctic. The northern boundary of the Southern Ocean is the Polar Front, which lies considerably to the north of the Antarctic Circle. The total area of the Southern Ocean is large ($\sim 36 \times 10^6$ km^2) and equal to about 12% of the world's ocean area. The mean depth of the Southern Ocean is greater than 4,000 m, with the deep (500–800 m) continental shelf areas being relatively small as compared with the area of pelagic waters. The continental shelf break as indicated by the 1,000 m depth contour (Fig. 1b) lies relatively close to the continent in sharp contrast to the situation seen in the Arctic. There is massive upwelling of deep, cold, and nutrient-rich water close to the continental shelf break around the continent, with the major source being southward-flowing North Atlantic Deep Water, which was produced mainly in the Greenland and Labrador Seas a century or more earlier. But with contributions also from the deep waters of the Pacific and Indian Oceans. These nutrient-rich waters upwell and flow in an east-northeast direction around the continent and is termed the Antarctic Circumpolar Current (ACC). Between the continent and the zone of divergence where the upwelling occurs, there is a westward flowing current called the West Wind Drift as indicated by the arrows in Fig. 1b. There is gradual warming of the surface waters of the ACC during this flow, so that there generally is a temperature gradient from close to zero near the continent to approximately 4 to 5 °C at the Polar Front. Within the Polar Front region these northeast-flowing waters of the ACC mix and submerge below the southward-flowing sub-Antarctic waters (8). Water temperatures north of the Polar front increase quite rapidly to about 10 °C at the Subtropical Convergence, which is the northern limit of sub-Antarctic waters northern limit of sub-Antarctic waters. The Polar Front region thus forms a natural boundary for many phytoplankton species that are found to the south in Antarctic waters, but are not present in waters to the north of the Polar Front.

Inorganic nutrient concentrations in pelagic Antarctic waters are very high, with the winter-time concentrations of nitrate, phosphate, and silicic acid being approximately 40 μM, 3.0 μM, and greater than 100 μM, respectively. Because of the low stability of the upper water column and the frequency of deep mixing by storm events that results in deep upper mixed layers, phytoplankton biomass in pelagic waters is generally low and the major inorganic nutrients are not depleted to the extent that the biomass of phytoplankton becomes limited by low concentrations of these elements. Data in Figure 2b show that the ranges of temperature, salinity, and water density in the upper 100 m of the water column in the Antarctic are much smaller than in the Arctic. Phytoplankton cells are generally fairly uniformly distributed by physical mixing processes throughout the depth of the upper mixed layer. This results in a low concentration of phytoplankton in the entire mixed layer, as the cells in the lower portion of the mixed layer will be limited by low light levels where the rate of photosynthesis approaches the rate of respiration. During the winter months the area of sea ice in the Antarctic is extensive and covers approximately 56% of the waters south of the Polar Front. This annual sea ice recedes fairly rapidly though in late winter and spring, so that by February or March ice covers only about 10% of the ocean area. Sea ice is of great importance for phytoplankton because (*1*) it attenuates solar radiation so that low light levels limit the photosynthetic rate in the water column below the ice, (*2*) it enables some species of phytoplankton to grow attached to or within the sea ice, with the result that large concentrations of phytoplankton may accumulate associated with the ice cover, and (*3*) with melting of the ice, the released algal cells may serve as an inoculum to initiate a bloom of phytoplankton in the ice-free waters.

INTERANNUAL VARIABILITY: IMPORTANCE OF GLOBAL CYCLIC CLIMATIC EVENTS

Marine climate is extremely variable at high latitudes, so there is no short-term "ecological balance," at least not in any meaningful steady state sense. Both polar regions are characterized by alternating "warm" and "cold" periods that may last for months or years, during which marine populations, including phytoplankton, may expand or contract. When the marine climate changes, primary producers respond within few days, and grazers within weeks to a few months. The impacts of such cyclic climate changes have been studied to a much greater extent in the Arctic regions than in the Antarctic. During the "warm" years in the Arctic, primary production may be up to 30 to 50% higher than in the "cold" years, primarily as a consequence of less ice cover. The high-productive years are characterized by greater frequency and intensity of summer storms that furnish nutrients after the conclusion of the spring and/or ice edge blooms. The warm and cold years in the Arctic Seas exhibit cyclicity, as evident from the longest existing arctic surface sea temperature (SST) time series, the Kola section in the Barents Sea. These data show that the 1930s were warm, as was the period 1946 to 1955, whereas the 1960s and the periods 1977 to 1981 and 1984 to 1988 were cold. However, because of the circulation pattern, the warm years in the Barents Sea are matched against cold anomalies off East Greenland, and thus the respective ecosystems cycle in counterphase. The causes of these cyclic climate changes are not well understood, although they appear to be related to atmospheric forcing related to changes in regional barometric pressure and wind systems, which in turn may have strong effects on ocean currents and upwelling processes. These cycles are generalized in a simple fashion by the North Atlantic, Arctic, and Pacific Decadal Oscillations, (NAO, AO, and PDO, respectively). Some cyclic climatic changes can have impacts on a global scale, such as the well-known El Nino and La Nina events, which often affected the entire marine food chain in both the Northern and Southern Hemispheres.

The impact on the marine environment caused by these cyclic climatic events may last for years or even decades

for long-lived and slow-reproducing organisms such as cod, some seabirds, and mammals. The impact of such cyclic events has not been documented in the Antarctic as well as it has for the Arctic, but it seems likely that the variability noted in the Antarctic for phytoplanktopn and higher trophic levels is related to the Southern Oscillation Index (SOI), which includes influences of the El Nino and La Nina events. All these cyclic climatic events mentioned above presumably embed the decadal Sunspot Cycles (11 and 22 years) and the Lunar Declination Cycle (18.6 years). The underlying mechanisms, however, are poorly understood, even though they ultimately have dramatic effects on marine productivieityt and to societal concerns as a whole.

RATES OF PRIMARY PRODUCTION

Both in the Southern Ocean and in the Arctic seas phytoplankton communities and photosynthetic rates are regulated by light received by the phytoplankton as they are carried up and down in more or less mixed water columns, and by nutrient supply. Light is regulated by surface irradiance, which depends on seasonality, latitude, and cloudiness, and the depth and intensity of vertical mixing, which in turn depends on wind speed and fetch and the resistance (stability) of the water column to mixing. Both polar regions have extensive cloud cover much of the time, often reducing incident solar irradiance to 15 to 40% of that occurring on a cloud free day. Mixing may also be forced by tides, shear forces between currents and island or bank effects. Mixing plays a dual role by also regulating nutrient supply to the surface layer; however, nutrient supplies can also be increased by upwelling that is wind-driven or by entrainment of deeper waters into brackish layers in near-coastal waters where there is ample freshwater supply, as in some of the Arctic shelf seas. The rate of primary production will be controlled primarily by the biomass of phytoplankton and the light intensity (solar irradiance) to which the cells are exposed. Some solar radiation is lost to the water by being reflected from the water surface; the light that enters the water column is attenuated with depth because of absorption and scattering by both particulate and dissolved materials. The depth to which 1% of the incident radiation penetrates the water column is referred to as the euphotic zone, and is commonly accepted as the lower depth at which net primary production can occur (i.e., where the rate of photosynthesis exceeds the rate of respiration). The euphotic zone may range from a meter or less in the case of rich phytoplankton blooms to greater than 100 meters in the clearest, nutrient-impoverished oceanic waters.

There is a fairly good relationship between the rate of primary production in surface waters (the upper few meters) and the magnitude of primary production when integrated for the depth of the entire euphotic zone. Availability of satellite imagery makes it possible to estimate chlorophyll-a concentrations on a synoptic basis over large geographic areas. Data in Figure 3 show the concentrations of chlorophyll-a in surface waters in both polar regions during the most productive spring-summer months. It is seen that most ice-free Arctic waters show a high biomass of phytoplankton, but that there is relatively little production within the Arctic basin because of persistent ice cover. Maximal chlorophyll-a concentrations in the Barents Sea are relatively low (range of 10 to 15 mg/cubic meter) because of depletion of nutrients. Because nutrients are higher over the Bering Sea shelf, chlorophyll-a concentrations of greater than 60 mg per cubic meter have been reported. Concentrations of chlorophyll-a in Antarctic waters are much lower than in the Arctic, except for a scattering of localized regions that show high biomass of phytoplankton. The areas of high phytoplankton biomass (usually 5 to 10 mg chl-a per cubic meter, but occasionally as high as 35 mg chl-a per cubic meter) are generally in coastal waters overlying the continental shelf (particularly in the Ross Sea), in waters close to the Antarctic Peninsula and Scotia Ridge, and in waters in proximity to receding ice edges. In contrast to these areas of high phytoplankton biomass (and associated primary production), most pelagic Antarctic waters have low phytoplankton concentrations (average of ~ 0.5 mg chl-a per cubic meter) throughout the entire summer period. However, there is considerable variability in surface chlorophyll-a concentrations in Antarctic pelagic waters as can be seen by the data in Figure 3b. The likely explanations for such low phytoplankton biomass despite high nutrient concentrations and ample solar radiation are discussed in Section Major factors affecting growth rates of phytoplankton.

The data presented in Figure 3 illustrate chlorophyll-a concentrations in the time period when phytoplankton are generally at their maximal levels. Because primary production supports all animal life in the sea, it is also important to consider rates of primary production throughout the entire year. In the Antarctic, rates of primary production in ice-free waters bear a fairly food relationship to the seasonal changes in solar radiation as essential macronutrients do not become limiting. Phytoplankton biomass starts to increase rapidly in spring (September–October), blooms develop in the late spring and summer period (November through February), after which the phytoplankton biomass declines with the progressively shorter days in March and April. The situation is slightly different in the Arctic, where the springtime blooms often assimilate nearly all the available nitrogen and silicic acid in the euphotic zone, resulting in a rapid decline in phytoplankton biomass and associated rates of primary production. Phytoplankton productivity during the remainder of the year depends largely on regeneration of nutrients in the upper water column by microbial processes (see section Phytoplankton and the Food Web). The timing sequences mentioned above may be modified in both polar regions by the presence of a receding ice edge, which will generally result in higher rates of primary production within 50 to 100 km of the ice edge. This enhancement of phytoplankton biomass is the result primarily of a shallower and more stable upper mixed layer induced by the freshwater ice-melt, but also by nutrient enrichment from materials contained in the melting ice. Such ice-edge blooms may occur as late as July in the highest latitudes of the Arctic.

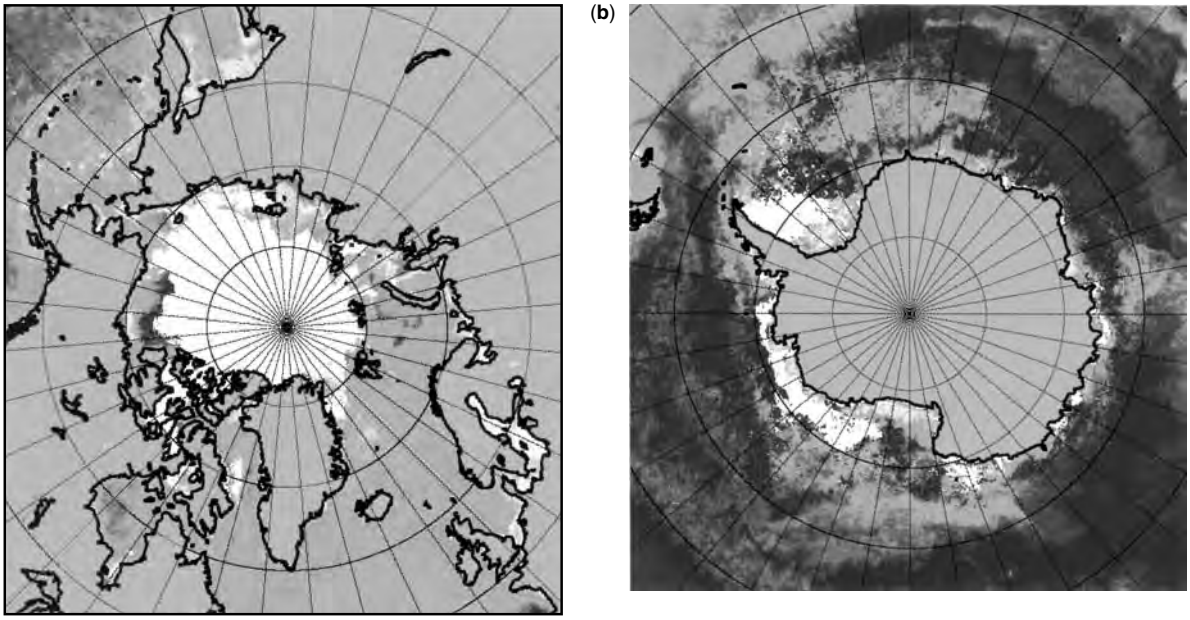

Figure 3. Satellite data images showing mean chlorophyll-a concentrations in surface waters during summer in the Arctic (**a**) and the Antarctic (**b**). In the Arctic, the data are composites for the months of May, June, and July for five years. In the Antarctic, the data are composites for the months of November, December, and January for three years. The same geographic and color scales have been used in both images. Highest chlorophyll-a concentrations are indicated by red (>30 mg chl-a per cubic meter), with decreasing concentrations as per the spectrum, with violet representing the lowest concentrations (<0.08 mg chl-a per cubic meter). White indicates areas where no data were obtained due to either ice or cloud cover. Images provided by the SeaWiFS Project, NASA/Goddard Space Flight Center, and ORBIMAGE, and the final figures were prepared by Mati Kahru.

As a result of the spatial and temporal variability in rates of primary production in both the Arctic and the Antarctic, it is difficult to give precise estimates for the total annual primary production in the polar regions. The rate of primary production in pelagic Antarctic waters is believed to be about 150 mg carbon per square meter per day during the growing season, whereas in coastal waters the rates are often between 0.5 and 3 grams carbon per square meter per day. Estimates for the mean annual primary production in the Southern Ocean range from a low of 20 to approximately 100 grams carbon per square meter per year. Estimates for rates of primary production in Arctic waters range from a low of about 15 grams carbon per square meter per year in the high Arctic, about 170 grams carbon per square meter per year in the ice-free Barents Sea, and between 200 and 800 grams carbon per square meter per year in waters over the Bering Shelf.

MAJOR FACTORS AFFECTING GROWTH RATES OF PHYTOPLANKTON

Solar Radiation

The portion of the solar electromagnetic spectrum incident upon the earth, which is of importance to phytoplankton, includes the ultraviolet wavelengths (UVR) from 285 to 400 nm and the visible wavelength radiation (400–700 nm), which are commonly referred to as photosynthetically available radiation (PAR). The absorption spectrum of chlorophyll extends into the UVR and hence the longer UVR wavelengths can also function to provide the energy needed to reduce CO_2 to carbohydrate, but this contribution by UVR is small compared with that of PAR. The deleterious impact of UVR on polar phytoplankton is discussed in the section Possible Impacts of Changing Climatic Conditions. This section thus deals only with photosynthetic rates as related to the intensity of visible radiation (PAR) or to the daily integrated flux of PAR. Phytoplankton photosynthetic rates as a function of solar irradiance varies considerably from species to species and also on the previous light history to which the cells have been exposed (11). The general relationship between the rate of photosynthesis and light intensity, however, is shown in Figure 4. The light compensation point (E_c) is where the rate of photosynthesis is equal to the rate of respiration, and hence there is no net gain in cellular carbon concentrations. The value for E_c is difficult to determine for natural phytoplankton assemblages, but it is usually in the range of 0.1 to 0.5% of the incident radiation ($\sim$1 to 5 μ Einsteins per square meter per second). At higher irradiances, photosynthetic rates increase in a hyperbolic fashion until the saturating light intensity (E_m) is reached. The value E_k, which resembles a half saturation constant to some degree is a useful indicator

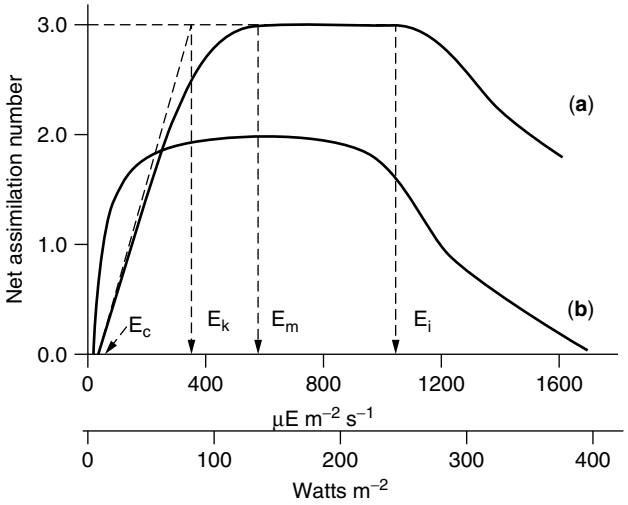

Figure 4. Generalized relationship between the net rate of primary production (mg carbon fixed per mg chl-a per hour) as a function of the solar irradiance to which the phytoplankton are exposed. Irradiance is expressed both as microEinsteins per square meter and also as Watts per square meter, as both these units are commonly used in the literature. The maximal values shown on the abscissa would be representative of maximal incident solar radiation on a clear day in the polar regions. Curve **a**, light-acclimated phytoplankton sampled from near-surface water; curve **b**, dark-acclimated cells sampled from close to the bottom of a deep upper mixed later. See text for details.

of the light-acclimation state of the phytoplankton. The higher the value of E_k, the more acclimated the phytoplankton are to high light conditions. Typical values of E_k for polar phytoplankton are generally in the range of 10 (shade acclimated cells) to 60 to 70 μ Einsteins per square meter per second, which is considerably lower than values for most phytoplankton in temperate or tropical waters. At E_m, the enzymatic capabilities of the photosynthetic mechanisms are functioning at their maximal rates. With increasing light intensity, the rate of photosynthesis remains fairly constant up to a certain point (E_i) where increasing irradiances will cause inhibition of CO_2 fixation. Such light inhibition of photosynthesis by PAR is not always found in polar phytoplankton assemblages, as the ability to utilize high light levels is dependent on the previous light history of the cells. Their nutritional status, and the seasonal variation in incident radiation (see data in Fig. 5).

Incident solar irradiance in the polar regions is much lower than at intemperate or tropical regions due to low sun angle to the horizon (Fig. 5a). However, as the day length is very long at high latitudes, the total solar radiation per day during the summer months can exceed that occurring near the equator (Fig. 5b). From the data shown in Figures 4 and 5, it is seen that irradiance will not limit rates of primary production in the upper portion of the euphotic zone of polar waters during the summer months. Light limitation does occur, however,

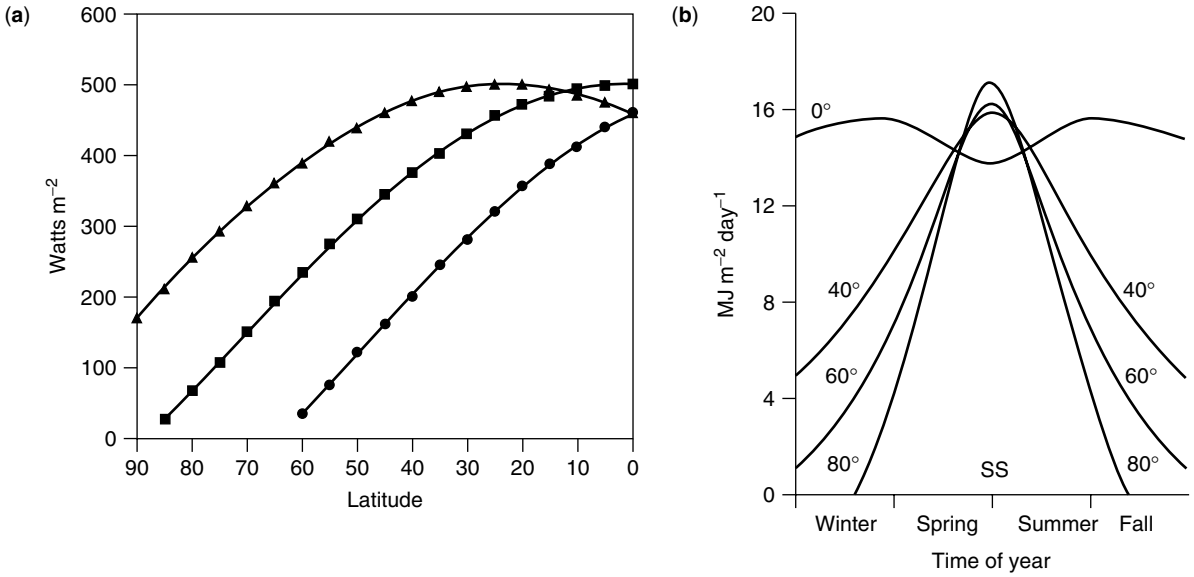

Figure 5. Solar radiation in the visible portion of the spectrum (400–700 nm) incident upon the Earth as a function of latitude and season; most of the Arctic marine region lies north of 60 degrees, while the Antarctic marine region lies sough of approximately 50 degrees. (**a**) Noontime solar irradiance at the times of the summer and winter solstice and the fall and spring equinox. The irradiance in the ultraviolet region (280–400 nm) shows a similar change with latitude, but the total energy in the UVR is only about 12 to 14% of that in the visible region. (**b**) Generalized values for total fluence of PAR (in megaJoules per square meter per day) as a function of latitude and time of year; SS is the time of summer solstice (June in the Northern Hemisphere and December in the Southern Hemisphere). Note that in the polar regions the daily fluence of PAR during the summer months can exceed the value in equatorial regions due to the long day length at high latitudes.

in surface waters during the winter months and also in the lower portions of the euphotic zone during summer. Spectral solar irradiance decreases in an exponential fashion with depth in the water column, with the shorter UVR and longer wavelengths in the visible portion of the spectrum being attenuated most rapidly, and the blue wavelengths in the visible portion penetrating the deepest into the water column. As chlorophyll-a shows maximal absorption of light in this same blue region of the spectrum, phytoplankton have efficient utilization of solar radiation in the lower portion of the euphotic zone. The photoresponse of polar phytoplankton to the changing spectral irradiance throughout the depth of the euphotic zone is illustrated by the data in Figure 6. Phytoplankton are generally fairly uniformly distributed throughout the upper mixed payer, which was at approximately 35 meter depth in Antarctic waters where the date for this figure were obtained. The photosynthetic rates due to PAR were saturated (and constant) throughout the depth of this upper mixed layer (from X to Y in Fig. 6), and declined rapidly in the lower portion of the euphotic zone (from Y to Z in Fig. 6) where light was limiting. The inhibition of photosynthesis in the upper portion of the water column is discussed in the section Possible Impacts of Changing Climatic Conditions.

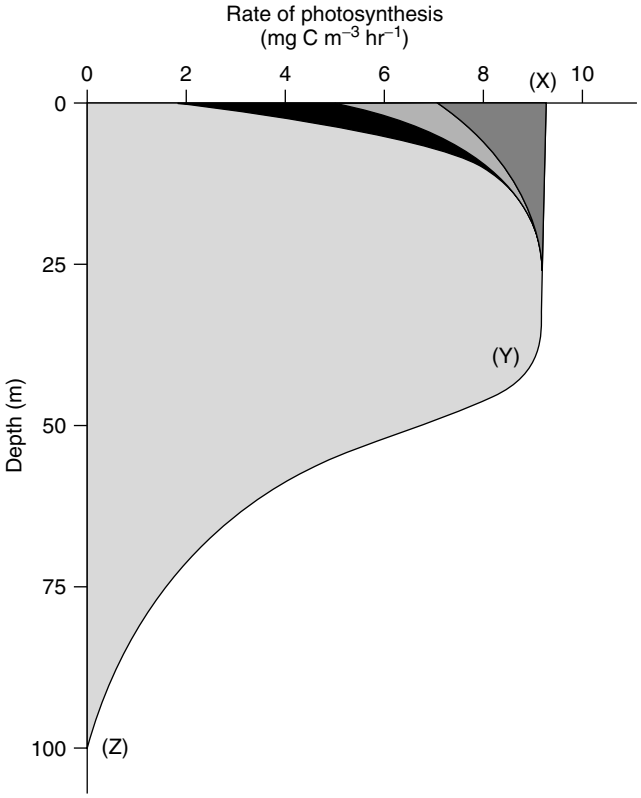

Figure 6. Diagram to illustrate the inhibitory effects of UV-A and UV-B radiation on rates of primary production under normal ozone conditions, and the impact of enhanced UV-B radiation under an extreme ozone hole in the Antarctic. The solid black area depicts the loss in primary production due to enhanced UV-B radiation. The lightly shaded area above that depicts the reduction in primary production due to normal levels of UV-B radiation, and the darker area above shows the loss due to UV-A radiation. The large lightly shaded area extending down to 100 m depth represents the profile of photosynthetic rates under conditions of depleted ozone concentrations. The depth of the upper mixed layer in the water column where these data were obtained was approximately 35 meters, and the 1% light level was at approximately 90 meters. From Lubin and Holm-Hansen (1995) with permission of the publisher, Academic Press, Inc.

Inorganic Nutrients

All plants, including phytoplankton, require the following essential macroelements for growth and viability: calcium, nitrogen, magnesium, sulfur, potassium, and phosphorus. Diatoms and silicoflagellates also require relatively high concentrations of silicon, which is a component of their outer cell walls. In addition to these elements, which are required in relatively high concentrations (half saturation constants are generally in the range of 0.1–0.5 μM), phytoplankton also require relatively low concentrations of the following essential microelements: manganese, molybdenum, copper, zinc, iron, boron, cobalt, and most likely selenium. Because the uptake of nutrients involves transport across the outer cell membrane, the ratio of the cell surface area to cellular volume is important and conveys some advantage to small cells when any essential nutrient element is present in limiting concentrations. One consequence of this is that when an element (e.g., Fe) is present in very low concentrations as in pelagic Antarctic waters, the growth rates of the small nanoplankton cells may not be limited by Fe availability, whereas the growth rates of the larger microplankton would be limited.

Macronutrients. Of the macroelements listed above, only nitrogen (N), phosphorus (P), and silicon (Si) have been found to limit phytoplankton growth in marine waters. These three elements are found in relatively high concentrations in surface Antarctic waters, with winter-time values (which are maximal because of upwelling of nutrient-rich deep water coupled with low phytoplankton assimilation due to low light levels) being approximately 40 μM nitrate (in addition to 0–2 μM ammonia), 3.0 μM phosphate, and more than 100 μM silicic acid. A few phytoplankton blooms have been reported in Antarctic waters where nitrate concentrations are less than 1.0 μM (but P and Si concentrations still sufficiently high that these elements are not limiting production), but concentrations of N, P, and Si in both coastal and pelagic waters generally are in excess (15 μM, 2.0 μM, and 40 μM, respectively) and not limiting phytoplankton growth rates. Because Si is a major constituent of diatom frustules and is not readily remineralized by microbial action in the upper water column when these cell walls settle to the sediments, the concentrations of silicic acid in surface waters close to the Polar Front may be relatively low (~10 μM) and possibly may be limiting phytoplankton biomass. The situation in the Arctic is very different, because the maximal winter-time concentrations of the three nutrients in surface waters of the Atlantic and Eurasian sides are 12 to 14 μM nitrate (in addition to 0–2 μM ammonia), 0-9 to 1.0 μM phosphate, and 6 to 8 μM silicic acid. On the Bering side the concentrations are

10 to 30 μM nitrate (+0–5 μM ammonia), 1 to 2 μM phosphate, and 25 to 50 μM silicate; these high levels are partly reflected in the Chukchi Sea and in the western Arctic at medium depths. Because of the shallower and more stable upper mixed layer in the Arctic, coupled with much less upwelling of deep water as compared with the Antarctic, these essential macroelements are often depleted to below detectable concentrations in the upper mixed layer during the phytoplankton bloom in spring. The relatively high winter nutrients and full depletion make large parts of the Bering Sea one of the most productive regions in the world. Following such nutrient depletion, phytoplankton primary production depends largely on regeneration of nutrients in the upper water column through the activity of grazing, heterotrophic protozoans, and zooplankton. Phytoplankton biomass and rates of primary production are low during such nutrient-limiting conditions. However, in the Nordic and Bering Seas, wind-induced mixing (with an input of nutrients into the euphotic zone) can be important also in the summer, as these waters are easier to mix than those farther north, which are stabilized by melt-water.

Micronutrients. Iron (Fe) is the only microelement for which there is convincing data showing that it is limiting phytoplankton biomass in pelagic Antarctic waters (1). Unlike most of the other essential elements, which are in high concentration in deep waters that upwell in both polar regions, the major source of Fe to surface waters is by aolian processes (transport and deposition of Fe via atmospheric fallout). As a result of its isolation and distance from the continental land masses, there is relatively little atmospheric input of Fe into the Southern Ocean. Recent experiments with adding large quantities of soluble iron salts to pelagic Antarctic waters have shown that such Fe additions result in rich phytoplankton blooms within 7 to 10 days and a change in the species composition of the phytoplankton from a nanoplankton-dominated assemblage to one dominated by microplanktonic diatoms. The variability in phytoplankton biomass in Antarctic pelagic waters (Fig. 3) is believed to be caused by variable Fe concentrations due to injection from coastal waters or upwelling associated with changes in bottom topography or with melting sea ice or icebergs. There are no data at present to indicate that Fe limits phytoplankton biomass in coastal Antarctic waters, but this possibility cannot be discounted. The Fe situation in the Arctic is very different because these waters are in close proximity of large land masses, and it is likely that substantial amounts of Fe are added by both aolian and river inputs into Arctic surface waters. It should be noted though that the chemical speciation of Fe in natural waters is complex, and the bulk of the iron input into Arctic surface waters may be complexed with particulates at the freshwater–seawater interface and then be lost to the euphotic zone by settling to the sediments. There are some preliminary data that suggest that Fe may at times limit phytoplankton production in Arctic waters, but because the macroelements N, P, and Si are also depleted during bloom formation, the addition of Fe to such waters would not be expected to have the same dramatic effect as found in Antarctic waters.

Temperature and Growth Rates. Temperature is a critical environmental variable for all living organisms because it affects enzymatic rates that control cellular metabolic processes. Compilation of literature data showing the relationship between temperature and growth rates of phytoplankton isolated from polar, temperate, and tropical waters shows that growth rates may be described by the van Hoff equation and predicts an exponential increase in reaction rates with an increase in temperature, with an approximate doubling of reaction rate with each 10 °C rise in temperature (12). Most polar phytoplankton are psychrophiles in that they are adapted to grow at low temperatures and do not survive at higher temperatures. The temperature range over which most Antarctic phytoplankton will grow and increase their photosynthetic rates is −1.8 °C to approximately 8 to 10 °C. Because water temperature at the Polar front is approximately 5 °C, Antarctic phytoplankton apparently have the metabolic capabilities to grow well even if ambient water temperatures should exceed that normally encountered by 3 to 4 °C. It is important to note that the effect of a change in temperature within the above range will not have the same effect on all species. Thus, temperature changes may have important consequences on species composition of the phytoplankton asemblages. Specific growth rates in polar phytoplankton generally range from 0.1 to 0.6, which is equivalent to doubling times of 0.15 to 0.9 doublings per day. The average specific growth rate in both polar regions is about at 0.5 per day, which is equivalent to 0.8 doublings per day.

Salinity. The salinity (a measure of the total salt content) of seawater is of importance to phytoplankton productivity in two ways. First, the density of seawater at the low temperatures occurring in the polar regions is largely determined by the salinity, and the profile of water density is of prime importance in affecting the distribution of planktonic cells in the water column. Second, the direct impact of salinity on phytoplankton plays a modest role for productivity unless it is less than 15 psu, which happens only in extreme cases. Such low salinities efficiently eliminate true marine species. Salinity, however, may play a role, albeit not a well known one, for the species composition of the community through effects on growth rate via osmotic regulation and nutrient uptake. A lowering of salinity may, for instance, shift the dominance to other species that originally made up a minority component. This may in turn make an impact on the quality of phytoplankton as food for grazers.

PHYTOPLANKTON AND THE FOOD WEB

The species composition and growth rates of natural phytoplankton assemblages must be considered in the context of interactions with all nonphotosynthetic organisms in water. Phytoplankton are being continually grazed (eaten) by heterotrophic organisms ranging in size from unicellular protozoans to large zooplankton and krill. There is thus a dynamic interaction between the producers (phytoplankton) and the consumers (all heterotrophic organisms), such that the biomass of phytoplankton tends to remain fairly

uniform from day to day, despite the daily fixation of carbon dioxide by the phytoplankton. As most zooplankton have the ability to graze preferentially (i.e., they select particles to be eaten rather than simply ingesting all particles) the zooplankton assemblages may thus have a strong impact on the species composition of the phytoplankton. Although diatoms are a major food item for most zooplankton, recent data suggest that they generally prefer small naked flagellates. This continual grazing of phytoplankton by zooplankton, coupled with the assimilation and breakdown of dissolved organic compounds by the bacterial populations, results in cycling of organic materials and the regeneration of inorganic nutrients within the euphotic zone. One result of these continual recycling processes is that all essential inorganic elements will always be present in the water column, albeit at very low concentrations. Because the assimilation of nutrients requires transport across the outer cell wall or membrane, the ratio of cell surface area to cellular volume will be important in regard to the ability of the organism to survive at very low concentrations of essential inorganic elements. Small nanoplankton thus have some advantage over the larger microplankton in regard to continued growth under nutrient-limiting conditions.

POSSIBLE IMPACTS OF CHANGING CLIMATIC CONDITIONS

Increase of Temperature. There is much concern that the increasing concentrations of CO_2 in the world's atmosphere will have a "greenhouse effect" and cause a rise in the world's temperature, with maximal effects in the polar regions. The projected increase for the polar regions is on the order of 2 to 5 °C. The impact of such a temperature rise in polar surface waters would be expected to have the following consequences in regard to phytoplankton. First, it would most likely increase the rate of primary production because of (*1*) Increasing cellular enzymatic rates, including the rate of photosynthesis. The projected increase in water temperature is well within the temperature range for growth by polar phytoplankton as discussed in the section Major Factors Affecting Growth Rates of Phytoplankton. (*2*) Heating of surface water would increase the stability of the upper mixed layer, which would help maintain phytoplankton at higher mean light intensities. Second, warming of polar environments would result in a dramatic decrease in the extent of annual sea ice. Such an increase in extent of ice-free waters would increase total primary production by phytoplankton. However, a decrease in extent and duration of annual sea ice would also have deleterious biological impacts as sea ice is very important for the marine biota because the variability in the formation and crystalline nature of sea ice provides excellent habitats for growth of a complex microbial food web, including unicellular algae (13). The algal layer on the underside of the ice may reach high biomass densities and persist throughout the dark winter periods. Sea ice and associated food resources provide an excellent habitat where juvenile krill find both protection from predation and sufficient food to meet their dietary requirements. This ice habitat is thus of much importance for the ability of many organisms, including juvenile krill, to have high overwintering survival rates. Because krill is a major food item for many higher trophic levels (e.g., birds, seals, whales) in the polar regions, such temperature-induced loss of sea ice might have serious consequences in the entire food chain in polar waters. Loss of sea ice would also have serious implications for polar bears, seals, and seabirds, which require annual sea ice to find sufficient sources of food.

Decrease of Ozone in the Stratosphere

British scientists at Halley Bay first detected the seasonal loss of ozone over Antarctica in the late 1950s, but the extent and severity of the ozone hole was not generally recognized until the mid-1980s. Because ozone absorbs the shorter wavelengths (UV-B radiation; 280–320 nm) of solar UVR, the biological significance of a decrease of ozone in the stratosphere is that there is an increase in the flux of UV-B radiation incident upon Earth (14). Ozone does not have any significant effect on the UV-A wavelengths (320–400 NM) of solar radiation. The energy content per quantum in the UV-B portion of the spectrum is high and capable of causing cellular damage, particularly to the genetic material (DNA). The total energy in the UV-B portion of the spectrum is relatively low ($\sim$ 0.5% of PAR). With the increasing size, depth, and duration of the ozone hole over Antarctica during the 1990s, much concern was expressed regarding the possibility of severe ecosystem damage in the Southern Ocean due to this enhanced UV-B radiation. The loss of ozone in the atmosphere is greatest in the polar regions and decreases in severity toward the equator. As a result of the unique atmospheric conditions prevailing over the Antarctic continent (particularly very low temperatures and the polar vortex with ice crystals), the depletion of ozone in Antarctica during spring (mainly October and November) is very severe, with the column ozone values decreasing to less then 100 Dobson units (DU) on occasion as compared with normal values of greater than 300 DU. The depletion of ozone in the Arctic is not as severe as in the Antarctic, as ozone levels generally do not fall below 300 DU. The impact of UV-B radiation as well as UV-A radiation (320–400 nm) on integrated primary production in the Antarctic water column during the period of the ozone hole is shown in Figure 6. Inhibition of photosynthesis by UV-B can only be detected in the upper 10 to 15 m of the water column, whereas that by enhanced UV-B radiation cannot be detected below approximately 10 m. Primary production, however, occurs down to at least the 1% light depth, which was at about 90 m where the experimental data for Figure 6 were obtained. In the worst case situation (<100 DU, sunny with no clouds), the loss of photosynthate due to enhanced UV-B radiation is less than 4% of the total production. If one calculates (taking into account ice and cloud cover) the annual loss in the magnitude of primary production due to enhanced UV-B radiation resulting from decreased ozone concentrations over the Southern Ocean, the value is less than 0.2% (15). This loss of primary production due to lowered ozone concentrations is small compared with normal variability in annual primary production in

the Antarctic (16), and hence it is not likely to result in serious consequences in regard to annual productivity in the polar regions.

GLOSSARY

Biomass

A value to express the total amount of live cells, which may be expressed in various terms such as cellular volume, wet or dry weight, or total cellular organic carbon. Chlorophyll-a concentrations are often used as a biomass indicator, but this is dependent on knowing the ratio of organic carbon to chlorophyll-a in the phytoplankton.

Dobson Units

A measure of the total amount of ozone in a unit column of the entire atmosphere. One Dobson Unit is equal to 1,000 times the thickness (in centimeters) of all the ozone if it were compressed to standard temperature and pressure.

Einstein

A unit commonly used to express solar irradiance in terms of quanta per unit area per unit time. One Einstein equals one Mole Quanta of solar radiation, which is equivalent to $602x10^{23}$ quanta.

Primary Production

The assimilation and reduction of carbon dioxide (CO_2) to organic compounds by chlorophyll-containing plants, with the energy required for these reactions being obtained by absorption of solar radiation, chiefly in the visible portion (400–700 nm) of the spectrum.

Photoautotrophic

The ability of chlorophyll-containing plants to synthesize all cellular organic materials from carbon dioxide and water, with the required energy for the reactions being provided by absorption of sunlight.

Phytoplankton Bloom

An expression to indicate that phytoplankton assemblages have increased in biomass so that chlorophyll-a concentrations exceed 1 mg chlorophyll-a per cubic meter.

Upper Mixed Layer

The depth of the upper surface layer of the water column where the water density remains close to constant and is characterized by a fairly uniform distribution of dissolved and plankton particles caused by vertical mixing processes.

Water Column Stability

A measure of the rate of change in water density with depth in the water column. With little or no change in water density with depth, the water column is easily mixed; when there is a large difference in water density with depth, the water column will be more stable and more difficult to mix vertically.

PRIMARY PRODUCTIVITY IN THE MARINE ENVIRONMENT

WALKER O. SMITH JR.
JILL PELOQUIN
College of William and Mary
Science
Gloucester Point, Virginia

Marine primary productivity is generally defined as the photosynthetic reduction by procaryotic and eucaryotic organisms of inorganic carbon to organic matter using solar radiation as the energy source. Therefore, it is the amount of CO_2 fixed in a volume of water per unit time, and is essentially an instantaneous measurement. Productivity varies as a function of solar radiation, which changes over short timescales (e.g., due to clouds), as well as on a daily and seasonal basis. Because solar radiation penetrates to some finite depth in the ocean, primary productivity also occurs throughout that layer (generally called the euphotic zone). Because productivity varies both with depth and time, it is often integrated through both to give a daily, depth-integrated rate with units of $g\ C\ m^{-2}\ d^{-1}$. This is an essential variable to understand the structure and function of ocean systems because it is this rate that quantifies the flow of organic matter to the food web (1) and defines the biological influence on marine biogeochemical cycles (2).

HISTORICAL APPROACHES TO THE ASSESSMENT OF PRIMARY PRODUCTIVITY

Direct Measurement of Productivity

During the early 1900s, productivity was estimated by reductions in dissolved carbon dioxide (3), phosphate (4), and nitrate (5) (all are used in the formation of organic matter in relatively uniform removal ratios, now known as the Redfield ratios, which is the removal of carbon, nitrogen, and phosphorus in ratios of 106 : 16 : 1; ref. 6). Because oxygen is generated during photosynthesis, its production was used to estimate productivity as well (7). But as a result of the relative insensitivity of the analytical procedures used to measure the inorganic constituents, it was not until the introduction of the use of the radioactive tracer $^{14}CO_2$ that allowed for the sensitive measurement of the incorporation of carbon dioxide into organic matter in a variety of oceanic realms (8). This method involves the addition of radioactive bicarbonate to an enclosed sample, and after an incubation period in light, the sample is filtered. Any radioactive material retained on the filter must be in particulate form because productivity by definition is the production of organic matter $(CH_2O)_n$ via photosynthesis (Eq. 1)

$$nCO_2 + nH_2O \longrightarrow (CH_2O)_n + nO_2 \qquad (1)$$

The radioactivity is incorporated as a linear function of the ratio of $^{14}CO_2 : {}^{12}CO_2$ in seawater. Furthermore, because the reaction is carried out only using solar energy captured and converted to ATP by living cells, it represents biological fixation of carbon. ^{14}C-organic matter is relatively simple to detect accurately, especially with the improvement of liquid scintillation techniques, and therefore productivity can be measured relatively unambiguously using this technique. As a result, it became the method of choice to assess spatial and temporal changes of productivity and to experimentally determine the factors regulating oceanic productivity, and remains so today.

The method is not without uncertainties (9), as the length of incubation, the incubation conditions, the size of bottles, and the production of dissolved organic matter during photosynthesis make both measurement and interpretation problematic. Individual sources of error can be as much as 25% (e.g., DOC production; 10), and hence a single measurement of productivity can be difficult to interpret in the context of ecosystem dynamics. Such errors can be minimized by using consistent techniques, but variations among investigators remains a troublesome (and poorly addressed) problem in studies of marine productivity.

Biomass of phytoplankton correlates well with productivity (11,12), although in many specific instances it displays rather large deviations from the generally observed linear relationship. Many of these deviations are derived from the differences in the vertical distribution of irradiance in the water column (which follows an exponential reduction) with those of biomass (which is often distributed evenly in the upper mixed layer, and may increase or decrease below that depth). It is possible to collect discrete samples from the water column, measure the biomass within those samples and the photosynthetic response (the rate of photosynthesis over a wide range of irradiances during a short incubation) and in situ irradiance, and calculate the water column productivity based on these results (13). Productivity at a known depth has units of $mg\ C\ m^{-3}\ h^{-1}$, whereas integrated values generally are expressed in units of $mg\ C^{-2}\ d^{-1}$. Such estimates minimize uncertainties due to incubation length and provide realistic assessments of productivity at one location.

Based on these techniques, broad patterns of productivity of the ocean and its subsystems have been estimated (14,15; Fig. 1). In viewing this composite it must be understood that when this was produced, much of the ocean was (and still is) greatly undersampled, and no direct estimates were available for vast portions of the ocean. To generate the map, over 7,000 stations were used, most of which were collected by far-reaching expeditions of the former Soviet Union. Even with this number of stations, the productivity of the ocean in large part remained unknown. Furthermore, methodological inconsistencies were not assessed, and these differences undoubtedly contributed to some of the variations reported. Regardless, this estimate was extremely useful, in that it clearly delineated the regions where productivity was high and where it was low. It also provided a very useful contrast to a theoretical prediction of global productivity provided earlier by Sverdrup (16).

Koblentz-Mischke and coworkers (14) found that much of the ocean was highly unproductive, and that the major locations of greatly enhanced productivity were associated with coastal regions and physical features that brought nutrients to the surface layer. Specifically, productivity was very large in the following coastal regions: the Arabian Sea, northwest Africa, southwest Africa, the Indonesian archipelago, southern Greenland, the Barents Sea, coastal China and Russia, and coastal British Columbia (Fig. 1). Other isolated pockets of high productivity existed scattered around the globe. Similarly, very low productivity was associated with the vast oceanic gyres, such the North and South Pacific Gyres, the South Atlantic Gyre, the Sargasso Sea, and the Arctic Ocean.

It was also suggested by Koblentz-Mischke and coworkers (14) that the annual production of the global ocean was approximately 25 to 30 pg C y^{-1} (1 pg = 10^{15} g). This figure was widely accepted and used in attempts to understand the trophic transfer of photosynthetic material within the food web. One such example was the analysis by John Ryther (1). He divided the ocean into provinces with known areas, assigned (based on his own measurements) mean production rates to each area, and calculated the annual ocean production. His estimate of oceanic production was 20 pg C y^{-1}, a figure not unlike that of Koblentz-Mischke and coworkers (14). Ryther went on to predict that the fish yield based on that production was indeed finite, and although the scientific rationale for his arguments was widely criticized, his conclusions have in large part been verified by fishing statistics since 1970, as well as further theoretical work (17). Thus, despite the fact that highly productive, but temporally restricted, "events" were not included by either Ryther (1) or Koblentz-Mischke and coworkers (14), and their approaches were

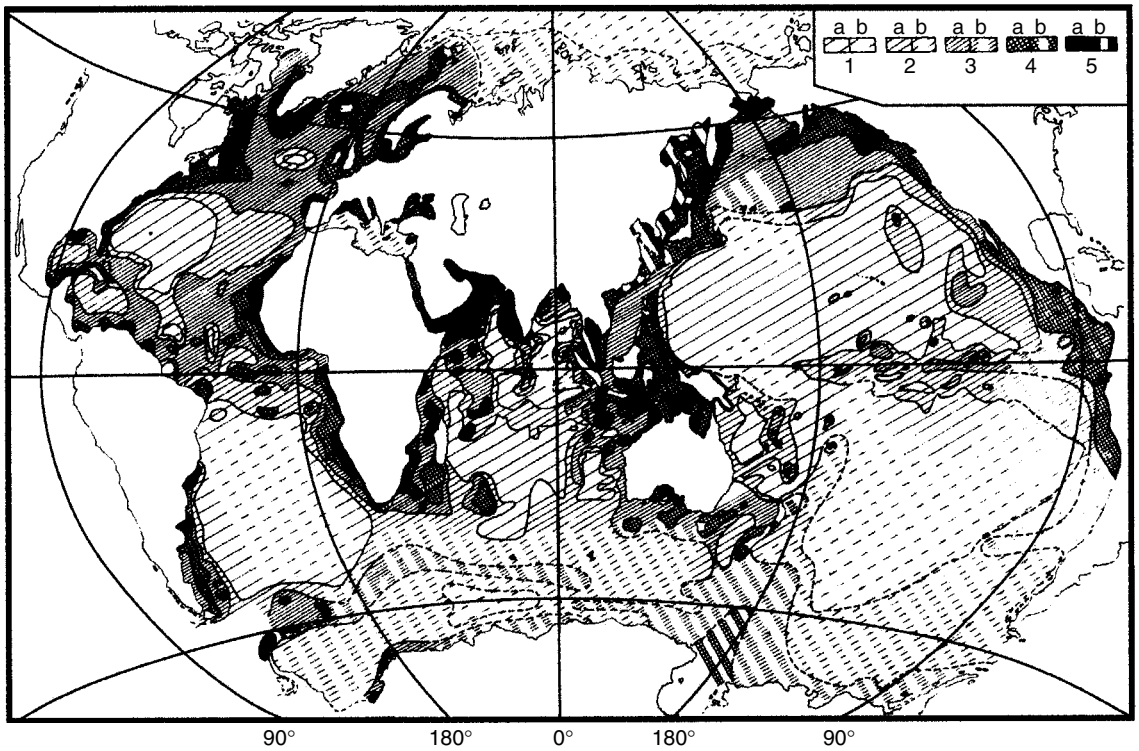

Figure 1. The distribution of primary productivity in the world's oceans as deduced from ^{14}C-primary productivity measurements (from O. J. Koblentz-Miscke, V. V. Volkovinsky, and J. G. Kabanova, in W. S. Wooster, ed., *Scientific Exploration of the South Pacific*, National Academy of Sciences, Washington, D.C., 1970, pp. 183–193.). Primary productivity is deduced from direct ^{14}C-primary productivity measurements (a) or indirect measurements of phytoplankton biomass, hydrogen, or oxygen saturation (b). Units are in mg of C per m^2 day^{-1}. (1) Less than 100; (2) 100–150; (3) 150–250; (4) 250–500, (5) more than 500. Courtesy of National Academy of Sciences, Washington, D.C.

very different, their estimate of the annual productivity of the ocean was largely equivalent.

Eppley and Peterson (19) compiled productivity data from a number of systems to understand the amount of productivity that can be exported from the euphotic zone. Their estimate of global productivity (and specifically, in offshore ocean areas with depths > 200 m) was between 19.1 and 23.7 pg C y^{-1} (based on independent compilations; 14,20), and they also suggested that neritic waters contributed another 3.9 pg C y^{-1}. The higher estimate specifically excluded productivity in polar systems in addition to that of coastal regimes. A later estimate using the Eppley and Peterson compilation suggested that by including Arctic and Antarctic waters global oceanic productivity would equal 27.2 pg C y^{-1} (Table 1; 21). DeVooys (21) estimated oceanic primary production to be about 43 Pg C y^{-1}, a figure which used corrections for release of dissolved organic matter during photosynthesis. Finally, the compilation of Pauly and Christensen (18) suggests that primary productivity of oceanic and coastal waters was 45.1 pg C y^{-1}, significantly above the earlier estimates. Their estimate was based on a theoretical division of the ocean into six ecosystem types. By using the known fisheries yield and by-catch and recalculating the transfer efficiencies, they estimated the primary production required to sustain the fisheries' yield. It is unclear why their value substantially exceeded other estimates.

MODERN APPROACHES TO THE ASSESSMENT OF PRIMARY PRODUCTIVITY

Indirect Measures of Phytoplankton Biomass and Productivity

Since 1980 tremendous advances have been made in the assessment of oceanic phytoplankton biomass using synoptic, whole-ocean assessments of pigment concentrations of the surface layer. These assessments have greatly altered our views of the ocean, in that we know more to fully appreciate the extent of the spatial and temporal changes in phytoplankton biomass, which occur in all areas of the ocean. Such an understanding was simply impossible using ship-based approaches to the determination of phytoplankton biomass. In addition to biomass measurement, a variety of models have taken the biomass and coupled that information with irradiance and predicted photosynthesis-irradiance relationships to produce either local (22–24) or global, synoptic estimates of primary productivity (25). Such estimates are invaluable because they incorporate the true variations in biomass and predict the temporal and/or spatial variations of productivity in the ocean. Although the prediction of productivity is highly dependent on the model used, they are by far the most powerful means to obtain synoptic, large-scale estimates of productivity. Furthermore, they then allow a means to test more refined hypotheses with either field programs or modeling.

Pigment concentrations (a proxy for phytoplankton biomass) can be ascertained by either moored deployments of fluorometers (26–28) or by sensors deployed on satellites. Moored fluorometers continuously measure the fluorescence of chlorophyll in the water at a known depth, and hence precisely assess the variations of phytoplankton in time at one location. Therefore, although they give no information on the spatial distribution of phytoplankton, they collect continuous measurements in time. When combined with ambient measurements of solar radiation and a model predicting photosynthesis as a function of irradiance and biomass, primary productivity can be estimated. This method was used in the Arabian Sea to give a continuous estimate of productivity (Fig. 2). It was found that whereas discrete measurements of productivity showed relatively little variation over the course of a year, predicted productivity ranged from approximately 0.35 to 1.3 g C m^{-2} d^{-1}, a fourfold difference (23). Thus, the ability to measure biomass and irradiance over daily intervals greatly improved the estimate of productivity in the region, as well as the understanding the processes influencing productivity. It has also been used in the western Sargasso Sea (22), and the annual estimate of productivity was 70% greater than historical estimates (29). This increase was probably due to the inclusion of short-term, hyperproductive events that were not sampled with ship-based measurements. As such, the ability of moored sensors greatly improved the precision of the productivity estimate. Furthermore, by providing an appreciation of the variability of these regions, it has facilitated a broad

Table 1. Oceanic Primary Production. Areas of Subregions Are Included in Total Area of Oceans, but Productivity Values Are Not [from W. O. Smith, *J. Mar. Chem.* 35, 245–258 (1991)]

Ocean	Offshore Area ($\times 10^{12}$ m^2)	Primary Production (g C m^{-2} y^{-1})	Total Primary Production ($\times 10^{15}$ g C y^{-1})
Indian	71.0	84	5.96
Atlantic	83.9	102	8.56
Pacific	167	55	9.14
Coastal	0.18	834	0.15
Equatorial	11.3	176	1.98
Antarctic	38.1	—	1.23
Ice edge	16.4	16	0.61
Open ocean	38.1	38	0.62
Arctic	13.1	1	0.13
Totals			27.2

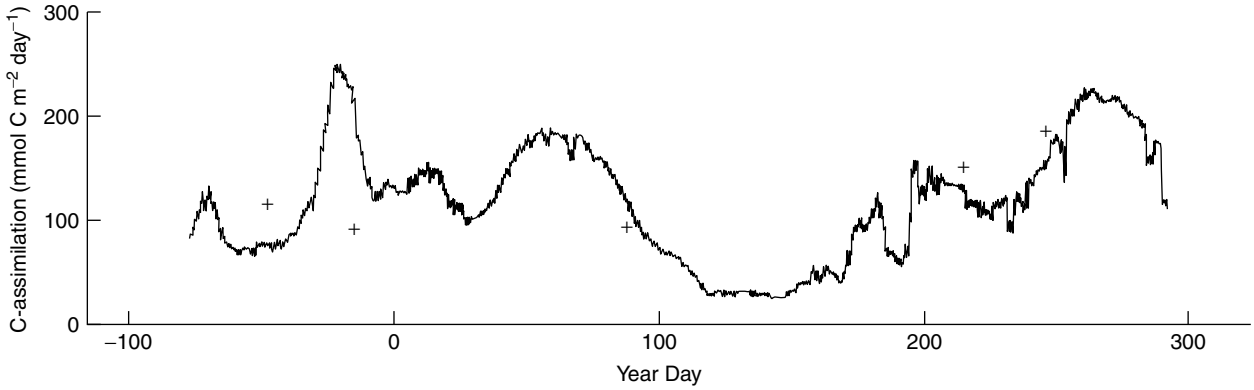

Figure 2. Estimates of primary production calculated from fluorometric estimates of chlorophyll, measurements of incident radiation, and a bio-optical model. Note the substantial variations in daily estimates, and the strong bias introduced by irregularly collected ^{14}C-estimates (+). From [J. Marra and coworkers, *Deep-Sea Res. II* **45**, 2,253–2,267 (1998)].

series of investigations into the productivity of oligotrophic regions and the mechanisms responsible for supporting it (30–32).

It is also possible to quantify pigments from space. The principle of operation is that solar radiation is reflected and spectrally modified according to the amount of pigment in the surface layer of the ocean. The resultant ocean color is quantifiable, and when calibrated with chlorophyll algorithms, relates directly to chlorophyll concentrations. Radiation penetrates to a depth of $1/k$ (where k is the attenuation coefficient in m^{-1} of the water), and this depth is known as an optical depth. Satellites can only see one optical depth, or approximately 22% of the euphotic zone. The attenuation of water is greatest when there is a large amount of particulate matter suspended in the water, and least when few particles and low concentrations of dissolved organic matter are present. Presently, there are two satellites with ocean color sensors operating, SeaWiFS (Sea-Viewing Wide Field of View Sensor) and MODIS (Moderate Resolution Imaging Spectroradiometer). They circle the Earth approximately once per day, and thereby provide ocean color nearly continuously. However, clouds interfere with the determination, and hence not all areas of the ocean are sampled as frequently as others. The resolution of the satellite sensor is approximately 1.1 km.

Generally, pigment data are binned over some time interval to produce a composite image, particularly if a global view of biomass is desired. Conversely, a single image of a cloud-free region can be mapped (Fig. 3). In this SeaWiFS image a fairly substantial phytoplankton bloom was observed in the upwelling region off northwest Africa, with chlorophyll concentrations exceeding 10 $\mu g\,L^{-1}$ in some locations, but with a steep gradient offshore to low values off the continental shelf. Similarly, the pigment concentration in the Gulf of Maine is shown in Figure 4. Not only is a large phytoplankton bloom off Cape Cod observed, but a mesoscale feature called a warm-core ring (33) is also shown off the coast. This feature is an oligotrophic patch of water that is physically trapped in an eddy-like feature, which transports warm water that originated on the eastern side of the Gulf Stream into the cooler coastal waters of New England, and has very low pigment levels. The variability of pigments within a relatively restricted area suggests that there are a number of factors simultaneously operating, which are responsible for controlling regional biomass.

These types of images can also be averaged over longer time periods (days to weeks) to elucidate seasonal trends of phytoplankton biomass. For example, pigment concentrations in the north Atlantic Ocean are known to increase rapidly in May of each year (26,34). Composite satellite images confirm this temporal trend, but also show that the increase is variable in space, producing different patterns at different locations, and also showing

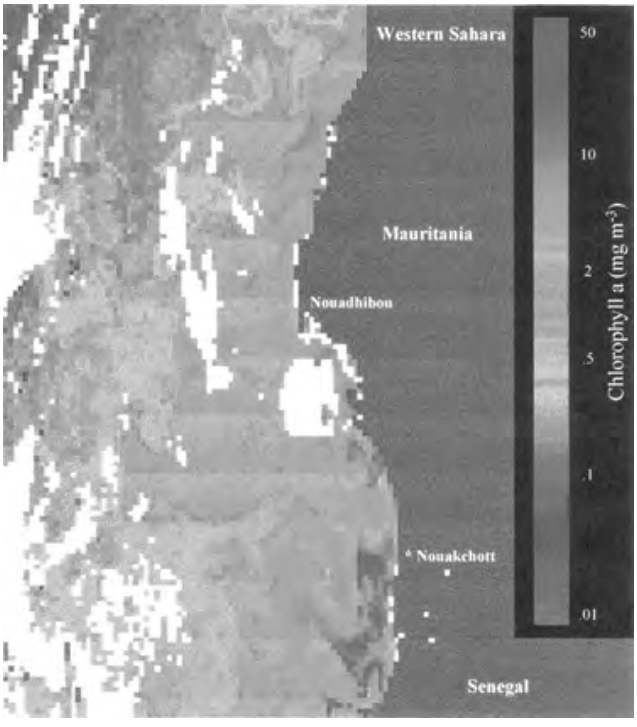

Figure 3. A SeaWiFS image of pigment concentrations off the coast of northwest Africa (March 22, 2001). Note the strong variations both offshore and along shore. See color insert.

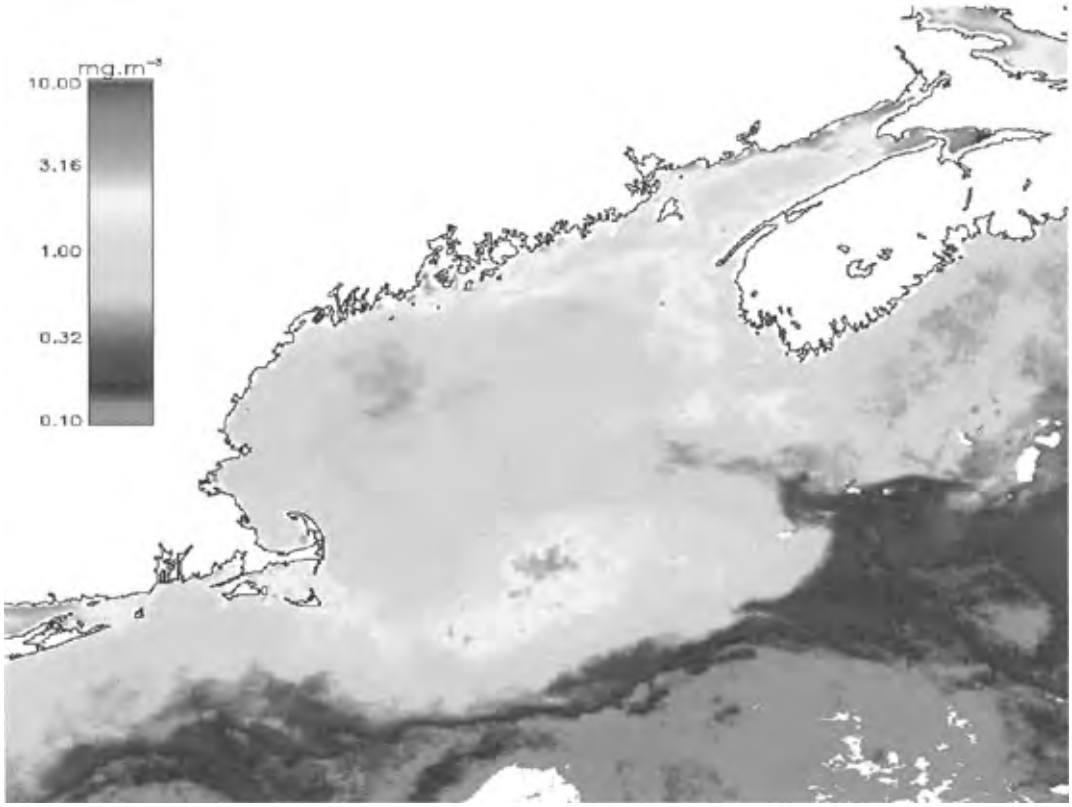

Figure 4. A SeaWiFS composite of pigment concentrations off the northeast coast of the United States (June 18–26, 1999). Note the presence of a large warm-core ring that substantially influences pigment concentrations and productivity. See color insert.

differences between years (Figs. 5a,b). Temporal trends as revealed from satellite images also show the expected south-north progression of the bloom in temperate waters (35,36).

If the biomass at the surface were measured each day and no vertical losses were to occur (via either ingestion or sinking), then the productivity could be estimated by the change in biomass at any location. However, such steady state conditions rarely if ever exist, and so productivity estimates are made in a different manner. In essence, the daily, depth-integrated productivity is modeled (25) using the following as input: (*1*) the pigment concentration of the surface layer (through one optical depth; C_{sat}), (*2*) daily incident solar radiation (photosynthetically active radiation; PAR in mol quanta $\mathrm{m}^{-2}\,\mathrm{d}^{-1}$), E_{o} (*3*) the length of the photoperiod in hours (D_{Irr}), (*4*) the depth of the euphotic zone [Z_{eu}, derived from the pigment concentration in the surface; (37)], and (*5*) the chlorophyll-specific optimum photosynthetic rate [$P^{\mathrm{B}}_{\mathrm{opt}}$ in units of mg C $(\mathrm{mg\ chl})^{-1}\,\mathrm{h}^{-1}$]. The equation relating these variables is as follows:

$$PP_{eu} = 0.66125 \times P^{\mathrm{B}}_{\mathrm{opt}} \frac{E_{\mathrm{o}}}{E_{\mathrm{o}} + 4.1} \times C_{\mathrm{sat}} \times Z_{\mathrm{eu}} \times D_{\mathrm{Irr}} \qquad (2)$$

The two variables in Equation 2 that are difficult to accurately estimate on a short-term basis are Z_{eu} and $P^{\mathrm{B}}_{\mathrm{opt}}$. The depth of the euphotic zone is difficult to predict because in many stratified regions of the ocean the maximum concentration of phytoplankton is found not at the surface but at depth (below the optical depth, which only includes the upper 22% of the euphotic zone). This deep-chlorophyll maximum has been repeatedly observed and occurs in nearly all areas of the ocean (38). Only in areas where vertical mixing is both vigorous and deep (so as to distribute phytoplankton evenly over the timescales of hours to days) is the distribution of pigments vertically uniform. To predict the total euphotic zone chlorophyll concentration from the amount in the upper portion of the layer requires a statistical analysis of a large number of chlorophyll profiles in a variety of regions.

A different approach to the same problem is to divide the ocean into a number of oceanic provinces, and to assume that the phytoplankton distribution within a province is similar throughout (39–41). This approach greatly simplifies the assumptions needed to assess chlorophyll vertical distributions, but also introduces a new set of assumptions (e.g., the spatial domain of oceanic provinces, their continuity in time, etc.). In general, more emphasis today is being placed on treating the ocean as a whole and reducing the variability in the estimates of vertical phytoplankton distribution via satellites.

Uncertainty is also introduced by the variable $P^{\mathrm{B}}_{\mathrm{opt}}$. Behrenfeld and Falkowski, 1997 (25) generated a seventh-order polynomial that related temperature with $P^{\mathrm{B}}_{\mathrm{opt}}$, and used temperature derived from satellite (AVHRR) images of the ocean to predict the optimum rate of photosynthesis.

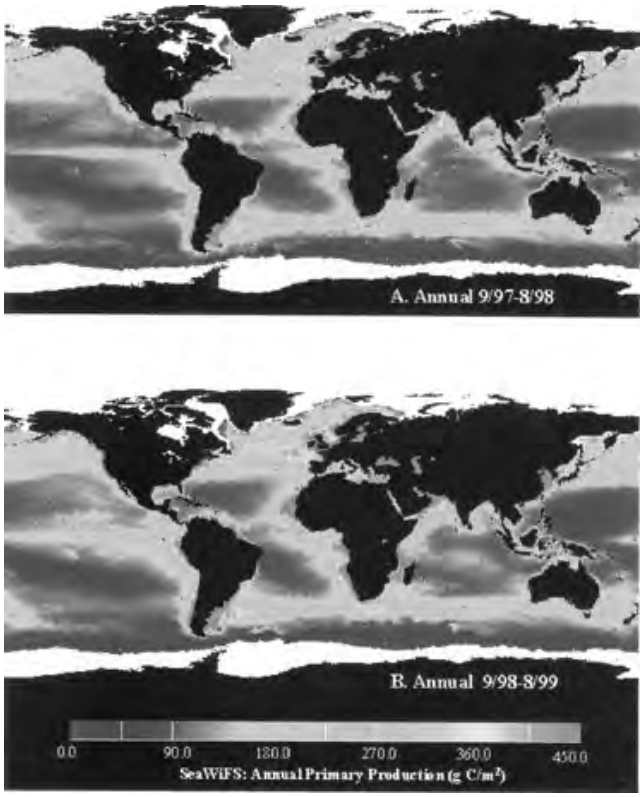

Figure 5. SeaWiFS annual composites of pigment concentrations throughout the ocean. (**a**) 1997–1998 and (**b**) 1998–1999. Strong spatial variations between years are observed, particularly in the equatorial pacific. See color insert.

It was also constrained at low and high temperatures, so that when T is less than $-1.0\,^{\circ}\mathrm{C}$, then $P^{\mathrm{B}}_{\mathrm{opt}} = 1.13\,\mathrm{mg\,C\,(mg\,chl)^{-1}\,h^{-1}}$ (42), and when T is greater than 28.5 $P^{\mathrm{B}}_{\mathrm{opt}} = 4.0\,\mathrm{(mg\,chl)^{-1}\,h^{-1}}$ (43).

Despite these uncertainties, global productivity can now be estimated using daily pigment data and photosynthetic models. Falkowski and colleagues estimate global productivity (2) to be approximately $47.5\,\mathrm{pg\,C\,m^{-2}\,y^{-1}}$ (Fig. 5a). This is substantially more than the analyses derived from discrete samples, and suggests that the productivity of the ocean is greater than thought a decade or more ago. They also investigated the sensitivity of the model to various parameters. For example, if $P^{\mathrm{B}}_{\mathrm{opt}}$ is held constant at a value of $4.54\,\mathrm{mg\,C\,(mg\,chl)^{-1}\,h^{-1}}$, the global productivity decreases by 2.3%. If $P^{\mathrm{B}}_{\mathrm{opt}}$ is generated from the Eppley, 1972 (44) temperature-growth relationship as modified for photosynthesis (43), global productivity decreases by 14.5%. Finally, if clear sky conditions are assumed and photosynthesis is modeled without photoinhibition (a decrease in photosynthesis at high light intensities), productivity increases by 6.1% (*http://marine.rutgers.edu/opp/Production/results/all2. html*). Such changes suggest that the estimates of productivity are relatively robust and are not overly dependent on the details of the model's formulation.

The seasonal changes in productivity can also be quantified using this approach. Global productivity in autumn is dominated by the widespread increase over much of the South Atlantic and South Indian Oceans (associated with the sub-Antarctic and subtropical waters), as well as the intense productivity of the Argentine coast, the coastal upwelling region of southern Africa, the Yellow Sea and the North Sea. The growth in the northern Atlantic and Pacific is also substantial (Fig. 6a). In winter (austral summer) the bloom in the south Atlantic and Indian Oceans intensifies, whereas that in the north Pacific and Atlantic all but disappears (Fig. 6b). Coastal productivity remains similar in the two seasons. In spring the opposite occurs — a large vernal bloom in the northern waters of the Atlantic and Pacific Oceans develops and that in the southern waters dissipates (Fig. 6c). Smaller features also change; for example, the extent of the high productivity region off the northwest African coast increases, whereas productivity in the Arabian Sea declines. In summer the northern bloom is the dominant productivity feature of the world's ocean, with productivity exceeding $50\,\mathrm{g\,C\,m^{-2}\,month^{-1}}$ over large areas (Fig. 6d). The productivity of the Arabian Sea also increased substantially, as did that of the Sea of Okhotsk, the Bering Sea, and the Barents Sea. The spring, summer, autumn, and winter global productivity estimates were 10.9, 13.0, 12.3 and $11.3\,\mathrm{pg\,C\,m^{-2}}$, respectively.

Regional estimates of productivity can also be made using the model (Table 2). The Pacific Ocean, by virtue of its size, has the greatest productivity, followed by the Atlantic, Indian, and Southern Oceans. The Mediterranean Sea contributes about 1% of the annual global production, and the Arctic Ocean (by virtue of the fact that it is largely ice-covered for significant portions of the year) less than 1% of the annual production.

A model similar to that of Behrenfeld and Falkowski (25) has been developed, but this model includes the effects of vertical mixing on the irradiance available to phytoplankton (45). In general, the two models reproduce the same general features, but the productivity derived from the Howard-Yoder model (45) is less than that from the Behrenfeld-Falkowski model due to greater irradiance limitation imposed by vertical mixing. It is presently uncertain which model reproduces the absolute productivity of a region more accurately.

Another method to estimate phytoplankton photosynthesis involves the evaluation of variable fluorescence to infer photochemical characteristics. For phytoplankton, a photon entering the cell can have one of three fates: utilized to drive photosynthesis, dissipated as heat, or reemitted as flyorescence. Thus, a change in active fluorescence can be indicative of a change in the efficiency of photochemistry. In recent years, a number of instruments have been designed primarily for this type of analysis such as Pump-and-Probe (PDP) (46,47,48) fast repetition rate fluorometry (FRRF) (49,50,51), and pulse amplitude modulated fluorescence (PAM) (52,53). These instruments (although they all accomplish this in a slightly different manner) evaluate the quantum yield of photochemistry to estimate phytoplankton photosynthesis. Although these methods are simple in practice, interpreting fluorescence signals in order to relate them to photosynthesis and productivity is complicated, and is still being developed and

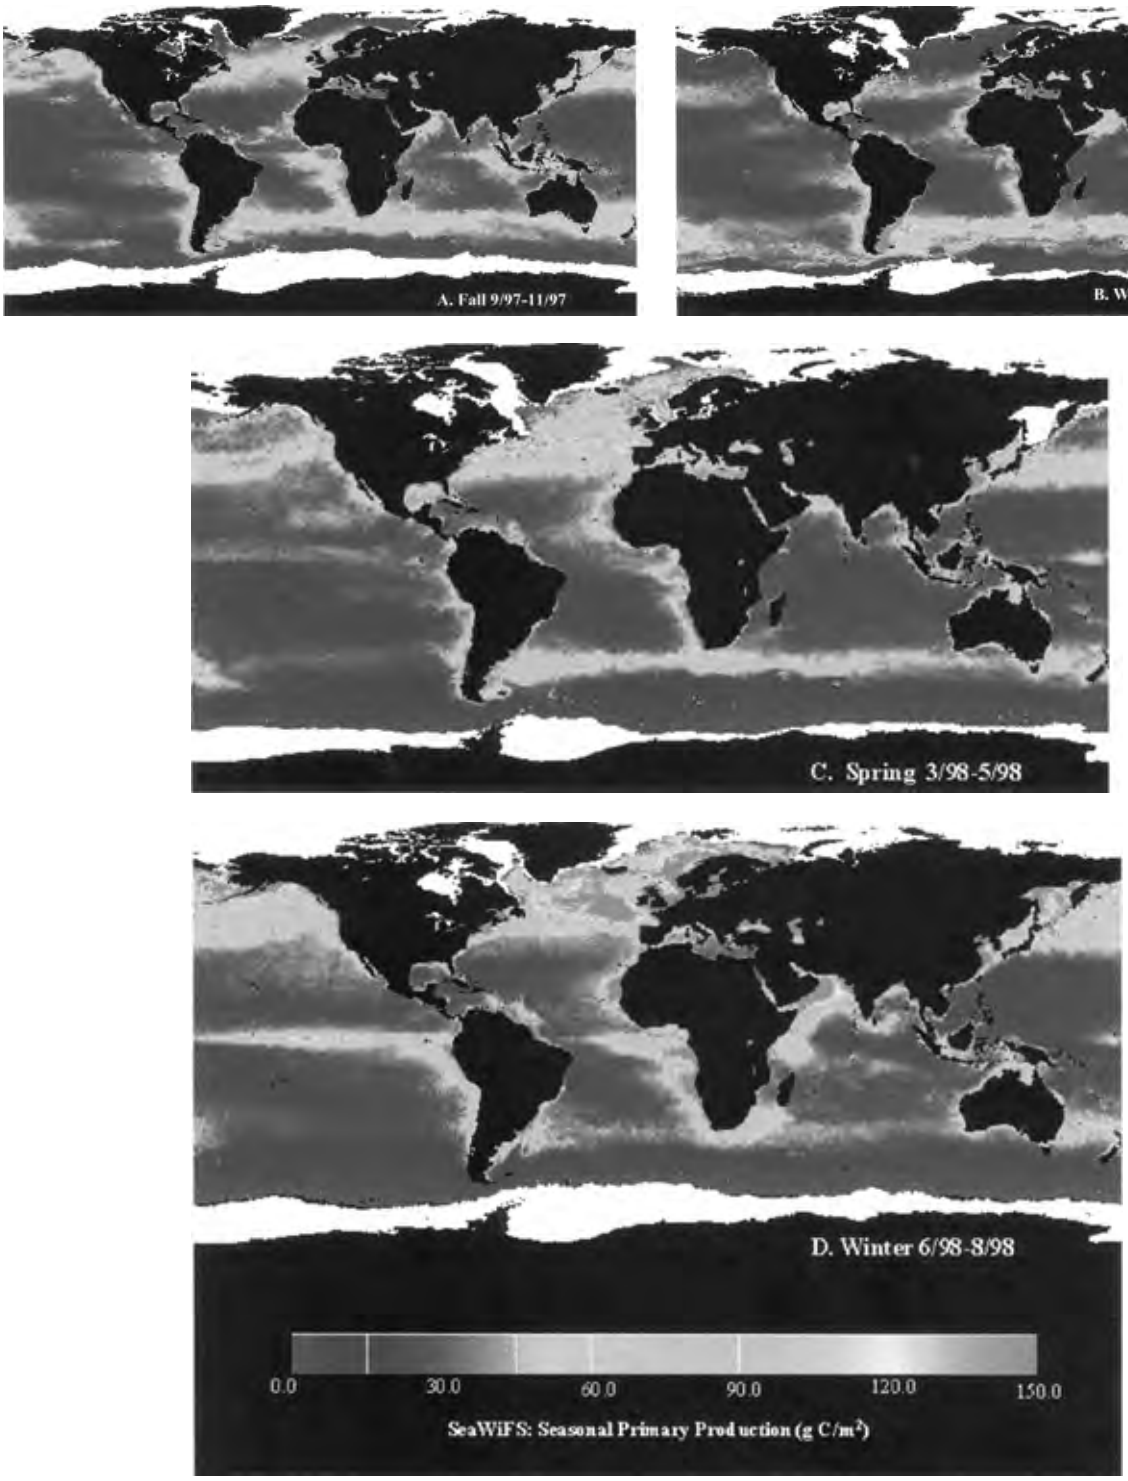

Figure 6. Estimates of primary productivity in (**a**) autumn, (**b**) winter, (**c**) spring, and (**d**) summer derived from satellite pigment estimates, incident irradiance, and the model of [M. Behrenfeld and P. G. Falkowski, *Limnol. Oceanogr.* **42**, 1–20 (1997)]. See color insert.

refined. One model by Kolber and Falkowski (49) estimates gross photosynthetic oxygen evolution normalized to chl a from the quantum yield of photochemistry, the functional absorption cross-section of PSII, the ratio of PSII reaction centers to chl a, the fraction of PSII reaction centers that are viable for oxygen evolution, the quantum yield of photochemistry at a particular light level, and that relative light level. All of these parameters, except for irradiance (which is measured directly) are estimated from fluorescence characteristics (for review, see 54). PAM based methods

Table 2. Regional Estimates of Primary Productivity from the Rutgers OPPT Model (see *http:/marine.rutgers.edu/opp/Production/results/all2.html*). Numbers in Parentheses Represent the Percentage of Global Productivity of Each Region

Region	Boundary	Productivity (pg C y^{-1})
Pacific Ocean	Pacific Ocean Basin, south of 70°N and north of 50 °S	19.7 (42.8)
Atlantic Ocean	Atlantic Ocean Basin, south of 70 °N and north of 50 °S	14.5 (31.5)
Indian Ocean	Indian Ocean Basin, north of 50 °S	8.0 (17.3)
Southern Ocean (Antarctic)	South of 50 °S	2.9 (6.3)
Mediterranean Sea	Mediterranean Sea	0.6 (1.2)
Arctic	North of 70 °N	0.4 (0.9)

can't directly measure the functional absorption cross-section of PSII directly, and therefore this parameter must be estimated spectrophotometrically (55). Because *in situ* fluorescence-based techniques are instantaneous and non-invasive, problems associated with "bottle effects" (when using ^{14}C or O_2 based methods) are eliminated. Another advantage of these types of instruments, especially FRRF, is that they can be towed underway to acquire real-time data for a broad area. Additionally, these types of instruments can be affixed to moorings for temporally refined measurements of phytoplankton photochemical efficiency.

Benthic-Associated Productivity

Benthic primary productivity, although generally limited to shallow shelf waters, can be a significant fraction of marine primary productivity at those locales. Thus, a substantial effort has been made to quantify total global benthic primary production. Bunt (56) hypothesized that benthic productivity equaled 0.65 to 6.5 pg C, which was equal to 2.8 to 28% of total global primary production. A revised estimate from Charpy-Roubaud and Sournia (57) suggested that productivity was closer to 2.89 pg C, or approximately 10% of estimates of total global primary productivity. Contributions to marine benthic primary productivity can be attributed to three broad groups: macroalgae (sea-weeds), including phaeophytes (brown algae), rhodophytes (red algae), and chlorophytes (green algae), microphytobenthic algae (such as diatoms living attached to the sediments), and algae in mutualistic associations, such as zooxanthellae. Excluded from this discussion are epiphytes, ice algae, seagrasses, and salt marshes.

The distribution of macroalgae is, in general, limited by light penetration, secure substrates for attachment, and sufficient physical energy to break boundary layer nutrient gradients (58). Daily carbon fixation rates are thought to be from 5 to 10 g C m^{-2} d^{-1} (59). Annual primary productivity of macroalgal communities was estimated at 1 pg C y^{-1} by Smith (60), while standing stocks were suggested to be approximately 400 times those of phytoplankton. Charpy-Roubard and Sournia (57) projected total global macroalgal production to be 2.55 pg C y^{-1}. These high production rates and limited distributions make sea-weed communities an integral and dynamic part of coastal ecosystems, allowing them to act as nursery grounds for fishes and invertebrates. Given their proximity to land, productivity of sea-weeds is particularly sensitive to anthropogenic eutrophication. Specifically, their productivity can be increased by direct input of nutrients or decreased by the stimulation of phytoplankton biomass through nutrient inputs, which in turn increases attenuation of PAR in the water column and decreasing the PAR available to macroalgal benthic producers.

Mutualistic algae or zooxanthellae — endosymbionts that fix carbon and transfer that reduced carbon to its host, and in return receives nutrients, maintained at a constant irradiance, and protection from predation — are dominated by the Dinophyceae. In general, these dinoflagellates have a biphasic life cycle; a free-swimming motile and a predominant coccoid symbiotic phase. Animal hosts include corals, sponges, radiolarians, foraminiferans, and mollusks. However, for models of primary productivity, high coral densities (10^6 cells cm^{-1}) of zooxanthellae provide considerable carbon fixation, with values close to 0.06 pg C y^{-1} (61). Muscatine and Weis (61) also suggest that if all zooxanthellae-invertebrate relationships were considered, then this number would effectively double.

Members of the microphytobenthos include any unicellular algal species living in or on benthic substrates, although diatoms tend to dominate this group. Microphytobenthic distribution is shallow and dependent on several factors, including size of sediment particles (62) and light and temperature interactions (63). Good global estimates of productivity for benthic diatoms are limited by several factors, including preferential sampling at midlatitude, shallow depths, and soft bottom conditions (57). Charpy-Roubaud and Sournia (57), after analyses of historical data, estimated global productivity to be 100 g C m^{-2} y^{-1}, although these rates varied from 5 to 300 g C m^{-2} y^{-1} from high to low latitudes.

NUTRIENT LIMITATION OF PRIMARY PRODUCTIVITY

Primary productivity can be reduced below maximum rates by a lack of a number of necessary metabolic needs, such as nutrients. Because carbon, nitrogen, and phosphorus assimilation occurs in ratios of 106 : 16 : 1 and

because nitrogen generally occurs (relative to phosphorus) in a slightly smaller ratio (6), it has long been considered that nitrogen limits productivity on short timescales (64). However, the presence of unused surface nutrients in a variety of environments (e.g., the Southern Ocean, the Equatorial Pacific, and Subarctic Pacific) have long perplexed oceanographers. These areas have been termed HNLC (high nutrient low chlorophyll) regions. Proposed explanations for lack of productivity in these areas have been trace metal limitation (65–67), intense grazing and phytoplankton removal (68,69), and advection (70). However, it was not until the development of ultra-clean analytical techniques that it became clear that iron could limit marine productivity. Martin (71) hypothesized that iron limited primary productivity in HNLCs, where the chief source of iron input was from atmospheric deposition. This was later confirmed through a series of in situ open ocean iron enrichments in the Equatorial Pacific (72,73). Since then, other expeditions, such as the Southern Ocean Iron Release Experiment (SOIREE) (74), have confirmed the overwhelming importance of iron in regulating marine productivity. Specifically, geographic variations in productivity (e.g., the contrast between the North Pacific and North Atlantic) are now largely attributed to variations in the influx of iron (both from below and from atmospheric sources).

Phytoplankton Size

The size of a phytoplankton cell can govern metabolic processes and primary productivity (75). This is largely due to the fact that as the size of a cell increases, its volume increases even more rapidly (i.e., smaller cells have a greater surface:volume ratio). If nutrients were supplied by diffusion (or any process linked to the relative surface area of the cell), then the rates of diffusion would be such that nutrients would be supplied more rapidly to smaller cells, thereby allowing them to grow faster than larger cells. Hence, if all other factors were equal, small cells should grow faster than large cells and dominate in the ocean. The fact that large cells do exist in nature, and at times are overwhelmingly important, signifies that larger cells have a variety of mechanisms, which allow them to exist and thrive in a variable environment. Conversely, small cells are apparently ingested rapidly by microzooplankton (such as ciliates and heterotrophic dinoflagellates) and thus can have larger loss rates than larger cells.

Further, the size classes and community composition can determine the quantity and quality of productivity. In the early years of discovery, phytoplankton were divided into two size classes: more than 22 μm (net plankton) and less than 22 μm (nanoplankton). Initial global estimates of primary productivity suggest that the contribution of nanoplankton is 88% (76). In contrast, temporally restricted high productivity events are dominated by net plankton (76,77). With technological advances such as flow cytometry, electron microscopy, and epifluorescence microscopy, a new size class has been introduced to account for very small (<2 μm) species, named *picoplankton*. Since the discovery of the relative high abundance of picoplankton, such as *Synechococcus* and *Prochlorococcus* (78), it is believed that nanoplankton modal size is much smaller (<5 μm). The difference in productivity for these two distinct groups is explained by complex biological and physical factors such as residence time due to upwelling, advection, and grazing, rather than inherent physiological efficiencies (79,80). For example, the nanoplankton size fraction tends to dominate physically stable environments and preferentially utilize ammonium (76,81), whereas the more than 5 μm fraction is most productive in nonsteady state environments (i.e., upwelling events) and primarily utilizes nitrate (76,79,80,82–84).

CONCLUSION

Studies of primary productivity have progressed dramatically in the twentieth century with advancements in technology. Ship-based studies demonstrated that broad patterns in productivity exist, as well as the locations of maxima and minima. However, satellite-based approaches improved the resolution in both space and time and afford us the capability of assessing productivity of regions and ocean basins accurately and repeatedly. As a result, insights into critical societal questions, such as the role of human impact on the global climate cycle, can now be investigated in detail. Understanding both the rate and fate of marine primary production is essential to the effective management of oceanic resources, and undoubtedly will be a focal point of future oceanic research.

Acknowledgments

This review would not have been possible without access to the data of Drs. Paul Falkowski and Paul Behrenfeld, whose efforts in estimating productivity from space have led to tremendous advancements in our knowledge since 1990. This research was supported by NSF grants OCE-0001799 and OPP-0087401.

PROCHLOROCOCCUS

LISA CAMPBELL
Texas A&M University
College Station, Texas

The unicellular cyanobacterium *Prochlorococcus marinus* is the smallest known photosynthetic organism. We now recognize that *Prochlorococcus*, which lives in surface waters of tropical and subtropical regions of the open ocean, is probably the most abundant photosynthetic organism in the ocean. Why had oceanographers overlooked such an important component of the marine plankton? *Prochlorococcus* was not "discovered" until the late 1980s when improved sensitivity in flow cytometry permitted enumeration of these extremely small ($\sim$0.7 μm) cells. *Prochlorococcus* spp. are oxygenic photosynthetic prokaryotes that contain a unique suite of photosynthetic pigments, including divinyl Chlorophylls *a* and *b* (Chl a_2 and b_2), α-carotene, zeaxanthin and, in some cases, true Chlorophyll *b* (Chl b_1) and phycoerythrin. Studies over the past decade have revealed that *Prochlorococcus* dominates the picophytoplankton in tropical and subtropical regions of the ocean. At abundances of 10^5 cells mL^{-1}, they are frequently 10 to 100 times more abundant than their close relatives *Synechococcus*, the oceanic phycoerythrin-containing strains of cyanobacteria. Moreover, *Prochlorococcus* can contribute more than 50% of the total Chlorophyll *a* biomass. Growth rates of approximately one doubling per day are balanced by mortality due to grazing primarily by microzooplankton. *Prochlorococcus* populations make the largest contribution to primary production in the most oligotrophic regions of the ocean; in the Sargasso Sea they can account for an estimated 25% of total primary production, whereas in the North Pacific this percentage can reach 80%. They are found throughout the entire euphotic zone — from the surface to more than 100 m — which indicates *Prochlorococcus* is capable of growth over a broad range of light intensities. High ratios of Chl b_2 : a_2 permit *Prochlorococcus* to optimize growth at low light levels. The success of *Prochlorococcus* has been explained by the coexistence of multiple ecotypes, genetically similar strains (yet distinguishable by Chl *b* : *a* ratios and 16S rRNA and RNA polymerase gene sequences) that are physiologically diverse. *Prochlorococcus marinus* is the only known photosynthetic organism to contain both true chlorophyll *b* and phycoerythrin, so has recently been suggested to be the model for the ancestral photosynthetic bacterium of cyanobacteria and chloroplasts.

DISCOVERY

The unicellular organism that we now recognize as *Prochlorococcus* was first observed as an unknown "red-shifted" chlorophyll *a* derivative by Gieskes and Kraay in 1983 (1). Using high-performance liquid chromatography (HPLC) to characterize this unknown pigment, they detected 90 to 170 ng L^{-1} at stations in the oligotrophic eastern and western tropical Atlantic, but found none at stations in the North Sea (1). Moreover, it appeared that all of this novel pigment was associated with particles less than 1 μm, as was a large fraction of the carotenoid zeaxanthin, a photoprotective pigment. Small nonflagellated fluorescent cells were observed by epifluorescence microscopy that obviously were not *Synechococcus*. The unicellular *Synechococcus* cyanobacteria are easily identified by their characteristic bright orange phycoerythrin fluorescence, and at the time of this study *Synechococcus* were thought to be the dominant and ubiquitous photosynthetic picoplankton (2,3). Interestingly, three different cyanobacterial ultrastructural cell types had been described by Johnson and Sieburth in 1979 (3); however, the identity of the novel, small cells remained unknown.

In 1987, after flow cytometry was applied in oceanographic research and instruments were taken aboard research vessels for sea-going observations, Chisholm, Olson, and their coworkers reported finding numerous weakly fluorescing cells at the base of the euphotic zone (4). The discovery of this previously overlooked, abundant group of photosynthetic picoplankters "visible" only by flow cytometry was a major discovery in oceanography (4). The tiny cells were detected at depths corresponding to peaks in a divinyl-chlorophyll *a* pigment (Chl a_2) and chlorophyll *b* (Chl b_1); thus, it was proposed that these cells were free-living representatives of the prochlorophytes. The Prochlorophyta (5) had been proposed as a new algal division following the discovery of *Prochloron*, a photosynthetic prokaryote containing both true chlorophyll *a* (Chl a_1) and *b* (Chl b_1) that is found only as a symbiont in some tropical colonial ascidians (Didemnidae) (see section on "Phylogeny").

Other teams of oceanographers made similar observations of abundant red-fluorescing cells. Li and Wood (6) observed "very small red fluorescing (VSRF) bodies" in the central north Atlantic (31 to 34 °N) using both epifluorescence microscopy and flow cytometry. Although they could not positively identify cells by flow cytometry, they suspected the cells were not the small eukaryotes typically observed (7) because abundances (up to 10^4 cells mL^{-1}) of these weakly fluorescent cells were so much greater than the typical small eukaryotic algae. Similarly, Neveux and coworkers (8) observed abundant "green photosynthetic bacteria" (0.7×10^5 to 1.2×10^5 cells mL^{-1}) at the deep chlorophyll maximum layer ($\sim$100 m) in the Sargasso Sea (20 to 30 °N along 61 °W). The major pigments of these tiny cells were identified as divinyl chlorophyll *a* (Chl a_2) and a Chl *b*-like pigment. Because these free-living coccoid cells

differed considerably from other known prochlorophytes, specifically in their unusual pigment composition, these researchers suggested this novel cell type belonged to a new class of photosynthetic prokaryotes (8). Furthermore, given the high abundance of these prokaryotes, Neveux and coworkers speculated they were similar to cells identified by ultrastructural examination in 1979 by Johnson and Sieburth (Type II and Type III cells, (3)). In fact, Johnson and Sieburth stated that Types II and III appeared to be difficult to culture and probably did not contain phycoerythrin (3).

By 1990, two isolates of this novel organism had been brought into culture, and both were assigned to the genus *Prochlorococcus*. The first culture of *Prochlorococcus* was isolated by B. Palenik in May 1988 from a depth of 120 m in the Sargasso Sea and so is known as *SARG* (9). A clonal isolate of *Prochlorococcus* was obtained by serial dilution of the SARG culture and was added to the Culture Collection of Marine Plankton (CCMP) as CCMP1375 (also known as *SS120*). CCMP1375 was designated as the type strain for *Prochlorococcus marinus* in the first formal description of *P. marinus* published in 1992 (9). Note, however, this strain is not clonal in a strict microbiological sense, that is, growth from a single colony grown on agar plate, as growth on agar plates has not been successful, despite numerous attempts by several laboratories (9,10).

The second culture of *Prochlorococcus* was established in January 1989 from Mediterranean surface water near the Rhone estuary and was designated *MED* (11,12). A clonal strain, CCMP1378 (also known as *MED4*), was also obtained by serial dilution and documented in 1992 (9). These two strains represent distinct physiological genotypes, or ecotypes, whose differing physiological properties appear to be consistent with conditions from which each was isolated. Over the past decade, a considerable number of additional high- and low-light isolates have been obtained from the Atlantic, Pacific, and Indian oceans (12–14).

In 2000, the first axenic *Prochlorococcus* strain became available (10). This represents a major achievement. Success in obtaining a pure culture free of any contaminating bacteria was a long arduous process combining serial dilution to obtain a single-cell "clone" together with centrifugation to remove a larger, heterotrophic bacterial contaminant (10). The new strain was named *Prochlorococcus marinus* subsp. *pastoris* subsp. nov. (10). Interestingly, this *Prochlorococcus* strain, although derived from the original SARG culture, has turned out to be more similar to the CCMP1378 (MED4) clone. Thus, it may have been a minor component of the parent culture that was positively selected for in the cloning process (10). The considerable number of differences in the physiological and morphological properties between this new strain and the Type strain CCMP1375 justify its classification as a subspecies. After additional review, this subspecies may be reclassified as a second species of *Prochlorococcus* (10). The axenic strain is available through the Pasteur Culture Collection of Cyanobacteria (PCC9511) or the American Type Culture Collection (ATCC 700925) (10).

Rules of microbial nomenclature require that the formal description of a new genus must be published in the *International Journal of Systematic and Evolutionary Microbiology*. A "type strain" must be designated when a name is first published. Recognized names are then published in the "List of Bacterial Names with Standing in Nomenclature" (*http://www.bacterio.cict.fr/*). Both the genus *Prochlorococcus* and the species *Prochlorococcus marinus* are not yet valid because they have not been published under the Rules of the Bacteriological Code (1990 Revision), but recognition will undoubtedly soon follow the publication and validation of PCC9511.

METHODS OF DETECTION AND CULTIVATION

Beginning with the first discoveries, HPLC and flow cytometry have remained the standard and most reliable methods employed for detection and enumeration of *Prochlorococcus*. Electron microscopy has also been crucial to the identification of these prokaryotic cells (see section on Ultrastructure), but it is not practical for routine quantitative oceanographic studies.

High Performance Liquid Chromatography (HPLC)

Reverse-phase high performance liquid chromatography (HPLC) is a rapid method to separate the chlorophylls and carotenoids present in marine phytoplankton. The ternary gradient method of Wright and coworkers (15) is the standard method, but has been modified and improved over the past decade (16–20). Chromatography methods rely on differences in partitioning behavior between a flowing mobile phase and a stationary phase to separate components in a mixture. In reverse-phase HPLC, the more polar compounds pass through the column faster, whereas the less polar compounds (e.g., α-carotene, Chl *a* and Chl *b*) spend a greater amount of time in the column and so have longer retention times. As pigment components elute from the column, they can be quantified with an absorbance detector at 436 nm. Monovinyl and divinyl chlorophylls cannot be completely separated by the reverse-phase HPLC, so to quantify these two forms either the normal-phase method of Gieskes and Kraay (1) can be used (but this is not routinely used for oceanographic measurements) or an on-line diode array spectrophotometric method so that different wavelengths can be monitored (16,18).

In the field, samples for HPLC analysis are collected onto glass fiber filters (Whatman GF/F) which retain 98 to 99% of all *Prochlorococcus* cells (21,22). Filters must be stored frozen at $-80\,^{\circ}C$ until analysis to prevent pigment degradation. Using pigment characterization by HPLC, the composition of the phytoplankton community can be determined (23,24). CHEMTAX (CHEMical TAXonomy) is a popular program written for MATLAB™ that allows calculation of phytoplankton community assemblage composition using pigment concentrations and ratios of marker pigments (25). The investigator provides initial diagnostic pigment ratios, and by iteration the program will arrive at actual ratios which best fit the data. This way the composition of the phytoplankton community biomass (expressed as a percentage of total chlorophyll) can be calculated. Since the recognition of *Prochlorococcus*

as an important member of the microbial community, algorithms used to partition the chlorophyll biomass have been modified to accurately reflect both *Prochlorococcus* and *Synechococcus* (23,24).

Flow Cytometry

Because *Prochlorococcus* cells are extremely small they cannot easily be distinguished from other bacteria by light microscopy. The autofluorescence of *Prochlorococcus* is also extremely faint because of their size, so accurate enumeration by epifluorescence microscopy is difficult, if not impossible, except in samples from the deepest portion of the water column where cell fluorescence is brighter. Consequently, flow cytometry is necessary for positive identification and accurate quantification of *Prochlorococcus*. Flow cytometry has become a well-recognized, if not essential, tool in the study of marine microbial ecology since the early 1980s (26–32). In flow cytometric analysis, cells pass through a focused laser in single file. A pressurized sheath, or carrier fluid, ensures laminar flow to maintain alignment of the cells. For each particle, both light scatter (related to cell size) and fluorescence parameters can also be collected. In Figure 1, the optical layout for a typical benchtop instrument, such as the FACSCalibur flow cytometer (Becton Dickinson, San Jose, California) is shown to illustrate the partitioning of fluorescence signals. The "red fluorescence" signal (fluorescence >640 nm) is related to cellular chlorophyll content (see section on Vertical Profiles in the following text) and can be useful to compare populations during time-course or nutrient addition experiments, for example, reference (33), over multi-year time series, for example reference (34), and to distinguish subpopulations, or ecotypes, of *Prochlorococcus*, for example references (35,36). Data are plotted as two parameter histograms to identify populations. The small scatter and red fluorescence signals (Fig. 2) distinguish *Prochlorococcus* as a unique population. Green-fluorescing DNA-specific dyes can also be used to stain a sample to quantify cellular DNA content for cell cycle analyses (see section on Growth). Thus, in addition to enumerating cell abundances, it is possible to quantify cell "size" and chlorophyll or DNA content as well. Although there is not always a direct linear relationship between cellular fluorescence and pigment content, for instance, reference (37), the red fluorescence of *Prochlorococcus* can be used to indicate relative changes in pigment over time, for example reference (38). Using this parameter together with FALS, see reference (39), one can infer a physiological response to environmental change. For example, in the Equatorial Pacific increased cellular fluorescence was observed as a tropical instability wave passed through the study site stimulating phytoplankton growth (38).

The extremely dim fluorescence of many surface populations of *Prochlorococcus* can make it difficult to resolve these populations from the background noise. Olson and coworkers (40) improved the sensitivity of an older EPICS V instrument (Coulter) by replacing the beam shaping optics with a confocal lens to obtain a smaller beam spot, decreasing the sheath pressure to obtain a lower flow rate, running the laser in "all lines" mode to obtain up to 4 W of power, and using a new flow cell designed with a lens and mirrors to increase the signal detection. With this type of configuration, surface populations of *Prochlorococcus* could be resolved in the oligotrophic subtropical North Pacific (35). In many newer instruments, optimizations in the optics have been significant, but in moving to an air-cooled laser in bench top instruments, such as the FACScan or FACSCalibur (Becton Dickinson), the laser power is much reduced. To improve the sensitivity of the FACScan, Dusenberry and coworkers (41) also changed the optics to decrease the laser spot size at the interrogation point, but this necessitated decreasing the flow rate as well. The consequence of these changes is that the overall time of sample analysis increases. Sensitivity of commercial instruments remains a limitation for detecting dim surface populations (12). Samples for flow cytometric analyses can be examined live, or fixed and frozen for analysis on return to the laboratory (42,43). Frozen seawater samples must be stored at $-80\,^{\circ}C$ to preserve the chlorophyll autofluorescence.

Cultivation

Cultures of *Prochlorococcus* have been grown in both enriched seawater and artificial seawater-based media (9,10). The original strains were grown in a modified "K" medium (44) using both urea and ammonia as

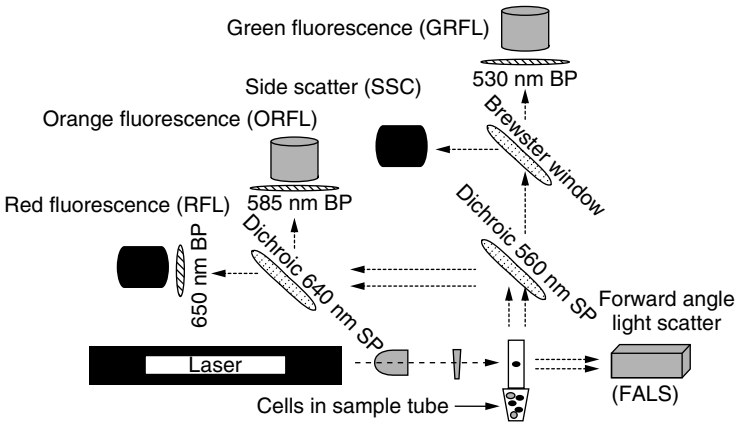

Figure 1. The optical configuration of the FACSCalibur (Becton Dickinson) flow cytometer used in analysis of photosynthetic picoplankton including *Prochlorococcus*. Laser provides blue light (488 nm) for excitation and as cells pass through focused laser, light is scattered. Detectors collect light scattered at small forward angles (FALS) and at a 90° angle, or "side scatter" (SSC). Fluorescence of cellular pigments is also collected. Using short pass (SP) dichroic mirrors — optical filters that pass all wavelengths of light shorter than stated cutoff and reflect all longer wavelengths — three different fluorescence signals 'colors' can be collected: red (chlorophyll), orange (phycoerythrin), and green fluorescence. Band pass filters (BP) are also used to further restrict wavelengths directed to each detector.

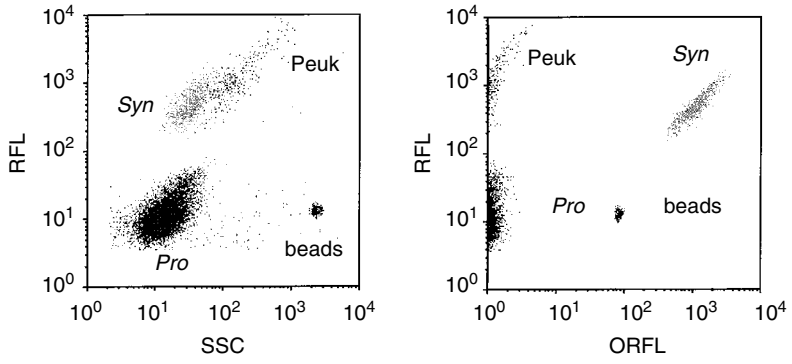

Figure 2. Cytograms for field samples of photosynthetic picoplankton collected in the eastern Gulf of Mexico at 27.50 °N 85.40 °W (August 1999). Data are plotted as 2-parameter histograms, "SSC versus red" and "orange versus red," to identify each population. *Prochlorococcus* (*Pro*) is distinguished from the larger picoeukaryotes (Peuk) by the smaller scatter (SSC) and chlorophyll (RFL) signals. *Prochlorococcus* is distinguished from the phycoerythrin-containing *Synechococcus* (*Syn*) by the absence of orange fluorescence (ORFL). Standard beads are added to all samples.

nitrogen sources, an organic phosphorus source, and eliminating copper from the trace metal mix (9). The "PC" medium (Bigelow Laboratory; *http://ccmp.bigelow.org/*) is similar (Table 1). The "Pro2" medium (13), which has been used successfully to isolate and maintain a variety of isolates, differs in that it utilizes inorganic phosphorus and lacks vitamins. The "PCR-S11" medium was designed during the task of achieving an axenic isolate. Modifications to provide greater maximum cell densities were investigated, including growth on ammonia as the sole nitrogen source and additional trace metals. These changes have been employed successfully in the new "PCR-S11" medium for the PCC9511 culture (Table 1) (10).

DESCRIPTION

Size

Prochlorococcus cells are extremely small. In the first formal description of *Prochlorococcus* by Chisholm and coworkers, the size of *Prochlorococcus* was estimated to be 0.6 to 0.8 μm in diameter and 1.2 to 1.6 μm in length (9). Initial field observations showed that most cells passed through a 0.8-μm Nucleopore filter but were retained on a 0.6-μm filter (4). Size measurements of cultures using the Coulter Multisizer ranged from 0.4 to 0.6 μm in width and 0.5 to 0.8 μm in length (39). For the axenic culture PCC9511, cell size was reported to range from 0.5 to 0.6 μm in width and 0.7 to 0.8 μm in length for newly divided cells, and up to 1.2 μm in length for cells ready to divide (10).

Ultrastructure

The prokaryotic nature of *Prochlorococcus* was established from transmission electron microscopy (TEM) images published in the initial report of their discovery (4). The cellular organization of these unicellular organisms shows a gram-negative-like cell wall and lack of a nucleus. Most of the DNA is concentrated in a central nucleoid area, a trait it shares with *Prochlorothrix*, but not Prochloron (45). The thylakoids, which house the light-harvesting and photosynthetic electron transport reactions, are arranged in closely spaced layers around the outer portion of the cell, parallel to the cell wall (Fig. 3). The fine structure of this internal membrane system differs between the two types of strains, or ecotypes. In the Type strain CCMP1375 and other low-light strains, the thylakoids are visible as concentric circles around the periphery of the cell (Fig. 3). In contrast, in high-light strains, such as CCMP1378 or PCC9511, the thylakoids are

arranged as a "horse-shoe" pattern, i.e., open at one end (10,46).

In cross-sectional views of *Prochlorococcus* CCMP 1375 cultures, the fine structure bears a strong resemblance to the "Type II" cyanobacterium described from TEM images of cells from the chlorophyll maximum depth (~100 m) reported by Johnson and Sieburth in their original description of cyanobacteria in the sea (3). It is now recognized that the low-light strains of *Prochlorococcus* are probably the "Type II" cyanobacteria, as reported by Chisholm and coworkers (9), whereas the high-light strains are probably the "Type III" cyanobacteria reported by Johnson and Sieburth (3,10).

One of the few additional distinguishing features is the presence of carboxysomes, the polyhedral bodies containing the enzyme ribulose bisphosphate carboxylase-oxygenase (RuBisCO), which is the primary CO_2-fixing enzyme of photosynthesis (Fig. 3). Immunolabeling *Prochlorococcus* cultures with probes targeting RuBisCO positively identified the presence of this enzyme (46).

Pigments of the Photosynthetic Apparatus

All *Prochlorococcus* are oxygenic phototrophs, which means they use the energy from sunlight to generate chemical energy and reducing power from water and obtain their cellular carbon requirement by fixing carbon dioxide. As in other phototrophs, light capture is accomplished by light harvesting centers, or antennae photosynthetic pigments. Light quanta absorbed by the light-harvesting complex are transferred to the reaction center, which is where the photochemical reactions occur. Reaction centers associated with antenna proteins are a common feature of photosynthetic systems to allow the organism to absorb a wider range of light energy.

The pigment composition of *Prochlorococcus* is unique, however, and unlike any other prokaryotic or eukaryotic photosynthetic organism (Table 2). Most notable is that all *Prochlorococcus* strains contain divinyl-chlorophyll *a* (Chl a_2), instead of the monovinyl or "true" chlorophyll *a* (Chl a_1) as their main photosynthetic pigment. In Chl a_2, an 8-vinyl group replaces the 8-ethyl group present in Chl a_1 (47). The structural change produces a red-shifted absorption spectrum, which means the maximum peak in absorption occurs at wavelengths that are 8 to 10 nm longer (towards the red end of the spectrum) than Chl a_1. As discussed in the preceding text, this "unknown chlorophyll *a*-like" pigment (1) has since been shown to be identical spectroscopically to Chl a_2 (21).

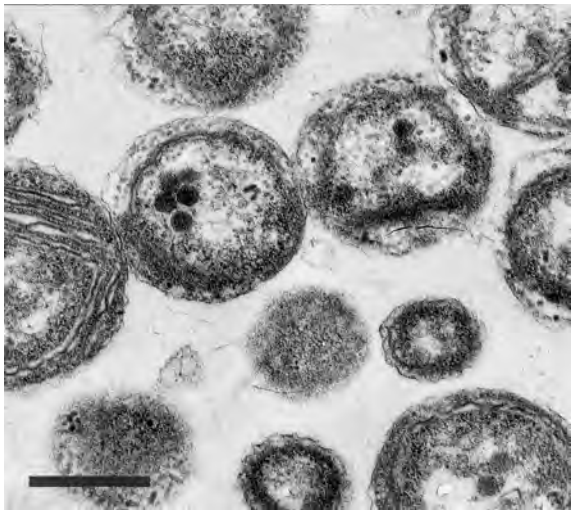

Figure 3. Transmission electron micrograph of *Prochlorococcus* culture, PAC1 (55). Scale bar = 0.5 μm. Sample TEM and photograph generously provided by Marcia Gowing (University of California, Santa Cruz).

The major accessory antenna pigment in *Prochlorococcus* is divinyl chlorophyll *b* (Chl b_2) for which the absorption peak is also red-shifted 8 to 10 nm (21). In addition to Chl b_2, several low-light ecotypes also synthesize monovinyl chlorophyll *b* (Chl b_1), but this only occurs under high-light conditions (Table 2; 11). Although most Chl b_2 in *Prochlorococcus* strains is associated with the light harvesting complexes of PSII, a significant amount is also associated with PSI. This is an unusual feature and is significantly different than the cyanobacteria, which do not have any antenna specific to PSI, and other phototrophs, which do not have Chl *b* associated with PSI (12).

All strains also possess small amounts of a chlorophyll *c*-like pigment. The identity of the Chl *c*-like pigment of *Prochlorococcus* was recently confirmed as Mg-3,8-divinylpheoporphyrin a(5) monomethylester (Mg 3,8 DVP a5) based on the characterization of a field sample from a deep layer of an almost pure "culture" of *Prochlorococcus* found in the suboxic portion of the water column in the Eastern Pacific (see section on Vertical Profiles) (51).

The carotenoids of *Prochlorococcus* include zeaxanthin and α-carotene. Carotenoids are generally considered to serve in a protective role; that is, they function to prevent or reduce photooxidation, the damage by excess visible light (58). Carotenoids are able to quench (inactivate) the excited states of molecules. In most cyanobacteria, zeaxanthin is bound to the phycobiliproteins. In the prochlorophyte *Prochlorothrix hollandia*, zeaxanthin is found between the plasma membrane and thylakoid membrane (59,60), but the location has not been identified *P. marinus*. Because photooxidation can be lethal, cells acclimated to high light generally have high zeaxanthin:Chl *a* ratios. For example, in North Atlantic field populations cellular levels of zeaxanthin in *Prochlorococcus* was constant at about 2 fg cell^{-1} (48). Consequently, the ratio of zeaxanthin:Chl a_2 increased for cells in the upper portion of the water column where light intensity was high. The ratio of zeaxanthin: Chl a_2 ranges from 0.4 to 1.2 in cultures (11) (Table 2).

In *Prochlorococcus*, α-carotene may serve a light-harvesting role as well. Evidence to support this function was seen in culture experiments (11) in which cellular concentrations of α-carotene and Chl a_2 co-vary over a range of light intensities. The exact function, however, has yet to be determined. The presence of α-carotene, typical of eukaryotic algae, is another unique characteristic of *Prochlorococcus* and distinguishes it from *Prochloron* and *Prochlorothrix*, which contain α-carotene (61).

The carotenoid complement of *Prochlorococcus* populations within the suboxic deep fluorescence maximum

layer (see section on Vertical Profiles) included high concentrations of an additional pigment: 7′,8′-dihydro-derivative of zeaxanthin (51). This pigment was identified as parasiloxanthin, a carotenoid that is found in prasinophytes. Intriguingly, both α-carotene and Mg 3,8 DVP a5 are also characteristic of prasinophytes.

A further example of the unusual pigment composition of *Prochlorococcus* is the recent discovery of a novel form of phycoerythrin (PE) in several strains (52,53). Algal biliproteins typically absorb light in the yellow-green regions, where chlorophylls generally absorb poorly or not at all, so extend the light harvesting capability of the cell. Following observations of orange, PE-like fluorescence in cells from below 100 m in the tropical Pacific Ocean, it was suggested *Prochlorococcus* may possess small amounts of a PE-like pigment (52). Subsequent examination of *Prochlorococcus* CCMP1375 identified functional genes for the α- and β-subunits of the PE pigment-protein

complex (52). Although similar to PE-II, the type found in *Synechococcus* which binds a phycourobilin-like pigment as the major chromophore, this novel PE-III differs significantly from previously known sequences of the α- and β- subunits and the presence of a single bilin attachment site on the α-subunit (52). Similar PE-III sequences have also been found in two strains from the North Pacific isolated from the chlorophyll maximum depth (100 m, PAC1 and PAC2) (53). All of these strains are characterized as low-light strains (55). These α- and β-subunit genes are not found in the high-light strain CCMP1378 or isolates from the surface waters of the Arabian Sea (53). The PE-III contains a unique phycourobilin chromophore that absorbs in the blue region (498 nm), which are the only wavelengths of light remaining at the base of the euphotic zone. Thus, this pigment complement would provide a selective advantage to the low-light strains inhabiting these depths.

Given the very low level of expression of the PE genes, the function of PE in *Prochlorococcus* was not immediately apparent in CCMP1375. Low-light *Prochlorococcus* strains lack not only phycobilisomes, but also the required pigments of light energy transfer that occur in cyanobacteria (i.e., the phycocyanin and allophycocyanin pathway to the reaction centers), so its role in light transfer was uncertain. Recently, however, it was demonstrated that in the low-light ecotype CCMP1375 PE-III may in fact serve a light-harvesting antenna function (62). The ability of PE-III to transfer of energy to divinyl chlorophylls was demonstrated by employing a spectrofluorometric assay, but the exact mechanism of energy transfer is still not known (62).

In summary, although *Prochlorococcus* was originally considered a 'prochlorophyte' based on the apparent presence of Chl *b* and absence of phycobiliproteins, the unique pigment composition (*Chl* a_2 and b_2, α-carotene, Mg 3,8 DVP a5, and, in some strains, PE-III) of this organism has distinguished it from the other two "prochlorophytes" and other cyanobacteria.

ECOLOGY

Geographic Distribution

Prochlorococcus can be found throughout the tropical and subtropical regions of the world's oceans. Initial studies of *Prochlorococcus* distribution and abundance focused principally on the North Atlantic (4,40,48). Since then, investigations have confirmed the overwhelming numerical dominance of *Prochlorococcus* worldwide (6,34,63–66). *Prochlorococcus* are most abundant between 40 °N and 40 °S, and their numbers diminish rapidly beyond this range (see Table 3). To date, the most northern latitude at which *Prochlorococcus* have been detected is 60 °N in the Atlantic (64). In the Southern Hemisphere, *Prochlorococcus* have been found at 48 °S in the Atlantic and at 40 °S in the southwestern Pacific, where they were found only at the base of the euphotic zone (67).

The geographical range of *Prochlorococcus* appears to be limited to regions where temperature is greater than 10 to 15 °C (12,64,71). Laboratory experiments have confirmed the temperature preferences of *Prochlorococcus* (see section on Growth); however, other factors may play a role as well. Generally, *Prochlorococcus* is most abundant in oligotrophic conditions, such as the subtropical central North Pacific (34) and the Arabian Sea (65), where nitrate concentrations are very low (<0.1 μM). The limitation of *Prochlorococcus* distribution with respect to nitrate has been reported numerous times and in a variety of oceanic regions (65,66,69,72). Surprisingly, *Prochlorococcus* are abundant in the equatorial upwelling regions of the Pacific and Atlantic (66,73). In the equatorial Pacific, however, abundances were greater during an El Niño-Southern Oscillation (ENSO) event than during normal conditions (73). *Prochlorococcus* are usually absent in

most shallow coastal waters and occurrence is generally negatively correlated with surface nitrate levels (65,74). Note, however, that the high-light strain MED4 was isolated from Mediterranean nearshore waters, just a few kilometers beyond the Rhône estuary. Absence of *Prochlorococcus* is also noted consistently in regions of well-mixed waters (75,76). Additional factors influencing *Prochlorococcus* distributions may be other limiting nutrients or perhaps inhibitory factors (see section on Physiology and Growth).

The occurrence of *Prochlorococcus* in atoll lagoons of the South Pacific was reported for the first time in 2000 (77). However, *Prochlorococcus* contributed only a small percentage (4%) of the biomass (77). Previously, the conspicuous absence of this organism was noted in coastal waters of tropical regions, such as Kaneohe Bay, Hawaii, which is a heavily impacted coastal subtropical bay (74).

"*Prochlorococcus*-like" cells, based on flow cytometric signature (small forward light scatter and chlorophyll fluorescence signals), have also been reported in some freshwater systems. For example, small cells in a eutrophic reservoir in southern Spain were characterized by flow cytometry, but the identity of the cells was not confirmed by HPLC pigment analyses (78). An additional example is the novel occurrence of small, red-fluorescing cells within the surface layer of a stratified saline lake on the island of Molokai, Hawaii. These cells were identified as *Prochlorococcus* based on their flow cytometric signature and the presence of Chl a_2, which was confirmed by HPLC (79).

Seasonal Patterns of Abundance

Given the apparent limitation by water temperature (see preceding text), the geographic distribution of *Prochlorococcus* may vary seasonally in some regions. For example, wintertime deep-mixing events appear to be responsible for seasonal minimum abundances observed in the North Atlantic at the Bermuda time-series station (BATS) (40,80). Conversely, summer/fall increases in abundance noted in a coastal bay in Japan evidently were linked to increased water temperatures, or were perhaps coincident with an intrusion of the Kuroshio (68).

Seasonal variations in abundance are observed for all three groups of the photosynthetic picoplankton community, although the magnitudes of the variations differ among regions. In the Sargasso Sea off Bermuda at 32° 15′N (North Atlantic), Olson and coworkers documented seasonal shifts in community structure that result in the alternation of *Prochlorococcus* dominance. In summer, the *Prochlorococcus*:*Synechococcus* ratio is 10 : 1, whereas in winter the ratio is close to 1 : 1 (40). In the Mediterranean Sea, winter and summer community structure is also considerably different (81). This contrasts with the observations in the North Pacific at 22 °N (34) where *Prochlorococcus* are always numerically dominant and the range in seasonal variation is much smaller. In the subtropical central North Pacific, small seasonal changes are evident for all three components of the picoplankton, not only for cell abundance but also for cellular parameters such as light scatter or pigment fluorescence (34). The difference between seasonal minimum and maximum values in 200-m integrated water column abundances was only twofold for *Prochlorococcus*, up to 10-fold for *Synechococcus* and up to 4-fold for the small eukaryotic algae (picoeukaryotes) (34). In addition, the timing of the seasonal cycles of the picoplankton is not in phase: abundance maxima of *Synechococcus* occur in winter, of picoeukaryotes in spring and of *Prochlorococcus* in summer or fall (34,40). In the Arabian Sea, strong seasonal forcing by monsoon winds produced much larger (up to 10-fold) seasonal and spatial variations in *Prochlorococcus* populations; however, highest abundances occurred during the Intermonsoon (65).

Vertical Profiles of Abundance

Throughout the majority of its range, *Prochlorococcus* abundance is uniform within the surface mixed layer (i.e., the well-homogenized uppermost layer of water characterized by constant temperature and density) and decreases rapidly below. Consequently, as the mixed-layer deepens, *Prochlorococcus* distribution extends deeper in the water column. A good example of the range in vertical distributions was seen in a transect in the eastern tropical Atlantic, where the *Prochlorococcus* uniform surface layer was 30 to 35 m at near shore eutrophic stations, deepened to 50 to 70 m in mesotrophic waters, and extended from 80 to 100 m depths at offshore oligotrophic stations (66). In some cases, there is a slight peak in *Prochlorococcus* abundance at the surface or near the chlorophyll maximum (35).

One of the most interesting features of the *Prochlorococcus* vertical distribution in the ocean is that it can exist successfully throughout the entire euphotic zone (surface lighted layer). In typical oligotrophic regions, where the euphotic zone extends to below 100 m, *Prochlorococcus* cells frequently are found down to 150 to 175 m below the surface (34,66). This represents an extremely broad range of light intensities to which *Prochlorococcus* can acclimate. The observed cellular chlorophyll fluorescence (Fig. 2) can increase up to 50-fold between the surface and deepest portion of its profile (35,38).

Another important feature of the vertical distribution of *Prochlorococcus* is the co-occurrence near the chlorophyll maximum depth of at least two distinct populations. Such "double" populations, each with distinct fluorescence properties, hence termed *dim* and *bright*, were first observed in the North Pacific (35) and in the Equatorial Pacific (38). Using the DNA-specific stain DAPI to investigate the DNA content of cell type, results confirmed they were two distinct populations with a slightly different DNA content (see section on Genome) (35). Subsequently, cultures of each cell type were established by flow cytometric sorting (36). The distinct fluorescence properties of each type have been maintained even after a number of years in culture. Physiological differences of these two cell types have also persisted in these strains and serve to distinguish the "dim" strains isolated from surface high-light and the "bright" strains isolated from the low-light depths. The physiological properties of these "ecotypes" (see section on Physiology and Growth) may

explain the vertical profiles observed and generally are consistent with their depth of isolation.

Suboxic Environments

Unusual vertical profiles have been observed within suboxic waters of the oxygen minimum zones in the Arabian Sea and eastern tropical North Pacific. Here, deep populations of *Prochlorococcus* were detected as discrete peaks or layers of almost "pure" cultures (51,82). The layers occurred between 80- and 140-m depths and were identified as "secondary fluorescence maxima" in profiles of in situ chlorophyll fluorescence. The "deep chlorophyll fluorescence maximum" is a common feature throughout the open ocean and most frequently seen at the base of the euphotic zone (where light is reduced to 1% of the surface irradiance, 1% I_0). These novel secondary fluorescence maxima occurred in suboxic waters at irradiances ranging from less than 0.1 to 2% of the surface irradiance. Initially, it was unknown if these secondary fluorescence populations could be growing at such low light intensities.

In the eastern tropical North Pacific, the biomass within the secondary fluorescence maximum made a significant contribution to standing stock of phytoplankton. Conversely, in the Arabian Sea this deep population apparently was only a small fraction of the biomass, and therefore thought to contribute little to primary production in this region (51). In situ experiments conducted in the Arabian Sea, however, suggested these populations may be more dynamic than predicted. Results from photosynthesis versus irradiance response curves indicated cells within this secondary fluorescence maximum are in fact an efficient population that is adapted to extremely low light (as low as 0.02 to 0.05% surface irradiance) because of their increased light absorption capabilities. Johnson and coworkers (82) suggested several possible hypotheses to explain these observations. The suboxic conditions could be inhibitory to microzooplankton grazers, thus the increased abundance of *Prochlorococcus* could be due to reduced grazing. Alternatively, the spatial variability or discontinuity in environmental conditions could lead to layering, suboxic conditions could produce enhanced growth, or physical mechanisms of aggregation might be operating to create the observed features.

Goericke and coworkers (51) suggested that as only *Prochlorococcus* thrive in this secondary fluorescence maximum layer, whereas both *Prochlorococcus* and eukaryotic picoplankton coexist in and below the primary chlorophyll maximum layer, the low oxygen concentrations of the secondary fluorescence maximum must be a crucial factor. However, they were not able to identify a particular physiological function that would be affected by low oxygen levels in eukaryotes but not in *Prochlorococcus*. There is no evidence for anoxygenic photosynthesis in *Prochlorococcus* (59); however, the capability for utilizing hydrogen sulfide as an electron donor for photosynthesis has been observed in other cyanobacteria species (83).

Contribution to Community Structure

Prochlorococcus are the numerically dominant members of the photosynthetic plankton community throughout most of the subtropical central gyres of the Pacific and Atlantic oceans. Abundance typically ranges from 100 to 500×10^3 cells mL^{-1} (Table 3), which greatly outnumbers all other picoplankton groups (34,40,84,85). Maximum abundances occur in nitrate-depleted, oligotrophic regions of the ocean. The highest cell abundance ever reported (700×10^3 cell mL^{-1}) was observed in the Arabian Sea during the Intermonsoon (65); the highest level of the *Prochlorococcus* marker Chl a_2 (up to 300 ng L^{-1}) was also measured during this season in the Arabian Sea (19).

In oligotrophic regions, the abundance of *Prochlorococcus* is usually 100-fold greater than *Synechococcus*; whereas in mesotrophic and coastal areas *Synechococcus* populations exceed *Prochlorococcus*. Thus, there appears to be an inverse relationship between *Prochlorococcus* and *Synechococcus* abundance (35). In fact, *Prochlorococcus* is frequently absent in coastal samples. The ratio of *Prochlorococcus:Synechococcus* abundance, therefore, can provide an index of community structure, with higher ratios indicative of more oligotrophic environments, see for example reference (65). This relationship appears to be consistent worldwide, with the exception of observations the Arabian Sea where monsoonal influences may affect the distributions (Fig. 4).

Total nonpigmented, heterotrophic bacteria typically occur at abundances of 10^6 cells mL^{-1} in open ocean regions. *Prochlorococcus* represents approximately 30% of the "total" bacteria throughout the euphotic zone of oligotrophic waters (43); however, this percentage is lower in the Equatorial Pacific (~20%) and at the Bermuda Atlantic Time Series (BATS) site (~10 to 20%) (38). Surface, dimly fluorescent populations of *Prochlorococcus* can be difficult to distinguish from the nonpigmented heterotrophic bacteria with standard epifluorescence microscopy and so may be counted as heterotrophic bacteria (43). Enumeration is more accurate using flow cytometry to analyze samples stained with a DNA-specific dye such as the UV-excitable dye Hoechst 33342 or the blue-light excited SYTO13 and SYBR dyes (86,87). In dual-beam analysis of Hoechst 33342-stained cells, the two lasers are tuned so that both DNA and chlorophyll fluorescence can be detected. Thus, heterotrophic bacterial cells (DNA-fluorescence signal only) can be distinguished from *Prochlorococcus* cells (both DNA-fluorescence and chlorophyll fluorescence signals) (43).

In terms of the total photosynthetic biomass, *Prochlorococcus* and cyanobacteria together account for more than half of the total Chl *a* biomass in many oligotrophic regions of the world's oceans (19,23). *Prochlorococcus* alone contributes an average of 67% of the estimated photosynthetic carbon biomass in the biomass in the subtropical North Pacific (65). The contribution by *Prochlorococcus* is the greatest in the most oligotrophic waters (33,88,89). In the Equatorial-Pacific *Prochlorococcus* contributed an estimated 41% of microbial C during an El Niño event (38), which greatly exceeded estimates of their contribution in the North Pacific (88). The contribution of *Prochlorococcus* to total gross primary production increases as the

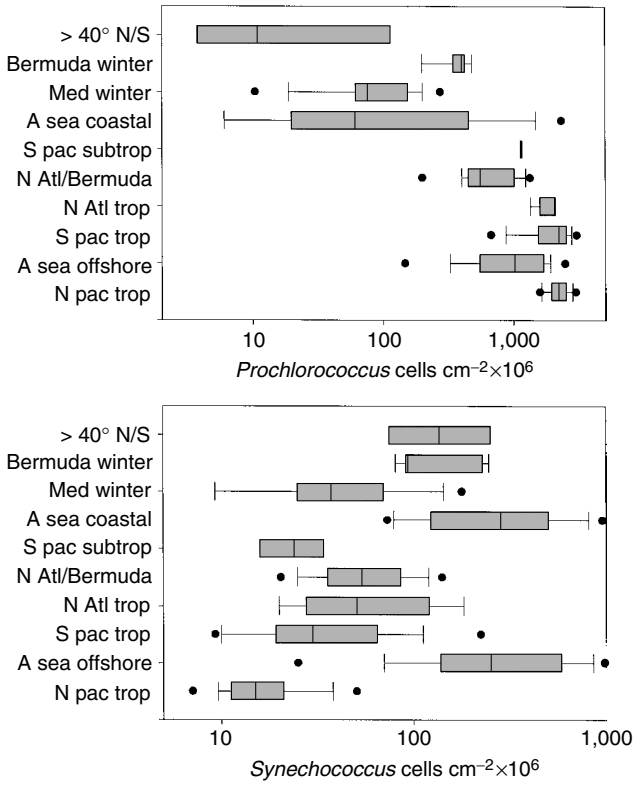

Figure 4. The inverse relationship between *Prochlorococcus* versus *Synechococcus* distributions is seen by comparing 200-m integrated abundances. Data are shown as a box-plot in which observations for each location are centered about the mean (indicated by the vertical line within box) and the 5th and 95th percentiles are shown as error bars, with data beyond these percentiles shown by filled circles. *Prochlorococcus* is more abundant in oligotrophic (tropical) regions of the open ocean, whereas *Synechococcus* exceeds *Prochlorococcus* abundance in mesotrophic waters and coastal areas. Data from selected sites in the Pacific (Pac), Atlantic (Atl), Mediterranean Sea (Med), and Arabian Sea (A Sea) as listed in Table 3 modified from reference (35).

euphotic zone of the water column becomes more oligotrophic. For instance, *Prochlorococcus* contribution was only 9% in the relatively nutrient-rich eastern Equatorial Pacific, but contributed 39% in the western Equatorial Pacific and 70 to 80% in the oligotrophic subtropical North Pacific (88). Similarly, the *Prochlorococcus* contribution was not appreciable in the Arabian Sea where nitrate was measurable in surface waters (90), but was 45 to greater than 90% in the Equatorial Northeastern Atlantic (66). Often, however, the small eukaryotic algae (picoeukaryotes) make the largest contribution to primary production (91).

A variety of conversion factors have been employed to estimate carbon biomass of each planktonic component and the contribution of each to total microbial biomass (89). Factors may vary under different growth conditions, so estimates from different studies may not always be directly comparable. Assumptions need to be carefully considered and viewed in terms of constraints by total particulate organic carbon and primary production.

PHYSIOLOGY AND GROWTH

Our knowledge concerning the factors that regulate the abundance, distribution, growth, and physiological status of *Prochlorococcus* in the open ocean remains limited. Here, known physiological and growth properties are discussed, and wherever possible the properties for the two ecotypes are contrasted (Table 2).

Temperature

One of the most significant factors to influence the large-scale distribution pattern of *Prochlorococcus* may be temperature, as discussed in the preceding text (see section on Distribution). Experimental work supports this hypothesis. In experiments designed to determine growth temperature optima, differences were observed in the temperature ranges of high- and low-light strains (50). Optimum growth occurred at 24 °C for both strains, however MED 4 was able to grow at 12.5 °C, whereas the minimum temperature for growth of SS120 was 15 °C (Table 3). Growth was observed up to 27 °C in culture; however, in field populations growth occurs at much higher temperatures. This suggests, again, that more than one ecotype of *Prochlorococcus* must exist among field populations.

Light

Growth of photosynthetic organisms is strongly linked to and limited by the availability of light (50). Growth of *Prochlorococcus* is tightly phased to the light-dark cycle (see section on Cell Cycle Analysis; Fig. 5), so that strong diel variations in abundance are observed (88,92). Cell division occurs after sunset, so that maximum cell abundances are observed around midnight, after which concentrations decrease until reaching a minimum the following afternoon. As division begins again prior to sunset (1,600 to 1,800 hours), cell abundance increases (88). Maximum growth rates have been observed at approximately 15% of the surface irradiance (88).

The success of *Prochlorococcus* throughout the entire euphotic zone suggests they have adapted to growth over a wide range of light intensities: from less than 1 μmol quanta $m^{-2}\,s^{-1}$ at the deepest occurrence up to near 2,000 μmol quanta $m^{-2}\,s^{-1}$ at the ocean surface. Several physiological properties of *Prochlorococcus* confer a definite selective advantage for growth under extreme low light levels at the base of the euphotic zone. The ability for photoacclimation is seen in the large increase in chlorophyll fluorescence per cell, often 50-fold, which suggests a significant increase in pigment per cell (35,40). In addition, the pigment complement of *Prochlorococcus* is consistent with growth at low light intensities because of the high Chl $b:a$ ratio. Strains with a high Chl $b:a$ ratio are optimized for absorption of blue light, which are the only wavelengths that penetrate to depth in the ocean (50). Flow cytometric measurements of *Prochlorococcus* populations reveal an extremely large

range in the ratio Chl b : Chl a_2. (note that Chl b measurements often include both b_1 and b_2). For example, ratios of Chl $b:a$ of 0.91 to 5.4 have been observed in the North Atlantic (48). This range vastly exceeds what is measured for any single culture grown in the laboratory under a wide range of light intensities (16,50) (see Table 2). Subsequent experiments with 10 different isolates have shown that strains can be distinguished based on their Chl $b:a$ pigment ratios and light responses. Light intensities that completely inhibit the low-light strains (high Chl $b:a$, high growth efficiencies) provide optimal growth conditions for some high-light strains (low Chl $b:a$) (13). It is interesting to note, however, that growth of all available *Prochlorococcus* strains under laboratory conditions is saturated at relatively low light intensities (18 to 87 μmol quanta $m^{-2}\,s^{-1}$) (13). So perhaps overall we may have only relatively low-light adapted strains in culture (12).

Photosynthesis

The two *Prochlorococcus* ecotypes have distinct photosynthetic characteristics that are consistent with their definitions as low or high Chl $b:a$ strains (11,13). Photosynthesis versus irradiance experiments were conducted with ten different strains to determine if photosynthetic parameters were consistent with pigment type (13). The parameter $_{chla}$, an index of the efficiency of photosynthesis, ranged from 0.03 to 0.125 fg C fg Chl $a^{-1}\,h^{-1}$ (μmol quanta $m^{-2}\,s^{-1})^{-1}$, but was twofold higher in low-light strains than in high-light strains (Table 2; 13). This increased efficiency apparently is because of an increased concentration of antenna complexes (11). Maximum rates of photosynthesis when normalized to Chl a_2, P^{chl}_{max}, ranged from 1.3 to 5.2 fg C fg Chl $a^{-1}\,h^{-1}$ and were higher for cells grown at high light (Table 2; 13). On a per cell basis, P^{cell}_{max} was highest for the low light strains (Table 2). All isolates of *Prochlorococcus* that have been investigated appear to be fairly sensitive to higher light irradiances, and most strains are photoinhibited above ~100 μmol quanta $m^{-2}\,s^{-1}$. The quantum yield of photosynthesis, $_{max}$, was relatively high for the strains examined and ranged from 0.063 to 0.107 mol C mol Q^{-1}. In experiments with MED4, the zeaxanthin/cell remained constant over varying light intensities (94), so absorption of light by zeaxanthin may explain some of the variation in $_{max}$ noted in the experiments of Chisholm and Moore (13).

The molecular basis for the physiological differences in photoacclimation between low- and high-light strains appears to result from the number of genes encoding Chl a/b-binding (*pcb*) proteins (54). The low-light-adapted *Prochlorococcus* strain SS120 possesses a gene family of seven transcribed genes, whereas the high-light-adapted strain MED4 possesses a single *pcb* gene. The presence of multiple antenna genes provides evidence to explain the capacity of low-light *Prochlorococcus* populations to survive at extremely low light levels (54) (Table 2). The pigment complement of *Prochlorococcus* (see preceding section on Light) also allows it to be very efficient at low light levels. Further information regarding photosynthetic performance and the photosynthetic apparatus itself is presented by Partensky and coworkers (12).

Regulation of photosynthetic activity has been investigated by measuring the transcription levels of the ribulose-1,5 diphosphate carobxylase/oxygenase (RuBisCO) large subunit (*rbcL*). RuBisCO is the essential, first enzyme in the photosynthetic fixation of carbon dioxide (95). A diel pattern in C-fixation and *rbcL* transcription (mRNA) was observed in field samples and in cultures, even when shifted to continuous light from a light/dark growth regime (96). Thus, in *Prochlorococcus* the expression of RuBisCO appears to be regulated, at least in part, by transcriptional control (96).

Nutrient Requirements for Growth

Throughout most of the oligotrophic subtropical gyres, where *Prochlorococcus* overwhelmingly outnumber other photosynthetic members of the plankton community, nutrient levels are extremely low, often below the limit of detection by standard methods (97). Therefore, investigation of the factors that may regulate growth of *Prochlorococcus* in this extremely oligotrophic environment is of considerable interest. Until now, definitive nutrient uptake experiments have not been possible because axenic cultures were unavailable. With results from the first axenic strain PCC9511, we now have a glimpse of some physiological properties of this novel group. Comparisons of

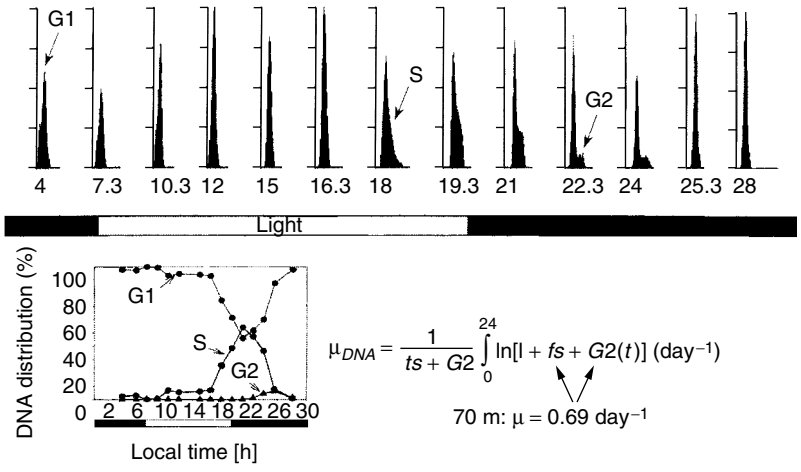

Figure 5. Flow cytometric analysis of *Prochlorococcus* cell cycle and growth rate calculation; following Carpenter and Chang (*Mar. Ecol. Prog. Ser.* **43**, 105–111 (1988)). The duration of the terminal event (S + G_2) is calculated as twice the period from maximum S to maximum G_2. Reproduced with permission, from Veldhuis and Kraay (*Sci. Mar.* **64**, 121–134 (2000)) (93).

nutrient requirements and preferences among strains will be determined as additional axenic strains become available.

Nitrogen

Growth of phytoplankton in the ocean is most often assumed to be nitrogen limited. From initial observations of *Prochlorococcus* abundance in the North Atlantic (40), it appeared that maximum population density tracked the nitracline (the depth at which a rapid increase in nitrate begins, often just below the base of the euphotic zone). Given the capability of *Prochlorococcus* for growth at low light levels (see preceding text) and the absence of detectable nitrate in surface waters of the oligotrophic subtropical gyres, this appeared to be a plausible explanation consistent with observed distributions. However, as more information detailing *Prochlorococcus* distributions was compiled (see earlier section on Ecology), it became apparent that *Prochlorococcus* was most often evenly distributed throughout the surface mixed layer (see preceding text), and not limited to a subsurface maximum near the nitracline.

Based on results from initial culturing attempts and recent development of the axenic high-light strain, it appears that urea and ammonia are the favored nitrogen sources. In fact, the high-light strain PCC9511 cannot grow on nitrate. This is not consistent with previous observations that *Prochlorococcus* appeared to track the nitracline and an increase in cell cycling noted with increased nitrate (40,98). Perhaps another factor covarying with nitrate may explain these results. Alternatively, there may be multiple strains with different nutrient preferences or capabilities. This would explain both situations: high-light strains typically are found in the surface mixed layer where nitrate is undetectable, and low-light strains in the lower portion of the euphotic zone capable of utilizing nitrate. Preliminary results have indicated a low-light strain is capable of nitrate uptake (10,99); however, definitive experiments will require axenic cultures of the different "ecotypes."

Phosphorus

In initial culturing attempts, an organic form of phosphorus appeared to be preferred, or at least led to greater success, when culturing *Prochlorococcus*. Further investigations with established cultures have shown growth to be equivalent in media with either inorganic orthophosphate or organic phosphate (NaH_2PO_4 or -glycerophosphate; see Table 1). Growth of PCC9511 was satisfactory with a number of alternative phosphorus sources (Na_2 -glycerophosphate, Na_4-pyrophosphate, glucose 6-phosphate or ATP) (10). Based on these results, it is hypothesized that *Prochlorococcus* may be capable of synthesizing ecto-phosphohydrolases, as both polyphosphate and organic phosphates require dephosphorylation before they can be taken up across the cell membrane (100). This capability would confer an advantage to *Prochlorococcus* because in much of its geographic range the supply of inorganic phosphate may be limiting (101–103). Experiments conducted in the North Pacific to examine the dynamics of phosphorus have shown that the microbial community appears to be P-limited (104). In this region, where *Prochlorococcus* numerically dominates the microbial community, dissolved organic sources of phosphorus may be important for growth.

Trace Metal Requirements

Iron is required by all photosynthetic organisms because it is an essential component of the electron transport system of photosynthesis. When iron is limiting, cells cannot synthesize functional electron transport components, which leads to loss of PSI and PSII reaction centers. Consequently, the quantum efficiency of photosynthesis is reduced. This means that when phytoplankton are iron-limited, the light absorbed by the antenna pigments is less likely to be trapped for photosynthesis and is more likely to be lost as fluorescence. Iron limitation of the larger phytoplankton (i.e., diatoms) was hypothesized to explain the low productivity observed in the equatorial Pacific where, in spite of high nutrient levels, chlorophyll biomass remains low. Experimental evidence suggests that iron may limit picoplankton as well. The cyanobacterium *Synechococcus*, a close relative of *Prochlorococcus*, has been shown to have a high iron demand (105).

Results from large-scale iron-enrichment studies conducted in situ in the equatorial Pacific (IRONEX I and IRONEX II) (106,107) showed that in experimental treatments with iron additions the quantum yield of photosynthesis of PSII increased rapidly in *Prochlorococcus* (108), as did cell division rates measured by cell cycle analysis (109) (see section on Growth). In spite of increased cell division, a concomitant increase in biomass was not observed because of the closely coupled grazer populations. Populations responding to nutrient additions in iron-enriched treatments were rapidly grazed, thus increased mortality balanced the growth of *Prochlorococcus*. Conversely, results in the subtropical North Pacific suggested *Prochlorococcus* were not iron limited (110).

The cobalt requirements of *Prochlorococcus* and *Synechococcus* have also been investigated. *Prochlorococcus* appears to have an absolute requirement for cobalt that exceeds typical concentrations found in the open ocean; thus, cobalt may be a limiting factor for *Prochlorococcus* in the oligotrophic ocean (111). Because total cobalt concentrations appear to be extremely low (20–100 pM) in the open ocean, an uptake mechanism utilizing cobalt-specific ligands has been proposed for *Prochlorococcus* (112). In the axenic high-light strain PCC9511, addition of vitamin B_{12} (cyanocobalamin) was not essential for growth (10).

The zinc requirement is low for most cyanobacteria, but is required for optimal growth by some strains (113). RNA polymerase is known to be a zinc-containing enzyme; thus, it is likely that zinc is an essential requirement for growth of cyanobacteria, including *Prochlorococcus*. The binding site is preserved among *rpoC1* sequences from eight cyanobacterial species, including *Prochlorococcus* (56), but the association of zinc with the binding pocket has yet to be demonstrated. For PCC9511, the addition of 1 μM zinc to a synthetic sea water medium had no effect on growth, but a 10 μM addition was toxic (10).

There are few known enzymes requiring copper in cyanobacteria, and a requirement of this element is not known in *Prochlorococcus* (10). Omission of copper from the medium apparently had no effect on growth. In fact, it has been proposed to have a toxic effect (4). The axenic high-light strain PCC9511 was tested for copper tolerance and growth was observed at 100 nM copper (10); however, growth at higher levels was not tested.

Nitrogen Fixation

The ability to fix atmospheric nitrogen (N_2-fixation) is an important property of some cyanobacteria, for example, *Trichodesmium* (114). No nitrogen fixation (*nif*) genes have been found in *Prochlorococcus* cultures (49,115); therefore, it seems likely that *Prochlorococcus* strains are not able to fix nitrogen. Nitrogen fixation has been observed in some unicellular *Synechococcus* cyanobacteria (116,117); however, these are benthic and freshwater strains rather than the marine phycoerythrin-containing *Synechococcus*, which are close relatives of *Prochlorococcus*. Reports of nitrogen fixation by *Prochloron* have been conflicting (118,119), but more recently evidence from the natural abundance of $^{15}N/^{14}N$ in isolated *Prochloron* cells indicated a significant percentage of the nitrogen was derived from nitrogen fixation. Thus, Kline and Lewin (120) suggest *Prochloron* may be capable of facultative nitrogen fixation. Given the tremendous diversity among the cyanobacteria, we cannot rule out the possibility that a nitrogen-fixing *Prochlorococcus* strain may yet be discovered.

pH

The effects of pH have not yet been examined specifically in *Prochlorococcus*. However, the marine *Synechococcus* cyanobacteria appear to prefer neutral, or slightly alkaline pH (121), which is typical of seawater throughout the geographic range of *Prochlorococcus*.

DYNAMICS OF *PROCHLOROCOCCUS* POPULATIONS

Estimates of *in situ* specific growth rates for *Prochlorococcus* are difficult to obtain in field samples using traditional oceanographic methods because it is not easy to separate *Prochlorococcus* from other picoplankton. Estimates of cell-specific growth rates for *Prochlorococcus* have been determined using the cell cycle method (88,92,122), ^{14}C-Chl a_2 labeling method (123), or zeaxanthin per cell (94). In addition, population dynamics have been examined using the dilution method (125,125) in combination with flow cytometric enumeration to obtain cell-specific growth and mortality rates. Some examples of these methods are discussed briefly in the following text; however, for full details and limitations of the methods the cited literature should be consulted.

Growth Rate Estimates Based on Cell Cycle Analysis

The cell cycle of *Prochlorococcus* is analogous to the eukaryotic cell cycle in that it has discrete periods of DNA synthesis following gap periods (98). Because the cell cycle of *Prochlorococcus* populations is highly synchronized with the light-dark cycle, DNA histograms display two peaks corresponding to G_1, the initial growth phase, and G_2, the late growth, separated by a DNA synthesis phase, S (Fig. 5). Using the model proposed by Carpenter and Chang (122), growth is computed from the fraction of cells in a terminal event (e.g., $S + G_2$). By measuring the DNA cell^{-1} distribution for a *Prochlorococcus* population frequently over a cell cycle and estimating the fraction (f) of cells in $S + G_2$, the growth rate can be calculated (see references (92,93,122)). An example of the cell cycle approach is shown in Figure 5 (93). Growth rates for *Prochlorococcus* in the equatorial Pacific were found to be 1 div day^{-1} in surface mixed layer and decreased to 0.2 div day^{-1} at 100 m. A comparative study in the eastern and western tropical Pacific revealed that *Prochlorococcus* grew equally well under mesotrophic and oligotrophic conditions, yet made a larger contribution to total primary production in the most oligotrophic regions of the North Pacific (88). In the Arabian Sea, growth rates computed by cell cycle analysis in some cases exceeded 1 div^{-1}, yet compared favorably with results of the dilution method (33) (see section on Ultradian Growth).

Because the growth rate of *Prochlorococcus* within the surface mixed layer appeared to be slower than for populations deeper in the water column, and the timing of cell division is often delayed as well, it was speculated that ultraviolet (UV) radiation exposure may have inhibitory effects on surface *Prochlorococcus* populations (92,126). The effect of UV radiation on *Prochlorococcus* has not been measured directly, however the picoplankton, such as *Prochlorococcus* are obviously subject to periodic high exposures of UV in clear oceanic waters. UV radiation is not limited to the immediate surface waters, but may penetrate fairly deep within euphotic zone. UV-B has been shown to penetrate to over 30 m and UV-A to 60 m (127). Experimental evidence suggests picoplankton, in general may be more sensitive to UV radiation. Boelen and coworkers (128) measured UV-B radiation vulnerability using the production of cyclobutane pyrimidine dimers (CPDs) as an index. In natural populations of plankton, they found production of CPDs to be size dependent; the DNA damage was greater in the 0.2 to 1.0 μm size fraction than in the 1 to 10 μm size fraction. A greater amount of damage was found at tropical latitudes, where *Prochlorococcus* is dominant, even though UV-B levels were higher elsewhere. In cases where CPD levels in field populations were low, it was speculated the communities received a low mean biologically effective dose because of wind-induced mixing, which would reduce overall exposure (128).

Phytoplankton class-specific growth rates can also be estimated using the pigment-labeling technique (129). Pigment synthesis rates are valid estimates of phytoplankton growth rates when growth is balanced. Because balanced growth is rarely the case in nature a precursor-product turnover model must be employed to accurately estimate growth rates from pigment labeling. Using this approach for *Prochlorococcus* in the Sargasso Sea, growth rates of 0.3 day^{-1} in surface waters and 0.1 day^{-1} at the base of the euphotic zone were obtained (123). Based on this

study, the average annual contribution to total primary production by *Prochlorococcus* populations was 25% (123).

Ultradian Growth and Rhythms

From most initial studies, it appeared that *Prochlorococcus* divided once per day (92). In many instances, however, *Prochlorococcus* exhibit ultradian growth (faster than 1 div day^{-1}), even though cell division is strictly phased to the light-dark cycle (14). Observations in both field populations and cultures showed that a second round of DNA replication and cell division proceeded immediately following the first division. This unique mode of ultradian growth suggests that control of the cell cycle is by a circadian clock or light-triggered timer rather than light intensity or duration. Most importantly, given *Prochlorococcus* are capable of division rates which exceed 1 div day^{-1}, these observations suggest *Prochlorococcus* could be nutrient-limited and so not growing at their maximal rate (14). If so, such results may have profound implications to our understanding of phytoplankton growth in the oligotrophic ocean.

Growth and Grazing Mortality

The dynamics of *Prochlorococcus* populations have also been investigated using the dilution method (124,125) combined with flow cytometric analysis to obtain specific growth rates (130–132). Maximal growth rates from 1.28 up to 2.2 day^{-1} have been reported (33,133). In almost all cases, the growth of *Prochlorococcus* is closely matched by losses due to mortality (e.g., 90% of growth in the Arabian Sea (33)). The coupling may become unbalanced if the environment changes, for example, because of strong environmental forcing. Although grazing by protozoans, such as heterotrophic flagellates and ciliates is the most significant fate of *Prochlorococcus* (74,130), losses owing to viral lysis could also be important (134,135). Grazing by the sponge, *Mycale lingua* was significant in the Gulf of Maine, where the efficiency of feeding on *Prochlorococcus* was 93% (136). Grazing by tropical appendicularians, which can effectively package *Prochlorococcus*, also contributes to mortality (137). In tropical coral reefs where the density of Gorgonian corals is high, the potential grazing impact on plankton communities is great (138). Thus, mortality because of coral grazing could be significant where *Prochlorococcus* are a large fraction of the community.

GENETIC DIVERSITY IN *PROCHLOROCOCCUS* POPULATIONS

Genetic Characterization

Prochlorococcus is thought to have the smallest known genome of all oxygenic photosynthetic bacteria (12). The genome size of MED4 is 1.6 Mbp based on results of genome sequencing (*http://spider.jgi-psf.org/JGI_microbial/html/prochlorococcus.med4.status.html*). Sequencing of a representative low-light strain, MIT9313, is underway (*http://spider.jgi-psf.org/JGI_microbial/html/prochlorococcus_homepage.html*); the preliminary size estimate is 1.9 Mbp (W. Hess, personal communication). This difference between high- and low-light strains in genome size is consistent with the 14% mean difference in DNA content reported earlier (35). The reported genome size for PCC9511 (2 Mbp) based on DNA renaturation kinetics and pulsed-field gel electrophoresis is slightly overestimated (10).

Overall, the cyanobacteria have a wide range in their DNA base pair composition, which is reported as percentage guanine + cytosine (mol% G + C). The marine *Synechococcus* cyanobacteria strains form a tight cluster within the range of 57 to 63% G + C (139). The mean DNA base composition in PCC9511 was reported to be 32.0 ± 0.1 mol% G + C (10). Thus, *Prochlorococcus* PCC9511 has a much lower mean DNA base composition than the typical marine *Synechococcus* cyanobacteria. Additional measurements will be possible as more axenic strains become available.

Diversity among Strains

The success of *Prochlorococcus* over such a wide range of light conditions has led to a number of investigations of *Prochlorococcus* diversity. Specific hypotheses related to the coexistence of genetically different populations adapted for growth at high- and low-light intensities have been examined using several different genes as markers. A high degree of genetic heterogeneity was observed within natural populations of *Prochlorococcus* based on sequences of a photosynthetic electron transport gene (*petB/D*) and intergenic region (140). Using flow cytometry to sort cells from depth profile samples, PCR amplification and cloning produced 6 to 21 different *petB/D* alleles. In samples from "double" populations (see earlier section on Vertical Profiles), overlapping sets of alleles were observed, which suggests that each population (genotype) was derived from a single gene pool. Sequences characteristic of the high-light *Prochlorococcus* clade were recovered at higher frequencies from cloned near-surface samples. This observation supports the hypothesis that *Prochlorococcus* populations are derived from a single gene pool; however, population shifts in response to environmental forcing (such as the surface nutrient-limited regime versus deeper light-limited regime) produce variations in genotype frequency (140).

Studies using the RNA polymerase ã subunit gene (*rpoC1*) examined diversity among both *Prochlorococcus* and *Synechococcus* sequences obtained by PCR amplification of field populations (141,142). From theses analyses, the strains could be divided into two clades, one genetically similar to the MED4 high-light strains and the second included low-light strains. The high-light clade could be further subdivided based on *rpoC1* sequences, however, physiological basis of this division is not known. Interestingly, none of the sequences matched the sequences of cultured isolates. An important result of these studies is that genetic diversity among *Prochlorococcus* is much greater than among *Synechococcus* clones, and may explain why *Prochlorococcus* are found over a greater range of depths (142). For example, in the North Pacific the *Prochlorococcus* distribution extends to a depth of 0.1% of surface light intensity, which is considerably deeper than *Synechococcus* (35).

Direct evidence to support the co-occurrence of multiple strains of *Prochlorococcus* was reported by Moore and coworkers (36). They found isolates established from the same water sample have very different light-dependent physiologies, for example, one growing maximally at light intensities that completely photoinhibit the other, yet their 16S ribosomal RNA sequences were remarkably similar (97%). Subsequently, Moore and Chisholm (13) have shown that there are at least two distinct physiological ecotypes. As discussed above, low-light strains have a higher concentration of Chl a_2 and b_2, a higher Chl $b_2 : a_2$ ratio, and higher photosynthetic efficiencies and photosynthetic capacities than strains adapted to high light intensities (see preceding section on Photosynthesis).

Diversity among *Prochlorococcus* strains is also demonstrated by analysis of the genes coding for the large subunit of RuBisCO (*rbcL*). Several forms of this enzyme (95) exist; Form IA is characteristic of the proteobacteria (e.g., nitrifying and manganese-oxidizing bacteria) and Form IB is characteristic of cyanobacteria (including most *Synechococcus*), green algae, and prasinophytes. However, *Prochlorococcus* strain GP2 and *Synechococcus* WH7803 possess a Form IA *rbcL* (143). A recent report from the Gulf of Mexico (144) provided the first description of Form IA *rbcL* transcriptional activity in the marine environment and suggested that Form IA *rbcL*-containing picoplankton (like *Prochlorococcus* GP2 and *Synechococcus* WH7803) may be important in the primary production of low salinity, surface water plumes of the Gulf of Mexico. It is not known how prevalent Form IA *rbcL*-containing picoplankton are worldwide. The other strains of *Prochlorococcus* examined to date (e.g., the MED and a North Pacific isolate) have a Form IB *rbcL* (145). There is no discernible relationship between the form of *rbcL* and the high- or low-light ecotypes defined by 16S rRNA sequences; however, based on only three sequences, it is probably premature to make any comparisons with 16S rRNA phylogeny (146). In field samples from the eastern Gulf of Mexico, six *Prochlorococcus* GP2-like Form IA *rbcL* sequences were obtained by PCR amplification, cloning, and sequencing (146). The similarity among these sequences (93–98%)—very similar, but not identical—again demonstrates that molecular microdiversity is commonly observed in marine microbial populations, for example see references (36,147). The coexistence of closely related, but physiologically distinct populations, may explain the microdiversity observed. As Moore and coworkers (36) conclude, "coexistence and distribution of multiple ecotypes permits the survival of the population as a whole over a broader range of environmental conditions than would be possible for a homogeneous population."

PHYLOGENY

When first discovered, *Prochlorococcus marinus* was described as a "prochlorophyte" because of the apparent similarity to *Prochloron didemni* (148) and *Prochlorothrix hollandica* (61), which are oxygenic prokaryotes containing Chl b_1 but lacking phycobilins. The pigment complement of *Prochlorococcus*, however, differs considerably from the other two prochlorophytes, specifically divinyl chlorophylls instead of true chlorophylls as their light-harvesting system (see earlier section on Pigments). Furthermore, analyses of the 16S ribosomal RNA (57) and RNA polymerase (*rpoC1*) genes (56) support a phylogenetic relationship between *Prochlorococcus* and the marine *Synechococcus* that is closer than with the other two prochlorophytes. Examination of two photosystem II genes (*psbA* and *psbB*) and photosynthetic electron transport genes (*petB* and *petD*) corroborate the close relationship of *Prochlorococcus* and *Synechococcus* as well (55,149). Lastly, the recent discovery of PE-containing *Prochlorococcus* strains further distinguishes *Prochlorococcus* and supports the close phylogenetic relationship with marine *Synechococcus* (52,53). Although data are available for only a limited number of strains, the presence of PE provides additional support for subdivision of *Prochlorococcus* clades: high-light adapted isolates, which lack PE genes, cluster together in a shallow recently arisen clade, whereas the low light adapted isolates, which have PE genes, are more basal (53,55).

Phylogenetic analysis of *Prochlorococcus* strains is of interest because of their role in the evolution of oxygenic photosynthetic organisms. Owing to their pigment complement, the "prochlorophytes" originally were thought to be ancestors of green algal and plant chloroplasts. But, based on molecular phylogeny of the 16S ribosomal RNA and RNA polymerase (*rpoC1*) genes they are now considered a polyphyletic group that is not any more closely related to chloroplasts than are the other cyanobacteria (56,57). In addition, examination of the Chl a/b binding proteins of all three prochlorophytes revealed a closer structural similarity to cyanobacterial Chl a binding proteins than to the Chl a/b binding proteins of green chloroplasts (150). Based on these studies, it was suggested that the prochlorophytes (*Prochloron didemni*, *Prochlorothrix hollandica*, and *Prochlorococcus marinus*) are not the specific ancestors of chloroplasts as originally proposed, but are diverged members of the cyanobacteria. Given the lack of phylogenetic unity among prochlorophytes, it was proposed that together with the cyanobacteria, they should be classified as Oxyphotobacteria (151).

One conclusion from these phylogenetic studies was that the ability to synthesize Chl b must have arisen independently several times in the prochlorophytes and in the chlorophyte ancestor (56,150). To test this hypothesis, Tomitani and coworkers (152) examined the genes responsible for Chl b synthesis, Chl a oxygenase (CAO), in two prochlorophytes and representative chlorophytes and higher plants. Phylogenetic analysis of the CAO sequences suggests a shared common evolutionary ancestor, and does not support the idea that Chl b arose independently in each of the prochlorophyte lines. Furthermore, they propose the hypothetical ancestral oxygenic photosynthetic bacterium was able to synthesize both Chl b and PE. *Prochlorococcus marinus* is the only oxygenic photosynthetic prokaryote known to contain Chl a_2 and Chl b_1 and b_2 as well as PE. Therefore, *Prochlorococcus* may be derived from this ancestral organism without changes in pigment complement, and thus may serve as a model for the ancestral oxygenic photosynthetic prokaryote (152).

GENOME SEQUENCING

Genome sequencing has been completed for two strains of *Prochlorococcus*: the high-light MED4 strain in 2000 and the low-light strain MIT9313 in 2001. Results from the Department of Energy Joint Genome Institute are available at: *http://www.jgi.doe.gov/tempweb/JGI_microbial/html/index.html*. MED4 is the smallest known photosynthetic organism, with a genome size of 1.67 Mbp, and MIT9313 has a genome size of 2.4 Mbp. Annotation of both genomes currently is underway. When analysis is complete, the results will complement the growing number of prokaryotic genomes that have been sequenced, including the first cyanobacterium *Synechocystis* PCC6308 (153) and a marine *Synechococcus* soon to be completed.

CONCLUSION

1. The novel complement of photosynthetic pigments of *Prochlorococcus* and improved HPLC techniques for separation of true chlorophyll a_1 and b_1 from the divinyl chlorophylls, Chl a_2 and b_2, has permitted estimates of the contribution of *Prochlorococcus* to the total chlorophyll biomass. Recognized differences in the ratio Chl b_2 : Chl a_2 are used to define the low- and high-light strains.
2. Improved sensitivity of flow cytometry was required to identify and enumerate *Prochlorococcus*. Flow cytometry remains an essential tool for the study of this organism.
3. Multiple ecotypes, clusters of genetically distinct strains with different physiological properties, coexist in the ocean. Consequently, *Prochlorococcus* are capable of growth at the surface to depths of approximately 200 m and so are thought to be the most abundant photosynthetic organisms in the ocean.
4. Throughout its range, *Prochlorococcus* growth rate is approximately 1 div day^{-1}. Maximal growth rates measured in cultures and in the field can exceed 1 div day^{-1}. Thus, the question of whether *Prochlorococcus* are in fact nutrient limited has been posed. As we learn more about the nutrition of the different ecotypes of *Prochlorococcus*, the factors limiting growth and distribution will be better understood.
5. In most regions, *Prochlorococcus* growth is closely balanced with losses owing to grazing by protozoans, such as heterotrophic flagellates. Additional grazers and viral lysis may be significant sources of mortality as well.
6. *Prochlorococcus* contribute a significant percentage of primary production; thus are important to the "biological pump" of carbon dioxide from the atmosphere to surface waters and ultimately to the ocean depths.
7. *Prochlorococcus* spp., with a genome size of approximately 2 Mbp, are the smallest recognized photosynthetic organisms. Until *Prochlorococcus* can be grown easily on agar plates, genetic studies will be difficult; however, tremendous progress has been made in just over a decade since their "discovery" by oceanographers. Most significant is their unique pigment complement that includes both chlorophyll b_2 and phycoerythrin. Phylogenetic analyses suggest that *Prochlorococcus* may serve as a model for the ancestral oxygenic photosynthetic bacteria, progenitor of cyanobacteria and chloroplasts.
8. Further development of PCR-based methods for rapid analysis of DNA sequences and probe development will provide a number of ways to address ecological, environmental, and evolutionary questions regarding this very important group of photosynthetic picoplankton.

PROTISTAN COMMUNITIES IN GROUNDWATER

NANCY E. KINNER
University of New Hampshire
Durham, New Hampshire

Protozoa are ubiquitous, single-celled eukaryotic organisms that range in size from 2 μm to greater than 1 cm and are found in many environments (1). (Note: The terms protozoa and protozoan will be used in this review instead of protists and protistan to improve retrieval of the topic by readers.) Approximately 40,000 species of protozoa have been described, but these probably represent only a fraction of the species that exist. The seven phyla of Protista are classified by cell morphology and locomotion, but only two free-living, nonpathogenic phyla — the Ciliophora (ciliates) and Sarcomastigophora (flagellates and amoebae) — are associated with subsurface environments. There are particular problems with detecting flagellates and amoebae because they are so small, thereby making them hard to observe. In the case of amoebae, they are so slow moving that they are often hard to discriminate from sediment debris. Ciliates, the largest group of protozoa, are easier to find, but tend to be excluded from the subsurface because of their large size. The ecology of the free-living protozoa has been studied in marine and freshwaters, wastewater treatment systems, and soils. Protozoa in these environments are known to be phagotrophic, effectively preying upon bacteria and consuming particulate matter.

Until recently, very little was known about the incidence and ecology of protozoa in the subsurface (>30 cm below land surface). However, the existing data suggest that they may be important members of the subsurface food web. The purpose of this review is to discuss the protozoa that inhabit the subsurface, specifically what organisms are known to live there, how they move through the environment, and what roles they might play in pristine and contaminated subsurface environments. The review will only address free-living protozoa and will use current taxonomic nomenclature, though protozoan systematics and taxonomy are changing and evolving rapidly.

STUDIES OF PROTOZOA IN SOILS AND THE SUBSURFACE

Until the beginning of the twentieth century, microbiologists believed that protozoa were only found in marine and fresh waters. In 1909, Russell and Hutchinsen (2) discovered free-living protozoa in soil and postulated they were preying upon bacteria. However, the common belief at that time was that protozoa were primarily present in the soil as cysts (a resting state) capable of withstanding deleterious conditions. Cutler (3) and Sandon (4) described trophic protozoa as primarily being present in the upper 5 cm of soil. Since the 1920s, many papers (e.g., Refs. 5–8) have described soil protozoa and their ecology. Most of the early research suggested that protozoa were harmful to soil productivity by killing algae, fungi, and bacteria, and transporting "disease producers" to plants.

Studies of protozoa in subsurface environments have been much more limited. Munch and Petzold (9) reported finding them in groundwater from a sandy alluvial aquifer located between natural springs and the sea. They concluded that protozoan existence in the subsurface was possible to great depths, provided the groundwater flow was adequate and there was sufficient supply of oxygen and nutrients. Hirsh and Rades-Rohkohl (10) also reported finding viable protozoa in groundwater wells in significant numbers. One problem with the early studies was that protozoan abundance data were generated using groundwater collected from boreholes that were open to the surface and may not have been purged of standing water, thus being subjected to contamination with soil- and/or airborne species.

Since 1987, there has been an increasing body of literature on subsurface protozoa. Sinclair and coworkers (11–16) found protozoa in sediment cores collected from an array of pristine and contaminated sites. Their enumerations were performed using most probable number (MPN) culturing methods similar to those developed by Singh (17) for detecting amoebae in soil. Kinner and coworkers (18–20) have also reported finding protozoa in sediment cores from pristine and contaminated sites by using direct count methods. Travis and Rosenberg (21), in their model of in situ biodegradation of trichloroethylene (TCE) in an aquifer, concluded that protozoan predation provided the best explanation for the oscillations they observed in populations of methanotrophic bacteria. Zarda and coworkers (22) and Kota and coworkers (23) detected protozoa in aquifer sediments subjected to refinery and BTEX contamination, respectively. Hence, they have been detected in almost all cases where protozoa have been actively sought in subsurface sediments.

TYPES, ABUNDANCE, AND ENUMERATION METHODS FOR PROTOZOA

Most of the protozoa reported in the subsurface since 1987 have been heterotrophs, with the predominant type being small (nano) flagellates, along with some amoebae and very few ciliates. Taxonomic identifications are rare (18,24), often because the cells are small and difficult to isolate. In addition, few samples of protozoa from the subsurface are available to researchers; existing descriptions of species in the literature are often dated, and many of the species collected are ones that have not yet been described. Several genera of flagellates have been found in aquifers (18), including *Bodo*, *Cercomonas*, *Spumella*, *Goniomonas*, *Cryptaulax*, and *Cyathomonas*. Novarino and coworkers (25) categorized the flagellates they found on the basis of their swimming behavior — those that creep on solid surfaces (amoeboid), actively swim in pore waters (rarely attached), and swim and temporarily attach (mixed mode).

In most cases, amoebae have been reported without taxonomic identification because they are very difficult to detect and to describe. Novarino and coworkers (18) identified several naked amoebae in groundwater, including *Acanthamoeba*, *Hartmanella*, *Mayorella*, *Rosculus*,

Vahlkampifia, and *Vannella / Platyamoeba*. Very few ciliates have been found, most likely because their size (>10 μm) precludes their transport through aquifer sediments (18). Foissner (24) identified 38 species of ciliates in rapid sand filters that were being used to treat groundwater, including *Acineria*, *Aspidisca*, *Cinetochilum*, *Colpidium*, *Glaucoma*, and *Holosticha*. However, it is not clear if these ciliates were actually living in the aquifer or were a source of contamination in the well or filters.

A wide range of concentrations has been reported for protozoa in aquifers (Table 1). Because they may inhabit both pore water and grain surfaces, abundances may be more useful if expressed as numbers per cubic centimeter of aquifer, but to date most data have been expressed as the number of organisms per gram dry weight of aquifer material. Higher numbers are present at contaminated sites, probably because greater amounts of organic carbon result in more protozoan biomass production and growth. The bioavailability of the food source to the microenvironment inhabited by the protozoa probably also influences their abundance. However, the toxicity of some organic contaminants may inhibit them, as it does in other environments (27,28).

The concentration of protozoa observed in the subsurface may be affected by a number of factors, including sediment type, moisture content, organic content (including contaminant loading and type), ambient oxygen concentration, pH, Eh, and mineral content. Generally, protozoan abundance is lower in clay than in sand-based aquifers (Fig. 1), though populations in sandy sediment may sometimes be low. Whereas few samples have been collected from clay-laden aquifers, the lack of protozoa appears to be related to the lower hydraulic conductivity (a factor originally noted by Munch and Petzold (9)). Some clay-laden sediments also have low pH (<5), which may inhibit the protozoa (13). In addition, transport through clay-laden sediments may be difficult for cells that are typically greater than or equal to 2 μm.

Table 1. Protozoan Abundance Reported in Pristine and Contaminated Aquifers

Environment	#/gdw[a]	Reference/Site Location
Pristine aquifers	10^0 to 10^1	Sinclair and Ghiorse (11), Lula, Okla.; Beloin and coworkers (12); Lula, Okla.; Sinclair and coworkers (14); northeastern Kansas
Jet fuel plume	10^0 to 10^5	Sinclair and coworkers (15); Traverse City, Mich.
Coal tar site	10^1 to 10^4	Madsen and coworkers (16); New York
Abandoned hydrocarbon refinery	10^0 to 10^3	Zarda and coworkers (22); Hünxe, Germany
Sewage-contaminated aquifer	10^3 to 10^5	Kinner and coworkers (26); Cape Cod, Mass.

Note: () indicates location of site.
[a]gram dry weight.

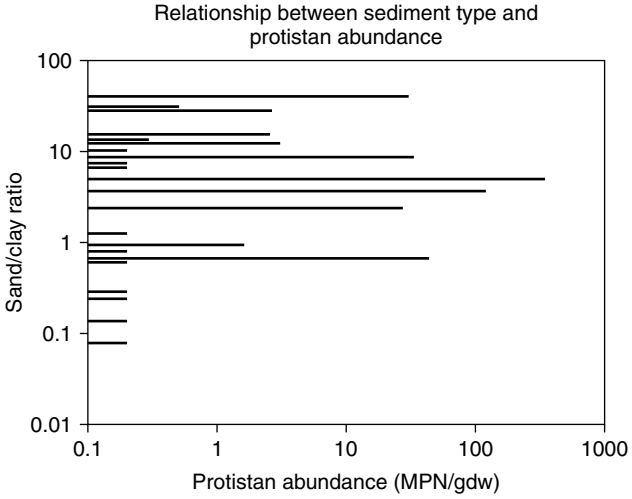

Figure 1. Relationship between sediment type and protozoan abundance in subsurface sediments from uncontaminated sites. Based on data from References 12 to 14.

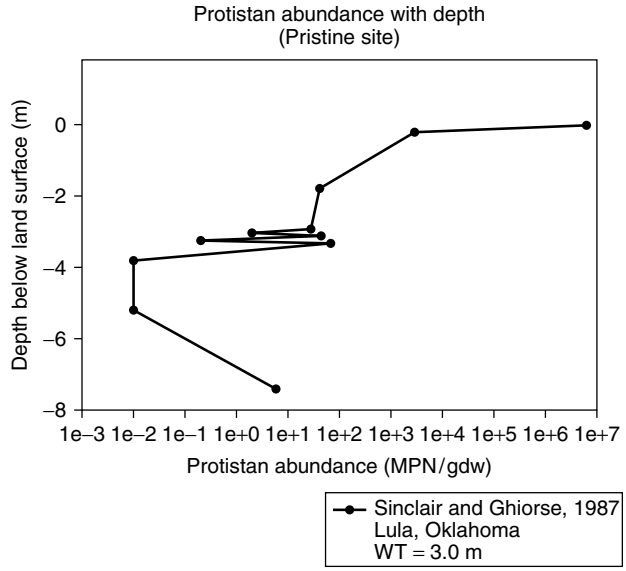

Figure 2. Protozoan abundance with depth in subsurface sediments from an uncontaminated site. The water table was located 3.0 m below the surface. Based on data from Reference 11.

Sinclair and Ghiorse (11) enumerated the protozoa from the surface to approximately 7.5-m below the surface in a pristine aquifer (Fig. 2) and observed the greatest numbers and diversity in the topsoil. Topsoils are organically rich, aerobic zones that provide favorable conditions for protozoan growth. The numbers decrease in the vadose (unsaturated) zone, most likely because the protozoa need moisture to live (29). In addition, there are fewer bacteria, a potential protozoan food source, in this zone. Many of the protozoa detected in the vadose zone are encysted, perhaps as a defense against desiccation. The only reported site where protozoan abundances were high in the vadose zone was in an area contaminated by jet fuel vapor (15), where bacteria were also abundant. In the saturated zone, protozoan abundance often increases above that detected

in the vadose zone or, occasionally, remains the same. Increases most often occur when bacterial abundance or organic content increases. Protozoan abundance within a given aquifer is usually lowest in pristine zones where organic content is generally minimal and the organic carbon available is often refractory (16,30). Kinner and coworkers (30) have shown that in a sandy aquifer, both the unattached bacterial and total protozoan abundances are related to the dissolved organic carbon (DOC) concentration. In the same aquifer, protozoan abundance decreases exponentially with the refractory nature of the DOC. The increase in protozoan abundance observed when DOC is elevated may result from a redistribution in bacteria from the attached to the unattached populations (31) because most protozoa graze on the unattached bacteria more readily than on those residing in a biofilm. There is little information on the toxicity of organic compounds, such as TCE and various petroleum hydrocarbons found at most contaminated sites, to subsurface protozoa.

Whereas protozoa were originally thought to inhabit only aerobic aquifers (32), more recent data suggest they can exist in suboxic and anoxic subsurface environments (22,30). Abundances of protozoa are generally higher in aerobic portions of aquifers (e.g., in contaminated aquifers where aerobic conditions are created to stimulate bioremediation (Fig. 3)). However, it is unclear whether greater protozoan abundance is related to increased bacterial activity and growth or the presence of oxygen.

There is little data on the effects of pH, Eh, and mineral content on protozoan abundance. Lower protozoan abundance has been documented at a pristine site with a pH less than 5 where clays were predominant (13). At that site, it was postulated that the lower pH could have caused a mobilization of metals, which inhibited the protozoa. Alternatively, the lower bacterial abundances at the site could have resulted in lower protozoan numbers. The pH in sandy aquifer sediments used to culture flagellates is known to affect their size (conditions of pH 6.0 and 7.0 resulted in 2 to 3 μm and 3 to 5 μm cells, respectively) (33).

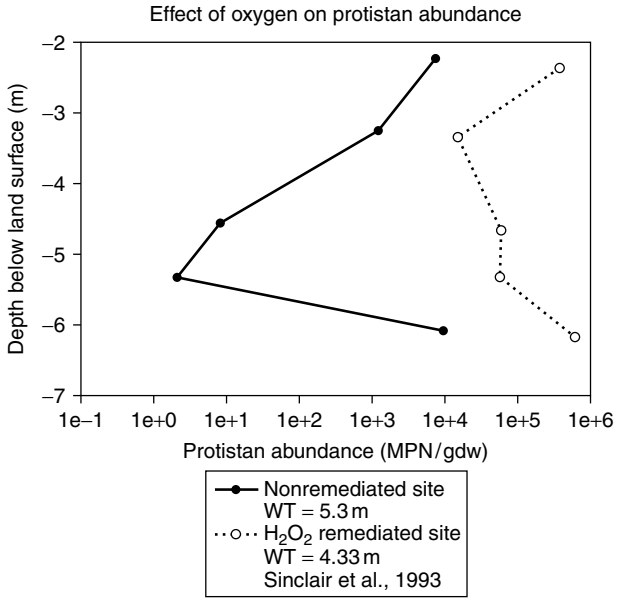

Figure 3. Protozoan abundance with depth in H_2O_2 remediated and unremediated subsurface sediments contaminated with jet fuel. The water tables were located at 4.3 and 5.3 m, respectively, for the two sites. Based on data from Reference 15.

Most of the recent studies reporting protozoan abundances (11–15,22,23) have used the MPN method of enumeration, originally developed by Singh (17) for amoebae in soil. In this method, a food source (i.e., bacteria) is provided to the protozoa in a series of dilutions of the sample. It is assumed that the protozoa consume the food source, grow, and reproduce during the incubation. Subsamples of the replicates at each dilution are usually examined microscopically for the presence of protozoa. An MPN estimate of the original population is made based on the amount of dilution necessary to eliminate the protozoa from the sample. Ronn and coworkers (34) optimized the MPN procedure for flagellates and amoebae in soil by comparing results obtained using different growth media and concentrations against *Enterobacter* as a standard. The MPN method is useful because it yields live material, so the types of protozoa present and their motility can be observed. As with all culturing-based enumeration methods, selectivity of the growth medium can affect the results. This problem is compounded with subsurface protozoa because their food source(s) is not usually known. Often *Enterobacter* is used as a model bacterial food source. In other cases, only the bacteria from the groundwater are used and diluted out simultaneously with the protozoa. Direct observation of the protozoa in the live samples from the MPN can be difficult because many of the cells are very small (2 to 3 μm) and hard to differentiate from bacteria and debris when using light microscopy. Overall, the MPN method can yield useful data, but it may underestimate protozoan abundance in situ.

Direct counts have been done on subsurface protozoa using methods developed for 4′,6-diamidino-2-phenylindole (DAPI) (19,20,30) and primulin stains (35,36). DAPI is problematic because it reacts with both prokaryotic and eukaryotic nucleic acids, so bacteria and protozoa are both stained. This means that the protozoa must be distinguished based on their morphology alone. Motility, which is often important in differentiating protozoa, is absent because the cells are fixed prior to DAPI staining. Primulin differentially stains eukaryotes and is, therefore, a preferred alternative to DAPI. However, primulin is also used on fixed material, so motility is absent. In addition, direct count methods are very tedious because the stain is often difficult to see in samples extracted from subsurface sediment where debris is present and there is background fluorescence.

Caron and coworkers (37) noted that differences between MPN- and direct count–derived abundances are a function of the trophic mode of the protozoa, their growth stage, and their ability to be cultured in the laboratory. Little is known about the trophic mode or growth stages of in situ protozoa in most subsurface environments. Novarino and coworkers (25) has noted that it is currently difficult to culture many subsurface protozoa because their food source(s) is not known.

Extraction procedures are used to remove the protozoa from sediment samples prior to direct counting and oftentimes before MPN dilutions. These protocols can consist of simply shaking the sediment in a buffer solution (35) or creating more complex density gradient separations that have 70 to 75% efficiency for extracting flagellates (25). Flagellates are easier to extract than amoebae because they are less-strongly surface associated. Hence, any enumeration method preceded by an extraction underestimates the abundances of amoebae.

Recently, gene probes have been used to enumerate the protozoa in the subsurface (22,25). Zarda and coworkers (22) have compared protistan abundances, at an abandoned oil refinery site, derived from an MPN method and a eukaryotic probe EUK516 (using an in situ hybridization technique). EUK516 yielded abundance estimates two to five orders of magnitude greater than the MPNs (Fig. 4),

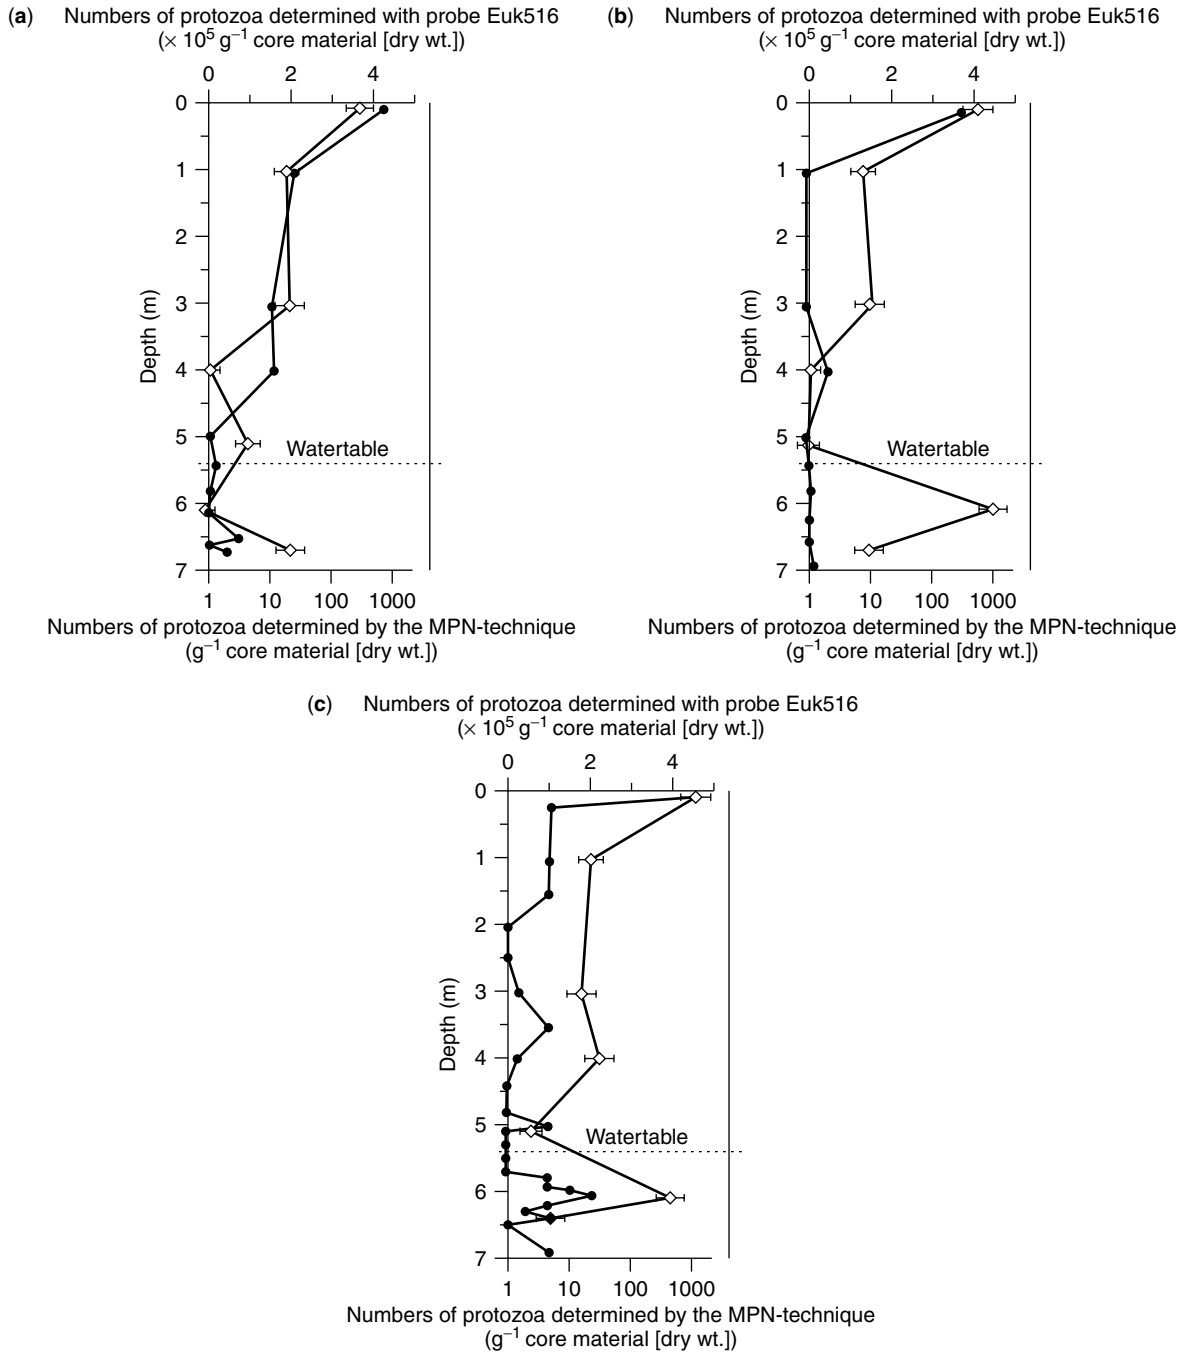

Figure 4. Total number of protozoa as determined by in situ hybridization with the Eukarya-specific probe EUK 516 (•) and by the MPN technique (◇) in cores A, B, and C from an aquifer located at an abandoned refinery for depths between 0.1 and 0.7 m. Reprinted from Reference 22.

but the trends in population density with depth were similar. Use of probes for enumeration of protozoa in the subsurface is very promising. Once issues concerning the lack of information on the protistan taxa present in the subsurface and contamination and interference issues are addressed, probes will probably be used widely to estimate in situ abundance.

Protozoa can exist in situ in a trophic (vegetative) form or an encysted (resting) stage where no reproduction or feeding occurs (1). Research on protozoa indicates that they are able to produce temporary cysts (38) to withstand unfavorable environmental conditions (e.g., presence of toxic chemicals and extremes of pH, temperature, or desiccation). The process and causes of encystment and excystment are not completely understood. Singh (17) developed an acid treatment, as part of his MPN enumeration procedure for soil amoebae, to differentiate between the numbers of trophic versus encysted cells present. Pretreatment with acid kills the trophic cells, whereas cysts survive. Subsequent neutralization of pH and MPN culturing causes the encysted protozoa to excyst, so that the abundance of encysted protozoa can be estimated. The effectiveness of the acid treatment as a method of calculating encystment is uncertain. Undoubtedly, direct observation of the samples with scanning electron microscopy (SEM) is the best method to discern the abundance of encysted cells, but this is impractical for most samples. Better methods that are more reliable than acidification and less tedious and expensive than SEM should be developed for characterizing the extent of encystment, which must be known for assessing the importance of protozoan activity in situ.

PROTOZOAN TRANSPORT IN THE SUBSURFACE

Harvey and his associates have conducted research on protozoan transport using laboratory columns of porous media and in situ injection and recovery experiments (39–42). Most of this work was conducted using the flagellate *Spumella guttula* cultured from sediment samples of an organically contaminated sandy aquifer located in Cape Cod, Massachusetts. *Spumella* can swim actively and also has the ability to attach temporarily to grain surfaces. Depending on the pH and organic content of the culturing medium used, its cells are 4 to 5 μm or 2 to 3 μm in diameter (33). Dimensionless concentration histories (P/P_0) of DAPI or hydroethidine-stained *Spumella* injected into the aquifer were compared to bromide recoveries downgradient, which were typically 80 to 100%. Both 2-μm, carboxylated, fluorescent microspheres and 2- to 3-μm, stained flagellates behaved similarly, the latter yielding a maximum abundance of 25% 1 m downgradient (Fig. 5), whereas 4- to 5-μm flagellates transported much more slowly (Fig. 6) with a maximum recovery of approximately 2%. All recoveries decreased with distance downgradient. Hydraulic perturbation caused remobilization of the 2- to 3-μm protozoa (Fig. 5).

The laboratory and field data indicate that cell size is critical in determining the extent of protozoan transport in the saturated subsurface. The Cape Cod

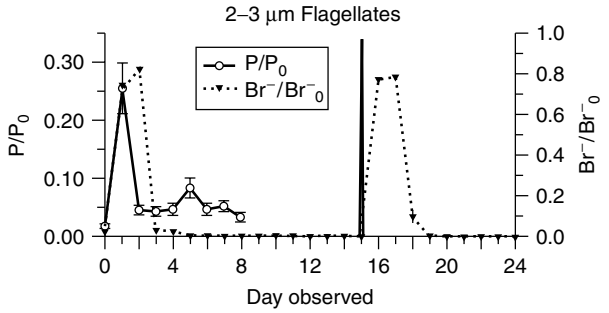

Figure 5. Dimensionless concentration histories of 2- to 3-μm diameter protozoa (P/P_0) and a bromide tracer (Br/Br_0) in a contaminated sandy aquifer. Data shown from a depth of 11 m below surface and 1.0 m downgradient from the injection point. No error bars are shown for $Br/Br_0 < 2\%$ RSD. Vertical line indicates time of hydraulic perturbation. Reprinted from Reference 33.

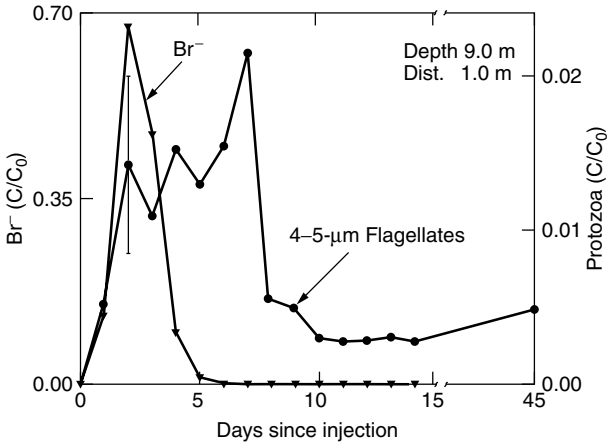

Figure 6. Dimensionless concentration histories (P/P_0) for 4- to 5-μm diameter flagellates and bromide in contaminated sandy aquifer sediments located 9.3 m below surface and 1.0 m downgradient from the injection point. The error bar at the first flagellate peak represents 1 standard deviation for replicate counts. Reprinted from Reference 48.

aquifer studies with microspheres (40) and the colloid-filtration theory (32) suggest that the 2- to 3-μm flagellates that are found in situ are approximately the optimum size for transport. Being highly mobile may be an effective strategy for a predator, allowing it to be rapidly advected downgradient when environmental conditions change (41). In addition, the low buoyant densities of the flagellates (1.02 to 1.03 g/cm^3) (42) further facilitate transport and are comparable to those of their potential food source, the unattached bacteria (41).

The effects of potential alteration of cell surface characteristics by staining and chemical fixation during laboratory and field studies need to be determined because these may change cell surface interactions. It is also likely that chemical, as well as hydraulic perturbations, in aquifers can affect protozoan transport because the cells are reversibly attached to grain surfaces (Fig. 5). Protozoan transport in the subsurface has ramifications for public health (e.g., movement of the pathogens such as *Cryptosporidium* and *Giardia*) and bioremediation

strategies. Further research is needed for understanding these effects.

PROTOZOAN ROLE IN THE SUBSURFACE

Most studies (Table 1) report higher protozoan abundance in contaminated aquifers where biodegradation is occurring than at pristine sites. An examination of the microbial ecology literature for aquatic and soil environments reveals several possible explanations for this relationship, including protozoan predation on bacteria and/or phage, protozoan an consumption of high molecular weight (MW) organics, and protozoan recycling of limiting nutrients (e.g., nitrogen, phosphorus).

Protozoan predation upon bacteria is well documented for marine and freshwaters, soil, and waste-treatment environments (43–47). Recent studies in an organically contaminated aquifer in Cape Cod, Massachusetts, have quantified flagellate predation on unattached bacteria (20,30,48). The first evidence of potential predation (20) was obtained from flow-through column studies where aquifer sediments containing bacteria and protozoa were injected with DAPI-stained bacteria. The effluent concentration of the DAPI-stained bacteria was monitored over time. Each column was then autoclaved to kill all microorganisms and the injection study was repeated. Bromide tracers were also injected into each column to ensure that they were hydraulically similar before and after sterilization. In the sterilized columns, approximately 80% of the influent DAPI-stained bacteria were detected in the effluent (C/C_0). When protozoa (primarily flagellates) were present, breakthrough was approximately 30% in one column and less than 5% in the other. The data suggested that the flagellates in the columns were preying on the DAPI-stained bacteria. Bacterial grazing and clearance rates (volume of water cleared of bacteria per protozoan cell per unit time) were calculated (Table 2). The difference in breakthrough for the two columns where protozoa were present was a function of the size of the microbes. Greater percentages of larger flagellates (3–5 μm) resulted in higher grazing and clearance rates. Because of the way these studies were designed, they did not provide direct evidence that the bacteria were ingested and degraded by the protozoa. In addition, the DAPI stain may have affected protozoan predation on the bacteria. It is likely the clearance rates were overestimated because the calculation ignored those protozoa residing in the sediments that were not being eluted.

In a second study (48), unattached bacteria from the aquifer were separated into four size classes and stained with DTAF. These bacteria were placed in flasks with 2- to 3-μm aquifer flagellates in time series grazing experiments, and the stained bacteria within the protozoa observed (Fig. 7). The protozoa preferentially grazed upon the 0.8- to 1.5-μm bacteria, the size class that exhibits the greatest productivity in the aquifer's organic contaminant plume. Clearance rates were similar to those in other environments (Table 3). The data suggested that the aquifer flagellates can consume, daily, as much as 12 to 74% of the unattached bacterial population.

These two studies showed that protozoa selectively prey on unattached bacteria and have the greatest impact on the most productive bacteria. Whereas attached bacteria constitute the greatest number and the most active bacteria in pristine aquifers, Murphy and coworkers (31) have shown that unattached bacteria play a greater role when organic contamination of an aquifer occurs, suggesting that protozoan predation on them could affect biodegradation rates. There are still no measurements of protozoan predation rates in situ and little is known about their effect on attached bacteria. Some of the attached bacteria are loosely attached to grain surfaces in the secondary minimum layer and these may be readily available to grazing protozoa. Novarino and coworkers (25) have suggested that the diverse group of protozoa present in aquifers feed in different ways and exhibit niche differentiation, perhaps based on their form of motility (creeping, swimming, temporarily attached).

Gonzalez and coworkers (54) reported that marine nanoflagellates can consume phages. There is data to suggest that phages are present in the subsurface (55), but the extent of protozoan grazing on them is unknown and needs to be explored.

Laboratory studies (56,57) with aquatic flagellates have shown that they can consume high MW organics (>40 K); however, this activity has not been documented in situ. In some aquifers, the organics have an MW of less than 30 K (30), suggesting that this potential protozoan food source is not abundant. It is possible that, under certain geochemical conditions, dissolved organic matter could be converted to colloidal (higher MW) material, but again this effect may be limited in most subsurface environments. Some evidence in aquatic environments indicates that protozoa may egest particles and reingest them (58,59), but the extent of this process in situ is also unknown.

Many studies (e.g., Refs. 60–62) have documented that protozoa in soil and aquatic environments recycle

Table 2. Grazing and Clearance Rates for Flagellates in Column Experiments with Sandy Aquifer Sediments (20)

Column	Grazing Rate (bact/protist•h)	Clearance Rate (nL/protist•h)	Bacterial Size (μm)	Flagellate Size (μm)
I	3	12	1.0 to 2.0	96% 2 to 3 μm 4% 3 to 5 μm
II	27	23	1.5 to 3.0	77% 2 to 3 μm 23% 3 to 5 μm

[c] The values from these references represent a range of experiments conducted by several researchers at various temperatures with various sizes of fluorescently labeled bacteria and flagellates.

the nutrients that limit bacterial growth. For example, Goldman and coworkers (63) and Zwart and Darbyshire (64) reported that the ammonia excreted by protozoa regenerates the supply of nitrogen for use by bacteria. In pristine aquifers or those contaminated aquifers where bacteria are nutrient-limited, this could be the major role of protozoa and may directly stimulate bacterial biodegradation of organics. It is also possible that protozoa may excrete other substances, such as vitamins or amino acids, needed by bacteria (65).

IMPACT OF PROTOZOA ON CONTAMINANT BIODEGRADATION IN AQUIFERS

Data from most natural environments clearly show that when protozoa are present they have an impact on contaminant biodegradation rates as a result of their predation upon bacteria (38). It is likely that this is their function in the subsurface. Protozoan predation could either reduce bacterial bioclogging in aquifers or decrease or enhance bacterial degradation of organic contaminants in situ.

Sinclair and coworkers (15) and Zarda and coworkers (22) hypothesized that, by grazing upon bacteria, protozoa prevent bioclogging of aquifers and maintain hydraulic conductivity. This is especially important where organics and nutrients are present in substantial amounts, stimulating excessive bacterial growth. DeLeo and Baveye (66) conducted column studies with soil colonized by *Bacillus* and *Acanthamoeba*. The short-term effect (over the first days) of protozoan predation was a reduction in bacterial abundance and a decrease in clogging. However, over the longer term, columns with and without *Acanthamoeba* exhibited a similar degree of clogging. DeLeo and Baveye speculated that in the short term, either the bacterial aggregates were too large for protozoan predation, *Bacillus* inhabited crevices that were inaccessible to *Acanthemoeba*, or the bacterial migration and colonization along the columns was greater than the rate of amoeboid movement through the sediments. Most aquifers, whether pristine or contaminated, are carbon- or nutrient-limited (i.e., contaminants are only present at the ppb or low ppm level). Hence, bacterial abundances and growth rates are usually low, and bioclogging is not a problem except around injection wells. In these aquifers, the impact of protozoan predation is probably not prevention of bioclogging and maintenance of hydraulic conductivity.

In their model of the Savannah River aquifer, Travis and Rosenberg (21) found that protozoan predation on methanotrophic bacteria decreased the TCE degradation rate by 25%. These results suggest that protozoa may negatively impact biodegradation, which would be especially problematic at sites undergoing natural or enhanced bioremediation. One problem with such ecosystem modeling approaches may be that the bacterial kinetic constants used in the models are the same whether predators are present or absent. However, various studies (30,67,68) indicate that the constants change. For example, the K_s (half-saturation constant) of bacteria degrading organics can increase when they are being preyed upon by protozoa (30). Data from short-term, aerobic incubation of subsurface bacteria has shown that biodegradation rates of benzene, toluene, ethylbenzene, and the xylenes are higher when protozoa are absent (23). However, this negative impact could be a short-term effect, as shown by Wiggins and Alexander (69) for 2,4-dichlorophenoxyacetic acid (2,4-D) and PNP (Fig. 8) where protozoa lengthen the period of bacterial acclimation to the contaminants, but increase the overall extent of mineralization. Mattison and Harayama (70) observed an increase of as much as 7.5 times the rate of toluene degradation by bacteria when a flagellate was present.

Laboratory studies of the effect of protozoa on bacterial degradation rates are very difficult to conduct because it is hard to eliminate them from the ecosystem in controls. Organic inhibitors are often used to eliminate the protozoa (e.g., nystatin, cycloheximide) (69,71), but they may not be effective (46,72,73) or the inhibitors may become carbon sources for bacteria. In addition, sampling in these types of experiments must be frequent because the data must account for the effects of short-term cycling in the populations of the predator and prey, unless "steady state" has been established.

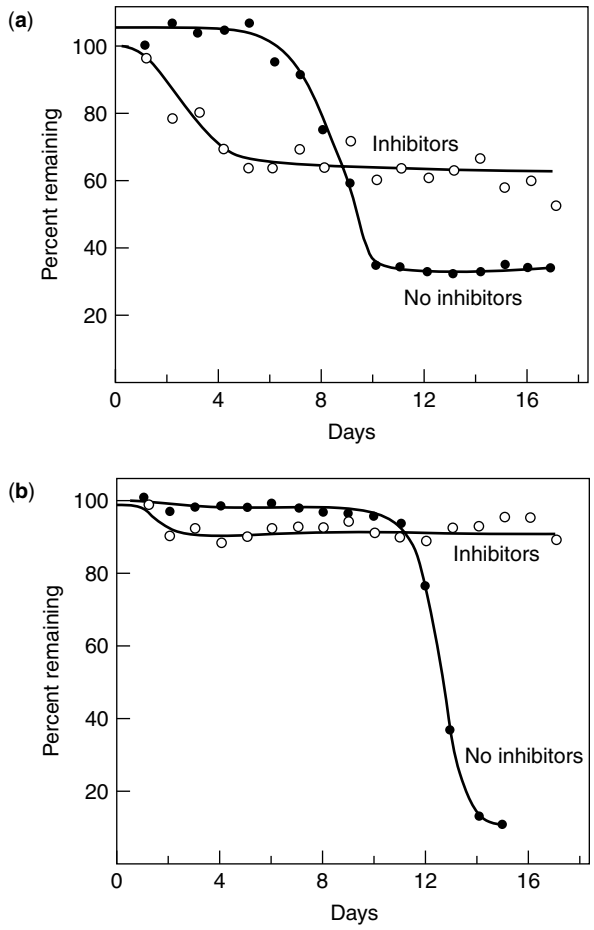

Figure 8. Effect of protozoa on the mineralization of 100 ng of 2,4-dichlorophenol (top) and 2,4-D (bottom) per milliliter of sewage. Cycloheximide and nystatin were used as inhibitors. Reprinted from Reference 69.

In many studies, starting with those by Cutler and coworkers (74) in soils, the observation that bacterial abundance is lower when protozoa are present, has led to the conclusion that bacteria, as a result, degrade less organic matter. The question that must be asked is whether the reduction in bacterial numbers caused by protozoan predation translates into less biodegradation of the organic contaminants by bacteria. This question relates directly to predator-prey dynamics.

Hunt and coworkers (67) and Kuikman and coworkers (68) have shown that protozoan predation decreases bacterial biomass. However, this results in more carbon, nitrogen, and phosphorus being available per bacterium. Both studies showed that increased carbon, nitrogen, and phosphorus stimulated the uptake and growth rates of the remaining bacteria and may have allowed the coexistence of bacterial species (75). Alexander (76) noted that the predator is "prudent" by not eliminating all prey. Rather than being an anthropogenic phenomenon, the prudent predator is simply exhibiting density-dependent feeding (i.e., the presence of fewer bacteria results in greater difficulty for the predator in locating the prey). As Sinclair and Alexander (71) have shown, slow-growing bacteria may be eliminated, whereas faster growing populations will not be. If the slow-growing bacteria in the subsurface are the only contaminant degraders or perform a critical step in the overall degradation process, then in situ degradation could be negatively impacted by protozoan predation. In addition, as Novarino and coworkers (25) have hypothesized, it is likely that because of niche differentiation (e.g., pore water swimmers versus surface-associated feeders), protozoa may not be able to consume all bacteria in a subsurface environment. Prey can also exhibit escape strategies, such as taking refuge in pores where protozoa cannot enter (77) or changing morphology to prevent ingestion (78).

There is preliminary laboratory evidence that unattached bacteria from a pristine sandy aquifer exhibit higher apparent growth rates and greater frequency of dividing cells when protozoa are present (Fig. 9) (30). Whereas this data suggests that protozoan predation may result in increased bacterial degradation of organic contaminants, experiments need to be conducted with more representative organic carbon sources (i.e., not just acetate) and in the field. It is also essential to have better estimates of the true bacterial growth rate (without protozoa present) to calculate more reliable bacteria kinetic constants and predation rates.

CONCLUSION

The last 15 years of the twentieth century saw a dramatic change in our fundamental knowledge of protozoa in the subsurface: from a realization that they are present in the environment to the understanding that they most likely impact in situ degradation of organic contaminants in some way. It has been shown that protozoan predation upon bacteria is occurring in the subsurface, as it does in other environments, and that it affects bacterial

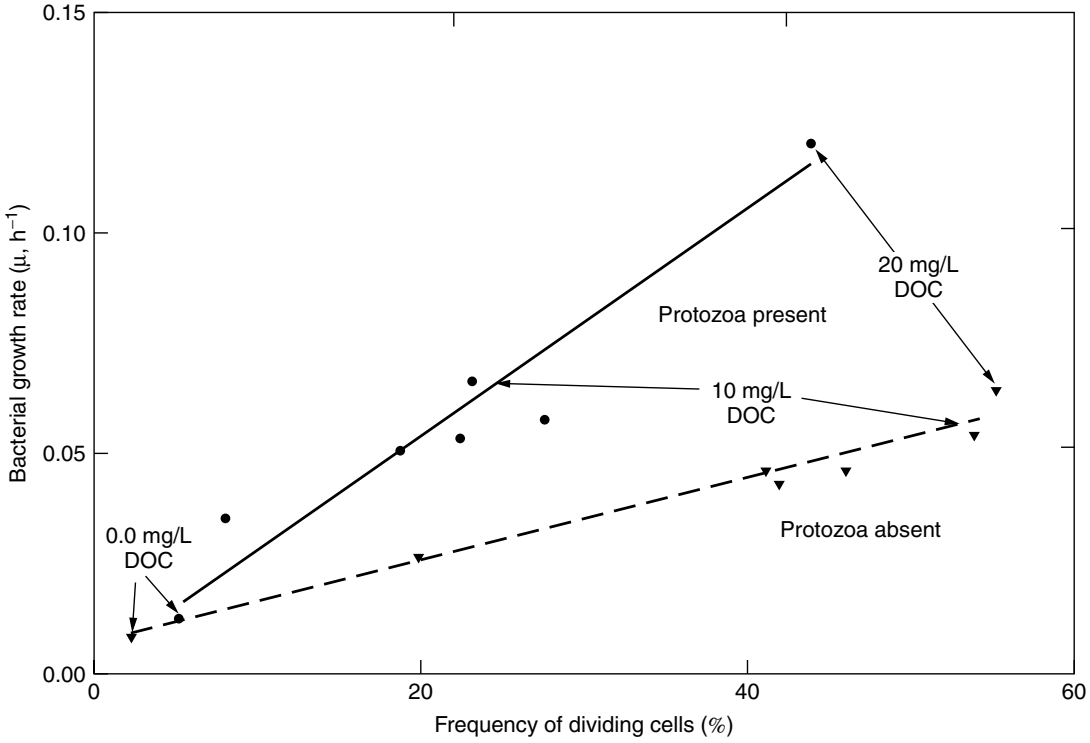

Figure 9. Measured (apparent) growth rates and the frequency of dividing cells for groundwater bacteria collected from an uncontaminated sandy aquifer with background dissolved organic carbon (DOC) of 0.9 mg/L at different concentrations of amended acetate (0 to 20 mg C/L) in 2-day closed bottle laboratory experiments. Source is Reference 30.

abundance. The question as to whether the predation aids or retards bacterial degradation of the organics remains unanswered and will be difficult to determine, primarily because contaminated aquifers are dynamic ecosystems. Fluctuations in bacterial and protozoan populations may be rapid (on the order of hours to days). This will necessitate laboratory experiments and field studies incorporating frequent sampling instead of using just a few "snapshots" of data to observe and determine the effects of predator-prey dynamics. For example, predator:prey ratios based on abundance or biomass have been used to determine possible relationships in aquifers, and these ratios vary widely in aquifers from $1 : 10^2$ to 10^6 (30) in both pristine and contaminated sites from the theoretical $1 : 10^3$ ratio (38). However, as Gasol and Vaqué (79) noted, such ratios may be misleading because they depend upon whether the predator:prey dynamics are at "steady state" and whether the correct prey (e.g., size class of bacteria, attached or unattached population) and predator (those that creep, swim, or exhibit a mixed mode of motility (25)) are used in the ratio.

The challenge ahead is to enumerate and characterize (e.g., niche differentiation, trophic versus encysted state) protozoa more carefully and to define their specific role(s) in pristine and contaminated subsurface environments (e.g., what are the protozoan food sources?, what is their impact on bacterial productivity and contaminant biodegradation?). In doing so, aquifer parameters and environmental geochemistry must be considered, as these may affect the ability of protozoa to survive and prey upon bacteria. It is possible that one explanation for reduced rates of contaminant biodegradation in some subsurface environments may be the result of inhibition or elimination of protozoa as a result of toxicity effects. Protozoa may be more susceptible to such inhibitions because they have a much less complex cell wall structure that separates them from the environment than do bacteria.

Madsen (80) concluded that the irony of studies of environmental microbiology is that laboratory experiments are simpler than fieldwork, but typically have less relevance. Hence, understanding the role and impact of protozoa in subsurface ecosystems will be difficult. Studies of predator-prey dynamics in other environments can provide direction and suggest approaches for laboratory and field research designed to study the ecology of subsurface protozoa. In addition, the food webs in the subsurface may be simpler to understand than those in most other natural environments because there are fewer trophic levels (Fig. 10): perhaps only one level of predator (protozoa) and prey (bacteria).

PROTOZOA IN ACTIVATED SLUDGE

PAOLO MADONI
University of Parma
Parma, Italy

The aim of the activated sludge process is to achieve a maximal reduction of the biological oxygen demand (BOD) of wastewater with a minimal production of biological solids. In this process, protozoa are important members of the communities involved in the removal of organic matter and dispersed bacteria. In fact, biological wastewater treatment processes rely on the natural self-purification capacity of aquatic environments, which is the result of the activity of microbial communities. Nevertheless, the activated sludge process differs from aquatic environments in the following characteristics:

- strong flow of organic matter into the system,
- accelerated decomposition processes,
- prevalence of heterotrophic organisms and then of the detritus food web,
- short biomass turnover time.

These characteristics deeply influence the organisms able to live in these artificial systems, so that among heterotrophic organisms only protozoa and small metazoa with life cycles shorter than the sludge retention time are able to compete in activated sludge process. It has long been known that protozoa are plentiful in activated sludge plants (1). It is common to find populations of protozoa on the order of more than 50,000 cells per mL in the mixed liquor, and this constitutes approximatively 9% of the dry weight of suspended solids in mixed liquor (2) (Fig. 1). The protozoa and small metazoa are able to feed on particulates, such as those coming in with the sewage or bacterial flocs. It is generally assumed that their primary role in the wastewater treatment is the clarification of the effluent (3,4).

PROTOZOAN OCCURRENCE AND DIVERSITY

Free-living Protozoa

Since the installation of the first activated sludge treatment facilities in 1922, many authors have noted the presence of free-living protozoa. Besides bacteria, the protozoan community is the most abundant and the species rich group within activated sludge. A total of more than 230 species of protozoa are encountered in activated sludge plants (5–7), and they are distributed among the following five classes or phyla: Phytomastigophora, Zoomastigophora, Rhizopoda, Actinopoda, and Ciliophora. Nevertheless, only a third of these species are regularly found in the mixed liquor, whereas the other forms drift into the aeration tank with the inflowing wastewater, and cannot establish themselves permanently within the protozoan community.

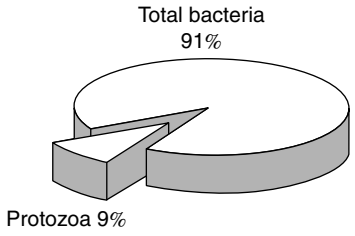

Figure 1. Proportion of protozoa biomass and sludge content in the activated sludge treatment process.

Flagellates. It is quite clear that although these protozoa from the two flagellate classes Phytomastigophora and Zoomastigophora are found in activated sludge plants, generally, they are relatively rarely seen because only 33 species have been identified. Small flagellates belonging to the class Zoomastigophora (*Bodo*, *Cercomonas*, *Trepomonas*) enter the plant in the influent wastewater, and their growth in the aeration tank is usually associated with poor operational parameters (poorly aerated sludge, overloaded plants, fermenting substances involved) (8,9). Large flagellates (Phytomastigophora) appear to occur less frequently in activated sludge and in smaller numbers than small flagellates, and their presence generally is associated with underloaded plants (10,11). Two genera are mainly found: *Euglena* and *Peranema*.

Amebae. A list of naked amebae observed in activated sludge plants is given in (6,12,13). Amebae occur in the raw, settled sewage and at the head of the aeration tank, but the greatest species diversity is found in the aeration tank, whereas the lowest number of species has been found in sedimentation tanks. The most common species observed in activated sludge plants belong to the genera *Vahlkampfia* (*V. avara*, *V. limax*), *Mayorella, Naegleria*, and *Hartmannella*. Among testate amebae, only few species (*Arcella*, *Euglypha*, *Centropyxis*, and *Pyxidicula*) are able to colonize activated sludge systems because of their high generation times that prevent them from growing in conventional plants with short sludge retention times. These protozoa develop high population densities mainly in extended aeration plants operating with high sludge age, high DO values and low sludge load that favor full nitrification (14,15,16). Among protozoa belonging to the phylum Actinopoda, only six species have been identified. These protozoa are infrequent in the activated sludge and their presence is associated with underloaded plants (15,17).

Ciliates. Of the 230 to 250 protozoan species that have been found so far in activated sludge plants, about 160 belong to the phylum Ciliophora, but less than half of them have been observed frequently (6,18,19). This number evidently is only a small part of the thousands of species of freshwater protista that could theoretically be observed in these environments. Table 1 shows the most important ciliates found in activated sludge. Ciliated protozoa are the most diverse group in terms of numbers of species in the protozoan community. Activated sludge mixed liquor of a plant treating domestic sewage normally contains up to 10 species of ciliates and numbers of individuals ranging from 10^6 to 10^7 L^{-1} (6,17). Although

Tokophrya spp.	*Tetrahymena* spp.	*Trochilia minuta*	

the rhizopods or the flagellates can dominate the protozoan community of activated sludge, this is infrequent and usually the ciliates hold the dominant position. Numerous species of carnivorous ciliates were found in activated sludge plants, nevertheless, the majority of ciliates present in the activated sludge are filter feeding on dispersed populations of bacteria. They are subdivided into three functional groups on the basis of their behavior (Fig. 2):

Free-swimming, those which swim in the bulk liquid phase and remain evenly in suspension in the sedimentation tank;

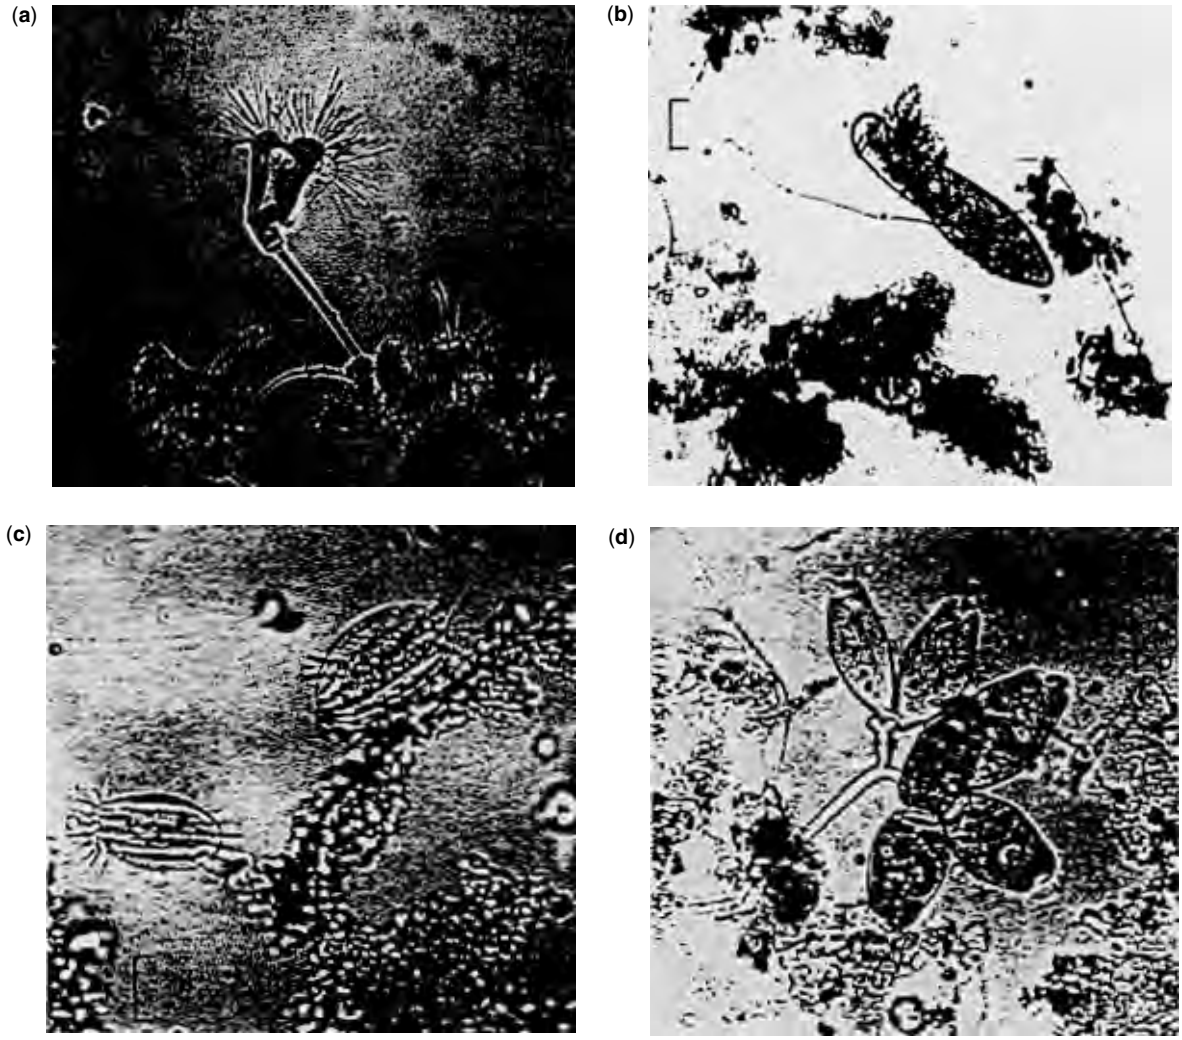

Figure 2. Micrographs showing the groups of ciliates found in activated sludge systems. (**a**) carnivorous ciliates (Suctoria); (**b**) free-swimming bacterivorous ciliates (*Paramecium*); (**c**) crawling bacterivorous ciliates (*Euplotes*); (**d**) Attached bacterivorous ciliates (*Opercularia*).

- *Crawling*, those that are not attached, but inhabit the surface of sludge flocs;
- *Attached*, those that are firmly fixed to the sludge floc by means of a stalk. They are strictly associated with flocs and thus settle during sedimentation.

All bacterivorous ciliates rely on ciliary currents to force suspended bacteria into their mouths (Fig. 3). Free-swimming and attached ciliates are in competition for bacteria and small flagellates dispersed in the liquid phase. Ciliates moving on the floc surface (crawling ciliates) feed on bacteria that lightly adhere to the floc, and to those that are dislodged by the ciliate feeding currents (4).

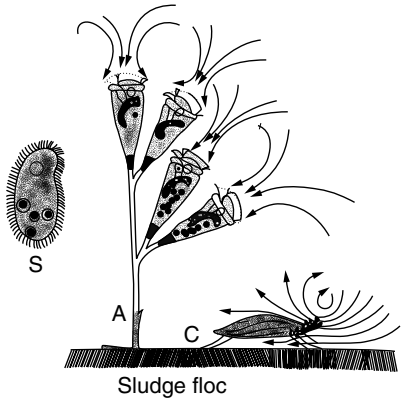

Figure 3. Feeding mechanisms of bacterivorous ciliates in the activated sludge system. Crawling ciliates (C) scrape bacteria from the surface of the flocs, while free-swimming (S) and attached (A) ciliates filter out dispersed bacteria in the mixed liquor (4).

Parasitic and Pathogenic Protozoa

Some protozoan parasites such as, *Giardia* and *Cryptosporidium* are recognized causes of diseases in humans and animals. *Cryptosporidium* is recognized worldwide as an important pathogen causing diarrheal illness in humans and animals. Routes of transmission involve contact with infected people and animals, and the waterborne route. However, only since 1985 has *Cryptosporidium* been recognized as the cause of waterborne disease (20). *Cryptosporidium* has many characteristics that enable its waterborne transmission, and common bacterial indicators of fecal pollution do not indicate its presence in water (21). *Giardia* is a protozoan capable of causing chronic diarrhea in humans. Fecally contaminated waters and consequent waterborne outbreaks of giardiasis have been widely reported (22). The cysts of the organism often remain viable for several months in water; furthermore, they are more resistant to disinfection than to fecal coliforms that are usually used as bacterial indicators of fecal pollution (23). For more details see PARASITIC PROTOZOA: FATE IN WASTEWATER TREATMENT PLANTS."

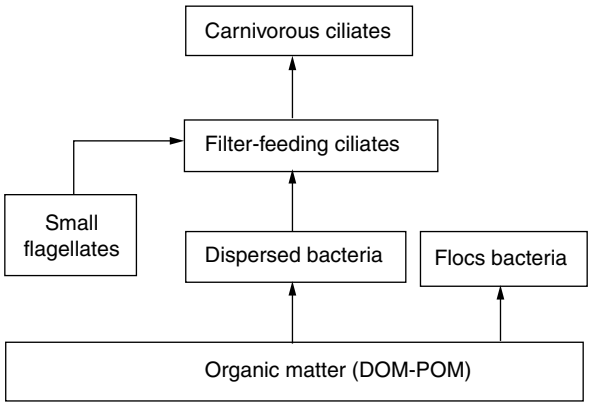

Figure 4. The microbial loop in the activated sludge of sewage treatment plants (27).

ROLE OF PROTOZOA IN PLANT OPERATION

Protozoa are known to have an important role in the activated sludge process, particularly in effluent clarification, and this in turn results in a reduced effluent BOD (24). In fact, in activated sludge, bacterivorous ciliates ingest large numbers of the dispersed bacteria, which are not associated with flocs, and whose growth would generate high turbidity of the effluent. In the absence of ciliated protozoa, in fact, effluents have a much higher BOD and are highly turbid because of the presence of many dispersed bacteria (3). Protozoa, moreover, feed on pathogenic and fecal bacteria contributing to their removal efficiency at 95% (25).

In aeration tanks of activated sludge plants a microbial loop is established (Fig. 4). The growth of the heterotrophic bacteria depends on quality and quantity of DOM. Conversely, for predator protozoa,, growth depends on the available prey. The dispersed bacteria serve as a food source for flagellates, rhizopods, and ciliates, whereas these in turn are prey for carnivorous protozoa.

The protozoan assemblage changes during the stabilization of activated sludge systems (Fig. 5). The plant start-up phase is characterized by the presence of species typical of raw sewage, such as small heterotrophic flagellates and free-swimming bacterivorous ciliates. These protozoa are not linked to the presence of flocs and cannot be considered typical components of the activated sludge microfauna. With the development of the biomass, they compete with protozoa better adapted to an aeration tank environment and rapidly decline in numbers. The following phase is characterized by the strong growth of protozoa typical of the aeration tank habitat, such as crawling and attached ciliates. The steady state phase is characterized by a protozoan community whose structure reflects the stable conditions in the aeration tank, with a balance between the organic loading and the mixed liquor suspended solids that are produced, removed and recycled (27). In a mature activated sludge, the species structure of the protozoan community is strictly dependent on plant management choices based on design characteristics aimed at guaranteeing optimum efficiency.

It should be emphasized that each of the three phases is characterized by a typical protozoan population structure. Free-swimming bacterivorous ciliates such as *Uronema*, *Cyclidium Colpidium* and small heterotrophic flagellates

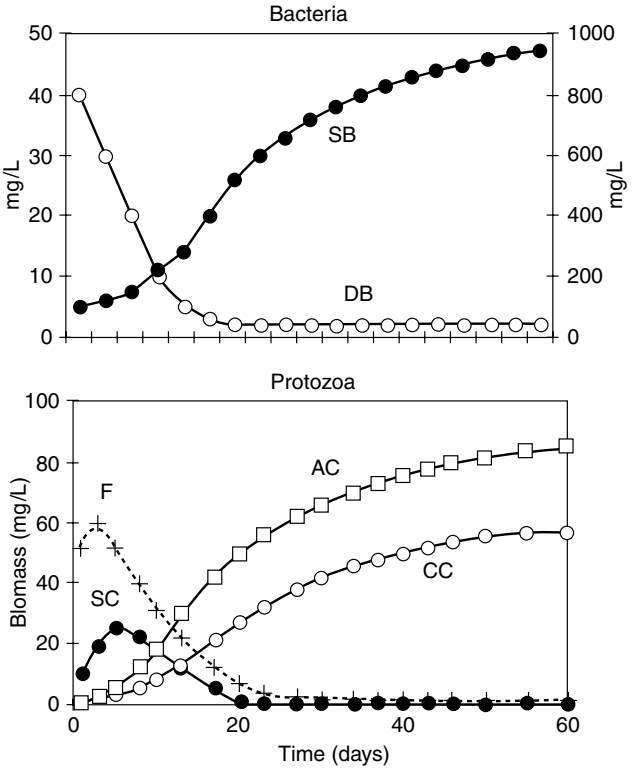

Figure 5. Dynamics of protozoa and bacteria biomass during the stabilization of activated sludge. (DB) Dispersed bacteria; (SB) floc bacteria; (F) small flagellates; (AC) attached ciliates; (CC) crawling ciliates; (SC) swimming ciliates.

such as *Bodo* and *Cercomonas*, are associated with the first phases of the colonization of the plant, whereas stalked ciliates such as *Epistylis* and *Vorticella*, and crawling forms such as *Aspidisca* are typical of the steady state phase (27). A fully functioning plant will not contain species characteristic of one of the colonization phases, unless dysfunctions cause instabilities in environmental conditions. These include changes in the amount of sludge, the degree of aeration, organic load, sludge retention time, and organic loading at input.

Nevertheless, there are some plant-operating conditions that heavily influence the microfauna assemblage. The dilution rate of the system is important since any species that cannot reproduce quickly enough to compensate for such a loss will be removed from the system. Thus, activated sludges with fast flow rates will tend to favor species with rapid rates of reproduction, usually the smaller protista such as heterotrophic flagellates or small ciliates (<30 μm). Activated sludge plants with slow flow rates host a greater diversity of organisms, including small metazoa, which, in contrast with protozoa, have slow rates of reproduction (10,17). Overloaded systems lead to a higher demand for dissolved oxygen, and low levels of free oxygen will favor those heterotrophic flagellates (9), amebae, and small ciliates (17) normally found in organically polluted habitats (Fig. 6). As the organic loading decreases, the diversity of organisms, which may colonize the mixed liquor, increases. In underloaded plants (i.e., extended aeration units), higher numbers of taxa are found but the number of individual population encountered is usually smaller (15,17).

PROTOZOA AS INDICATORS OF PLANT PERFORMANCE

The prevalent reactor operating conditions, in particular the sludge age, dissolved oxygen, and organic loading rate (F/M ratio), together with the composition of the influent wastewater, have a profound effect on the microbial populations inhabiting the aeration tank because these operating conditions dictate both the amount of time an organism has to reproduce in the reactor, and the amount of nutrients which are available to it (28). Changes in F/M ratio and sludge age, together with MLSS in the aeration tank, and the effluent BOD, correspond to quantitative and qualitative changes in the protozoan community. It has been demonstrated that the identification and enumeration of protozoa in activated sludge mixed liquor, may provide rapid information on plant operating conditions and performance (17,24,29).

Crawling ciliates (hypotrichs) decrease with increasing loading (no hypotrichs would be observed in sludge loaded above 0.6 kg BOD/kgMLSS/day), whereas stalked ciliates (peritrichs) are able to grow throughout a large range of sludge loadings (24). Nevertheless, at low loadings (0.1 e 0.3 kg BOD/kg MLSS/day) a wider diversity of ciliates, in terms of numbers of species with a more uniform distribution between the three functional groups, would be observed (24).

In field studies, the number of ciliated protists observed in a normally functioning plant ranged from 10^3 to 10^4 individuals/mL (17). Numbers of ciliates falling below 10^2/mL, corresponded to lower treatment efficiency (29). In this case, the low ciliate density was accompanied with increased BOD values in treated effluent, and a higher effluent turbidity caused by the presence of dispersed bacteria. Higher densities of ciliates ($>10^4$/mL) instead, were almost always associated with good purification and optimum plant performance (17,29). The microfauna of a well-operating activated sludge system is almost always

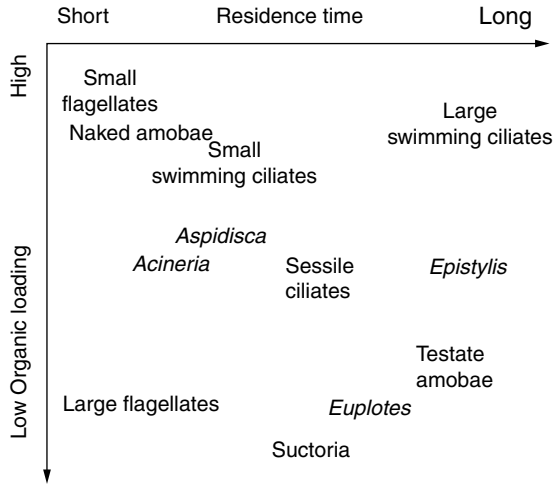

Figure 6. Influence of organic loading and sludge residence time on the protozoan assemblage in activated sludge.

highly diversified. More than 10 species of ciliated protozoa may be found in a sample of activated sludge mixed liquor, in which each species is never numerically dominant over the others, even though the ratios among species can differ (4). The sludge of plants affected by conditions such as shock load of toxic discharge, underloading or overloading, strong sludge extraction, lack of aeration, is often dominated by one species or functional group more tolerant to these conditions.

Thus, the structure of the microfauna is a valid indicator of plant performance and an efficient activated sludge plant possesses the following characteristics:

- High numbers of protozoa ($\geq 10^3$/mL).
- Microfauna composed chiefly of crawling and attached ciliates, with almost no small heterotrophic flagellates and free-swimming ciliates.
- High number of species in which none dominates numerically over the others by a factor greater than 10.

When the protozoan community lacks these characteristics, identification of the dominant group of the microfauna present allows a diagnosis of the problem with the plant (Table 2). In addition, identification of the protozoan species allows more complete information on the biological performance in the aeration tank to be obtained. In fact, if it is true that a protozoan community rich in attached and crawling ciliates indicates improved performance with respect to that found when free-swimming ciliates dominate, it also true that different species of crawling and attached ciliates can be associated with different operating conditions. Each species is able to provide additional information. This is the case for the attached ciliates *Vorticella convallaria* and *Vorticella microstoma*. These two peritrich ciliates are in direct competition in the activated sludge. *Vorticella microstoma* characterizes the first phase of colonization but it is then substituted by *V. convallaria*, which may reach high numbers during the steady state phase. In cases of lack of aeration in the mixed liquor, the importance of these two species may change due to their differing degree of tolerance to the lack of oxygen (30). Thus, dominance of *V. microstoma* indicates a poorly aerated sludge (24,30).

Table 2. Relationships Between Dominant Group of the Microfauna and Plant Performance (37)

Dominant Group	Performance	Possible Causes
Attached + crawling ciliates	Good	
Attached ciliates	Decreasing	Discontinuous load recent sludge extraction
Crawling ciliates	Good	
Free-swimming ciliates	Mediocre	Poor aerated sludge; overloading
Small heterotrophic flagellates	Low	Overloading; poorly aerated sludge; fermenting substances involved
Small naked amebae and Small heterotrophic flagellates	Poor	Very high load, not easily degradable
Testate amebae	Good	Very low sludge load; long sludge retention time; high DO in aeration tank; complete nitrification

THE SLUDGE BIOTIC INDEX (SBI)

It has been recognized that changes in the community structure and types of protozoa species in the mixed liquor of activated sludge may affect the food web of these artificial ecosystems, and, thus, may also influence the biological performance of plants. Results obtained from correlation analysis showed which physicochemical and operational parameters have the greatest influence on the functional groups of protozoa in the activated sludge (29). Small flagellates, free-swimming ciliates, and the peritrichs *V. microstoma* and *Opercularia* spp. are negatively correlated with DO, nitrifying ability of the plant, and the level of BOD removed, whereas these are positively correlated with the effluent turbidity. On the contrary, crawling ciliates and testate amebae appear to be positively correlate with DO, nitrifying ability, BOD removed, and negatively correlated with effluent turbidity.

Numerous biotic indices have been developed to assess the degree of pollution in freshwater environments. The performance of the plants has to be constantly monitored and is subjected to strict regulation. Nevertheless, malfunctions resulting in decreased purification efficacy are frequent. In the last decade the routine analysis of the microfauna as an indicator of activated sludge plant performance has become more common because it provides rapid and useful information on the biological activity of the sludge based on the community structure of the protozoa present (28,31). Some of these methods, however, are subjective indices based on the analyst's personal interpretation of the microfauna that colonize the activated sludge system under investigation. These indices cannot necessarily be applied directly to other similar plants. Objective indices have a great advantage over subjective ones, in that, index values assessed by different operators are comparable.

The SBI, an objective index based on protistan community, has been devised to monitor activated-sludge plant performance (29). This method is based on two principles:

- the dominance of protistan keygroups changes in relation to environmental and operational conditions of the plant,
- cell density and number of taxa diminish as the efficiency of the plant drops.

The SBI enables the operator to define the biological quality of the sludge by means of conventional numerical values (from 0 to 10) that are grouped into four quality classes (Table 3). An accurate identification of the various species of protista is important to obtain an accurate SBI value. However, some keys written

Note: Conversion of SBI values into four quality classes

SBI value	Class	Judgment
8–10	I	Very well colonized and stable sludge; excellent biological activity; very good performance.
6–7	II	Well colonized and stable sludge; biological activity on decrease; good performance.
4–5	III	Insufficient biological purification in the aeration tank; mediocre performance.
0–3	IV	Poor biological purification in the aeration tank; low performance.

specifically for protista in sewage treatment processes and polluted waters are available (32–37). Organisms considered in the SBI method are: small and large flagellates, ciliates, testate amebae, and some small metazoa such as rotifers, nematodes and gastrotrichs. While all the species of ciliated protozoa and testate amebae contribute to the determination of the microfauna diversity, small flagellates and metazoa are very difficult to identify at species level and thus contribute each with one systematic unit only. Since carnivorous ciliates do not play an important role in the purification process, they contribute only to estimates of the total density and diversity of the microfauna.

The ecological characteristics of the seven keygroups used for to determine the SBI are the following:

Testate Amoebae

Testate amoebae are more abundant or dominant in sludges characterized by low loading, long sludge retention time, and high DO in aeration tanks that enable complete nitrification (14,15). Under these conditions, the quality of the effluent is excellent and a high biological performance of the plant is attained. Testate amebae grow only in plants with a long sludge age since these protists have low growth rates. Since their growth rate increases with temperature, testate amebae are often more common in summer. Nevertheless, when the sludge loading reaches high values (>1 kgBOD/kgMLSS · d) and the COD of the effluent is elevated, these protists are replaced by the peritrich ciliate *Opercularia* and by free-swimming ciliates (16).

Crawling and Attached Ciliates

These two functional groups normally codominate the protistan community in activated sludge plants. This is due to their different food habits, preventing competition. In fact, while attached ciliates feed on bacteria and small flagellates that are dispersed in the liquid phase, crawling ciliates are in close proximity to substrates of flocs and graze on bacteria loosely attached to them. Nevertheless, the ratio between the two functional groups tends to change with sludge loading. Crawling ciliates reduce their numbers as sludge loading increases so that above 0.6 kg BOD/kgMLSS · d most species of this group disappear (24).

Even if attached ciliates are normally codominant in the activated sludge, their numbers increase rapidly (over 80% of the whole microfauna) under transient conditions that reduce plant performance (17,26). Such transient conditions are:

- discontinuous input of organic load from the influent,
- quick increase of the sludge load due to loss of sludge

Attached ciliates are able to grow over a wide range of sludge loadings; nevertheless, at values ranging from 0.3 to 0.6 kg BOD/kgMLSS · d, these protists dominate, whereas for sludge loadings of 0.6–0.9 kg BOD/kgMLSS · d sessile ciliates and flagellates codominate (24).

Among stalked peritrich ciliates some species such as *V. microstoma* and *Opercularia* spp. are able to survive and grow in activated sludge systems under severe conditions (lack of oxygen, toxicants). When these forms are present as dominant or prevalent species, they must be considered separate key groups.

Opercularia spp.

Low numbers of *Opercularia* often occur in activated sludge, but their population density increases when the plant produces low-quality effluent. *Opercularia* spp. are associated with high final effluent BOD concentrations, and are among the most abundant forms at high plant loadings (24,31). These ciliates moreover can survive in stressed environments better than other protists. In fact, large numbers of *Opercularia* have been found in plants receiving industrial waste containing toxic substances (38). Moreover, these peritrich ciliates have been associated with high final effluent BOD and ammoniacal-N concentrations (14,15). *Opercularia* may be the only ciliate protozoan in sludges of plants treating industrial waste containing metal salts. High numbers of *Opercularia asymmetrica* have been found in activated sludge receiving heavily loaded organic waste from pharmaceutical companies (9). *Opercularia* spp. often are associated with *V. microstoma*.

Vorticella microstoma Complex and *Vorticella infusionum* Complex

The peritrich ciliates *V. microstoma* is a rare species, which often has been confused with the much more frequent *V. infusionum*. The main difference between *V. microstoma* and *V. infusionum* resides in the macronucleus: C-shaped or rod-shaped and in longitudinal axis of the cell (*V. microstoma*), semicircular and in transverse axis of cell (*V. infusionum*) (33). These two species are very similar ecologically and are commonly present in plants during the early phase of colonization but are soon substituted by other stalked ciliates during steady state conditions. When drastic and prolonged reductions in the dissolved oxygen concentration in the mixed liquor occur, dominance of *V. microstoma* or *V. infusionum* can be observed due to their high degree of tolerance to the lack of oxygen (30). In fact, these ciliate are considered as a polysaprobic species (33). Presence of these species thus, indicates a lack of dissolved oxygen in the aeration tank of activated sludge plants.

Free-swimming Bacterivorous Ciliates

Free-swimming bacterivorous ciliates together with small flagellates are the first to appear during the establishment of a sludge (39). They are soon replaced by attached peritrich ciliates owing to competition for bacteria dispersed in the mixed liquor. Attached forms, in fact, are filter feeders and more efficient than free-swimming ciliates in capturing suspended bacteria by means of ciliary currents. In fully functioning activated sludges, bacterivorous free-swimming ciliates sometimes dominate the protozoan communities of plants operating at sludge age too short or with both high sludge loading ($0.6-0.9$ kg BOD/kgMLSS $\cdot$ d) and lack of oxygen (40). These bacterivorous ciliates, in fact, require high concentrations of dispersed bacteria but survive better than other protists in the presence of toxic compounds in the influent and in conditions of inadequate of oxygen.

Small Flagellates

Small heterotrophic flagellates continuously enter the plant with influent where they are very numerous (39). These protozoans feed on dispersed bacteria and, in time, are substituted by bacterivorous ciliates. In a fully functioning activated sludge, in fact, these protists are outcompeted by bacterivorous ciliates and are subject to predaceous activity by other protists. These biotic pressures limit the presence of small flagellates in activated sludge to few individuals. By contrast, the presence of large numbers of these protists in a stable activated sludge system, is associated with poor performance in the aeration tank, caused by environmental or operating conditions, such as poorly aerated sludge, over loading, and fermenting substances entering the plant (17,26). In this case, the effluent from the system has an elevated BOD and is highly turbid as a result of the high density of these protists. Flagellates become the dominant protistan forms in over loaded sludges (>0.9 kg BOD/kgMLSS $\cdot$ d) (9,24).

Large flagellates greater than 20 μm (*Euglena, Peranema*) are infrequently found in the activated sludge systems. In contrast to the small flagellates, the presence of these protists is associated with very diluted organic matter entering the plant (10,11).

The values of SBI have been grouped into four quality classes representing the biological quality of the activated sludge through four ranges of judgments that are rather wide, and thus of reliable diagnostic value. The SBI method enables the operator to monitor the aeration tank performance. The strict applicability of the SBI was tested by investigating more than two hundred activated sludge plants, and results showed that the method gives correct analysis of the reactor performance in all the cases investigated. Although of proven accuracy, there is a limitation that restricts its application in practice. In fact, the technique relies on the identification of ciliate species, which can be time consuming and difficult, even for familiar genera. Species that may be difficult to separate taxonomically can exhibit quite different ecological characteristics, and the use of these species as the sole indicators of plants performance is therefore questionable. Moreover, since the SBI was set up specifically for the evaluation of the biological reactor performance, this index is unable to reveal any dysfunction in the final sedimentation tank (i.e., bulking, rising). The index was designed to be applied in all activated sludge plants including oxidation ditch, conventional aeration plants and extended aeration units. Nowadays, the SBI method is widely applied in Italy, Portugal and Spain, and to a less extent, in other countries.

CONCLUSION

The expanding role of biotechnology in the field of waste treatment, increased the interest in the application of biological indicators to better control the plant performance, and to improve the waste treatment in general. The biological reactors of waste treatment systems have been regarded as ecosystems made by humans and are subjected to extreme conditions. In activated sludge systems biotic components are represented by decomposers (floc-forming bacteria), which utilize the dissolved organic matter in the wastewater, and by consumers (heterotrophic flagellates, ciliates, amebae, and small metazoans) that feed on dispersed bacteria and other organisms. Activated sludge systems develop specific communities of protista, which are sustained by large populations of bacteria. Ciliates play an important role improving the quality of the effluent by filter-feeding bacteria dispersed in the mixed liquor. Since species and groups of protista depend on the environmental conditions in the aeration tank, the structure of the microfauna is a valid indicator of purification plant performance. The major part of situations regarding the plant performance are thus indicated by the dominant group of the microfauna. For these characteristics, the routine analysis of the microfauna as an indicator of activated sludge plant performance is becoming increasingly common. It quickly gives useful information on the biological activity of the flocs based on the community structure of the microorganisms present. The microfauna is also used to indicate changes in the performance of specific activated sludge plants (28,31), but these methods cannot necessarily be applied directly to other similar plants. On the contrary, the SBI, a objective index in which index values assessed by different operators are comparable, can be applied to any activated sludge plant to estimate the performance of the aeration tank (29). Potential gains from this technique include improved performance of BOD removal, nitrification, and the improvement of waste treatment in general.

PROTOZOA IN MARINE AND ESTUARINE WATERS

David A. Caron
Peter D. Countway
Sarah E. Lambert
Julie M. Rose
Rebecca A. Schaffner
University of Southern California
Los Angeles, California

Protozoa have been defined historically as unicellular, eukaryotic organisms that obtain their nutrition heterotrophically. This mode of nutrition is typically accomplished by the ingestion of prey (phagocytosis), although the uptake of dissolved organic material also contributes to the nutrition of some species. The term "protozoa" originated as a means of distinguishing unicellular species exhibiting animal-like nutrition from those capable of photosynthesis (the microalgae). Since the 1970s, it has remained a primary distinction, albeit a problematic one, among taxa within the Kingdom Protista (1).

There are conspicuous problems with the term "protozoa." It is now widely accepted that this term does not indicate a true evolutionary lineage. One issue involves the grouping of organisms on the basis of nutritional mode, artificially separating unicellular organisms with animal nutrition from the photosynthetic unicellular algae. The phylogenetic inappropriateness of separating the algae from the classically defined protozoa has become clear as ecological, ultrastructural, and molecular studies of these species have progressed. Combined photosynthetic and heterotrophic ability (i.e., mixotrophy) has now been demonstrated for a large number of protistan species. More importantly, evolutionary relationships among protists derived from ultrastructural data (during the past few decades) and DNA sequencing studies (during the last decade) have indicated that the division of protists based on the presence or absence of chloroplasts does not reflect true phylogeny. It is noteworthy that use among ecologists of the term "protozoa" is slowly yielding to the term "phagotrophic protists," which recognizes the ability of unicells to consume prey irrespective of their ability to photosynthesize.

Another difficulty with the now-traditional classification of Whittaker arises from the rather arbitrary distinction between unicellular and multicellular species. For example, some groups such as water molds and slime molds that can form macroscopic, multicellular structures, are typically included within the protozoa, whereas macroscopic, multicellular algae are excluded. The latter distinction is inconsistent with the results of phylogenetic analyses that have demonstrated close affinities between micro- and macroalgae.

These deficiencies of past and present systematic schemes for unicellular eukaryotes have instigated a massive revision in the classification of these taxa (2). Modern hypotheses now favor highly revised (and diverse) taxa of unicellular eukaryotes grouped together with the plants, fungi, and animals within the Domain Eukarya. From these taxonomic building blocks, which are based largely on ultrastructural features (2), new hypotheses are emerging on the evolutionary relationships among these species.

Despite the polyphyletic nature of the traditional taxonomic groupings and the inconsistencies regarding nutritional modes, however, the term "protozoa" is still commonly employed today (3). In this article we will use the term synonymously with "phagotrophic protists," recognizing that the presence of a chloroplast would also classify many of these taxa as microalgae. Emphasis will also be placed on dominant, free-living forms in estuarine and marine ecosystems.

DIVERSITY OF PROTOZOAN FORM AND FUNCTION

Free-living protozoa inhabit nearly all aquatic (and terrestrial) ecosystems. Protozoa constitute a significant component of the living biomass of these ecosystems and represent a taxonomically diverse group of species. Tens of thousands of extant and extinct species (the latter based on fossil evidence) have been described and many more undoubtedly await discovery and description. Recent genetic studies of marine plankton assemblages have demonstrated previously undescribed species of protists (4,5). In addition, the existence of so-called "cryptic" species that are morphologically indistinguishable from one another has also been demonstrated by DNA sequencing (6,7). Discoveries similar to these will certainly increase in frequency as more molecular-based studies are conducted.

Nevertheless, a considerable controversy presently exists regarding the true species richness of protozoan assemblages and the degree to which these species are distributed globally. Some recent reports have claimed that many species of protozoa are cosmopolitan in their distribution, and thus global diversity might not be as great as previously suggested (8). These latter claims will continue to be tested as molecular and morphological data accumulate. Regardless of the final tally, however, protozoa will remain an enormously diverse assemblage of organisms.

Protozoa vary greatly in size, spanning several orders of magnitude. Most species are microscopic and range in size from some flagellated individuals that are less than 2 μm in cell diameter (9,10) to flagellated and ciliated protozoa that can attain a length of a few hundred micrometers in length (Fig. 1). A limited number are visible to the unaided eye. Some solitary radiolaria and foraminifera form structures that exceed a centimeter in size. Certain species of polycystine radiolaria that inhabit warm oceanic ecosystems form cylindrical, gelatinous colonies that can be more than a centimeter in diameter and several meters long. Collectively, protozoa form a conspicuous and important component of living biota over an immense size range.

Nutrition

Diversity in protozoan size and form is matched by diversity in diet. Osmotrophy (the absorption of organic

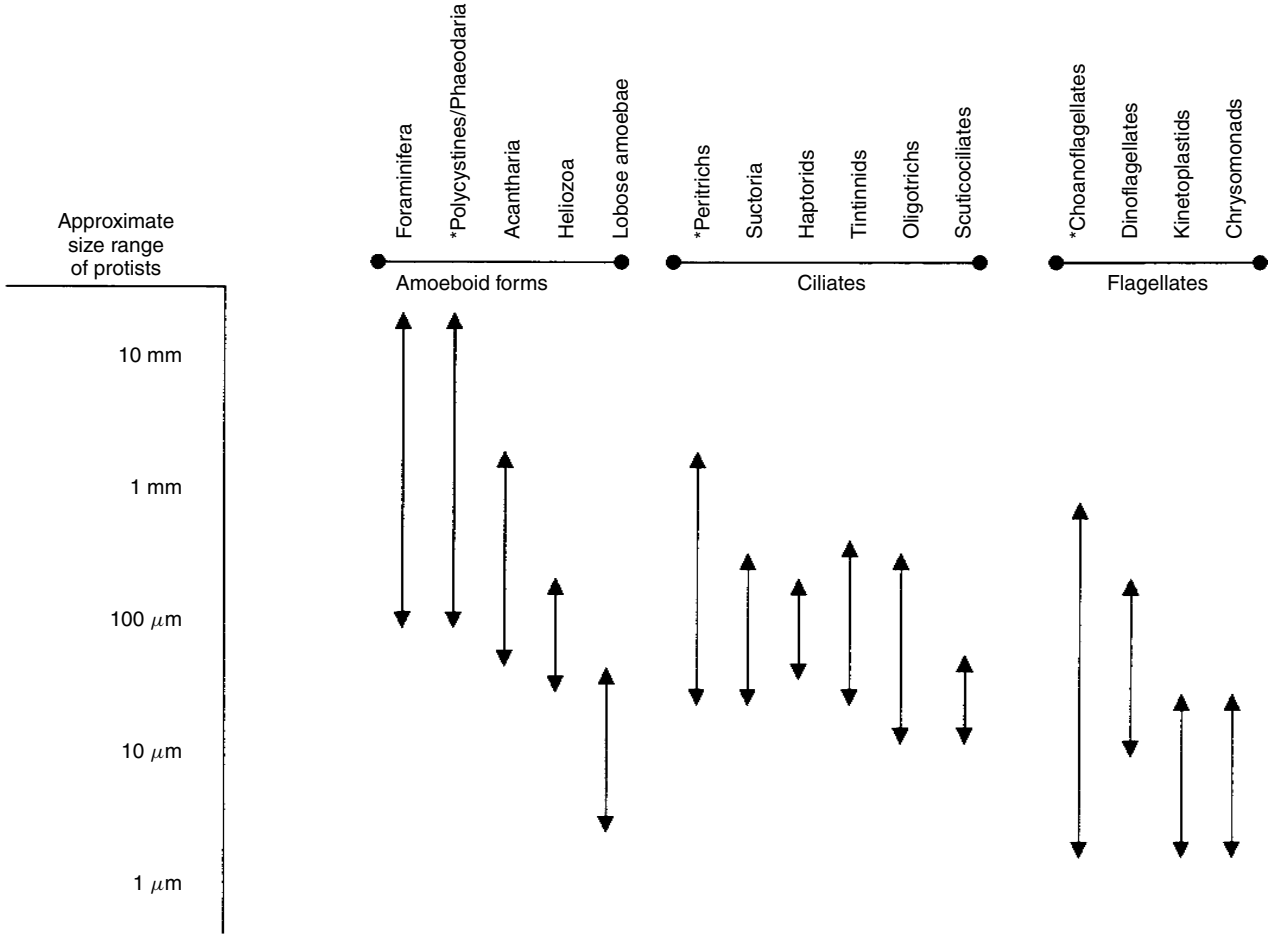

Figure 1. Approximate size ranges of some common marine protozoan taxa. Note that, collectively, protozoan sizes span more than four orders of magnitude. Most species, however, are generally between 2 and 200 μm in size.

compounds) and pinocytosis (the uptake of water and dissolved organic compounds into food vacuoles) are modes of nutrition exhibited by some protozoa, but phagocytosis (the capture and ingestion of particulate prey) is by far the most common means of protozoan food acquisition. Many species have developed specialized strategies and/or structures to facilitate phagocytosis. Most flagellated and ciliated species collect prey at the cell surface via the action of flagella or cilia or by water currents created by the action of those organelles. However, many variations on this theme exist. Some phagotrophic dinoflagellates possess a pseudopodial veil that can be extended from a pore in the thecal wall and used to surround and digest prey. Other phagotrophic dinoflagellates make use of a peduncle, which is a highly extensible, fingerlike projection of cytoplasm that attaches to prey and provides a portal for the extraction of the prey's cytoplasmic contents.

Amoeboid protozoa feed by using different types of pseudopodia, which are transient projections used in locomotion and to engulf prey. For small amoebae, this process is relatively straightforward. Suitable particles (usually bacteria and small protists) are ingested at the anterior edge of the cell as they are encountered during the movement of the amoebae along surfaces. Larger amoeboid forms (e.g., Foraminifera and actinopod protozoa) produce complex pseudopodial networks that are used to entangle and capture prey and then digest them. Pseudopodia can also be used to pierce the exoskeleton and remove tissues of prey such as copepods.

Diets among free-living phagotrophic protists differ among the various taxa and can be fairly specialized or quite broad depending on the species, its size, and its particular method of prey capture. For example, some minute flagellated protozoa are so small that they are capable of consuming only unicellular, prokaryotic prey (10). Although not limited by size, the planktonic ciliate *Didinium nasutum* also feeds rather selectively on other ciliates in the water column (11). In contrast, many of the larger amoeboid protozoa (Acantharia, Radiolaria, and Foraminifera) consume a wide array of microalgae, protozoa, and multicellular animals (12,13). Thus, protozoa may be bacterivorous, herbivorous, carnivorous, or omnivorous. Some are even cannibalistic.

Protozoan digestion differs from this process in multicellular animals because, as single cells, protozoa lack a digestive cavity. However, the process of digestion is analogous to that in higher organisms in that the prey undergoes acidification and then enzymatic

digestion in membrane-bound vacuoles formed around the prey at the time of ingestion. The digestive process can take 20 minutes to several hours, depending on the protozoan species, prey item, and environmental conditions. Utilizable compounds move from the food vacuoles into the cytoplasm of the protozoan during digestion, and the remaining material is then released to the external environment as a mixture of dissolved and particulate organic matter and remineralized compounds.

Growth, Reproduction, and Life Cycles

Protozoa (and protists in general) reproduce asexually, sexually, or by both methods. Asexual reproduction is usually accomplished by binary fission, multiple fission, or budding. By far, the most common form of reproduction among free-living protozoa is binary fission. This process involves mitotic division of an individual, with the duplication and distribution of organelles, to produce two more or less identical daughter cells. The relative simplicity of unicellularity and reproduction by binary fission allows protistan species to grow and reproduce rapidly when biological and environmental conditions are favorable. The fastest growing species can undergo several doublings per day under optimum conditions. Thus, most protists are capable of population growth rates that greatly exceed rates for most multicellular eukaryotes. This behavior explains the ability of microalgae and protozoa to grow rapidly and form "blooms" in many aquatic ecosystems.

Multiple fission and budding are less common modes of asexual reproduction among protozoa, but they are characteristic of some taxa. Some parasitic protozoa reproduce by multiple fission, presumably a mechanism for overwhelming the immunological defenses of the host. The nucleus divides repeatedly in this mode of reproduction, which is followed by cellular fission, giving rise to many daughter cells. Budding occurs in a number of free-living species, most notably in some groups of ciliated protozoa such as suctoria and peritrichs that have sessile adult forms. Ciliated swarmers provide a dispersal mechanism for these species.

Most protozoa increase in number by asexual cell division, and some flagellated and amoeboid taxa may use only this mode of reproduction. The life cycles of many protozoa, however, also involve sexual processes that can take several forms. Variations in the type of gamete produced include flagellated and amoeboid forms, as well as nuclei that simply migrate among attached cells. Three main modes of fertilization have been identified: autogamy, gametogamy, and gamontogamy. Autogamy is the process of fertilization in which both gametes come from the same parent. Cross-fertilization does not occur in this process and therefore all offspring are genetically identical. Gametogamy occurs when gametes are released into the water, and individuals of opposite mating types fuse to form zygotes. Gamontogamy occurs when two individuals (gamonts) physically unite to share gametes or gametogenic nuclei.

Some protozoa exhibit both asexual reproduction and sexual processes at different stages of their life cycles. Sexual processes in at least some of these species appear to serve the purpose of recombination, providing genetic variability that might allow the population to adapt to changing environmental conditions. For example, many ciliates reproduce by binary fission while growing under optimum conditions. Conjugation (a form of gamontogamy) initiates as food supply wanes or other conditions change. Conjugation in these species appears to be responsive to external environmental cues because the number of conjugating individuals in a population can be affected by changes in factors such as temperature, light, or population density. The process results in genetic recombination between paired individuals but it does not result in an increase in protozoan number (14). Although it does not increase the number of individuals in the population, conjugation may confer a competitive advantage on the species by maintaining genetic diversity within the population and thus allowing some segment of it to survive under a different set of growth conditions.

Other strategies for sexual processes exist. A number of protozoa alternate between generations of sexually and asexually reproducing life stages. This form of life cycle is common among foraminifera. In contrast to the rapid reproductive rates associated with species reproducing by binary fission, growth of an individual foraminifer to reproductive maturity can take weeks or months. When reproduction does take place, however, a great number of immature individuals or gametes are often produced simultaneously. Thus, slow reproductive rates in these species are compensated by large output at the time of reproduction.

Rapid reproduction rates allow protozoan populations to be highly responsive to favorable conditions. Additionally, these species also have life strategies for coping with unfavorable conditions such as adverse environmental factors (temperature, desiccation, etc.) or starvation. Many protozoa are capable of autophagocytosis of their own cellular constituents in the absence of food. These species greatly reduce their metabolic rates and shrink significantly in size as starvation progresses (15). Some species even divide one last time at the onset of starvation to form fast-swimming swarmer cells that presumably disperse in an attempt to find more favorable conditions. Other protozoa form resting stages called cysts that are highly resistant to changes in environmental parameters. The ability to form some type of cyst is common throughout many protozoan taxa. In some species, sexual processes are linked to cyst formation.

MAJOR PROTOZOAN TAXA, ABUNDANCES, AND DISTRIBUTIONS

As noted earlier, there is a tremendous diversity of protozoan morphology, motility, and diet. There are some common body forms, however, which have provided the rationale for the historical groupings of these taxa. Although there is a growing realization that some of these classifications are polyphyletic, in some cases they are still sensible on the basis of similarities regarding the ecological roles of the taxa.

On the basis of the older (and still commonly employed) taxonomic scheme, free-living protozoa are divided into

three large groups defined by their overall morphology and means of locomotion and feeding: amoeboid, flagellated, and ciliated forms. Many of the pathogenic or parasitic species display unique (or multiple) life stages and have been separated into their own taxa and thus constitute a few additional groups.

Amoeboid Protozoa

Free-living amoeboid protozoa have historically been grouped together into one subphylum on the basis of the presence of a single character during their life cycle, the pseudopodium. Pseudopodia are projections of the cytoplasm used for locomotion and food capture. Amoeboid protozoa lack rigid cell walls that give the cells great plasticity and thus the ability to form these projections. These structures vary in complexity among the different amoeboid taxa from relatively simple, lobed projections of the cell (e.g., in the lobose amoebae) to complex, anastomozing networks of pseudopodia (e.g., in the Foraminifera) to radiate structures stiffened by bundles of microtubules (e.g., in the Actinopoda). There is strong evidence that the presence of the pseudopodium is a result of convergent evolution. Thus, the amoeboid protozoa are actually a collection of a phylogenetically diverse group of taxa that exhibit outwardly similar cellular morphology and feeding behavior.

The amoeboid cell shape is highly amorphous, but many of these species possess mineralized skeletal structures that provide support for the pseudopodia and serve as taxonomic characters for identification. These skeletal structures can be elaborate, beautiful fabrications composed of silica, calcium carbonate, or strontium sulfate. Their presence allows many of these species to attain macroscopic size.

Lobose Amoebae. The simplest amoeboid forms are those bearing lobate, conic, or tubelike pseudopodia (Fig. 2a). This polyphyletic group contains the species that are most commonly encountered in introductory biology courses. Some lobose amoebae completely lack shells (the "naked" amoebae), whereas others bear simple scales, shells composed of secreted organic substances or agglutinated materials from the environment (sand grains, algal scales, etc.).

Lobose amoebae move by extending pseudopodia and drawing the remaining cytoplasm forward into the pseudopodia. Prey capture is accomplished by engulfing prey as the cell moves along a surface. Characteristic features for identification include cell size, shape, pseudopodial type, the presence or absence of cysts, and the form taken by the cell when it is dislodged from a surface (i.e., the "floating form"). Species of amoebae are typically identified from characters present in living specimens because preservation can distort cell and pseudopodial morphology. Thus, the taxonomic system is not very useful for ecological studies of natural protozoan assemblages in which many samples may be collected in a short period of time and preserved for later analysis. As a result, information on the distribution, abundance, and overall impact of these species in estuarine and marine ecosystems is meager relative to shelled amoeboid forms and other protozoa in general.

Free-living marine amoebae range in size from several micrometers to more than 100 μm. Most consume prokaryotes, microalgae, and other protozoa. Amoebae are most common on surfaces and in sediments in estuarine benthic ecosystems (16,17). Abundances of tens per cm^2 have been reported on macroalgal surfaces, although abundances in sediments range up to several thousand per cm^3. Amoebae are also present in the plankton in which they presumably colonize biotic and abiotic surfaces and the air-water interface (18–23).

Foraminifera. The foraminifera are a wide-ranging group of amoeboid protozoa possessing complex, branching networks of pseudopodia and shells (tests) composed of organic material, agglutinated particles, or calcium carbonate. The calcium carbonate tests of foraminifera preserve well, and the fossil record of these species is an important tool for paleoclimatological reconstruction (Fig. 2f). Foraminifera are conspicuous components of the marine benthos and the oceanic plankton (Fig. 2d). Benthic species are numerous, and specimens are abundant throughout all marine environments from salt marshes to the deep-sea, at abundances up to several hundred per cm^2 (24–26). Some species contribute significantly to the formation of coral reefs in tropical ecosystems. A small number of foraminiferal taxa have adapted to life in the water column. Planktonic forms are restricted to oceanic waters in which typical abundances are tens per liter for juvenile specimens to tens per m^3 for adults (27). One species even survives being frozen into polar ice (28).

Foraminifera form some of the largest individual structures of all protists. Disk-shaped benthic foraminiferal tests can exceed 1 cm in diameter (Fig. 2e), and some planktonic foraminifera form tests that are nearly a millimeter in diameter. Spines radiating from these latter tests produce an extraordinarily beautiful, delicate structure that can exceed a few centimeters in diameter. Large pseudopodial networks strewn upon these spines make these species highly conspicuous in the oceanic plankton.

Many of the foraminifera have lengthy life spans compared with other protozoa. The life cycles of relatively few species have been accurately described at this time, but those that have been characterized indicate complex life histories involving alternation of sexual and asexual life stages. Developmental times (from zygote to reproductively mature adult) can be weeks to months and perhaps longer. This can result in a wide spectrum of sizes for individual foraminiferal species in natural communities.

Large size for many species allows foraminifera to capture an enormous variety of prey ranging from bacteria to metazoan species (12,13,29). Virtually any organism that can be immobilized and infiltrated by the pseudopodial network will be consumed. Cannibalism has been observed in laboratory cultures.

Feeding rates on prey in these species are highly variable. This variability is due in part to differences in size and pseudopodial mass. It is also due to the

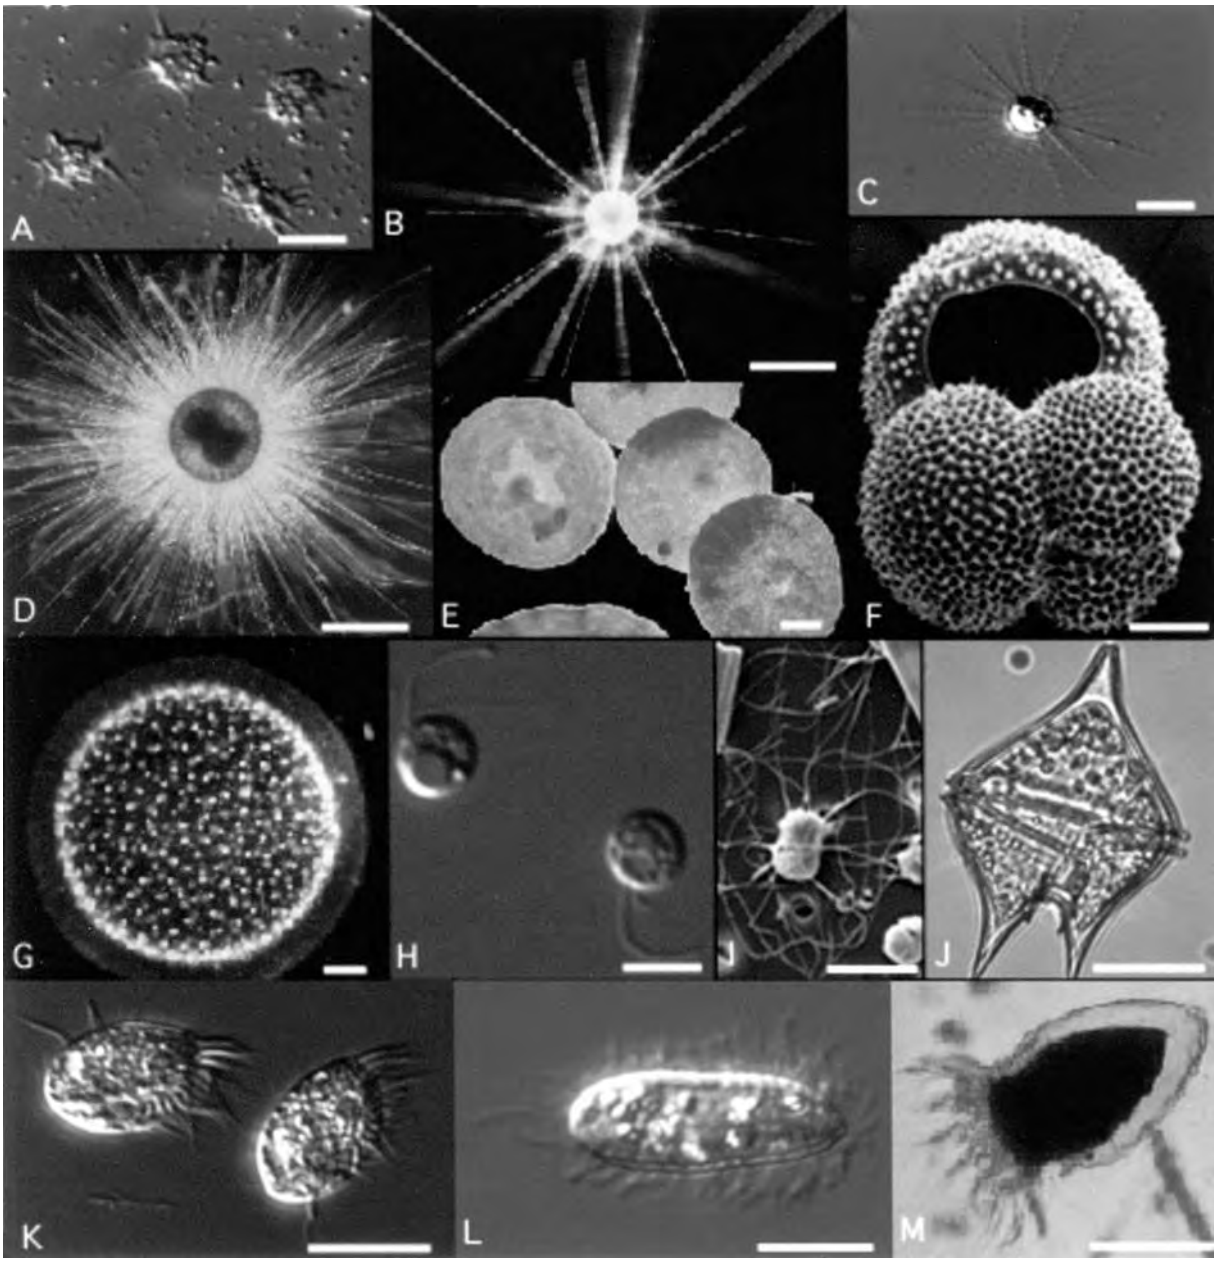

Figure 2. Micrographs of representative taxa of amoeboid, flagellated, and ciliated protozoa. (**a**) Four lobose amoebae enriched from the coastal plankton. (**b**) A live, oceanic acantharian with radiating spines of strontium sulfate. (**c**) An estuarine heliozoan. (**d**) A live planktonic foraminifer with radiating spines and a thick pseudopodial net. (**e**) Calcium carbonate tests of large, benthic, tropical foraminifera. (**f**) Calcium carbonate tests of a planktonic foraminifer. (**g**) A "small" gelatinous colony of living polycystine radiolaria. These colonies can reach meters in length. (**h**) Small chrysomonad flagellates. (**i**) Electron micrograph of a choanoflagellate. The dried basketlike structure is visible around the specimen. (**j**) A heterotrophic dinoflagellate. (**k**) Two hypotrichous ciliates showing azoral zones of membranelles (to the right) and cirri (upper left on lefthand specimen). (**l**) Scuticociliate showing relatively uniform ciliature on its surface. (**m**) Tintinnid ciliate. The transparent lorica is apparent around the opaque ciliate. Note similar body plans among the larger amoeboid forms (**b,c,d,g**). Also note that the overall size differential among these species is more than three orders of magnitude. Marker bars indicate 5 (**i**), 10 (**h**), 20 (**c,j,l**), 30 (**a**), 50 (**k,m**), 100 (**b,f**), 500 (**d**), and 1,000 (**e,g**) μm.

fact that many shallow-dwelling species derive nutrition from symbiotic algae that are present in high abundance within the cytoplasm. Symbiont photosynthesis in some foraminiferal species can provide sufficient nutrition to support normal vegetative growth without the need for particulate food, whereas other species require particulate food (30). Even among the latter species, symbiont nutrition can be important for survival in highly oligotrophic environments (31).

Actinopoda. The actinopod protozoa are a polyphyletic assemblage composed of amoeboid protozoa that form pseudopodia that are stiffened by microtubules. Traditionally this group has included the Acantharea, Polycystinea, Phaeodarea, and Heliozoea. The polycystines and the phaeodaria are still referred to, collectively, by the older term "radiolaria." The acantharia and radiolaria are unique in that most species are planktonic and largely restricted to oceanic environments. Similar to the foraminifera, these specimens can form complex networks of pseudopodia and (in some cases) mineralized skeletal components that are visible to the unaided eye. Some species of polycystines form colonies that are easily mistaken by divers for strings or clumps of minute eggs (the central capsules) embedded in a gelatinous matrix (Fig. 2g). Collectively, acantharia, radiolaria, and foraminifera are often the most conspicuous macroscopic organisms in tropical and subtropical pelagic ecosystems.

The actinopod taxa are distinguished from one another on the basis of details of cell morphology and ultrastructure as well as the geometry and composition of mineralized structures (when present). Acantharia produce strontium sulfate skeletal structures in some variation of either 10 or 20 radially oriented spikes (Fig. 2b). Radiolaria produce siliceous skeletons (when present) of diverse architecture, whereas members of the polyphyletic heliozoa produce organic or siliceous structures.

At a gross level of comparison, acantharia and radiolaria are functionally similar to planktonic foraminifera because of analogous cell designs (see Figs. 2b–d,g). This similarity results in a high degree of overlap in the types of prey captured by these species (12). Further ecological similarity is shown by the fact that many surface-dwelling acantharia and polycystines also possess intracytoplasmic symbiotic algae that contribute to the nutrition of the host. The morphological resemblance and trophic activities displayed by these species may represent convergent evolution to a body form and trophic activity that is particularly suitable for life in highly oligotrophic oceanic ecosystems.

In contrast to the acantharia and radiolaria, the heliozoa or "sun animalcules" are largely neritic where they are common in the plankton and benthos. These specimens also possess radially oriented pseudopodia (Fig. 2c). Although they have been historically classified as actinopods, the heliozoa appear to bear little phylogenetic relationship to polycystines, phaeodaria, or acantharia. Their shape is presumably an example of convergent evolution toward a comparable cell design.

Information on the distributions and abundances of polycystines and phaeodaria in the ocean are largely confined to skeleton-bearing forms that can be collected in plankton nets. As with the foraminifera, abundances vary greatly with location, depth, and whether or not one includes juvenile forms, but values of tens per m^3 to tens per liter are common (27). Acantharia can be considerably more abundant than radiolaria, but fewer data exist because their skeletons readily dissolve in most common preservatives. Acantharian abundances of tens per liter are typical. Heliozoan abundances are not well documented.

Flagellated Protozoa

This polyphyletic group of protozoa is composed of a wide assemblage of taxa that possess one to several eukaryotic flagella, flexible structures strengthened internally by a characteristic arrangement of microtubules. Flagella are responsible for locomotion in these species, and aid in feeding, either directly or via the creation of water currents that cause food particles to contact the cell surface where ingestion takes place.

Dinoflagellates are the largest (some $>100\ \mu m$) and probably the most conspicuous flagellated protozoa in the ocean (Fig. 2j). This group is usually claimed by botanists as a phytoplankton taxon, but nearly half of these species are heterotrophic and many chloroplast-bearing forms are actually mixotrophic (capable of prey ingestion as well as photosynthesis). Abundances of heterotrophic dinoflagellates can attain hundreds per ml even in oceanic plankton communities when diatoms (common dinoflagellate prey) are abundant (32), and photosynthetic species are well known as bloom formers. Dinoflagellates are biflagellate and usually possess a transverse furrow and longitudinal groove in which the flagella are situated. Their beating provides motility and gives most dinoflagellates a characteristic whirling or spiralling motion as they swim.

Dinoflagellates use a variety of mechanisms for obtaining nutrition (33). Some phagotrophic forms can feed by engulfing prey completely within the dinoflagellate cell. However, larger prey can also be attacked by means of a peduncle, or by extending a large feeding veil. The latter behaviors are used by some dinoflagellates to feed on animal prey or diatom chains that are often much larger than the dinoflagellate predator. Dinoflagellates can also be parasitic, invading appropriate hosts and multiplying within them. Finally, some heterotrophic dinoflagellates consume algae and digest most of the prey but retain the chloroplasts in a functional state for a limited period (34).

Another morphologically distinct group of flagellated protozoa is the Choanoflagellata. These uniflagellated species possess funnel-shaped or basketlike silicified structures or "collars" that aid in prey capture (Fig. 2i). They are common and abundant in the plankton. Abundances in coastal planktonic communities can reach thousands per ml (35,36), and these species appear to be particularly important in polar environments (37). Choanoflagellates are also common on surfaces to which they attach by means of a stalk. Individuals are mostly small ($<20\ \mu m$), but some attached and planktonic species can form large colonies. They feed primarily by phagocytosis of bacteria and cyanobacteria.

The remaining taxa of flagellated protozoa are less morphologically distinct (by light microscopy) than the dinoflagellates or choanoflagellates but no less important ecologically. Two groups of heterokont flagellates (cells bearing two flagella of unequal length and function) are particularly important; the chrysomonads and biocosoecids. Chrysomonads are small (generally <20 μm) flagellates often grouped with their chloroplast-containing relatives, the chrysophyte algae (Fig. 2h). Many chrysomonad species are devoid of chloroplasts, however, and feed by phagocytizing bacteria, small algae, and other small protozoa. These species are quite common in planktonic environments. The biocosoecids also possess heterokont flagellation but produce a lorica, a vaselike structure of chitin in which they live. These forms can be free-swimming or attached and, together with the chrysomonads and choanoflagellates, constitute an important source of mortality for prokaryotic organisms in the marine plankton.

The bodonids are a biflagellate taxon composed of small species (generally ≤ 10 μm) grouped together with the parasitic trypanosomes. Many bodonids are free-living, abundant in sediments, and are associated with suspended particulate material in the plankton in which they feed on attached and suspended bacteria (38,39). These species typically use one flagellum for maintaining contact with the substratum and the other for motility and prey capture.

In addition to these truly heterotrophic flagellates, a number of chloroplast-bearing protists (i.e., microalgae) also consume prey and can contribute to predation on bacteria, other algae, or protozoa in the ocean. These mixotrophic algae include numerous species of chrysophytes, prymnesiophytes, dinoflagellates, cryptophytes, and euglenophytes (40).

Collectively, the flagellated protozoa are probably the most numerous protozoa of both benthic and pelagic ecosystems. Typical abundances in the plankton range from hundreds per ml to tens of thousands per ml (41). Estimating the densities of minute flagellates in benthic ecosystems has proven more difficult because of the problems associated with distinguishing these small cells within the sediment matrix (42,43). As a consequence, less is known about the abundance or species composition of this community. Very little information is available for the deep-sea benthos (44–46).

Most studies of flagellate abundance in natural ecosystems have not reported the contributions of individual taxa of flagellates to total flagellate abundance because these communities are usually dominated by small species (<10 μm in size). The identifications of many of these small specimens are dubious when performed by light microscopy (the method of choice for enumerating these assemblages) because few morphological criteria can be distinguished at this level of examination. Electron microscopy, and sometimes observations of living specimens, is required for accurate identification of these taxa. Thus, most reports on the abundances of these species simply group them together as "colorless flagellates" or "nanoflagellates" (the latter term is a reference to their size; see Placing Protozoa into Models of Marine Food Webs, which is discussed later.)

Ciliated Protozoa

Ciliates appear to be the only monophyletic group of the three taxa of free-living protozoa thus described. These species are characterized by the presence of cilia (ultrastructurally similar to the eukaryotic flagellum) during some phase of their life cycle, two types of nuclei, and various aspects of cellular construction and reproduction. The ciliates have phylogenetic affinities with the dinoflagellates and the parasitic apicomplexans with which they share unique ultrastructural features (47). Recent systematic revisions group these three taxa into a single phylum, the Alveolata.

Ciliated protozoa tend to exhibit more structural complexity than the flagellates or amoeboid protozoa. Cilia are the fundamental character of the ciliates, but the nature and extent of ciliation can vary greatly among these species. For example, ciliature is totally lacking in the suctoria except for ciliated swarmers that are produced by budding from a parental cell. On the other end of the spectrum are species that have nearly uniform ciliation covering their surfaces. Other species form complex ciliary structures including an adoral zone of membranelles (rows of cilia fused to form membranelike veils that are used for locomotion and creating feeding currents) or cirri (groups of fused cilia that act as single appendages, usually for locomotion).

The site of phagocytosis on the surface of ciliates (the cytostome) tends to be more apparent in ciliates than in flagellates or amoeboid forms. It is often located in a furrow or depression and the cilia (when present) are typically oriented to create water currents that will deliver suspended particles to this area. The nonciliated suctoria possess tentacles that are used for grasping/holding prey and removing their cellular contents.

Ciliates are common and important protozoa in pelagic and benthic marine ecosystems. However, the taxonomic composition of the group varies considerably between these two environments. Marine planktonic ciliate communities are typically dominated by spirotrichous ciliates with a few notable exceptions. The spirotrichs include the tintinnids that live within loricae, and "naked" oligotrichs that lack loricae (Fig. 2m). These planktonic species play a major role in the consumption of small phytoplankton (and presumably small protozoa). Bacterivorous species of ciliates within the class Oligohymenphorea (e.g., *Uronema, Pleuronema*) occasionally become abundant in coastal and estuarine waters when prokaryote abundances are high (Fig. 2l). In addition, predatory ciliates within the subclass Haptoria often occur in the plankton. Abundances of planktonic ciliates range up to tens per ml for coastal ecosystems and approximately an order of magnitude less for oceanic ecosystems (48,49).

A common phenomenon among many planktonic marine ciliates is the ability to ingest algal prey and retain the chloroplasts of these prey in a functional state inside the ciliate for a limited period of time (generally less than a few days). This ability to retain functional chloroplasts provides these ciliates with additional nutrition relative to purely heterotrophic species. Not surprisingly, these mixotrophic species can constitute a very significant fraction of the total

assemblage of planktonic ciliates (50). One common "bloom-forming" genus (*Mesodinium*) is occasionally able to attain extremely high abundances (51).

The ciliate fauna of marine benthic environments is abundant, and typically much more diverse than planktonic assemblages. This tendency presumably reflects the greater diversity of physical microenvironments and generally higher abundances of prey in the benthos relative to pelagic ecosystems. Sediment grain size, organic loading, oxygen penetration, and other factors affect the ciliate community structure (52–54). Abundances of ciliates in coastal sediments can reach thousands per cm^2, with highest abundances in the oxygenated zone. Benthic ciliates often have elongated shapes and are highly flexible to allow penetration into and among sediment particles. The cilia of many of these species are often modified into fused clusters (cirri) that are used for crawling, and large membranelles for creating water currents to transport food to the cytostome (Fig. 2k).

Feeding of benthic ciliates has been addressed only sporadically. The definitive work on this topic, now more than 30 years old (55), demonstrated some degree of feeding specialization among benthic ciliates but also a fair degree of overlap in the type of prey consumed. This result is somewhat analogous to feeding preferences observed for planktonic foraminfera, acantharia, and radiolaria (12).

Biotic and abiotic surfaces are also important environments for ciliate colonization and growth. Species of vorticellids (*Vorticella, Zoothamnium*) and suctoria (*Acineta*) are commonly found in biofilms, or "Aufwuchs" communities, as are surface-associated forms of hypotrichous ciliates such as *Euplotes*.

ECOLOGICAL ROLES OF PROTOZOA

Most protozoan species are microscopic, but the magnitude of the ecological roles they play and their biogeochemical activities in marine ecosystems are anything but minute. Protozoa are the major consumers of microorganisms in the ocean, and are in turn prey for a wide variety of protistan and metazoan organisms. As such they constitute important trophic links between a variety of microbial taxa and larger consumers in marine food webs. In addition, protozoa remineralize and release what they do not incorporate, functioning as sources of dissolved and particulate organic matter in the ocean. Remineralization of organic material by protozoa is thus an important mechanism by which primary producers obtain essential nutrients.

Protozoa as Trophic Links in Food Webs

Protozoa constitute crucial links in marine food webs. With the exception of a few crustacea (mostly in freshwater), some marine tunicates, bivalves and sponges that feed on exceptionally small particles, they are the primary biological link between small (<2–3 μm) microorganisms and larger metazoa in marine food webs. Their grazing activities are essential for the conversion of the smallest marine microorganisms into particles large enough to serve as prey items for metazoan grazers such as copepods, fish larvae, and other suspension-feeding organisms in the plankton and benthos.

Protozoa are particularly important in habitats (such as oligotrophic gyres) where the primary producer assemblage is dominated by small algae and cyanobacteria (i.e., by species that are too small to be captured by most metazoa). They are also important where the production of living biomass is dominated by bacteria or detritus-based food webs (e.g., areas with high loading of labile organic material, and most oceanic ecosystems below a few hundred meters depth). In these locations protozoa may serve as the primary source of food for larger mesozooplankton or suspension-feeding benthic species.

Protozoa as Predators (Bacterivory, Herbivory, Carnivory). The rapid growth rates of protozoa in the ocean imply that significant amounts of prey biomass are consumed in marine food webs. Indeed, clearance rates (volume of water cleared of prey per unit time) and ingestion rates (number of prey organisms consumed per unit time) are much higher for protozoa on a "per weight" or "per volume" basis than for most metazoan species. These high weight-specific metabolic rates are consistent with well-known allometric relationships between the size of organisms and their rates of metabolism.

Gross growth efficiencies of protozoa (the percentage of prey biomass converted into protozoan biomass) are also high, relative to conversion efficiencies for most metazoa. Growth efficiencies reported in the literature vary widely, but a median value for most protozoa appears to be 30 to 40%, (56) that is, 30 to 40% of the prey biomass ingested by these species is converted into protozoan biomass. Thus, these species are efficient at "repackaging" small prey into particles that might be large enough to serve as food for species at higher trophic levels.

Marine protozoa are important consumers of prokaryote biomass (bacteria and cyanobacteria). Small flagellates appear to be the major bacterivores in many planktonic ecosystems (57), whereas ciliates and amoebae make a more significant contribution to bacterivory in benthic ecosystems. Lysis by bacteriophage is also an important source of mortality for marine bacteria, but the production of viral particles does not contribute directly to the nutrition of higher organisms. On a global basis, bacterial production must be matched by bacterial mortality because the overall abundance of these prokaryotes remains relatively constant over long timescales. Analysis of a large data set spanning observations in numerous marine and freshwater environments indicated a direct 1 : 1 relationship between bacterial production and bacterivory (41). This relationship implies a close match between production of bacteria on one hand and removal on the other hand. Protozoa play a fundamental role in the removal process.

Protistan herbivory of cyanobacteria and phytoplankton is also an important trophic process in the ocean. Ciliated protozoa alone probably remove more than half of the annual primary production in some marine environments. Ciliate herbivory can equal or even exceed production on short timescales (48,58). One can expect similar rates of consumption of small protozoa by ciliates,

but this form of protozoan predation is poorly quantified. Heterotrophic dinoflagellates play a significant role as herbivores when diatoms dominate the phytoplankton community (32,33).

Rates of ingestion among protozoa are highly variable. They are dependent on the protozoan species and its mode of prey capture, the type of prey being ingested, prey abundance, and the environmental conditions (particularly temperature). Maximal ingestion rates of bacteria by protozoa typically vary from a few per hour up to several tens per hour for small flagellated protozoa (i.e., 2–10 μm in size), to several thousand per hour for bacterivorous ciliates (20 to 50 μm in size). The former species rely on particle interception or weak feeding currents created by their flagella to capture prey. Many of these species handle and ingest bacteria individually. In contrast, most ciliate species use complex ciliary structures and rapid filtration rates to capture large numbers of bacterial prey.

Capture of animal prey (carnivory) by large amoeboid protozoa is at the opposite end of the ingestion rate spectrum. Some planktonic foraminifera that prey on copepods may capture only one prey organism every several days (29). This rate still constitutes a very significant source of nutrition because of the relatively large size of the prey. Ingestion rates of other free-living protozoa feeding on microalgae and protozoa are intermediate to the extremes just mentioned.

Protozoa feeding at maximal rates in laboratory cultures typically can consume their body weight in a short period (a few hours to a few days depending on the species), although these maximal rates may seldom be attained in nature. The ingestion rates of free-living phagotrophic protists in marine ecosystems are probably most affected by prey abundance. Suboptimum prey abundance results in a rapid decline in the ingestion rates for these species (59). Some species also exhibit "grazing thresholds"; prey concentrations below which feeding activities are either curtailed or are less effective at capturing prey (Fig. 3). In addition to prey abundance, ingestion rates are further modified by temperature, light, and other physical/chemical factors (60,61).

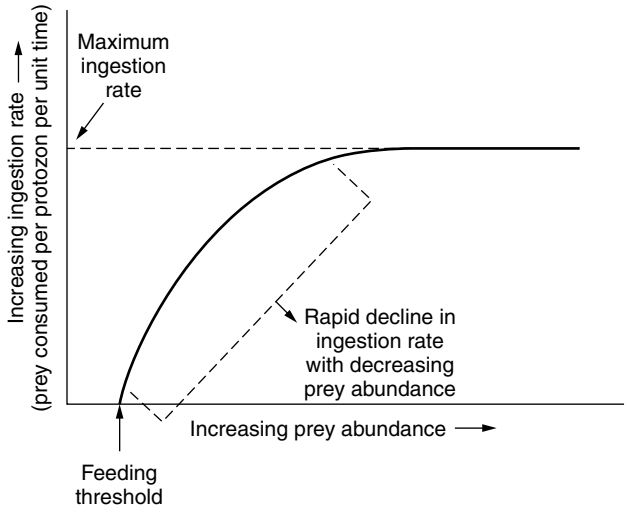

Figure 3. Idealized relationship between ingestion rate and prey abundance for phagotrophic protists. Feeding for some species does not take place below some nominal prey abundance (the feeding threshold; lower arrow). Above the threshold concentration, ingestion rate increases in direct proportion to prey abundance (bracketed area). At higher prey concentrations ingestion rate stabilizes at a maximum value (upper arrow). The maximum rate is dependent on the rate at which prey can be ingested, digested, and remains voided by the protozoa. The specific shape of this generalized curve varies with protozoan species and prey type.

Symbiosis and Mixotrophy. Most studies of protozoan trophic activity in marine ecosystems have focused on their roles as bacterivores, herbivores, and, to a lesser extent, as carnivores. However, protozoa participate in other types of interspecies interactions including various forms of symbiosis (used here in the general sense of "organisms living together"). These interactions are generally classified on the basis of whether they are beneficial, harmful, or neutral for the two partners.

Parasitic protozoa obtain nutrition from their respective hosts. This relationship is obviously beneficial to the protozoan but harmful to the host. Invasion of the host and evasion of the host's immunological defenses play important roles in obtaining nutrition. Protozoan parasitism in humans constitutes a major health issue in our society, and considerable effort has been expended to understand these infections. Much less is known regarding protozoan parasitism in the ocean. Parasitism of algae, other protozoa, and numerous multicellular organisms have been described, but extant knowledge indicates that parasitic forms are not a major component of the total abundance or biomass of protozoa in marine ecosystems. Nevertheless, there is a growing realization that these species can be an important factor in determining the population dynamics of their hosts (62–64).

A few protozoan classes are composed exclusively (or nearly so) of parasitic species. For example, the apicomplexans are obligately parasitic species whose free-living stages serve the purposes of dispersal and reinfection. Other taxa contain mixtures of free-living and parasitic species. A number of kinetoplastid flagellates are parasitic (e.g., trypanosomes that cause human and other animal diseases), whereas other species within this taxon are free-living and primarily bacterivorous (e.g., many bodonid flagellates). A significant number of dinoflagellates are parasites in other organisms, including a number of protists (e.g., in some dinoflagellates, radiolaria, and ciliates). One of these species, *Pfiesteria piscicida* has recently achieved infamy as a parasite and pathogen of fish, and for the amnesic effects on short-term memory in humans caused by exposure to this organism (65).

Mutualisms are associations between species in which both partners benefit from the association. Although the details of many of these relationships are not well characterized, many of these partners appear to trade nutrition for protection. Mutualistic relationships involving protists are numerous and diverse. They may involve two protistan

species (e.g., many foraminifera, radiolaria, and acantharia harbor photosynthetic dinoflagellates as intracellular symbionts), or they may involve a protistan species and a metazoan or prokaryotic species. Many well-documented mutualisms exist between photosynthetic dinoflagellate symbionts and cnidarian hosts (66). A number of mutualistic symbioses also exist between heterotrophic dinoflagellate hosts and photosynthetic cyanobacterial symbionts that colonize their outer surfaces (67). The photosynthetic symbionts in these relationships contribute to the nutrition of their hosts, presumably in exchange for the physical protection afforded by the host. These symbiotic associations appear to be excellent strategies for the host to cope with the highly oligotrophic conditions of oceanic ecosystems.

Commensalisms are associations between species in which one partner may benefit but the other is neither benefited nor harmed. Many protozoa exist as ectocommensals, attaching to or associating with the exterior surfaces of other protists, macroalgae, plants, or animals. An interesting example in the estuarine plankton is the attachment of vorticellid ciliates to the posterior end of some copepods (68). This relationship appears to have little effect on the copepod but presumably benefits the ciliate by creating water currents that bring prey to the ciliate, or perhaps by carrying the ciliate into an environment with high prey abundance.

Mixotrophy among protists is defined as the combination of photosynthetic and heterotrophic nutrition in a single individual. There are many variations on this theme among phagotrophic protists. One type of mixotrophy involves protozoa that are capable of ingesting and digesting microalgal prey but retaining the prey chloroplasts and maintaining them in a functional state (69). Several ciliate species, heterotrophic dinoflagellates, and at least one benthic foraminifer are capable of chloroplast retention. The chloroplasts retain photosynthetic ability in their new hosts for periods ranging from a few days to weeks but eventually lose function and are replaced with new chloroplasts from ingested prey. This ability enables these protozoa to function partially as photosynthetic organisms.

Another common form of mixotrophy involves the ingestion of particulate prey by photosynthetic flagellated protists. These species possess their own "true" chloroplasts but have also the ability to phagocytize prey (usually bacteria or other small protists). Numerous species of microalgae from a diverse array of taxa possess this form of mixotrophic ability (40). Prey ingestion in photosynthetic flagellates may serve several nutritional purposes including the acquisition of energy, major nutrients (nitrogen or phosphorus), or other specific growth factors such as vitamins or trace metals that might otherwise be difficult for them to obtain.

Protozoa as Prey. The biomass of phagotrophic protists in the marine plankton may be on the order of 10 to 20% of the total living biomass in these ecosystems and may comprise as much as 50% of the biomass available for consumption by planktonic metazoa. A global-scale synthesis has not yet been conducted but several regional surveys indicate that protozoa are a quantitatively important component of pelagic communities (32,49,70–72). Heterotrophic flagellates in the 2 to 20 μm size class of coastal and pelagic ecosystems can be as abundant as algae in the same size class, whereas ciliates and larger heterotrophic dinoflagellates constitute a significant fraction of total living biomass in the 20 to 200 μm size class. These heterotrophic assemblages are utilized as food by rotifers, cladocerans, some copepods, fish larvae, and many invertebrates (58,73). Unfortunately, the overall nutritional value of protozoan biomass to most zooplankton species is still not resolved.

In the benthos, recent work has shed light on the potential importance of protozoa as a food source for filter-feeding bivalves such as oysters (74). Bivalves efficiently retain particles over the entire size range of protozoan species. Protozoa act as a vital trophic link by repackaging very small primary producers and bacteria into sizes that can be effectively captured.

Protozoa as Trophic Sinks in Food Webs: Carbon and Nutrient Remineralization

Although biomass incorporated into protozoa is available as food for larger organisms capable of capturing them (i.e., a trophic "link" in food webs), unincorporated material is lost to the process of trophic transfer (i.e., a "sink" in these food webs) through respiration and the release of undigestable remains. These latter materials serve as substrates and nutrients for bacteria, phytoplankton, and other organisms capable of taking them up from seawater. Thus, what constitutes a "sink" for higher organisms actually provides a source of energy and/or nutrients for other biological components in marine food webs.

Early conceptualizations of the role of protozoa in marine food webs tended to argue that protozoa act rather exclusively as either links or sinks, but more recent depictions have recognized that they play a role in both functions simultaneously. Unincorporated material released by protozoa includes both organic and inorganic (i.e., remineralized) compounds. Respiration can oxidize food completely to carbon dioxide and inorganic nutrients, or digestion may be incomplete and result in the release of a variety of organic compounds.

On average, 60 to 70% of the prey biomass ingested by protozoa is released to their seawater environment. This release contributes significantly to the pool of inorganic nutrients and labile organic compounds utilized by bacteria and primary producers. Approximately half of the prey carbon that is not incorporated into protozoan biomass during digestion is released as particulate and dissolved organic material (75–79). These materials increase the concentration of labile dissolved organic compounds that are taken up by bacteria for energy and production. Thus, on one hand protozoan trophic activities act to reduce bacterial abundance by ingesting these prokaryotes, whereas on the other hand they stimulate bacterial growth by releasing organic matter that can serve as bacterial substrate.

The paucity of bioavailable forms of nitrogen and phosphorus is a major factor limiting primary production in most marine waters. Thus, the remineralization and

release of nitrogen and phosphorus by heterotrophic protists may constitute vital sources of these elements in the ocean (80). Most remineralized nitrogen and phosphorus is released by protozoa as ammonium and phosphate, respectively, and these compounds are readily taken up by most algae. Bacterivorous protozoa may play a particularly important role in this regard. By consuming bacteria and remineralizing a portion of the bacterial biomass into inorganic compounds, these protozoa serve a dual role of providing inorganic nitrogen and phosphorus to primary producers and removing bacteria that might compete for these materials with the primary producers (81,82). The importance of protozoa in remineralization processes has been recognized for many years and has been put to practical use in the biological treatment of sewage to reduce bacterial biomass, organic content, and biological oxygen demand.

Placing Protozoa into Models of Marine Food Webs

Aquatic ecologists have endeavored to place phagotrophic protists, and their biological significance, into the overall context of marine food webs since the inception of the concept of a "microbial food loop" in the 1970s (83). This has proven to be a daunting task because of the extremely high species diversity and huge range in size, form, and function encompassed by this group. Therefore, most formal modeling exercises have tended to aggregate protists into ecologically relevant groupings or "compartments" to reduce protistan complexity to a manageable number for mathematical models (59,84–86).

A fundamental manner of sorting organisms in most food web models continues to be the time-honored distinction between photosynthetic and heterotrophic modes of nutrition. Thus, protists in these models are typically split into "algae" and "protozoa" according to traditional descriptions of unicellular eukaryotes. There is generally no regard for mixotrophy or symbioses in these compartmental models.

Size is also an easy characteristic by which to classify organisms, and this criterion has been commonly applied to protistan assemblages in food web models. For example, plankton biologists typically group organisms according to cell size, with each class comprising approximately one order of magnitude. One of the systems most commonly used for planktonic microorganisms was described by Sieburth and coworkers (87). It designates organisms as "picoplankton" (0.2 to 2 μm in size), "nanoplankton" (2–20 μm), "microplankton" (20–200 μm), "mesoplankton" (200 μm–2 mm), and so forth. Protozoa fall largely into the nano- and microsize categories, although there are conspicuous exceptions to this rule. Size characterization of phagotrophic protists is generally combined with the expectation that "larger things eat smaller things," and thus trophic relationships in mathematical descriptions of microbial food webs usually represent each size category as food for the next largest heterotrophic category.

The food web descriptions resulting from these exercises typically reduce protistan diversity into a few manageable compartments, and depict carbon and energy flow in the microbial community in the direction from photosynthetic compartments toward heterotrophic compartments, and from smaller species toward larger consumers. In addition, some adjustments in the number of biological compartments has been made in recent years to accommodate protistan species that participate in both photosynthesis and heterotrophy simultaneously (via mixotrophy or symbiotic relationships) (Fig. 4).

There are some distinct disadvantages of this "box model" approach for representing protozoan activities in the ocean. These models obscure much of the biological diversity expressed within this enormous group of species by reducing the complex ecological strategies of thousands of species to a few functional groups. Also, they misrepresent some of the details of trophic interactions. For example, the ability of many heterotrophic dinoflagellates to feed on diatoms larger than themselves is not encompassed by the size-dependent grazing scheme that most of these models employ.

Nevertheless, these formal descriptions of protozoan activities in food webs allow the role of these unicellular eukaryotic species to be placed within the context of all marine life. This work has focused attention on how fundamental protozoa are in the overall function of marine food webs and the important roles that they play in biogeochemical cycles within the sea. More appropriate (and accurate) depictions will emerge as new information on protozoan diversity and activity becomes available and is incorporated into models of microbial food webs.

CONCLUSION

There is now wide recognition of the essential ecological roles played by protozoa in estuarine and marine environments. These species are phylogenetically, morphologically, and trophically diverse. They are, as a group, virtually ubiquitous in all marine habitats where they play pivotal roles in food webs as consumers of bacteria, cyanobacteria, microalgae, and protozoa, and as prey for a variety of multicellular species. In addition, many protozoan species participate in a variety of symbiotic associations ranging from parasitism to mutualism, and numerous species are capable of combining phototrophic and heterotrophic nutrition (mixotrophy). Collectively, these single-celled organisms constitute a significant portion of the energy utilization and elemental flow in the ocean.

Most free-living protozoan species have one of three basic body plans (amoeboid, flagellated, and ciliated forms). The abundances and trophic activities (herbivory, bacterivory) of these broad assemblages of protozoa have been characterized for many estuaries and for surface waters of much of the world ocean. In many instances, protozoan biomass and activities have been placed into context with these features for other groups of organisms. Thus, we now have a reasonably good appreciation of the relative importance of protozoan assemblages in many marine food webs and biogeochemical cycles. Recent mathematical models of energy and carbon flow have included protozoa as integral components of system function.

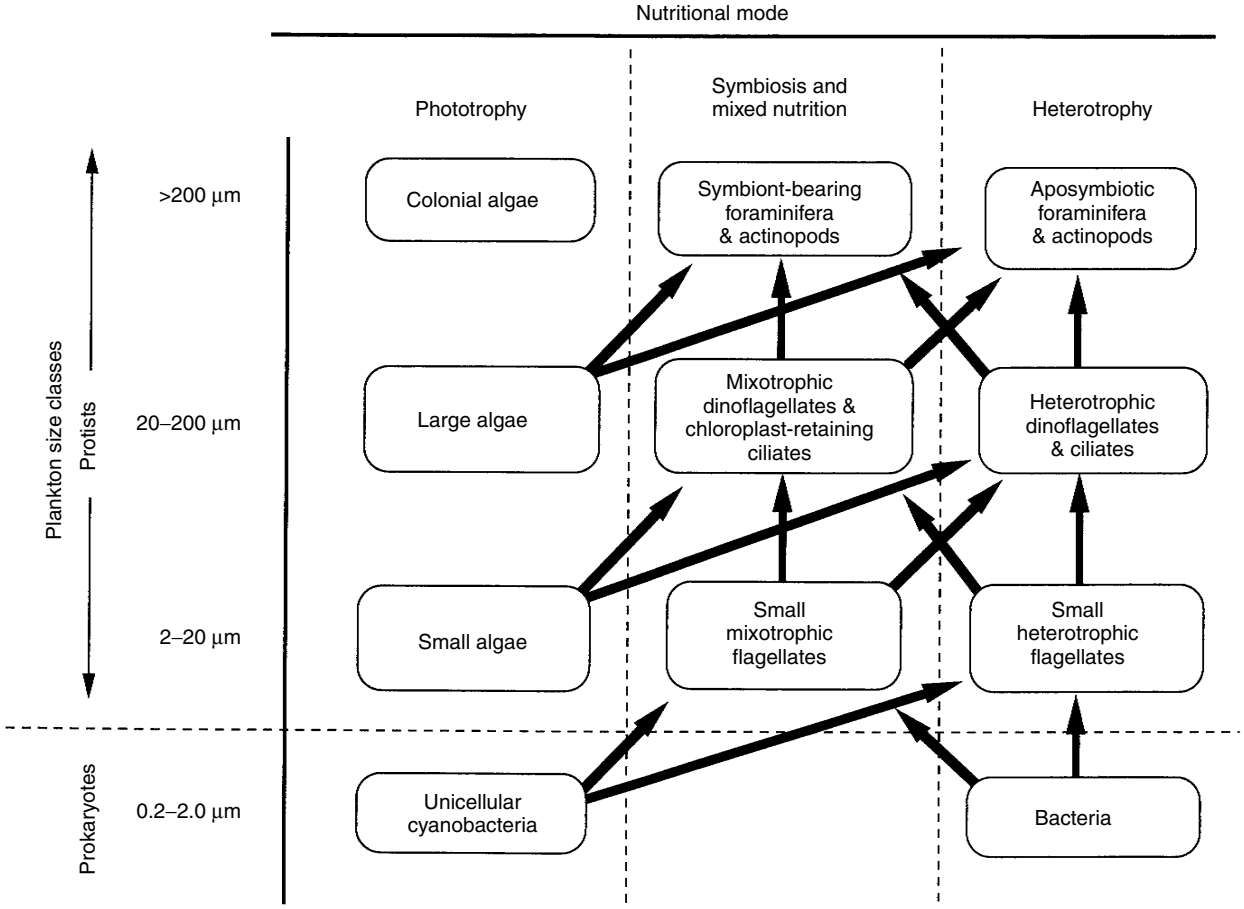

Figure 4. Box model of a generalized microbial food web indicating the roles of protozoa. Protists (and prokaryotes) are represented as aggregations of species of similar ecological function (i.e., protists with similar trophic status and activity). The species in this model have been aggregated according to nutritional mode (phototrophy, mixotrophy/symbiosis, heterotrophy) and by size. Energy is fixed into organic material by photosynthesis conducted by organisms in the two left-hand columns. Biomass is consumed by organisms in the two right-hand columns. Arrows indicate the presumed predator-prey interactions in the food web. In this particular model it is assumed that consumers eat all microorganisms one order of magnitude smaller than themselves. (modified from Caron and Finlay, 85).

Compared with significant progress in placing protozoa into proper ecological context, however, there is presently less consensus concerning the true species diversity within the group. Historically, these species have been defined morphologically, and it has been difficult to obtain a consensus regarding the validity of species distinctions based on minor differences in body size, shape, and ultrastructural features. This controversy regarding species diversity should diminish as new genetic methods of identification are intertwined with morphological criteria of species descriptions. In addition, as more physiological information is generated from cultured species of protozoa, this information should help define the species concept of these complex and fascinating creatures.

PROTOZOAN CILIATES IN FRESHWATER ECOSYSTEMS

THOMAS L. CRISMAN
University of Florida
Gainesville, Florida

The term protozoa has traditionally been used as an all-inclusive designation for the most primitive unicellular and colonial animals (1). Recognizing the transitional nature of many of these forms and the possession of both plant and animal characteristics and functions by some, protozoans have now been divided into seven separate phyla. Most orders of the protozoan class Phytomastigophorea are considered plant phyla by phycologists because of their photosynthesizing ability. Likewise, four classes of the subphylum Sarcodina and the phylum Labyrinthomorpha are considered slime molds by mycologists. Even within the ciliated protozoans (phylum Ciliophora), there are mixotrophs, which possess both plant and animal characteristics.

Ciliates belong to the phylum Ciliophora, a group distinguished by the presence of cilia during at least one stage of their life cycle. There are eight classes of the phylum Ciliophora, of which five represent the dominant ciliates in freshwater lakes: Colpodea, Litostomatea, Nassophorea, Oligohymenophorea, and Spirotrichea. Colpodea possess resting cysts and are represented by the order Colpodida in freshwater. The Litostomatea are characterized by simple oral cilia and are represented in freshwater lakes mainly by the order Haptorida (representative genus *Mesodinium*). Many Nassophorea possess cirral polykinetids and are represented in fresh waters by the subclass Hypotrichia, order Euplotida (genus *Euplotes*). Perhaps the best-represented class of ciliates in lakes is Oligohymenophorea, a group characterized by oral structures in a ventral oral cavity and an oral apparatus, when present, which is distinct from body cilia. Of its two orders, Hymenostomatida (genus *Colpidium*) and Scuticociliatida (genus *Cyclidium*), the latter is dominant in most lakes, especially those of higher trophic state. Spirotrichea is the second most important class of ciliates in the plankton of freshwater lakes and is best represented in oligotrophic to mesotrophic lakes. These ciliates possess conspicuous right and left oral and/or preoral ciliature and are represented by two important orders in the freshwater plankton, Oligotrichida (genus *Strombidium*) and Choreotrichida (genus *Strobilidium*).

There are three additional minor classes of ciliates. Class Prostomatea possesses a cytostome that is apical to subapical and is represented mainly by the order Prorodontida (genus *Urotricha*). Karyorelictea are long, vermiform, and flattened, and are mainly components of the benthos. Phyllopharyngea have radially arranged microtubular ribbons.

Reproduction within the eight classes of Ciliophora is typically via transverse fission, but budding and multiple fission have also been reported (1). Sexuality involves conjugation, autogamy, and cytogamy. Under ideal conditions, populations can double in a matter of hours. Movement is achieved through synchronous beating of cilia that are arranged around the oral cavity and/or along the length of the organism, resulting in spiral movement through the water by many taxa. Ciliates range in size from smaller than 10 μm to larger than 3 mm, and taxonomy is based on features of the oral region and the positioning and patterning of cilia.

The vast majority of investigations of ciliates in freshwater ecosystems have focused on planktonic, and to a lesser degree benthic, assemblages in lakes. In addition to large-bodied predators feeding on smaller ciliates and rotifers, most ciliates are grazers on bacteria and algae that are funneled into their buccal cavity as they spiral through the water. The relative proportion of bacteria and algae in the diet is dictated by ciliate body size, with those taxa smaller than 30 μm feeding predominately on bacteria (2). The largest-bodied taxa are found at the sediment–water interface and only enter the water column during times of extreme hypoxia or anoxia in this zone (3). Within the water column, there is a dominance shift from large-bodied (>40 μm) to small-bodied (<30 μm) taxa with progressive eutrophication (4). Recently, increased attention has been given to mixotrophic taxa, those predominately large-bodied ciliates contributing to ecosystem primary productivity via either endosymbiotic algae (5) or organellar sequestering of plastids from ingested algae (6).

Traditionally, freshwater zooplankton research was limited to those forms retained by vertical tows through the water column with Wisconsin plankton nets equipped with either a 158-μm (#10 silk bolting cloth) or a 76-μm (#20 silk bolting cloth) filtering surface. The smaller mesh size was used in cases in which particular emphasis was to be placed on microzooplankton (rotifers and copepod nauplii) in addition to macrozooplankton (cladocerans and copepodite or adult copepods) (7,8). Protozoan ciliates were not components of routine zooplankton investigations until the 1970s because they were not retained by accepted net-sampling techniques, were severely damaged during water filtration, and/or were destroyed by the harsh preservatives used for zooplankton. Far too many early limnologists defined the biotic realm of the field narrowly to the exclusion of fish at the upper end of the food web and microorganisms at the lower end. Protozoans were considered a part of the latter. Fortunately, such omissions have been corrected, and protozoans are recognized as essential components of the structure and function of freshwater ecosystems.

SAMPLING AND LABORATORY APPROACHES

Recognizing problems associated with use of traditional plankton nets, most investigations of planktonic ciliates

in lakes rely on preserved ciliates settled out from discrete interval or integrated samplings of the water column. Such an approach produces statistically more reliable counts than those obtained from net or pump sampling of the water column (9). Cairns and his associates pioneered the use of artificial substrates, especially polyurethane foam, for temporally integrating ciliate composition in the sediments and water columns of streams, rivers, wetlands, and lakes (10–13). A subsequent investigation by Foissner and coworkers (14), however, demonstrated that such polyurethane foam substrates sampled significantly fewer (122 taxa) ciliates than were isolated from the natural substrate of a European river (174 taxa), whereas the use of litter bags as a substrate medium (150 taxa) was statistically comparable to the natural substrate values. To date, there is no standard methodology for sampling ciliates in freshwaters, but artificial substrates are still viewed favorably by many investigators because of the need to integrate assemblages in water quality studies temporally.

Delicate taxa of rotifers and ciliates can disintegrate in the 4% buffered formalin solution long used to preserve zooplankton samples (8). Instead, ciliate samples have been preserved either with mercuric chloride after staining with bromophenyl blue (4,15) or Lugol's solution, especially if samples are also being utilized for phytoplankton enumeration. James (9) noted that counts of most ciliate taxa were significantly higher in samples preserved with Lugol's solution and mercuric chloride rather than either formalin or glutaraldehyde. Concerns over mercury toxicity, however, favor the use of Lugol's solution for preservation.

Routine zooplankton enumeration is often done under a light microscope using Sedgwick-Rafter cells. Detailed taxonomy for rotifers, however, often requires slide preparation of mouthparts; and dissection of individual legs is needed for determination of adults of copepods and some copepodite stages. Because of their generally smaller body size and the need for close examination of cilia placement patterns, routine counts of protozoan ciliates are often based on settled samples in Utermohl chambers (16) examined at 400X, using an inverted microscope. Many taxa require even higher magnification and resolution for proper identification. Ciliate biomass is calculated by assigning a geometric shape to each taxon and estimating cell volume based on cell dimensions, and then applying a specific gravity of 1.025 and a carbon content of 7.5% (4).

SEASONALITY

Although best developed for the subtropics and tropics, a generalized pattern of planktonic-ciliate seasonality in lakes is beginning to emerge (Fig. 1). Oligotrophic lakes generally display maximum biomass of ciliates during fall (17–20) associated with expansion of oligotrich populations. Secondary components of the assemblages, Haptorida and Scuticociliatida, also peak during this period. Mesotrophic lakes often display bimodal peaks during late spring and early fall dominated by Scuticociliatida (17,21). Finally, eutrophic and hypertrophic lakes are characterized by peak planktonic ciliate biomass during summer dominated by small-bodied Scuticociliates (17). Ciliate abundance can display differences according to trophic

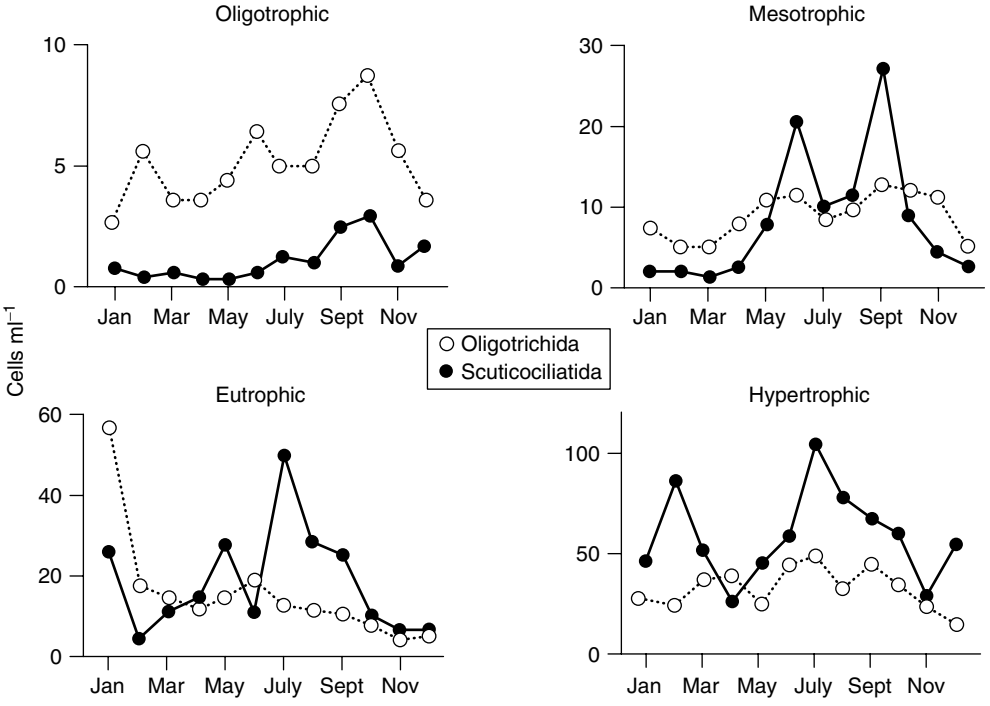

Figure 1. Seasonality of the protozoan orders Oligotrichida and Scuticociliatida in Florida. Values within trophic categories are means of multiple lakes. Figure adapted from J. R. Beaver and T. L. Crisman, *Hydrobiologia* **190**, 127–135 (1990).

state, but does not necessarily peak concurrently with biomass even within a particular trophic state category.

Large-bodied Oligotrichida are the dominant contributors to biomass and abundance peaks in oligotrophic lakes, whereas small-bodied Scuticociliatida dominate in eutrophic and hypertrophic lakes. It appears that seasonal patterns along trophic gradients are reflective of differences in food availability and lake mixing regimes (22). Small-bodied ciliates (i.e., scuticociliates) are principally bacterivorous and display maximum grazing efficiency on particles between 0.3 μm and 1.0 μm (23), and their biomass peaks in mesotrophic and eutrophic Florida lakes correspond well to bacterioplankton peaks (17). Large-bodied ciliates graze heavily on both picoplankton and nannoplankton in addition to bacterioplankton, and their seasonality would be expected to follow pulses in primary productivity with a strong contribution by these phytoplankton-size categories.

Although organically colored lakes can span the range from oligotrophic to hypertrophic, they differ from clear lakes of comparable trophic state by displaying an altered light regime, dissolved organic carbon (DOC) as an alternative biotic carbon pathway for the food web, and oxygen concentrations in the water column strongly negatively correlated with color levels and little influenced by lake trophic state (24). Beaver and coworkers (5) provided evidence that the seasonality of planktonic ciliates differs between clear and organically colored Florida lakes. Unlike oligotrophic lakes, it is the clear lakes that displayed peak biomass during fall and late winter, and the colored oligotrophic lakes that peaked during summer. Ciliate seasonality in mesotrophic and eutrophic lakes, however, resembled that of comparable clear lakes. The most pronounced difference across the trophic gradient was that colored lakes displayed significant numbers of mixotrophic ciliates during summer.

The vertical distribution of planktonic-ciliate abundance and biomass in the water column of lakes can change markedly seasonally (2). The vertical distribution of ciliate abundance in a Georgia (U.S.A.) reservoir was relatively uniform during winter, a period of mixing in this warm monomictic (water column mixing one time per year) lake, but after development of stratification in spring, abundance increased progressively in the epilimnion and decreased in the hypolimnion (25,26). A peak in scuticociliates developed just below the thermocline and was sustained from midsummer through early fall.

The vertical distribution of individual planktonic taxa in temperate and tropical lakes appears closely related to the development of thermal stratification, layering of phytoplankton, and bacterioplankton, and degree of hypoxia or anoxia in profundal waters (2,18,19,25). Large-bodied benthic ciliates (> 100 μm) in highly productive temperate lakes leave the sediment–water interface and ascend into the water column during summer as hypoxic or anoxic conditions develop at the sediment surface and move upward in the hypolimnion (3,27,28). A similar movement of large Hymenostomatida and Trichostomatida from sediments during peak productivity has been observed in eutrophic subtropical lakes (17).

RELATION OF CILIATE BIOMASS AND SIZE TO TROPHIC STATE

Several studies have noted a strong positive relationship between ciliate abundance and biomass and lake trophic state (4,26,29,30). For subtropical Florida lakes (4), the relationship between ciliate biomass and chlorophyll ($r^2 = 0.85$) was the strongest regression exhibited by any zooplankton component (31), and the values declined with increasing body size from rotifers ($r^2 = 0.54$) through cladocerans ($r^2 = 0.23$) to calanoid copepods ($r^2 = 0.07$). In a comparison with a similar suite of Canadian lakes, Beaver and Crisman (32) demonstrated that although the Florida lakes tend to have greater ciliate biomass for a given level of chlorophyll, there was not a significant difference between the biomass to chlorophyll regressions derived for the two lake regions (Fig. 2). Ciliate biomass does not appear to be significantly different between clear and organically colored lakes of a given trophic state in Florida (5).

In addition to biomass, ciliate assemblages change both structurally and functionally along trophic gradients. Small-bodied taxa (<30 μm) dominate the ciliate assemblages of most lakes, whereas larger-bodied ones (>40 to 50 μm) are replaced progressively with increasing phytoplankton production (4,32) reflecting a loss of Oligotrichida and an increase of Scuticociliatida (Fig. 3). This size shift is also evident within the Oligotrichida, and the largest-bodied euplanktonic ciliate found in Florida, *Stentor niger* (150 to 200 μm), is restricted to the most acidic ultraoligotrophic lakes, where it can contribute over 60% of total ciliate biomass (33).

Ciliates contribute approximately 10 to 60% of the total annual biomass of zooplankton in lakes, with values generally increasing as a function of trophic state (31,34–37). There is suggestive evidence that macrophyte-dominated eutrophic lakes have major structural, and presumably functional, differences in their ciliate assemblages (37) from phytoplankton-dominated

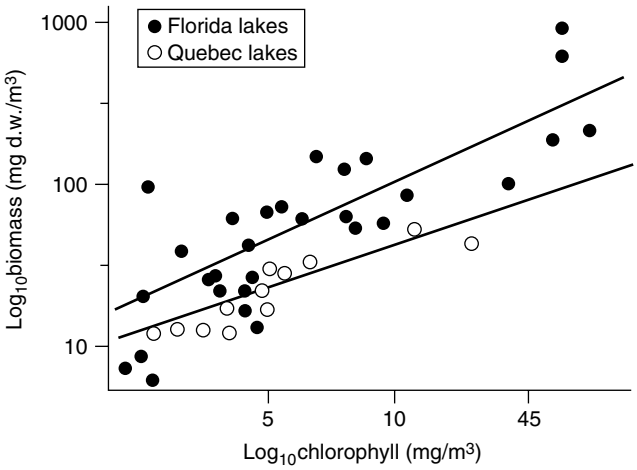

Figure 2. Relationships of annual mean biomass of ciliate protozoans versus chlorophyll for Florida and Quebec lakes. Figure adapted from J. R. Beaver and T. L. Crisman, *Hydrobiologia* **174**, 177–184 (1989).

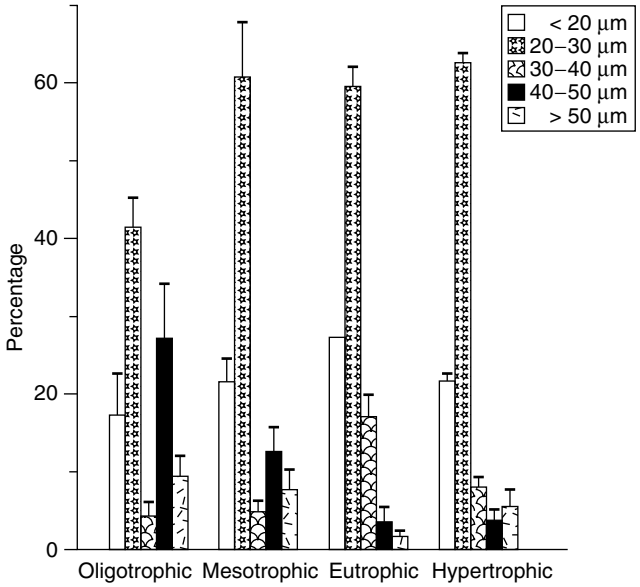

Figure 3. Contribution of ciliate size categories to annual mean ciliate biomass in Florida by trophic state. Figure adapted from J. R. Beaver and T. L. Crisman, *Limnol. Oceanogr.* **22**, 246–253 (1982).

ones, and this type of comparison is a promising research area for detailed investigation.

CONTROL OF CILIATE POPULATIONS

The structure of ciliate assemblages is controlled both by available food resources and predation and interference from higher trophic levels. Small-bodied ciliates (<30 µm) feed primarily on bacterioplankton and picoplanktonic algae, whereas the dominant food shifts from bacteria to progressively larger algal sizes with increasing ciliate body size (2,38). Heterotrophic microflagellates (39) and phagotrophic phytoflagellates (40) can compete with ciliates for food resources, especially bacterioplankton, but ciliate predation directly on such potential competitors can be significant seasonally in lakes (41). Ciliates and rotifers graze both heterotrophic nanoflagellates and bacterioplankton and thus assist carbon transfer to higher trophic levels (42).

While it has been suggested that ciliate populations can be severely food limited (43), numerous studies suggest that predation from larger ciliates and macrozooplankton (metazooplankton) is the principal regulator of ciliate abundance and structure (44–46). Although cladoceran predation is not insignificant, copepods, especially calanoids, appear to be the major zooplankton predators structuring the composition of ciliate assemblages (42,44,45). Experimental evidence suggests that although zooplanktivorus fish strongly control macrozooplankton composition and biomass, they have only weak control over ciliates, which can actually increase under high predation pressure (47). The trophic cascade effects on ciliates from piscivorous fish such as trout appears to be minor for lakes ranging from oligotrophic to slightly eutrophic (30). Burns and Schallenberg (44) caution researchers not to make broad generalizations on the role of individual trophic levels, especially zooplankton, regarding their control over ciliate composition and biomass, but instead to consider the importance of specific taxa.

NUTRIENT CYCLING

Zooplankton excretion of phosphorus can have a major influence over phytoplankton productivity (48), and release rates are inversely proportional to zooplankton body weight and size. Ciliates should display the highest excretion rates based on their small size and high metabolic rates (compared to crustacean zooplankton) (49–51). A ciliate population comprising as little as 1% of total zooplankton biomass could contribute approximately 50% of total phosphorus regeneration by zooplankton (52).

Both phytoflagellates and ciliates can be important regenerators of nitrogen in marine and freshwater ecosystems, but research for the latter systems is sparse (51,53–55). The role of ciliates for nitrogen and phosphorus regeneration is probably greatest when assimilable bacterial substrates have high carbon to limiting-nutrient ratios (e.g., nitrogen and phosphorus) (55).

MIXOTROPHY

Both phytoflagellates and ciliates can exhibit mixotrophy, a combination of phototrophy and phagotrophy in the same organism. In ciliates, mixotrophy is exhibited almost exclusively by select large-bodied taxa that contribute to ecosystem primary productivity via either endosymbiotic algae (5) or organellar sequestering of plastids from ingested algae (6). Mixotrophic ciliates are found in both marine and freshwater ecosystems, the latter spanning all trophic states and degree of organic color (5,56,57). Although a great deal is known about the role of phytoflagellates in freshwater, the literature on mixotrophic ciliates is surprisingly sparse.

Beaver and coworkers (5) reported that the large-bodied mixotrophic ciliate, *Strombidium* cf *oculatum*, dominated total ciliate biomass of several colored Florida lakes during summer and accounted for more than 50% of total annual biomass (Fig. 4). In addition, the proportion of total autotrophic biomass contributed by mixotrophic ciliates often exceeded that of phytoplankton during summer, approaching 96% on one occasion in a lake. Hecky and Kling (58) reported that mixotrophic ciliate biomass can exceed that of phytoplankton in Lake Tanganyika, and such mixotrophs contributed 4 to 69% of total primary production in two Australian lakes seasonally (59).

In nutrient-poor environments, possession of algal symbionts provides an additional food source, namely, algal metabolites, for the ciliate. The ciliate in turn would supply the algae with a dependable nutrient supply released during digestion of bacterial prey and would provide a predation refugium from zooplankton grazing. The importance of ciliate vertical migration patterns

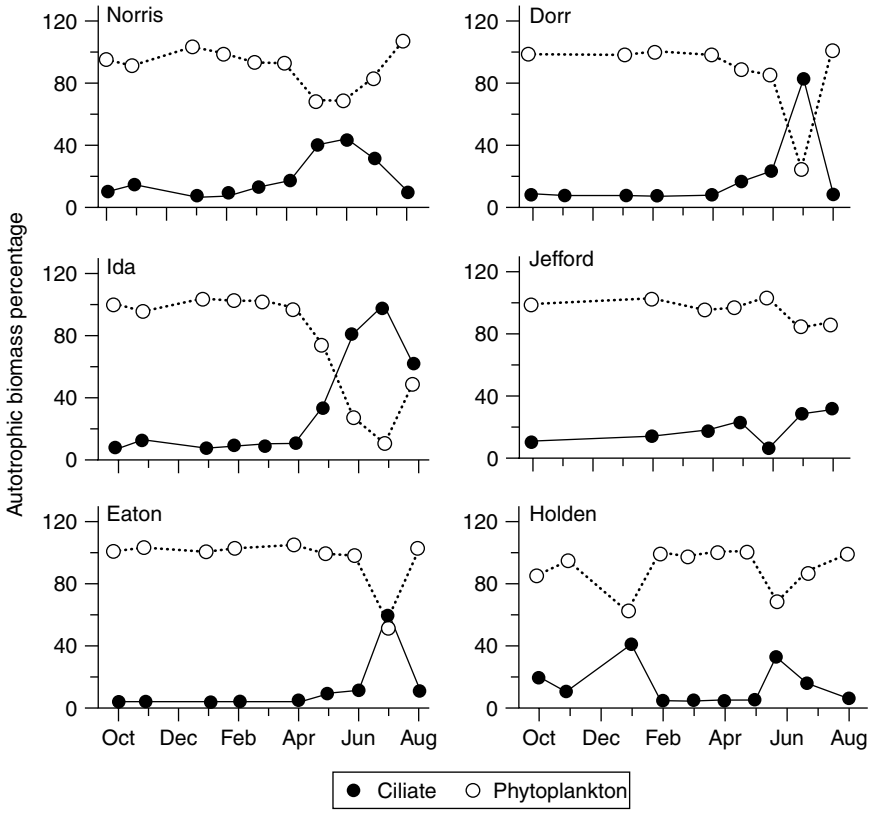

Figure 4. Percentage contribution of mixotrophic ciliates and phytoplankton to total autotrophic plankton biomass in six highly colored Florida lakes. Figure adapted from J. R. Beaver, T. L. Crisman, and R. W. Bienert, Jr., *Freshwater Biol.* **20**, 51–60 (1988).

for getting the algae to a more favorable light regime, especially in colored waters, is not well understood.

CILIATES AND THE MICROBIAL LOOP

The transfer and transformation of energy (carbon) from its production (photosynthesis) to its decomposition or deposition in the ecosystem memory (sediments) is fundamental to understanding the structure and function of aquatic ecosystems. Initially, ecologists viewed this as a unidirectional process (food chain) progressing through successive levels of heterotrophic consumers (trophic levels). With time came the realization that individual heterotrophs could function on multiple trophic levels as well as within a trophic level. Recognition of all such linkages led to the concept of the food web, with a feedback loop from all biotic components of the ecosystem to detrital and nutrient pools. The detrital and nutrient pools constituted both a short-term (recycled into the food web) and long-term (sealed from the food web in sediments) memory. Thus was developed a duality of energy transformation through food webs, primary production, and detritus.

Traditionally, limnologists focused on factors affecting phytoplankton production and its passage through zooplankton to planktivorous fish and finally to piscivorous fish. Rotifers, cladocerans, and copepods comprised most zooplankton investigations, and ciliates were excluded. It was not until the last quarter of the twentieth century that limnologists realized that direct utilization of picoplankton and bacterioplankton biomass by higher trophic levels in aquatic food webs depended on passage through phytoflagellates and ciliates. This alternative energy pathway was termed the microbial loop.

Ciliates play a key role in the microbial loop (Fig. 5). Small-bodied taxa are effective grazers on bacterioplankton and picoplankton, whereas larger-bodied taxa eat a wider array of foods. Some large taxa can be significant predators on small ciliates and phytoflagellates. Heterotrophic ciliates, in turn, pass energy to higher trophic levels via predation from macrozooplankton (metazooplankton) and fish.

The role of mixotrophic ciliates in the microbial loop is only beginning to be delineated. These tend to be the largest-bodied taxa in the ciliate assemblage and are probably beyond the size range preyed upon by zooplankton. Predation interactions with larval and adult fish are poorly known. Mixotrophic ciliates can contain a significant fraction of algal biomass, estimated from chlorophyll, especially in clear and dystrophic oligotrophic lakes (5,60). Currently, it is not known whether mixotrophic ciliates provide a shunting of energy directly to fish, thus bypassing zooplankton, or whether they are an energetic dead end in ecosystem carbon flow. Additional research is vitally needed to elucidate this pathway.

CILIATES AS EARLY WARNING BIOINDICATORS OF ECOSYSTEM CHANGE

Munawar and Weisse (61), relying on field data from the Laurentian Great Lakes, noted a dramatic decrease

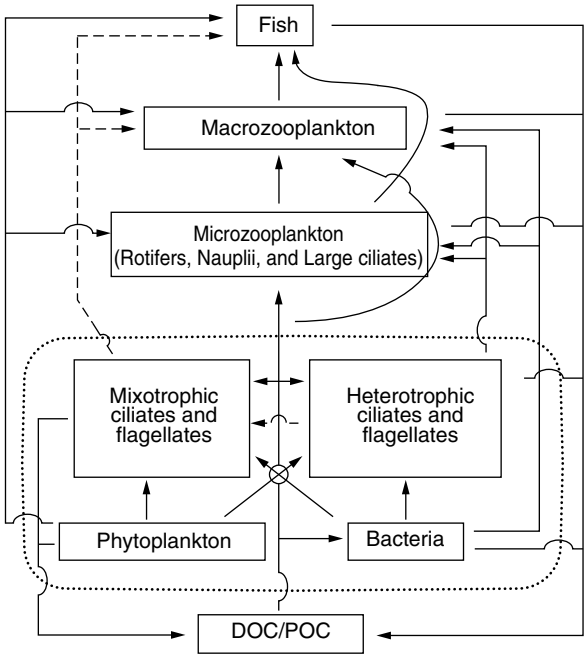

Figure 5. Conceptual model of the microbial loop in freshwater lakes and the role of heterotrophic and mixotrophic ciliates. The microbial loop is contained within the dotted circle.

of autotrophic picoplankton in eutrophic waters. They suggested that this important component of the microbial loop changed its structural and functional aspects along a trophic gradient and could possibly serve as an early warning indicator of pending environmental perturbation in lakes. Weisse (62) noted that the microbial loop operates in a similar manner in marine, estuarine, and freshwaters, but suggested that the overall importance of the microbial loop to ecosystem functioning decreases with increasing trophic state.

Beaver and Crisman (63) suggested that bacterioplankton should respond the quickest to cultural eutrophication because of their essential role in nutrient cycling. Bacterivorous ciliates should therefore respond rapidly to a shift in food availability and provide the first heterotrophic grazer documented change. In response to citizen complaints, an investigation was conducted between 1987 and 1988 for comparison with one conducted in 1979 to determine the extent of cultural eutrophication in Lake Weir, Florida. Although water clarity and nutrients did not change significantly during the period, microzooplankton in general, and ciliates in particular, increased significantly in response to increased food availability supporting concerns of the public and the need for pollution abatement.

Ciliates display a significant response to reduced pH, with a structural shift from a predominately small-bodied assemblage (20 to 30 μm) dominated by Oligotrichida, Scuticociliatida, and Haptorida in less acidic oligotrophic lakes to a large-bodied (40 to 50 μm) assemblage dominated almost exclusively by Oligotrichida in lakes at pH less than 5.2 (33). Both the impact of such changes on the structure and function of the microbial loop and its application to predicating ecosystem responses to acid rain are not clear. There is, however, great potential for utilization of ciliate assemblages as early warning indicators for climate change, heavy metal contamination, and eutrophication management.

CONCLUSION

Protozoan ciliates were largely forgotten from zooplankton investigations in freshwater lakes until the latter quarter of the twentieth century. Ciliates are well represented in freshwater and can be a major biomass contributor to the zooplankton community. Oligotrophic lakes are dominated by large-bodied taxa, which are progressively replaced by small-bodied taxa with increasing trophic state reflecting a dietary shift from predominately small phytoplankton to bacteria with increased biomass of the latter, especially in eutrophic and hypertrophic lakes. Ciliate biomass displays a strong positive relationship with increasing trophic state and is the strongest relationship noted for any zooplankton component. Both heterotrophic and mixotrophic ciliates play important roles in the microbial loop of lakes and affect energy transfer to higher trophic levels in the food web and nutrient cycling. It is proposed that ciliate biomass and taxonomic composition can be valuable early warning indicators of ecosystem change, including advancing cultural eutrophication and lake acidification.

PSEUDOMONAS

GARY A. TORANZOS
University of Puerto Rico
San Juan, Puerto Rico

Members of the genus *Pseudomonas* are among the most commonly encountered microorganisms, in the environment. They are tremendously versatile microorganisms

that can survive under conditions that include nutrient-poor to toxic, abilities that have made it a favorite microorganism to study transformation of xenobiotic compounds. Several species are opportunistic pathogens that cause myriads of diseases. Their ability to attach to and colonize surfaces not only makes them important in biofouling, but also allows them to be protected against biocides.

The role of *Pseudomonas* spp. in the environment, especially as a biotechnological tool for the degradation of xenobiotic compounds, and all the clinical aspects has been thoroughly covered elsewhere. Although the genus *Pseudomonas*, in general, is covered in this article, the main focus is on *Pseudomonas aeruginosa*, its ecology and its role in public health.

GENERAL DESCRIPTION OF THE MICROORGANISM

Pseudomonas is a ubiquitous genus in nature found in association with a large variety of matrices such as soil, water, plants, and animals (1). They are gram-negative rods with one or several polar flagella, with a notable nonmotile exception, *Pseudomonas mallei*. These morphological characteristics are nonspecific and are used to describe a rather large group known as the "pseudomonads" (a nontaxonomic term). The genus *Pseudomonas* is composed of straight or slightly curved rods approximately 0.5 to 1.0 by 1.5 to 5.0 μm (2) and strict aerobic respirers. However, some species can also use nitrate as an alternate terminal electron acceptor and can thus also be found under anoxic conditions in the presence of this electron acceptor. One of the reasons for its ubiquity may be that these microoganisms do not require the presence of growth factors except for a few species such as *Pseudomonas diminuta* and *Pseudomonas vesicularis* (pantothenate, biotin, cyanocobalimin, methionine, or cystine) (2) and *Pseudomonas maltophilia* (some amino acids) (1). Although none of the pseudomonads can fix molecular nitrogen, at least one species has been reported to grow under nitrogen-limiting conditions.

Another reason for *Pseudomonas*' ubiquity may be the ability to use a large number of organic compounds as the source of carbon and energy. For example, some species may use more than a 100 different organic compounds (1), including some aromatic compounds. Additionally, members of this genus have the ability to grow and live under extremely low-nutrient conditions such as distilled water, and have a high tolerance to a variety of extreme environmental conditions such as high (43 °C) and low (4 °C) temperatures. Favero and coworkers (3) studied the prevalence and multiplication of *P. aeruginosa* in distilled waters and found that these bacteria can be present in apparently clear distilled water at concentrations up to 10^4 cells/ml.

Although it is well known that *Pseudomonas* can in fact grow under conditions that are nutrient limiting for most microorganisms, it is still not clear how *Pseudomonas* can multiply under these conditions. It has been suggested that they can use gaseous nutrients dissolved in distilled water, but this hypothesis is not entirely convincing (4).

Because *Pseudomonas* spp. can grow at such extremely low-nutrient concentrations and use such a variety of organic compounds, one species (*P. aeruginosa*, strain P1525), has been used to measure the Assimilable Organic Carbon (AOC) concentration in waters (5) as an indirect measure of the potential regrowth of microorganisms in potable water distribution systems (6).

ECOLOGY

Pseudomonas spp., and especially *P. aeruginosa* can be isolated from animal and inanimate environments (4) and can easily adapt to the existing environmental conditions. Studies by Favero and coworkers (3), showed that *P. aeruginosa* can initiate replication with a minimal lag phase of growth in such nutrient-poor environments as distilled waters.

In the hospital environment, they can be isolated easily from clinical specimens and the surrounding environment and can be readily grown in routine culture media. Humidity seems to be critical in the survival of these microorganisms in the environment, consequently *Pseudomonas* can be found in moist environments such as respiratory equipment, ventilators, endoscopes, pressure monitors, sinks, mops, vegetables, and in some humans they may be found as part of the normal microbiota in areas such as the axillae, perineum, and ears (7,8).

Ringen and Drake (9) were able to isolate *Pseudomonas* from soils that had been allowed to dry for several months at room temperature. Additionally, *P. aeruginosa* sprayed on soils and grasses could be recovered for up to 130 days, and it seems that the soil acts as a protective matrix for these microorganisms because their half-life was observed to be as short as 10.2 min under low humidity (10) conditions on metal surfaces (11).

A study by Correa and coworkers (12) in an oncology hospital in Brazil indicated that *P. aeruginosa* could be isolated from vegetable surfaces in spite of previous washing using a 1% hypochlorite solution as a disinfectant. Several vegetables were tested for the presence of this microorganism, including onions, green peppers, and tomatoes, although lettuce, chicory, and watercress seemed to be the most common sources of the bacteria. Some of the clinical isolates were found to be serotypically identical to the vegetable isolates, suggesting that the vegetables may be a source of these microorganisms in the hospital environment. A previous study by Kominos and coworkers (13), had already implicated vegetables as a possible source of *P. aeruginosa* in a general hospital. The latter study showed that *Pseudomonas* could be isolated from several vegetables in the hospital kitchen, and from cutting boards and the hands of kitchen personnel. From these data, Kominos and coworkers (13), also suggested that hospital patients could possibly ingest up to 5×10^3 of *P. aeruginosa* cells in an 80-g salad, which is considered to be the amount consumed in a typical meal. Similar to the study by Correa and coworkers (12), the vegetable isolates were similar (if not identical) to clinical isolates from the same hospital. It has also been suggested that flowers could be a possible source of *Pseudomonas* in the hospital environment.

The consumption of bottled water in North America has grown yearly by up to 25% (14). *Pseudomonas aeruginosa* in bottled water is regulated in the European Community but not in North America (15). Studies by Burge and Hunter (16) and Gonzalez and coworkers (17), showed that *P. aeruginosa* could survive in mineral water from 70 days to over one year depending, perhaps on the bacterial strain (18). These data indicate that bottled water may not necessarily be free of *P. aeruginosa*. However, the health implications of this for the general public remain in question (15). Bottled water could possibly serve as a source of these microorganisms if present in high concentrations.

Pseudomonas spp. are highly resistant to disinfectants, including those used during drinking water disinfection procedures. *Pseudomonas* were enumerated at different stages during water treatment processes by Grabow (19) who found concentrations ranging from 260 (in sand filtration), to 90,000 cells/100 mL in activated sludge effluents (19) at water reclamation plants as measured by the Most Probable Number method. They are an important part of the microbiota in wastewater treatment processes and have been isolated from fixed-film bed reactors, activated sludge, and stabilization ponds (20). They can also be readily isolated from soils, and are among the most important members of the denitrifying group of microorganisms (21) in biological processes as well as during wastewater treatment processes.

Denitrification is the bacterial-mediated reduction of nitrate or nitrite to gaseous nitrogen under low dissolved oxygen conditions (22). *Pseudomonas* spp. are among the most important species of denitrifiers in environments such as marine and fresh waters and sewage (2,23). Denitrification is rare in flowing waters as a result of the presence of dissolved oxygen, and nitrate reduction is possible only when oxygen is present at concentrations of 50% below the saturation level. However, the presence of high concentrations of organics in matrices such as sewage, would also affect the concentration of oxygen, and thus the rate of denitrification.

ISOLATION

Gilardi (24) indicated that peptone agar (that can be supplemented with 5% sheep or rabbit red blood cells) is used to isolate *Pseudomonas* in the clinical laboratory, although selective media such as MacConkey, eosin-methylene blue and Leifson deoxycholate are also useful. For the selective isolation of *P. aeruginosa* and some other species, cetrimide agar, Pseudomonas agar F, and Pseudosel agar can be successfully used. Although they can be grown readily in the above media, it is advised that during isolation the analyst use certain tests as a screening procedure, including (for example) a typical grapelike odor (*P. aeruginosa*) nonfermentation of carbohydrates, ability to grow at 42 °C (positive), gram reaction (negative), spore formation (negative), motility (positive, except for one species), production of hydrogen sulfide, and oxidation of glucose, xylose, lactose, and maltose (24). Some strains produce pigments that are also used as a means of screening isolates, for example, pyocyanin, a blue phenazine pigment (*P. aeruginosa*), and several other diffusible and nondiffusible fluorescent and nonfluorescent pigments (2).

Pseudomonas aeruginosa can be readily detected in waters using either the most probable number (MPN) method or membrane filtration (MF). Media used for MPN analyses include asparagine broth and acetamide broth. After incubation at 35 to 37 °C for 24 to 48 hours the tubes are observed under long-wavelength ultraviolet light. The presence of a greenish fluorescent pigment is considered positive. The medium M-PA is used for membrane filtration and results can be obtained after 72 hours (25), and the typical colonies are flat with light outer rims and centers that appear brownish- to- greenish-black. Positive samples for both the MPN and the MF need to be confirmed using the appropriate media such as acetamide broth or agar slants for the MPN and milk agar for MF. The reader is directed to APHA Standard Methods for the Examination of Water and Wastewater (26), or later editions, for details regarding all these procedures.

ENVIRONMENTAL SOURCES

As indicated previously, *Pseudomonas* spp. are ubiquitous, and thus, it is not clear as to what the source of these microorganisms is in a given matrix, or even in clinical specimens. They can be found associated with water, soil, vegetable material, animal feces, and fomites. However, it is not clear whether the microorganisms are intrinsically a part of the normal microbiota of those environments. It has been shown that new hospital sinks can be free of *Pseudomonas*, but are rapidly colonized (27). It is not entirely clear if *Pseudomonas* is part of the human or animal normal microbiota or if it is simply an allocthonous microorganism in these environments. Tannock (28) did not include *Pseudomonas* spp. as part of the normal microbiota of humans. Noble (29) included *Pseudomonas* as a microorganism that can be found on human skin, especially the feet, however, these are most likely transient microorganisms originating from environmental sources, because they are present primarily in those persons whose feet get wet at work. *Pseudomonas* can also be isolated from the oral cavity in which it is considered allocthonous and the source seems to be water, especially colonized dental units (30).

The presence of *Pseudomonas* in animal feces does not seem to be prevalent as shown by Ringen and Drake (9) in which only 11% of the fecal samples tested were positive for *P. aeruginosa*. Forty-seven percent of the sewage samples analyzed during this study were positive for *P. aeruginosa*. These data comparing fecal and sewage samples simultaneously indicate that the feces may not be the actual source of *Pseudomonas*, but rather that these microorganisms are multiplying under the conditions of the wastewater environment. These microorganisms are seldom isolated from the feces of healthy individuals (4). Between 3 and 6% of individuals in the nonhospital environment seem to harbor *Pseudomonas* in their feces, although the source may be the ingestion of food or water containing these microorganisms. This is in contrast to feces from hospitalized individuals

in which 18 to 20% are positive for *P. aeruginosa* (13) indicating that the hospital food, and perhaps water may be the main source of these microorganisms. *Pseudomonas* spp. are not listed as part of the normal microbiota of human and animal feces (31,32), although they are considered prominent members of domestic wastewater. Because of the presence of biodegradable hydrocarbons in wastewaters, high concentrations of *Pseudomonas* can be detected (23). One species, *Pseudomonas hirudinicola*, is found as part of the gut microbiota of the blood leech (*Hirudo medicinalis*). This microorganism actually lyses the erythrocytes in the gut of the leeches, allowing the host to use the nutrients (23); however, because of the specificity of its reservoir, this species is not likely to be found in most surface waters.

PSEUDOMONAS COLONIZATION

On the basis of previously published literature, Geldreich (33) suggested that the colonization of the gastrointestinal tract of healthy humans by *Pseudomonas* is not a common event. Work in the 1960s by Samish and Etinger-Tulczynska (34) suggested *P. aeruginosa* as an epiphytic microorganism capable of colonizing vegetables, such as tomatoes. Their work showed that the microorganism could be detected in the stem scar and the underlying core of tomatoes. They also indicated that the stem depression could be the point of entry of the microorganisms into the tomatoes. However, it has been difficult to determine if the true source of these microorganisms was the soil, water, or the fertilizers used (13). Other species such as *Pseudomonas fluorescens*, *Pseudomonas putida*, *Pseudomonas multivorans*, *P. maltophilia* and *Pseudomonas stutzeri* may be indigenous to the water environment (33).

If microorganisms attach to solid matrices, and the conditions are favorable for their replication, the attached cells may start the production of exopolysaccharides to form a thick layer of growth, referred to as the aufwuchs (growth upon, in German) (35) or biofilm (36). This structure, in the case of *Pseudomonas*, is composed of alginate, which are repeating units of D-mannuronic and L-glucuronic acids (10). The production of alginate can be observed in *Pseudomonas* by the ability to change from a nonmucoid to a mucoid phenotype, and this seems to be the key to colonize different environments (4). The mucoid phenotype produces large amounts of exopolysaccharide in the form of alginate. This mucoid phenotype may allow the microorganism to anchor to substrata in aqueous environments and it may also help prevent its dislodgement from the respiratory tract of infected individuals.

Davies and coworkers (10), showed there was activation of alginate production as a result of attachment. Using *P. aeruginosa* they demonstrated that planktonic cells produced less alginate than the attached cells, thus indicating that attachment may indeed lead to colonization of the substratum. In similar studies, Boyd and Chakrabarty (37) showed that the enzyme alginate lyase and its statement play a role in *Pseudomonas* detachment from biofilms.

Pseudomonas cells can also produce a biofilm when attached to epithelial cells and, as described by Pollack (7), colonization is preceded by attachment during infections. Alginate biofilm production is important in diseases such as cystic fibrosis (37,38) and urinary tract infections (39) because of the anchoring that prevents dislodgement, and perhaps because the alginate matrix may protect the underlying microorganisms from the action of antibacterial agents.

Sagripanti and Bonifacino (40) tested seven commonly used chemical disinfectants on *P. aeruginosa* anchored to metallic and plastic devices and it was noted that cell anchored to either matrix were 300-fold more resistant to the disinfectants than freely suspended cells.

Pseudomonas aeruginosa is also capable of colonizing potable water distribution systems, and can be found growing in a variety of materials (41). This microorganism has also been detected in swimming pools and whirlpools, and Rhame (42) has proposed that the high temperatures in these environments may help the growth and multiplication of these microorganisms. This is most probable, as supported by the disease outbreaks outlined in Table 1.

Pseudomonas aeruginosa cells seem to control the production of colonization factors via mechanisms of cell-to-cell signaling (48). These mechanisms referred to as quorum sensing, allow bacteria to behave as a community rather than as individual cells via the production of homoserine lactone-based molecules that control the expression of extracellular virulence factors, possibly including colonization factors. The reader is directed to Van Delden and Iglewski (48) for a thorough review of the quorum-sensing mechanisms. Work by Singh and coworkers (49) strongly suggested that *P. aeruginosa* cells in cystic fibrosis patients produce a biofilm and that most cells in the lungs of these patients are in the biofilm state. Additionally, the biofilm state may be the definite factor in the chronicity of *Pseudomonas* infections in cystic fibrosis patients.

PSEUDOMONAS AND DISEASE

Although *Pseudomonas* spp. were originally thought to be nonpathogens, their opportunistic pathogenicity was finally accepted in the mid-twentieth century (4), and were observed to be the etiological agents in a myriad of infections as opportunistic pathogens. *Pseudomonas* spp. have been implicated in cases of (*1*) melioidosis (*P. pseudomallei*), (*2*) glanders (*P. mallei*), (*3*) bacteremia, pseudobacteremia, endocarditis, pneumonia, keratitis, urinary tract infections (mainly *P. aeruginosa*, but also *Burkholderia (Pseudomonas) cepacia*, *P. pickettii* and *Xanthomonas (Pseudomonas) maltophilia*) (8). *Pseudomonas aeruginosa* has also been implicated in sclerokeratitis in contact and noncontact lens wearers (50).

Pseudomonas is an opportunistic pathogen; and thus, is rarely an infectious agent in the immunocompetent individual, even if it is sometimes found as part of the normal human microbiota. With the advent of antibiotic use, advances in intensive care as well as life-extending therapies, the number of *Pseudomonas* infections has

Table 1. Selected Outbreaks of Disease Associated with *Pseudomonas/Burkholderia* in Water (1990–Present)

Country	Source	Number of Cases	Disease
Australia (1990–1991)[a]	Treated Drinking Water	5	Melioidosis/Septicemia
Netherlands (1995)[b]	Freshwater Lake	98	Otitis Externa

[e]Beckett et al., (47).

apparently increased. In the early twentieth century, severely burned patients as well as those with cystic fibrosis usually died because of the lack of treatment (4) that is currently commonplace. *Pseudomonas* infections in humans are usually caused by disruptions in the integrity of the physical barriers such as cuts and abrasions. In the hospital environment the circumvention of the barriers via catheters or parenteral drug injections (7) seems to be the most common route of infection. They are clearly opportunistic etiological agents of nosocomial infections commonly infecting burn patients as well as those undergoing chemotherapy. Data from 1980 to 1990 indicated that *P. aeruginosa* was the second most frequent gram-negative bacterium causing infections in hospitalized patients (4). They are in fact so common that the outer membrane proteins have been tested in vaccines in order to protect burn patients from *P. aeruginosa* bacteremia. A study by Kim and coworkers (51), concluded that the vaccine tested in patients with burns in 10% or greater of total body surface area was successful in protecting the patients (6.1% bacteremia in patients receiving the vaccine versus 40% in the patients receiving a placebo).

Pseudomonas endocarditis is common among illicit parenteral drug users, accounting for 58% of infections with gram-negative bacteria (52) and thus seems to be the most prevalent risk factor, however the authors indicated that there exist regional variations in its occurrence (7). Bacteremia seems to be an almost exclusively nosocomial infection common in hospitals and nursing homes (53), and the risk factors include antibiotic or corticosteroid therapy, prematurity, organ transplants, and traumatic injury. They are also common etiological agents in central nervous system infections that result from neurosurgery, head trauma, or bacteremic spread from other infection sites. *Pseudomonas aeruginosa* is the second most common isolate in cases of meningitis (7).

Cystic fibrosis patients typically died before the advent of antibiotic therapy was established. These patients can be infected with various microorganisms; however, mucoid strains of *P. aeruginosa* and *Burkholderia (Pseudomonas) cepacia* are among the most common. The reader is directed to Govan and Deretic (54) for a thorough review on cystic fibrosis and *Pseudomonas*.

Pseudomonas spp. are frequently the responsible agents in infections related to recreational water contact causing dermatitis, ear infections, and conjunctivitis (55). Although associated with infections in the immunocompromised, they have also been the etiological agents in community-acquired pneumonia in healthy patients (56). The latter study reported that previously healthy adults with a history of smoking are susceptible to community-acquired pneumonia. The risk factor seems to be exposure to aerosols of *Pseudomonas*-containing waters.

ENVIRONMENT AND PUBLIC HEALTH

It is clear that *Pseudomonas* spp. are an intrinsic part of certain environments, and as such it would be impossible to erradicate this microorganism. The mode of transmission may be via ingestion of food or water containing high concentrations of the microorganisms, although this may not necessarily lead to a diseased state in the host. In young infants and the immunocompromised, *Pseudomonas* may cause gastrointestinal infections such as necrotizing enterocolitis that can be fatal (57). However, gastrointestinal infections are perhaps underdiagnosed because they may be clinically inapparent (7).

Pseudomonas may result in skin and soft-tissue infections and there have been several outbreaks related to

the use of whirlpools, swimming pools, hot tubs, and spas (Table 1). Levine and coworkers (58), and Herwaldt and coworkers (59), reported several outbreaks of dermatitis associated with the use of these recreational waters. A more recent report by Beckett and coworkers (47), described two outbreaks of dermatitis/folliculitis associated with swimming pools and hot tubs that occurred between 1999 and 2000. In both outbreaks the levels of disinfectant had fallen below 2 mg/L and the pools and hot tubs were subjected to crowded conditions. A similar outbreak occurred in immunocompromised patients who had used a whirlpool bathtub (60). In this outbreak the source seemed to be a bathtub drain that was found to be positive for *P. aeruginosa* with a similar pulsed field electrophoregram as the patient isolates. Some of the outbreaks of dermatitis that have occurred in recent years are enumerated in Table 1.

A fatal septicemia outbreak occurred in Trinidad (61) affecting infants in a neonatal intensive care unit. A nurse, who failed to wash hands in between patients, may have been the source. Although no environmental sources of the *Pseudomonas* could be found, a strain with the same antibiotic resistance pattern was isolated from the only water tap at the intensive care unit.

All these outbreaks indicate that *Pseudomonas* is indeed an important opportunistic pathogen affecting particularly special populations. In almost every one of the outbreaks there seemed to be an environmental source that had been colonized by *Pseudomonas*. The fact that these microorganisms can form a biofilm and colonize pipes, faucets, drains, and other fomites is a clear indication that extreme care should be taken to try to keep colonization to a minimum. The study carried out by Sagripanti and Bonifacino (40) clearly indicates that disinfectants by themselves may not be enough to keep fomites free of *Pseudomonas*. This study showed that anchored cells are 300-fold more resistant to commonly used disinfectants than suspended cells. This may indicate that mechanical cleaning may be in order; together with disinfection procedures so as to better protect public health.

Although this chapter has mainly focused on *P. aeruginosa*, it is important to note that there have been reports of outbreaks of melioidosis associated with water treatment plants (43). *Burkholderia (Pseudomonas) pseudomallei* was isolated from environmental sources (Table 1) and the authors indicated that an aerator at a water treatment plant may have been the source of microorganisms that contaminated the potable water that served as a source of infection. The microorganisms can grow rapidly in well-aerated environments and can thus rapidly increase to concentrations that may present a public health problem. *Pseudomonas* spp. have been observed to grow well in the water-air interfaces of all water treatment processes, as well as on home water treatment devices. In the latter case, proper maintenance of the treatment devices is required to prevent colonization and growth of *Pseudomonas* as well as other microorganisms (25).

Burkholderia (Pseudomonas) pseudomallei and associated cases of meliodosis have been reported to occur mostly in the Far East (62) and Australia. However, a few cases have also been reported in Africa, Mexico, and South America (7), Oklahoma (63) and Georgia (64). Thus, this indicates that this microorganism is also present in the Western Hemisphere and thus may present a future public health problem as an emerging pathogen.

Hardalo and Edberg (15) proposed that perhaps the health risk posed by *P. aeruginosa* in drinking waters is overstated. In a thorough review of the literature they indicated that most of the outbreaks previously associated with drinking water and *Pseudomonas* were in fact linked to other sources of infection. Thus, in spite of the pathogenicity and omnipresence of this microorganism in the environment it would not be practical to try to eliminate it from drinking water, because it also has the ability to regrow in the distribution network, posttreatment. However, these are microorganisms that are important pathogens affecting primarily special populations, and therefore public health may be better served by public education and health advisories rather than by attempts to control or eliminate them from water and food.

CONCLUSION

Pseudomonas spp. are among the most commonly isolated microorganisms from the environment, although these data may be biased as a result of the media and methods currently used for their isolation, which may inhibit the growth of other microorganisms. Nonetheless, their importance in the environment is tremendous as is their role as opportunistic pathogens of the immunocompromised. Although the term "contamination" is often used when referring to the presence of *Pseudomonas* in recreational or other types of water, this is not the correct terminology. As indicated previously, *Pseudomonas* is omnipresent in the environment (e.g., soil, water, plants) as part of the resident microbiota, thus its presence in waters does not necessarily indicate contamination. The fact that these microorganisms are naturally present in the environment presents a true health problem as a result of the opportunistic nature of the pathogenicity. *Pseudomonas* may be present in tap water, bottled water, recreational waters, raw vegetables, and aerosols. Thus, it is advisable that special populations take special precautions because they are at the highest risk of infection.

It has also been mentioned that high concentrations of *Pseudomonas* can be found in treated and untreated sewage, thus it may be expected that in surface waters receiving sewage effluent *Pseudomonas* may be present in high numbers. In the latter case, the risk of exposure would be twofold, as a result of the possible presence of enteric pathogens and the opportunistic pathogen, *Pseudomonas*. Several epidemiological studies have been carried out in marine recreational waters (65,66) and freshwaters (67) in order to determine the public health risks of water exposure. These studies measured the concentrations of indicators of fecal contamination as well as the concentrations of *Pseudomonas*. However, these and other epidemiological studies to date have focused mostly on gastrointestinal diseases, thus it is currently difficult to

determine the true impact of the presence of *Pseudomonas* spp. in recreational waters on public health.

It is encouraging that new materials are being developed that may prevent or minimize biofilm formation in tubes used in catheters (68). Investigators are currently modifying polymers by incorporating the antibiotic ciprofloxacin. These materials act by slow release of the antibiotic, thus preventing colonization of the tubes and thus minimizing infection.

It is also encouraging that progress is being made to counteract the effects of colonization factors produced by *Pseudomonas*. The production of these colonization factors may be most important in terms of public health, first because of the increased resistance of the microorganisms to antimicrobial agents in infected patients and second because the ability to colonize the environment insures a constant reservoir of the microorganism. If all aspects of colonization are elucidated we will be well on the way to better protect public health from a very dangerous opportunist.

Acknowledgments

The author wishes to thank Joanna Santamaria, Francisco Calderon, and Roberto Rodriguez for their help in reading and editing the manuscript. The auspices of the RCMI Program, NASA-IRA, University of Puerto Rico and Water Resources Research Center, University of the Virgin Islands are also acknowledged.

PSYCHROPHILIC BACTERIA: ISOLATION AND CHARACTERIZATION

JOHN P. BOWMAN
University of Tasmania
Hobart, Tasmania, Australia

Life-forms proliferating in perpetually cold environments have developed ecophysiological and biochemical adaptations to optimize their activity at low temperatures. A broad spectrum of life is cold-adapted and includes bacteria, archaea, and simple and complex eukaryotes, ranging from algae to fish. Organisms that are cold-adapted are often referred to as *psychrophiles*, a word derived from ancient Greek and Latin, meaning literally cold-loving (psychros: cold, philus/phile: lover, loving). In the eponymous review on bacterial psychrophiles by Morita (1), a "true" psychrophile included any organism able to grow optimally at about 15–20 °C or less but was unable to grow at room temperature (20–25 °C) or higher. Research suggests true psychrophiles are comparatively uncommon as the majority of bacteria isolated in cold ecosystems are what have been termed psychrotrophic or facultative psychrophiles (2,3). These bacteria have temperature optima at 20 °C or more but are able to grow at 0 °C and the growth rates are usually equivalent to that of psychrophiles at low temperatures. These bacteria are most appropriately considered psychrotolerant (2). Psychrotolerant bacteria abound even in the coldest of environments, simply because many of them are ecophysiologically resilient and nutritionally versatile species.

The aim of this review is to provide an overview of various procedures useful for the isolation and characterization of psychrophilic bacteria. Most procedures detailed are general methods modified for cold-adapted bacteria. The review covers isolation, routine cultivation, maintenance, and general characterization of psychrophiles. Procedures to accurately determine cardinal growth temperatures using a temperature gradient incubator (TGI) are then detailed. Techniques for definitively identifying and quantifying fatty acids implicated in cold adaptation of cellular membranes, including polyunsaturated fatty acids (PUFA) and branched chain fatty acids, are explained.

ISOLATION OF PSYCHROPHILES

General Principles

Psychrophilic taxa are generally found only in permanently cold habitats, environments that have constant annual temperatures of less than 4 °C (1) and which have not been subject to warming over 25 °C even for a short duration. Psychrophilic species have been isolated from a variety of terrestrial environments, including vegetation and ornithogenic soils of Antarctica, boreal tundra soils, some chilled food products, surface snow and ice, and underlying sediments (Table 1). Other terrestrial environments have the potential to yield novel psychrophilic and psychrotolerant bacteria, including high alpine lakes (4) and subterranean karsts (5). As an example, Tasmanian karsts (Australia) have a constant annual average temperature of only 7 °C (D. Nichols, pers. comm.). Unusual

Table 1. *Psychrophilic taxa* That Have Been Well Characterized, Including Their Known Phylogenetic Affiliation, Habitat, Optimum Growth Temperature, and Isolation and Growth Medium

Species[a]	Phylogenetic Affiliation	Habitat	T_{OPT} (°C)[b]	Isolation and Growth Medium[c]	Reference
Colwellia demingiae	Gamma proteobacteria	Sea ice	10	Marine 2216	9

Terrestrial species:					
"*Methylobacter psychrophilum*"	Gamma proteobacteria	Tundra soil	~10	NMS (1 : 1 CH_4 : air)	29
Psychrobacter urativorans	Gamma proteobacteria	Ornithogenic soil, food	18	Trypticase soy + 1% NaCl	30
Psychrobacter frigidicola	Gamma proteobacteria	Ornithogenic soil	14–15	Trypticase soy + 1% NaCl	30
Aquaspirillum arcticum	Alpha proteobacteria	Sediment below snow and ice	10–15	Trypticase soy agar	31

Table 1. (*Continued*)

Species[a]	Phylogenetic Affiliation	Habitat	T_{OPT} (°C)[b]	Isolation and Growth Medium[c]	Reference
Flavobacterium psychrophilum	Cytophagales	Salmon with cold water disease; cold streams	~20	Anacker-Ordal medium	32
Flavobacterium xanthum	Cytophagales	Pond mud	~17	Nutrient agar	33
Clostridium estertheticum	Bacillus/Clostridium group	Frozen, chilled food	10–12	DMSZ Medium 642	34
Micrococcus antarcticum	Actinobacteria	Soil	16–17	Nutrient agar	35

[a]Only species with a growth temperature optima of up to 20 °C are included.
[b]T_{OPT} for several species are only approximate values.
[c]Media formulations are detailed in the indicated reference. DMSZ media are media from the DMSZ, German Collection of Microorganisms, Braunschweig, Germany (refer to website *www.dmsz.de* or the catalogue).
[d]*Colwellia hadaliensis* and *Moritella yayanosii* are extremely barophilic and require hydrostatic pressure at 70–90 MP for optimum growth (10,15); *Shewanella benthica*, *Shewanella violacea*, and *Moritella japonica* are moderately barophilic with optimum growth occurring at approximately 30 MPa of pressure (13,18).

sites, such as the subglacial Lake Vostok (78 °S 106 °E) buried about 3,700 m below the Antarctic ice sheet (6–8), may also offer opportunities for novel discoveries of unique and unusual cold-adapted bacteria.

The marine ecosystem appears to be the best place to find psychrophilic bacteria as the majority of the oceanic volume is cold (<5 °C) and insulated from periodic or intermittent solar insolation. Marine psychrophiles, almost without exception, are able to grow at temperatures down to the limit at which normal seawater stays liquid (−2 to −5 °C) and most known psychrophiles originate from the marine environment, isolated from deep waters, sea ice, and polar sediments (Table 1). Some anecdotal evidence suggests that ideal environments for isolating psychrophiles are both permanently cold and relatively eutrophic. For example Burton Lake, a moderately eutrophic seasonal marine basin located in Eastern Antarctica (Vestfold Hills, 68 °S 78 °E) has enriched psychrophilic bacterial populations throughout its waters (2), whereas adjacent coastal under-ice waters only have relatively low psychrophilic bacterial populations (3,16). The production of psychrophilic bacterial populations, as in other mostly heterotrophic bacteria is closely coupled to primary production (36) and the presence of enhanced levels of substrate, deriving from photosynthetic exudates and from lysed cells are thought to allow more efficient growth at low temperature (16,36,37). Studies by Pomeroy and Deibel (38) have suggested that at low temperatures, marine bacterial productivity becomes uncoupled from primary production. More recent evidence suggests that environmental spatio-temporal variability makes generalization in this respect difficult. It has been surmised that specific components of the marine bacterial community probably respond quite differently to the availability of substrate at low temperatures (39). On this basis, psychrophilic bacterial populations may undergo substantial changes in abundance and may have to be sampled over time at a given site to get a true indication of their presence or absence.

Psychrophiles may also abound in attached communities, on organic detritus or on the surfaces of aquatic biota in polar waters (Bowman, unpublished data). Data from sea ice communities and Antarctic seawater suggest that species of the order *Cytophagales* and gamma proteobacteria make up the majority of marine psychrophiles (16,40). Species of the order *Cytophagales* appear to be closely associated with phytoplankton, whereas gamma proteobacteria are more likely to be free-living. Many psychrophilic bacteria, all grouping in the gamma subclass of *Proteobacteria*, have been isolated from the abyssal ocean and are usually barophilic or barotolerant. Specialized methods are required for their study (41–44). As isolation efforts today have not been particularly extensive in most cases, there still appears to be a significant scope for the isolation of novel psychrophiles from the natural environment.

Sample Treatment

The samples to be investigated for psychrophiles should be stored at all times at 0 to 4 °C until used in experiments; exposure to higher temperatures (<25 °C for a few hours at most) should be avoided when possible; in any case short exposures will usually only have a modest deleterious effect on the psychrophilic populations present. Samples should never be frozen, particularly if the samples are marine in origin, as many psychrophiles are easily lysed by freeze-thawing in the absence of cyroprotectants. For example, sea ice samples must be thawed in seawater at 0 to 4 °C to prevent hypotonic shock to the microorganisms present.

Samples can be added directly to or spread onto isolation media as is usual for traditional isolation. The receiving media, and if dilutions are needed the diluent medium, should be chilled before use (on ice or in the refrigerator). Primary incubation of isolation plates, enrichments cultures and the like should proceed at temperatures of 0 to 5 °C. Some psychrophiles may not grow on agar at temperatures of 10 °C or greater. However, virtually all known psychrophiles can grow at 10 °C in liquid media. Incubation at very low temperatures (<0 °C) has little apparent benefit in selective isolation of psychrophiles as psychrotolerant bacteria can grow almost as fast as psychrophiles at these temperatures. Incubation times required for the development of visible

growth are dependent on the initial populations present in the samples.

Media, Enrichment, and Enumeration

Essentially, most existing isolation protocol for bacterial isolation can be directly adapted to the isolation of psychrophilic bacteria. The only critical criterion is that the source material must have a history of permanently low temperature (1). A useful way to enhance the isolation of psychrophiles is to briefly enrich the sample in the liquid isolation media at in situ temperature (1). This has been found to work quite well for the isolation of psychrophiles from sea ice diatom assemblages (16) in which enrichments were performed at about 0 to 1 °C for 24 hours. The enrichment should be carried out for up to only 48 hours and the sample immediately plated or transferred to fresh media.

The direct enumeration of psychrophiles is only practical if their populations are greater than that of psychrotolerant bacteria, for example, in sea ice algal assemblages (2,3,36; Bowman, unpublished data). By determining most probable number (MPN) counts (45) at 0 to 2 °C and at 25 °C for a given sample, the proportion of psychrophilic versus psychrotolerant bacteria can be revealed.

Routine Maintenance and Preservation

Many chemoheterotrophic psychrophiles can be maintained on agar plates or slants for long periods at 1 to 2 °C in a frost-free cooler or refrigerator. Care must be taken to avoid freezing of the media due to ice-nucleation events, as it will result in complete loss of viability of the cultures. Media should be supplemented with suitable antifungal agents, such as cycloheximide (at 100 μg ml^{-1}, add from a filter-sterilized 10% ethanol stock) and nystatin (at 250 U ml^{-1}, add from a 25,000 U ml^{-1} filter-sterilized methanol stock). If agar plates are used, they need to be reasonably dry to avoid bacterial contamination. Most psychrophiles that have been isolated should be subcultured every four to six months when stored at 2 °C. Storage at higher temperatures (4 to 10 °C) requires more frequent transfer (once every 1–3 months) as viability is lost at a higher rate. Some psychrophiles, such as the species *Colwellia psychrerythreae* and some members of the *Cytophagales*, are quite delicate and will die on plates in only a few days. These species can be preserved as dense suspensions in sterile seawater and stored at 2 °C for several months.

For longer-term storage, including preservation of delicate strains, a dense suspension of cells is prepared in about 2 to 5 ml of growth media that has been supplemented with 20 to 30% glycerol or dimethyl sulfoxide. The suspensions should then be frozen initially at −20 °C and then stored at −70 to −80 °C. For continued recovery of cells from the frozen suspension, repeated thawing should be kept to a minimum. For most psychrophiles, direct inoculation of frozen cryopreserved culture directly to plates or liquid media is usually sufficient. Large numbers of small aliquots of the cryopreserved culture(s) may also be a convenient safeguard as they are thawed only once, used, and then discarded. Special tubes and boxes for cryopreservation storage are available from a number of laboratory suppliers.

Characterization

Characterization data has a variety of uses; firstly, the data is required for taxonomic analysis, particularly if the objective is to describe psychrophilic strains as a novel species or genus. Beyond the purposes of taxonomy, many "traditional" phenotypic tests can also used for the prescreening of psychrophiles for cold-adapted enzymes. Methods for the quantitative analysis of cold-adapted enzymes are much the same as for normal enzymes. The only safeguard to be taken is to prevent denaturation of enzymes due to their generally greater heat lability. The characterization, mechanistic characteristics, and features of cold-adapted enzymes have been covered in numerous reviews (46,47) and are covered in the other chapter in this book on psychrophiles (see PSYCHROPHILIC BACTERIA: ISOLATION AND CHARACTERIZATION, this Encyclopedia). There are no phenotypic tests specifically dedicated to the characterization of psychrophilic bacteria. Tests that should be used depend on the bacterial group in which the strain falls among, whether it is a chemoheterotroph or a more specialized group such as a methanotroph. Most other techniques required for bacterial characterization, including chemotaxonomic and genotypic methods, follow the same approach as that for other prokaryotes. The methods for detailed fatty acid analysis are given later in this chapter because psychrophiles may have unusual fatty acid components.

DETERMINATION OF CARDINAL TEMPERATURE VALUES

Principal and Applications

The square root growth model (48) has been implemented to accurately determine cardinal growth temperatures of a variety of psychrophilic and psychrotolerant bacteria (2,9,49–50). This model is based on the principle that the square root of the growth rate is linearly related to temperature and can predict growth rates across the entire biokinetic range (48). The model can be defined as follows:

$$\sqrt{r} = b(T - T_{MIN})(1 - \exp c(T - T_{MAX})) \qquad (1)$$

where r is the growth rate at temperature T, T_{MIN} is the notional minimum growth temperature (where $\sqrt{r} = 0$), T_{MAX} is the notional maximum growth temperature (where $\sqrt{r} = 0$), b is the slope of the regression line and c is the coefficient to be estimated experimentally. Together with the optimum growth temperature (T_{OPT}), T_{MIN} and T_{MAX} are cardinal temperatures for the biokinetic range of a given organism. All cardinal temperatures occur over a continuum range, including T_{MIN}. For marine psychrophilic and psychrotolerant bacteria, T_{MIN} values are usually in the range of −5 °C to −22 °C. TGI-based analysis of cardinal temperatures provides a useful set of autoecological data for psychrophilic bacteria, can be

used for physiological and environmental comparisons and provides useful data for strain characterization.

To accurately obtain growth rate data over a temperature range, a temperature gradient incubator (TGI) (available from Advantec or Terratec Pacific Ltd.) is employed. Alternatively, several temperature-adjustable water baths can be used. The TGI has a bar shaped block that is fitted at each end with thermal and cooling units that can contain 24 to 30 test tubes and can also be oscillated to keep cell suspensions evenly mixed and to avoid oxygen gradients. The test tubes used are custom-made L-shaped tubes (18-cm stem, 7-cm side arm) made of optical quality glass, designed such that spillage does not occur when the TGI is operating and so that they can be placed directly in a spectrophotometer (e.g. Spectronic 20D series made by Spectronic Instruments is very suitable for the task) to read optical densities.

Inocula used in the experiment should be grown to the late logarithmic or stationary growth phase in a suitable growth medium and at a temperature that ensures rapid growth. L-tubes, containing 10 ml of the growth medium, are placed in the TGI for at least one hour to allow for temperature equilibration with the TGI, set with a minimum temperature of about 0 °C and a maximum temperature of 30 °C or so (for psychrophiles); for psychrotolerant bacteria, the maximum temperature end of the TGI should be set to about 45 to 50 °C. The L-tubes are inoculated with sufficient growth to achieve an absorbance at 540 nm of about 0.1 (if the initial cell concentration is about 10^{10} cells ml^{-1} the amount would be 200–300 µl). Optical density readings are then taken just following inoculation. L-tubes are agitated at about 40 oscillations per minute. At periodic intervals after inoculation, optical density values at 540 nm and the time since inoculation are recorded. Between optical densities of 0.01 and 1.5, turbidity increases linearly (51). The experiment is effectively complete for an L-tube once its optical density at 540 nm exceeds about 1.5, because only the exponential growth rate area of the growth curve is needed and recordings into the stationary growth phase are not necessary. In any case, a minimum of 15 readings should be recorded for each tube. At approximately one-generation intervals and following growth cessation, the temperature is recorded using an electronic thermometer fitted with a thermocouple from each L-tube (e.g. Fluke Inc). Optical density values plotted against time should form a sigmoid curve from which maximum specific growth rate (μ_{max}) and doubling time (t_d) can be determined from the steepest tangent to the fitted curve as follows:

$$\mu_{max} = \frac{Ln2}{t_d} = \frac{Ln(10)B}{e^1} \qquad (2)$$

where B is the slope of the steepest tangent. The doubling time can be thus determined by fitting the linear section of the growth curve (exponential growth region) with a regression line and then by determining the time interval (in minutes) required for the optical density to double in this region. To determine cardinal temperatures, the reciprocal square roots of either growth rates or generation times are taken and plotted against their respective temperatures. A nonlinear regression is then fitted using appropriate software (e.g., SigmaPlot, UltraFit) as shown in Figure 1.

It should be noted that a detectable decrease in growth yield occurs at the extremes of the supra- and suboptimum temperature range. This has the effect of potentially skewing growth rate information. Thus, T_{MIN} and T_{MAX} values are subject to a potential level of error (i.e. ±1–2 °C). To counter this, viable count data derived by serially diluting cultures from high and low end of the TGI and plating onto agar (incubated at the T_{OPT}) can also be used to help pinpoint the temperature of the growth–no growth interface.

Determination of the T_{OPT} of Cold-Adapted Enzymes

TGI technology can also be conveniently used for assaying enzymes over a range of temperatures to determine T_{OPT}. Colorimetric procedures are useful because they can be measured directly from L-tubes spectrophotometrically, following termination of the reaction. A simple Arrhenius-type model can be used to predict enzyme T_{OPT}, T_{MAX} and T_{MIN} and can be shown in logarithmic form (52):

$$\ln k = \ln \mathrm{A} \exp(-E_a/\mathrm{RT}) \qquad (3)$$

k = the enzyme rate.
A = the collision factor (a constant equal to the number of collisions between reactants per unit time).
E_a = the "activation energy" (related to the enthalpy of activation).
R = the gas constant (1.987×10^{-3} kcal mol^{-1} K^{-1} = 8.314 J mol^{-1} K^{-1}).
T = the absolute temperature (°K).

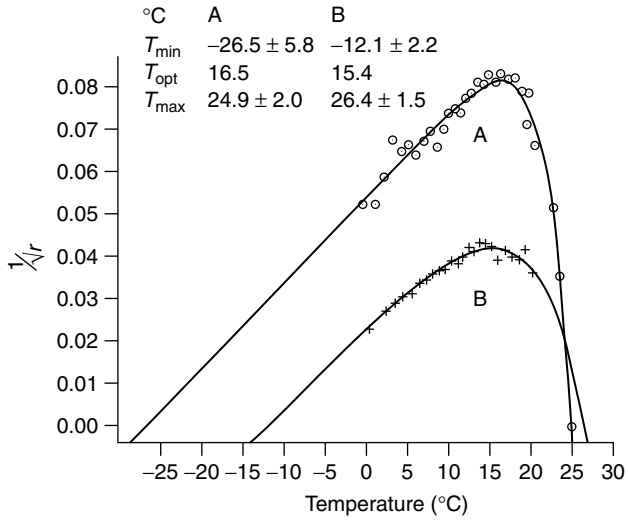

Figure 1. Square root growth rate–temperature plots of the type strains of A) *Shewanella gelidimarina* and B) *Glaciecola punicea*. The cardinal temperatures ($T_{MIN}/T_{OPT}/T_{MAX}$) for *Shewanella gelidimarina* and *Glaciecola punicea* are −26.5±5.8/16.5/24.9±0.2 and −12.1±2.2/15.4/26.4±1.5, respectively. The plotlines are nonlinear regressions based on the square root-growth model (48), using the Macintosh program UltraFit (v 3.0). The data shown was adapted from references (49) and (50).

From the TGI enzyme data, the natural logarithm of the rate is plotted versus the reciprocal of the absolute temperature (°K). A linear fit should be obtained for temperatures in the suboptimum range, the slope of which is equal to the activation energy (E_a) for the enzyme reaction. This model is only intended to describe enzyme function in the suboptimum temperature range.

It has been hypothesized that bacterial growth response to temperature is dictated by a rate-limiting enzyme-catalyzed "master reaction" and thus protein synthesis and ribosomal integrity govern the limits of growth. Models developed to test this are based on the changes of protein conformation with relation to temperature. A more exacting mechanistic model for determining the effects of temperature on enzyme catalysis rates, throughout the entire kinetic range, has been synthesized by combining the Arrhenius-based models of Brandts (53), Murphy and coworkers (52,54):

$$\text{rate} = \frac{CT\exp(\Delta H^{\ddagger}/RT)}{1+\exp(-n(\Delta H^{*}-T\Delta S^{*})+\Delta C_{\text{p}}[(T-T^{*}_{\text{H}})-T\ln(T/T^{*}_{\text{S}})])/RT} \quad (4),$$

C = an experimentally derived value, encompassing enzyme concentration; substrate concentration; a proportionality constant to account for measurement units, and the factor kT/h where k = the Boltzman constant and h = the Planck constant.

$\Delta H^{\ddagger}$ = activation enthalpy of the reaction catalyzed by the enzyme.

ΔC_{p} = difference in heat capacity (mol^{-1} amino acid residue) between the native and denatured-state of the enzyme.

T^{*}_{H} = temperature (K) at which the ΔC_{p} contribution to enthalpy is 0.

T^{*}_{S} = temperature (K) at which the ΔC_{p} contribution to entropy is 0.

ΔH^{*} = value of enthalpy at mol^{-1} amino acid residue of the enzyme.

ΔS^{*} = value of entropy at mol^{-1} amino acid residue of the enzyme.

n = number of amino acid residues in the enzyme.

For this model, the values C, the number of amino acids, the heat capacity change (ΔC_{p}) involved in denaturing the enzyme, and the activation energy ($\Delta H^{\ddagger}$) need to be estimated from the available data. Values for T^{*}_{H}, T^{*}_{S}, ΔH^{*} and ΔS^{*} have been previously reported to be constant for all globular proteins (54). An example of the application of this method is shown in Figure 2.

Analysis of Fatty Acids Associated with Psychrophiles

The ability to maintain cellular membranes in a homeoviscous state is an important adaptation of psychrophilic bacteria to cold (2). In this respect, psychrophilic bacteria often express high levels of anteiso- and iso-branched fatty acids and unsaturated fatty acids, depending on the taxonomic group (2,56). Several psychrophiles have the ability to form polyunsaturated fatty acids (PUFA), a trait unusual among bacteria (57). PUFAs produced by psychrophiles include eicosapentaenoic acid ($20:5\omega3$), docosahexaenoic acid ($22:6\omega3$) and arachidonic acid ($20:4\omega6$); fatty acids that are important "nutriceuticals" (58).

For the analysis of these fatty acids, a modified Bligh and Dyer procedure (59,60) is used to obtain an extract of whole-cell fatty acids and of neutral lipids (hydrocarbons, sterols, waxes etc.). Fatty acids are then transesterified to form methyl esters (fatty acid methyl esters, FAME) and analyzed by GC-MS techniques (61). GC-only systems that allow for rapid fatty acid analysis, such as the MIDI system, identify FAME components by retention times alone and are not able to definitively identify all fatty acids, including many monounsaturated fatty acids and unusual fatty acids

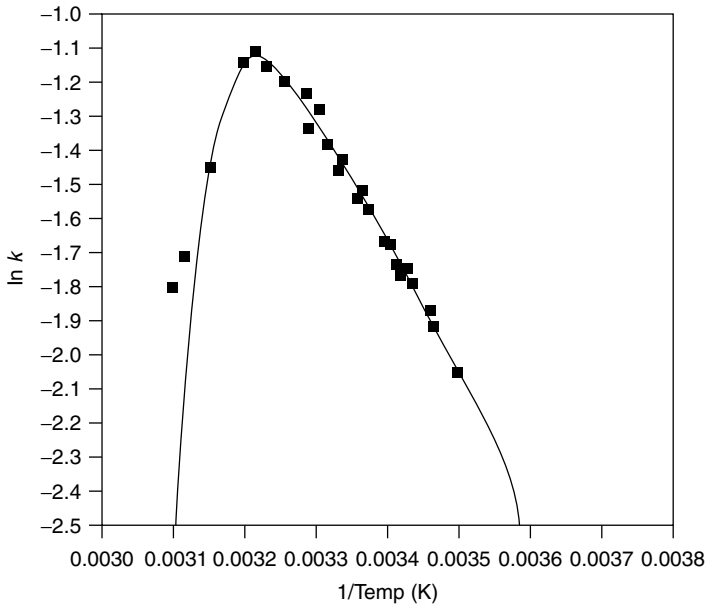

Figure 2. The effect of temperature on the catalytic rate of β-galactosidase from the psychrotolerant Antarctic bacterium *Flavobacterium hibernum*. The data (55) was fitted with an Arrhenius mechanistic model (52), which in this case assumes the constant C to be 85.1, the parameter $\Delta H^{\ddagger}$ (activation energy) was equivalent to 2.88×10^4 kJ, Cp (heat capacity) was equal to 67.2 kJ mol^{-1} amino acid residues and the number of amino acids (n) was equal to 167.

such as PUFAs. Thus, a high proportion of the fatty acid profile can be left unidentified or even misidentified. Using GC-MS based procedures, accurate and definitive identification of fatty acids can be achieved, including those with unusual or novel structures. Thus, if it is possible, GC-MS methods should be used when describing the fatty acids of psychrophiles. Identification of the position of double bonds in the monounsaturated fatty acid FAME is possible by dimethyldisulphide (DMDS) derivatization (62). In this method, DMDS in a chemical reaction catalyzed by iodine and attacks the fatty acid at the double bond, resulting in CH3S adducts that can be identified by GC-MS. For more complex PUFAs, such as those indicated in the preceding section, the number of mass fragments derived from DMDS derivatization makes mass spectra too complicated to be interpreted. Instead, PUFA FAME can be reacted with 2-amino-2-methylpropanol to create 2-alkenyl-4,4-dimethyloxazoline (DMOX) derivatives (63). DMOX derivatives have the advantages of having high volatility and allowing direct GC analysis, and their mass spectra are easily recognizable, allowing unambiguous determination of the positions of unsaturation.

CONCLUSION

Continued investigation of the biodiversity, ecology, physiology, and genetics of psychrophilic prokaryotes is clearly needed. There are opportunities to increase our understanding of adaptation of life to extreme environments and learning new concepts in how biological mechanisms have adapted to operate at the lowest temperatures. Further isolation of novel psychrophilic taxa, covering all types of microbial processes, will obviously aid in this learning process and provide opportunities in the biotechnological arena. The study of psychrophiles should continue to advance our knowledge for some time at both basic and applied research levels.

PULP AND PAPER INDUSTRY: MICROBIOLOGICAL ASPECTS OF

Todd Burnes
University of Minnesota
St. Paul, Minnesota

Pulp is a fibrous material produced either by mechanical or chemical means, or a combination of the two, that separate the cells of woody plants into lignin, cellulose, and hemicellulose. This pulp is then used to form a homogenous sheet of interwoven cellulose fibers that can be made into a variety of paper products. Pulp and paper products are an important part of economies and the lives of individuals throughout the world, and natural resources, including trees and water, are consumed in the production process. Paper provides a means of transferring and documenting information through newspapers, journals, books, and for writing and computers. It is estimated that 155 million tons of wood pulp are produced each year and this number is expected to increase by 67% by 2010 (1). Also, nonwoody plants are an important source of fiber for the production of pulp and paper in many countries where wood fiber is limited (2,3). Microorganisms are involved in many aspects of the pulp and paper making processes and can have a profound effect on the quality of the final product and the effects on the environment. Several negative aspects of microorganisms are the degradation and discoloration of wood fibers that reduce pulp yields, brightness and paper quality, and the formation of biofilms during the pulp and paper making process that can reduce the quality of the final products by causing deposits on the paper. Several positive aspects of microorganisms are the use of lignin-degrading fungi to produce pulp and paper, the use of microorganisms and enzymes to bleach pulp, and the use of fungi and bacteria to reduce pitch problems and associated toxic levels of resin acids in mill effluents.

WOOD DEGRADATION AND BIOLOGICAL PULPING AND BLEACHING

Fungal Wood Degradation

Wood fibers are made of lignin, cellulose, and hemicellulose. The percentage of each component varies between tree species (4). Cellulose is composed of repeating glucose anhydride units, whereas hemicellulose is a polymer of five sugars, including glucose, mannose, galactose, xylose, and arabinose. Lignin is a complex phenolic polymer that can be found between wood fibers in the middle lamella and is incorporated with cellulose and hemicellulose within the cell walls of the fibers (4). Lignin imparts the rigidity and stiffness to the wood and is a difficult polymer to break down by most microorganisms except fungi.

White and brown rot fungi are found in the Basidiomycete family and are most commonly associated with substantial loss of wood fiber in trees and wood stored as chips or whole logs. Decayed wood fibers used in the pulp and paper process can cause reduced pulp yields, reduced paper strength, and discoloration of the pulp. Fungi are composed of filamentous cells called *hyphae* that make up the mass of mycelium. Fungi utilize the available sugars and nutrients in wood, and the hyphae penetrate and degrade cell walls and pit membranes by excreting different enzymes that can break down a variety of cell wall components in wood cells. Some species of white rot fungi simultaneously degrade lignin, cellulose, and hemicellulose. Some white rot fungi can selectively degrade substantially more lignin and hemicellulose than cellulose. Some examples of important white rot decay fungi are *Heterobasidion annosum*, *Inonotus circinatus*,

Inonotus tomentosus, and *Phellinus weirii*, in conifers and *Ganoderma* sp. *Tremetes versicolor*, *Phellinus termulae*, and *Fomes fomentarius* in hardwoods (5). It has been estimated that decay in coniferous trees from *P. weirii* causes 4 million cubic meters of lost wood each year (5). Brown rot fungi degrade the carbohydrate component of the cell walls and leave the lignin. Some examples of important brown rot decay fungi are *Phaeolus schweinitzii* in conifers, *Fomitopsis pinicola* and *Laetiporus sulphureus* found in both conifers and hardwoods, and *Piptoporus betulinus* in hardwoods (5). Other microbial pathogens can cause substantial loss or reduced growth of trees that can have an effect on the availability and quality of wood fiber used for the pulp and paper industry.

Biological Pulping

In the pulp and paper making process, cellulose is the most important component that must be separated from lignin by chemical, mechanical, or both chemical and mechanical methods. Recent studies have looked at pretreating wood chips with lignin-degrading fungi prior to pulping to reduce the amount of chemicals and energy needed during the pulping process (6–9). Several white rot fungi have been screened and found to substantially remove more lignin than cellulose (6,7) (Table 1).

From laboratory studies of these and other fungi *Ceriporiopsis subvermispora* was selected for further study because it grew equally well on aspen and loblolly pine chips, substantially reduced the amount of energy needed during the mechanical pulping process, increased the strength of the paper, and enhanced brightness of the pulp (6). A large-scale study was done at the Forest Products laboratory in Madison, Wisconsin, with 40 tons of spruce chips inoculated with *C. subvermispora* and incubated for two weeks. Chips were mechanically pulped and it was determined that a 30% savings in energy was achieved versus nontreated chips under the same conditions. The strength and brightness properties of the pulp were also significantly enhanced compared to nontreated chips (10). Pretreatment of wood chips with *C. subvermispora* before chemical pulping was also found to reduce residual lignin contents by 30% over control chips. However, the brightness of the pulp from this treatment was lower because of the production of chromophores by the fungus (11).

Pulp from nonwoody plant materials constitute 10.6% of the fiber used to make paper products in many developing countries and could be a source of fiber to help supply the growing demand for pulp and paper (3). Jute is a nonwoody plant grown in Bangladesh, India, China, and Thailand. Mechanically pulped jute fibers pretreated with *C. subvermispora* and incubated for two weeks had a 33% reduction in the amount of energy needed for pulping versus control fibers not treated and incubated under the same conditions (2). Also, the strength of the paper was increased by 33% compared to control jute fibers not treated with *C. subvermispora* (2). Other nonwoody fiber material are available throughout the world that could benefit from pretreatment with microorganisms to produce pulp and paper with less energy and enhanced paper quality.

Substantial amount of research has been done on the mechanisms and selection of lignin-degrading fungi, and the engineering process needed to produce pulp and paper using fungi to pretreat wood or pulp. The production of pulp and paper using fungi is a promising environmentally friendly approach that could reduce dependency on chemicals and also maintain the quality of paper products needed for today's market. Some problems still remain, as it is difficult and expensive to provide a hospitable environment for the targeted fungi to grow because the temperature, moisture, and competition from other microorganisms need to be regulated. Also, the cost of producing the inoculum and engineering and converting the individual mills for a biological pulping process may be costly as each mill is unique in that they use different processes, wood species, and are located in different climates.

Biological Bleaching

After the wood has been pulped, its color is too dark to be used for printing grade and tissue paper because of the high residual lignin content. Further treatments are needed to bleach the pulp, which may include the use of chlorine dioxide or chlorine-free bleaching using oxygen, ozone, hydrogen peroxide, and peracids (12). Delignifing white rot fungi such as *T. versicolor*, *Phanerochaete chrysosporium* and *P. sordida* have been used as a pretreatment to reduce the amount of residual lignin in the pulp. Pulp treated with *T. versicolor* showed increased brightness, with substantial decrease in the residual lignin of the pulp, and reduction of the amount of chlorine needed for bleaching (12). Several important enzymes, including laccases, manganese peroxidases, and lignin peroxidases, derived from fungi are responsible for the degradation of the lignin and the biological bleaching

Table 1. Results of Lignin and Wood Sugar Analyses of White Pine Decayed for 12 Weeks by Several White Rot Fungi[a]

	Loss (%)				
Fungi	Biomass	Lignin	Glucan	Xylan	Mannan
Ceriporiopsis subvermispora	25	50	3	48	13
Phanerochaete chrysosporium	20	31	4	44	0
Phlebia brevispora	27	49	11	60	16
Phellinus pini	27	45	8	55	40

[a] Composition of sound *Pinus strobus* = 33% lignin, 41% glucose, 8% xylose, and 11 % mannose. Data based on information from reference 6.

effect. Attempts have been made to use these individual lignin-degrading enzymes extracted from fungi in pulp for biological bleaching with limited success.

Xylanase enzymes from bacteria and fungi have been successively used to treat pulp before bleaching in both laboratory and mill trials (13). It was demonstrated that xylanase-treated hardwood and softwood pulps had higher pulp yields, increased brightness, and reduced amounts of bleaching chemicals needed by 20% in hardwoods and 15% in softwoods (13). The mechanism of how xylanase works to improve the properties of pulp is still not fully understood.

Microbial Degradation of Pitch and Staining of Wood

Pitch is a term used to describe resin and fatty acids, sterols, steryl esters, waxes, terpenes, and glycerol esters found in woody plants that are not part of the cell structure and are soluble in neutral, nonpolar organic solvents (14,15). These pitch components can be problematic in the pulp and paper manufacturing process by causing deposits on machines and paper, resulting in reduced paper quality and increase costs to mills (15,16). It has been estimated that a 1,000-ton pulp per day mill could lose more than two million dollars per year to problems associated with pitch (17). High resin acid concentration in effluents produced by the pulp and paper making process has been demonstrated to be toxic to fish and other aquatic organisms (18). The amount and types of resins and fatty acids differ greatly between hardwoods and softwoods and within these two groups (15). Pitch in softwoods is located in resin canals and parenchyma cells, whereas in hardwoods it is located in ray parenchyma cells (14). Current methods employed to reduce pitch include the use of additives such as talc, dispersants, enzymes added to pulp, and seasoning of logs and chips before pulping (16).

Seasoning of wood has long been used as a method by paper mills to reduce pitch and the problems associated with deposits on paper (14). The degradation of resin and fatty acids in seasoned wood is the result of oxidation, volatilization, enzymatic hydrolysis, and activities of microorganisms. A detrimental effect of long-term wood storage is the increased loss of fiber caused by fungi that decay the wood and reduce fiber yield and the proliferation of staining fungi in the Ascomycete family such as *Ophiostoma* and *Ceratocystis* species. These staining fungi are pioneering microorganisms that can quickly colonize and discolor wood, resulting in increased use of bleaching chemicals being added to the pulping process. Hyphae from stain fungi invade the surface of the wood and penetrate the ray parenchyma cells and resin canals of pine species and vessel elements and longitudinal and ray parenchyma cells in hardwoods (Fig. 1) (19).

Stain fungi also have the beneficial effect of degrading substantial amounts of resin and fatty acids with little or no destruction of wood fibers (19). The stain fungus *Ophiostoma piliferum* was selected for further study because of its fast growth and its ability to degrade pitch in southern yellow pine (19). Since *O. piliferum* stains wood, an albino strain was developed by an ascospore mating of different isolates of *O. piliferum*. This albino strain, called Cartapip™ was developed by Sandoz Chemical Corporation of Charlotte, North Carolina (now Agrasol, Inc., Raleigh, North Carolina), and demonstrated rapid surface and internal growth of mycelium, and substantial degradation of pitch. It also controlled the growth of wild-type stain fungi naturally found growing in the wood (19,20). This can greatly reduce the time that chips need to be stored with the same or better results as long-term storage with minimal loss of wood fiber, reduced wood staining, and a decrease in the use of chemicals during the pulping process. When logs are cut for use in pulp and paper production, they are sometimes stored for varying lengths of time. Cartapip™ has been used in the field to inoculate freshly cut pine logs. It has been demonstrated to control the growth of wild-type blue staining fungi (21). In mill trials, loblolly pine chips treated with Cartapip™

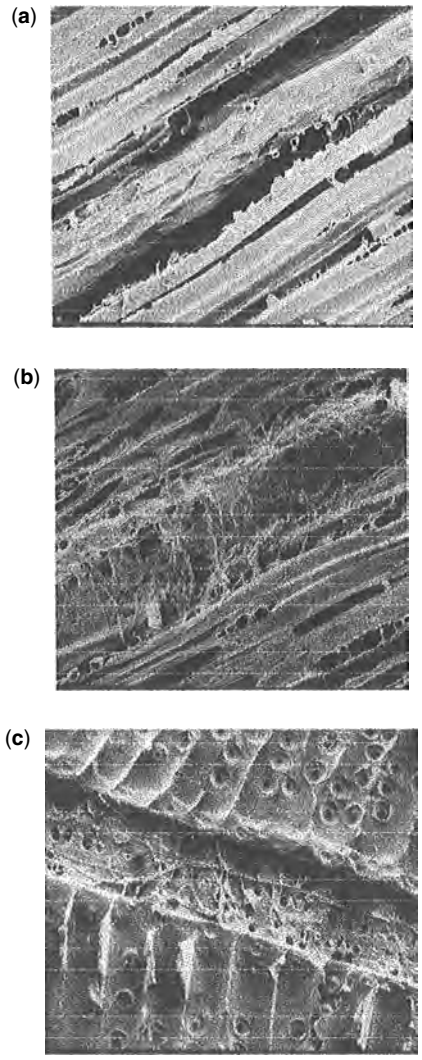

Figure 1. Scanning electron microscope of mycelium from the albino strain of *Ophiostoma piliferum* (Cartapip™) pretreated loblolly pine chips two weeks after inoculation. (**a**) Resin canal of loblolly pine before pretreatment. (**b**) Resin canal two weeks after pretreatment showing mycelium and removal of pitch. (**c**) Ray parenchyma cell two weeks after pretreatment showing mycelium.

degraded 45% of the pitch over a 12-day period versus chips at the beginning of the trial. Individual resin and fatty acids were also reduced (19,20). Cartapip™ can also grow and degrade pitch in hemlock, fir, jack, radiata and southern yellow pines, birch, cottonwood, aspen, and maple (22) (Table 2).

Loblolly pine chips pretreated with the albino strain of *O. piliferum* (Cartapip™) in the mill increased the production of paper by 17%, improved paper strength and quality, and reduced the amount of sodium hydrosulfide by 28% during the bleaching process, as compared with chips that were not pretreated (22).

Other fungi have also been found to degrade pitch in pine, including *Ophiostoma piceae*, *O. ainoae*, and *Lecythophora* species (23). A variety of microorganisms can easily degrade fatty acids and triglycerides in pitch, but the degradation of steryl esters and waxes mostly found in hardwoods is more difficult for fungi to degrade (24). Several fungi were screened and found to degrade these steryl esters and waxes extracted from aspen, including Basidiomycetes (*Bjerkandera adusta*, *P. chrysosporium*, *T. versicolor*, *Peniophora polygonia*), Zygomycetes (*Cunninghamella elegans*), and imperfect fungi (*Aspergillus luchuensis*, *A. awamori*, *A. flavus*, *Aureobasidium pullulans*, and *Gliocladium roseum*) (25). Other important wood species used for pulp and paper are eucalyptus in which fungi (*Phlebia radiata*, *Funalia trogii*, *Bjerkandera adjust*, and *Poria subvermispora*) have been shown to degrade 75 to 100% of the esterified sterols and other pitch components in *Eucalyptus globulus* (26).

Bacteria are ubiquitous and a variety of species were isolated from wood in which several demonstrated the ability to degrade pitch in pretreated southern yellow pine chips over a two-week incubation period (27) (Fig. 2a). The species *Pseudomonas fluorescens* NRRL B21432 degraded substantial amounts of individual resin and fatty acids found in the wood (27) (Table 3). In U.S. Pat. 5,766,926, Blanchette and coworkers demonstrated that pitch was also reduced in other woods, including aspen, spruce, maple, and mixed hardwoods pretreated with bacteria (28).

It was also demonstrated that the bacteria could degrade the pit membranes inside pretreated loblolly pine chips incubated for 14 days, which could facilitate the penetration of pulping chemicals and reduce cooking times (27) (Fig. 2b).

Lipase enzymes have also been used in the pulp and paper industry to reduce pitch and problems associated with wood resins. In Japan, laboratory and mill trials used a lipase enzyme produced from *Candida cylindracea* that was applied to ground Japanese Red pine pulp. This enzyme hydrolyzed 70% of the triglycerides (29). Triglycerides are a major component of pitch and their reduction could decrease the use of chemicals to control the pitch content in pulp and increase the quality of the paper (29). In a study by Fisher and Messner (1992), unbleached softwoods treated with a lipase called Resinase A (provided by NOVO Enzyme Process Division Bagsvaerd, Denmark) for two hours demonstrated a 80% reduction in triglycerides. Lipase, however, does not affect the fatty acid component, which can also cause pitch problems. Further treatment with sodium hydroxide solution was needed to remove the remaining fatty acids (30).

Table 2. Reduction of Pitch in a Variety of Woods[a] Pretreated with the Albino Strain of the Staining Fungus *Ophiostoma piliferum* (Cartapip™) for Two Weeks. The Percent Reduction is in Comparison with Control Wood Chips Incubated in the Same Conditions as the Wood Inoculated with Cartapip™

Wood Species	% Reduction
Hemlock-Fir mix	6.5
Jack Pine	22.2
Radiata Pine	21.5
Southern Yellow Pine	18.1
Aspen	10.0
Birch	10.7
Cottonwood	14.4
Maple	22.5

[c]Represents the amount of pitch at the beginning of the experiment.
Data based on information from reference 27.

Another important role of biological treatment of wood or pulp with pitch degrading microorganisms and enzymes is the reduction of toxic levels of resin acids released into the environment from pulp and paper mills, which can account for up to 70% of the effluent toxicity and a major source of fish toxicity (18). Current methods to treat effluents that are derived from pulp and paper manufacturing is to remove the solids by sedimentation and clarification, followed by secondary or biological treatments using aerobic or anaerobic conditions (31–33). The aerobic biological treatment of pulp and paper effluents is the most widely used method to remove dissolved organic molecules by indigenous microorganisms. These include oxidation basins, stabilization ponds, lagoons, sludge areas, or batch reactors (31). The mixed microflora of these aerobic treatments include bacteria, fungi, protozoa, rotifers, yeast and viruses, which are responsible for oxidation of organic molecules (32). Bacteria, including several *Pseudomonas* species, such as *Pseudomonas abietaniphila* BKME-9, and *Zoogloea resinophila* Dha-35 were isolated from pulp and paper biological treatment processes and have demonstrated the ability to degrade different resin acids (34,35). A polymerase chain reaction assay has been developed to screen for resin acid–degrading bacteria. The use of these bacteria could greatly reduce toxic levels of resin acids in the effluent systems and their release into the environment (35).

The treatment of wood and/or pulp with fungi, bacteria or enzymes could be a more environmentally safe way to treat wood and pulp to remove harmful pitch in the pulp and paper making process; however, it has its limitations. Microorganisms must be selected for the best growth on the particular wood species used in mills, environmental conditions need to be modified to enhance the growth of the microorganisms and enzymes in the wood or pulp, and the cost to the mills to implement and set up a process for the use of biological treatments may not be economically viable.

Associated Problems with Biofilms

During the pulp and paper making process, biofilms or slime can build up in machines in the mill and cause deposits on the final product and economic loss to the mill (36). Slime is the accumulation of microorganisms, their by-products, and organic and inorganic materials that can take on strange shapes and sizes (36). Water is the main source of microorganism contamination, along with the raw materials and preexisting biofilms. Bacteria, fungi, and yeast are the predominant microorganisms present in these biofilms and biocides are the main control mechanism (36). The type of biocide that is selected for use in controlling biofilms is also important and may affect the quality of the paper products (37,38) (see BIOFOULING OF INDUSTRIAL SYSTEMS).

CONCLUSION

The production of pulp and paper will continue to play a vital role in the economies of many countries and in the advancement of our society. Microorganisms are involved in many aspects of this process. Research in microbiology will continue to provide information on understanding the role microorganisms have in fiber and pitch degradation, staining of wood, biofilm production, bioremediation of effluents from mills, and other aspects relating to pulp and paper production. Understanding these processes will help us select microorganisms that will improve pulp and paper production and reduce the impact it may have on our environment.

QUANTIFICATION OF MICROBIAL BIOMASS

SUSAN D. SUTTON
Miami University
Oxford, Ohio

Recent estimates of global microbial biomass indicate that prokaryotic cellular carbon ranges from 330 to 550 Pg (1 Pg = 10^{15} g). This is more than half the estimated carbon found in plants. Bacteria are also rich in nitrogen and phosphorous and prokaryotic biomass may represent the largest living reservoir of these essential elements (1). One of the greatest challenges of microbial ecology has been the development of quantitative and nonselective methods for the study of microorganisms in their natural environments. Microbial biomass is one of many parameters that help examine the roles microorganisms play within natural systems. On a global scale, the quantification of living microbial biomass is important in understanding biogeochemical cycling, global carbon budgets, ecosystem energy flow, food-web dynamics, and carbon turnover and sequestration. On smaller spatial and temporal scales, it can be used to detect disturbance and perturbation in both natural and engineered systems. Biomass is defined as the mass of living biological material in a defined area. In most environments, it cannot be measured directly because of the difficulty in distinguishing viable carbon biomass from other organic components in the sample matrix. Historically, researchers have used abundance measurements or activity-based assays to estimate microbial biomass (Fig. 1). In this review, the advantages and disadvantages of some of these procedures are discussed and specific methods for the determination of viable biomass using cell

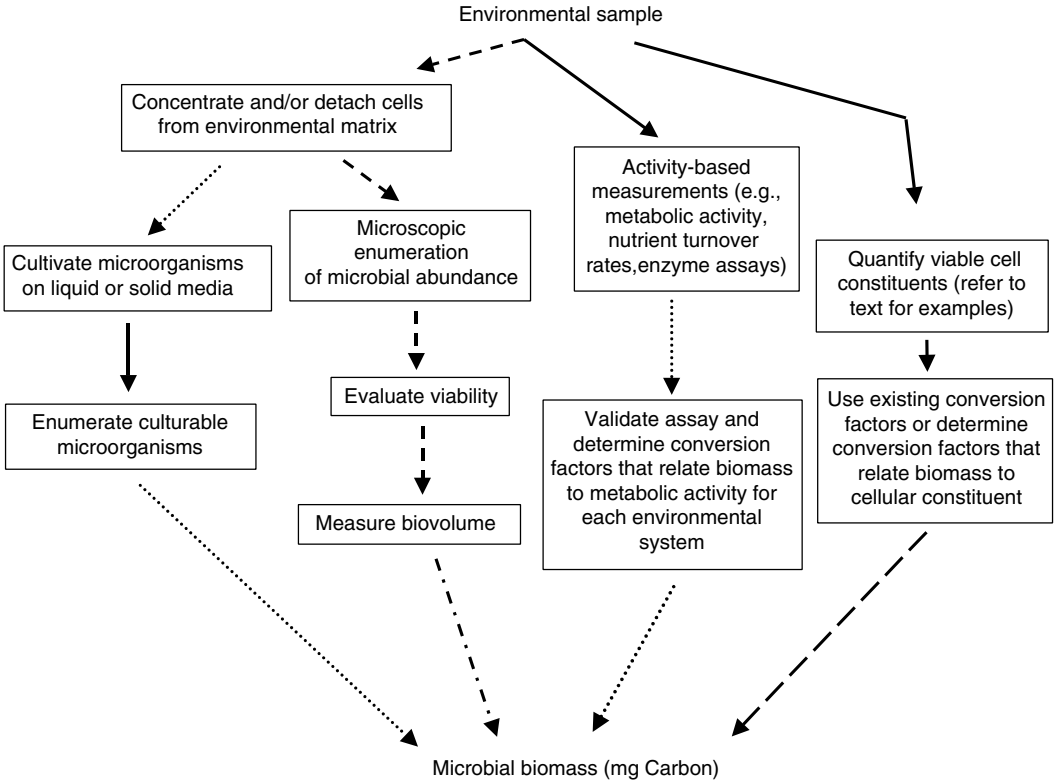

Figure 1. Experimental approaches commonly used for estimating microbial biomass. Dashed arrows indicate steps in the procedures in which current methods may introduce bias or uncertainty to the final biomass estimate. The extent of bias or uncertainty is indicated by the size of the dash where finely dashed lines indicate that current methods for measurement or calculation of these parameters may be indeterminate.

constituents as biological index molecules are elaborated (Fig. 1). Assays specifically designed for the quantification of microeukaryote or archaeal biomass are discussed separately.

CLASSICAL METHODS OF BIOMASS ESTIMATION

Culture-based methods such as the direct viable count or the most probable number procedure have proven to be inadequate for estimating total viable microbial biomass. These techniques are often selective and only permit the growth of organisms that are able to flourish under certain defined laboratory conditions. Typically, these techniques detect only 0.1 to 10% of the microbial community when compared to direct measurements of abundance (2–6).

The quantification of microbial abundance is another approach commonly used for the indirect calculation of microbial biomass. Epifluorescence microscopy coupled with the use of nucleic acid stains such as acridine orange and 4′,6-diamidino-2-phenylindol (DAPI) is commonly used for the enumeration of total number of bacteria in aquatic samples. Scanning electron microscopy and transmission electron microscopy provide higher resolution and have also been used for enumeration and sizing of microbial populations (7). Phytoplankton biomass has been estimated in a similar manner using fluorochrome-induced fluorescence and autofluorescence of plant pigments (8). The use of cell sorting techniques and high-resolution flow cytometry is an improvement on traditional methods of bacterial enumeration and can help monitor the dynamics of specific microbial populations (9,10) when combined with specific fluorescent probes (either antibodies or oligonucleotides).
