In most cases the size of the partners is unequal, and the terms host and symbiont are used for the larger and the smaller, respectively. The smaller size of the symbiont implies that it may be positioned in different ways with regard to the body host; some multicellular hosts have also developed specialized organs or cells to contain the symbiont. The terms *ectosymbiont* or *ectobiont* are used if the symbiont is external to the body of the host, and the terms *endosymbiont* or *endobiont* if it is located within the body of the host (Fig. 1). Furthermore, the endosymbiont may reside outside or within the cells of the host; it is then termed *extracellular endosymbiont* or *extracytobiont* and *intracellular endosymbiont* or *intracytobiont*. The intracytobiont may be free in the cytoplasm of the host cell or reside within a host cell-derived vacuole, called a *symbiosome*. The terms *parasitophorous vacuole* or *inclusion* are adopted when the intracytobiont is a parasite. The symbiotic association may be facultative or obligate for one or both the partners, if they may survive or not when the association is disrupted. However, such a distinction may be highly influenced by the laboratory techniques. For example, the term *obligate intracytobiont* is often applied to those microorganisms that could not be cultivated on available artificial media. As such situation may change with the development of more appropriate techniques, the distinction between *culturable* and *unculturable* organisms should be preferred. Finally it is experimentally possible to eliminate the symbiont by a treatment with antibiotics or by exposure to elevated temperatures. The symbiont-cured host is called *aposymbiotic*. This manipulation allows studying the effects of the symbiont on the host's phenotype.

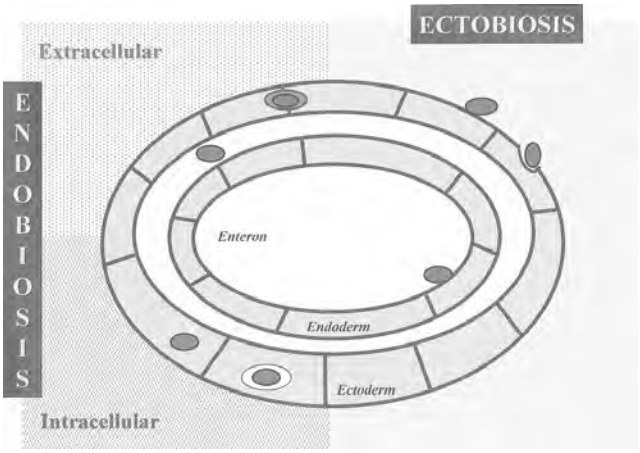

Figure 1. Terminology. Schematic drawing of a cross-section of a multicellular host to illustrate the relative position of symbionts. Ectosymbionts (at right) are positioned on the external surfaces of the host body, on the ectoderm, or on the intestinal cavity. Endosymbionts (at left) may be extracellular, or in other words, located between cells of tissues or within the host body fluids (e.g., the blood), or the endosymbionts may be harbored within the host cells, free into the cytoplasm, or enclosed in a membrane (symbiosome). See color insert.

SYMBIOTROPHIC SYSTEMS

Almost all the symbiotic associations are based on a form of *syntrophy*, that is, a nutritional situation in which two or more organisms combine their metabolic capabilities to metabolize a compound otherwise impossible to be metabolized by one alone. These are called *symbiotrophic systems*. Insects with restricted diets (i.e., plant sap- or blood-sucking insects), harbor symbiotic bacteria that provide the host with some essential nutrients, such as amino acids and/or vitamins. A very widespread symbiotrophic system is the one involving autotrophic endosymbionts, either photosynthetic (symbio-photoautotrophy) or chemoautotrophic. Finally of importance are the nitrogen-fixing bacterial symbionts of the plants.

Primary and Secondary Symbionts of Insects

Extra- and intracellular endosymbionts are commonly found in a large majority of insects, particularly in those living on nutritionally restricted diets, such as plant sap, blood, or wood. Most of these associations are obligate, the symbiont providing some essential nutrients to the host, through the synthesis of amino acids or vitamins or through the degradation of diet materials (1). The symbionts are rarely cultivated in laboratory media, and the aposymbiotic insects show several alterations, such as sterility or high mortality rates (5). These associations have been known for a long time on the basis of morphological studies (6). Recently, the development of molecular biological techniques has allowed the phylogenetic identification of most of these symbionts and the reconstruction of the evolutionary history of the symbiosis. We can distinguish two main types of insect endosymbionts: the gut symbionts, prevalently anaerobic and extracellular, and the mycetocyte symbionts, aerobic and intracellular. Additional examples of insect symbioses are those of the ants, in which both extra- and intracellular bacterial symbionts are reported, as well as complex tripartite associations involving ants and bacterial symbionts essential for the cultivation of fungal gardens (7).

The Gut Symbiosis. The gut endosymbionts are almost always extracellular, residing into the anoxic region of the insect hindgut. Such a microbiota is very heterogeneous, including both prokaryotes and protists, most being found only in this habitat. Such a microbiota is responsible for the degradation of cellulosic materials in some wood-heating insects like the lower termites (Isoptera) (the protist biota is lacking in the higher termites), but also carries out other specific anaerobic metabolic processes, such as N_2 fixation (see following section on "Nitrogen Fixation") and methanogenesis. The latter is performed exclusively by some archaebacteria, free-living in the gut or epi/endosymbiont of intestinal protists.

The Mycetocyte Symbiosis. The mycetocyte or bacteriocyte is a specialized cell harboring endosymbionts within a symbiosome; the endosymbionts are generally prokaryotes, called *Primary* (P) symbionts, and are maternally inherited. Bacteriocytes are often organized into a multicellular complex, called the *bacteriome*, generally located in the abdomen of the insect. For each P-symbiont/insect host system examined so far, the P-symbionts form independent monophyletic lineages whose phylogenies are congruent with those of the respective insect host taxon. These associations seem to be very ancient, arising once in the ancestor of the insect and evolving by cospeciation via vertical transmission of the symbiont to the successive host generations (Table 1).

The bacteriocyte symbiosis within the suborder Sternorrhyncha of the order Homoptera has been the more studied of these associations. This suborder comprises a very large group of plant sap feeding insects, partitioned into four superfamilies: Aphidoidea (aphids), Coccoidea (pseudococcids, mealybugs), Aleyrodoidea (whiteflies), and Psylloidea (psyllids). Estimates based on molecular clocks and fossils indicate a very old origin for the association between aphids and their P-symbiont *Buchnera*, a γ-proteobacterium, back to 150 to 250 million years ago (mya) (8). *Buchnera* is absent in the phylloxerids (9), and has been secondarily replaced by extracellular yeasts in a monophyletic subgroup of the family Hormaphidinae (Fig. 2; 10). The origin of the symbiosis between whiteflies and psyllids and their specific P-symbionts is estimated to about 240 mya. The P-symbiont of psyllids, for which the genus name of *Carsonella* has been proposed (11), is relatively close to the P-symbiont of whiteflies, suggesting that the two symbionts may have derived from a unique γ-proteobacterium infecting the common ancestor of the two insect lineages, about 280 mya (12). Coccoidea harbor both γ- and β-proteobacterial symbionts, phylogenetically distinct from the P-symbionts of the other superfamilies (Fig. 2).

Table 1. Examples of Cospeciation Between Insect Host Taxa and Their P-Symbionts

Insect Taxon	P-Symbiont	Bacterial Lineage[a]
Homoptera Sternorrhyncha		
Aphidoidea[b]	*Buchnera*	γ-Proteobacteria
Coccoidea[c]	P sym	β-Proteobacteria
Aleyrodoidea	P sym	γ-Proteobacteria
Psylloidea	*Carsonella*	γ-Proteobacteria
Diptera		
Glossina sp.	*Wigglesworthia*	γ-Proteobacteria
Hymenoptera		
Carpenter ants	*Blochmannia*	γ-Proteobacteria
Blattoidea		
Cockroaches	*Blattabacterium*	Flavobacteria

[a] Each γ-proteobacterial P-symbiont forms distinct lineages. However the symbionts of Aleyrodoidea and Psylloidea may have derived from an ancestral P-symbiont infecting their common ancestor.
[b] *Buchnera* is absent in the family Phylloxeridae, whereas in a monophyletic group of cerathaphidins (subfamily Hormaphidinae) it was replaced by extracellular yeasts.
[c] Both β- and γ-proteobacterial symbionts have been reported for Coccoidea.

In many insect lineages, other vertically transmitted intracellular symbionts are present, collectively called *Secondary* (S) symbionts. Whereas P-symbionts are hosted in bacteriocytes, the S-symbionts infect several organs and the hemolymph, and some may also be hosted in the bacteriome within the syncytial sheath cells and/or within a different type of bacteriocyte, called an *S-bacteriocyte*. In aphids and psyllids P- and S-symbionts are located in different cells of the bacteriome (13,14), whereas in whiteflies and pseudococcids the same bacteriocyte may harbor two different lineages of symbionts (15,16). Molecular phylogenetic analyses have demonstrated the polyphyletic origins of the S-symbionts and the complexity of the symbiotic systems, as several S-symbionts may be present in the same individual. Different species of a same insect taxon may harbor separate S-symbionts (15). Furthermore, closely related S-symbionts may be hosted by distantly related insect taxa, suggesting the possibility of horizontal transmission. For example, closely related *Spiroplasma* strains (Mollicutes) are found in *Acyrthosiphon*

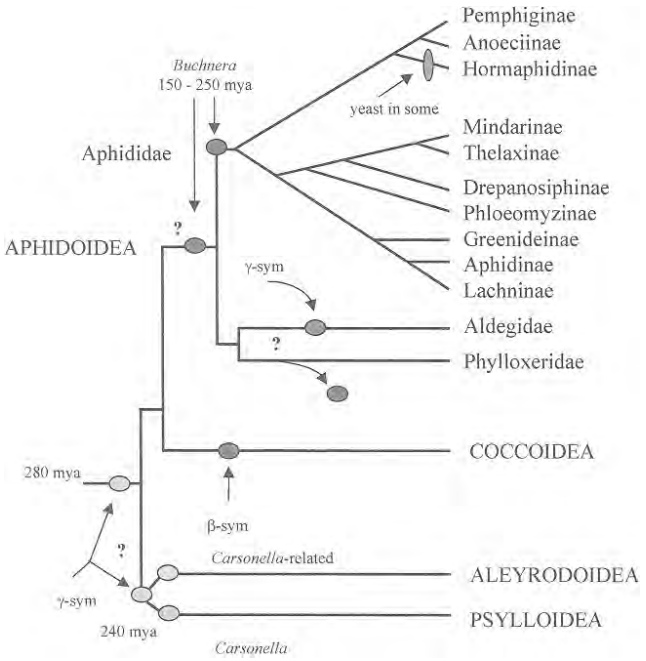

Figure 2. Phylogeny of Sternorrhyncha and origin of P-symbionts. Dendrogramm showing the evolutionary history of the four superfamilies (in capitals) of the suborder Sternorrhyncha (order Homoptera). For the superfamily Aphidoidea, the three families are indicated, and for the family Aphididae, the subfamilies are also indicated. Circles indicate the origin of the infection by the primary symbionts, with the estimated time in million of years ago (mya). Extracellular yeasts have replaced *Buchnera* in the tribe Cerataphidini within the subfamily Hormaphidinae. Members of the family Aldegidae possess a γ-symbiont, but it is not known whether it belongs to *Buchnera*, whereas the family Phylloxeridae is lacking of symbiont, perhaps lost. Coccoidea harbor both γ- and β-symbionts, but the β-symbionts seem to be the P-symbionts. They form a monophyletic clade in molecular phylogenies based on 16S rDNA analyses, whereas the γ-symbionts appear polyphyletic. Members of the superfamilies Aleyrodoidea and Psylloidea harbor closely related γ -symbionts, perhaps evolving from a unique γ -symbiont infecting a common ancestor. See color insert.

pisum (Aphididae), in *Antonina crawii* (Pseudococcidae), in ladybird beetles (Coleoptera, Coccinellidae), in a butterfly, and also in an *Ixodes* tick (15,17) (and references therein). The possibility of horizontal transmissions is suggested by the life history of both symbionts and hosts. Spiroplasmas are often maintained in nature in cycles involving the phloem of a plant and the body of a sap-sucking insect, and Coccinellidae are among the most important predators of aphids, and some species of coccinellids prey also upon coccids. Phloem sap may be a route of transmission of bacteria (18), as well as the animal blood, when the same plant or animal serves as a common source of food for different insect taxa.

More complex trophic relationships exist for parasitoid insects, which grow on an insect host. The parasitoid may be itself the host of a secondary parasitoid insect (called *hyperparasitoid*) (19). Then the parasitoid insects may be also considered as potential agents of horizontal transmissions of symbionts [(20), see following section on *Wolbachia*]. A detrimental effect caused by some S-symbionts has been reported for the insect host, but it is likely that a more complex interaction exists between the host, the S-symbiont and some environmental factors. The γ-proteobacterial genus *Arsenophonus* is a multitissue infecting S-symbiont found in both parasitoid wasps (order Hymenoptera) and triatomine bugs (order Heteroptera). Whereas *Arsenophonus triatominarum* seems to cause no effect in the triatomine host *Triatoma infestans* (21), *Arsenophonus nasoniae* has been identified as a male-killing agent in the parasitoid wasp *Nasonia vitripennis* (22). Even if the wasp is not a triatomine parasitoid, it is conceivable that an ancestor of the wasp or perhaps another parasitoid species, parasitizing the bug, has acted in the past as a vector for the horizontal transmission of the common ancestor of *Arsenophonus* sp. from one host to the other.

Symbio-Photoautotrophy

Cyanobacteria and eukaryotic algae are commonly found in symbiosis with a wide range of organisms, including several lineages of protists, invertebrate animals and plants. In the case of cyanobacteria hosted by photosynthetic organisms (plants and diatom algae), the role of the endosymbiotic cyanobacteria is almost exclusively devoted to nitrogen fixation (see following section). The symbiophototrophy seems to be very ancient, and was probably started several times since the emergence of the eukaryotes. It has been proposed that the plated forms characterizing the peculiar precambrian fauna of Ediacara may be the result of adaptations to harbor endosymbiotic algae (23). Several species of large foraminifera harbor many types of eukaryotic algae including chlorophytes, rhodophytes, dinoflagellates, chrysophytes, and diatoms, whereas planktonic ciliates are frequently found to host chlorophytes and cryptophytes. Sponges and cnidarians host cyanobacteria, *Chlorella*, and dinoflagellates; the endosymbiosis of the latter with stony corals (order Scleractinia, Anthozoa) plays a key role in the formation of tropical coral reefs, which represent a very species-rich marine habitat in mineral-poor seas. Generally, based on the type of photosynthetic pigments, the endosymbiotic algae are also called cyanellae for the blue-green cyanobacteria, chlorellae for the green algae (chlorophytes but also cyanobacterial prochlorophytes), and xanthellae for the chlorophyll *c*-containing algae (dinoflagellates and chromistan algae).

The symbiotic algae are generally intracellular, and restricted to delimited regions of the host body, for example, the gastrodermal layer of cnidaria (24), or the nondigestive zones of the regionalized cytoplasm of some protists, as the intermediary zone of the test of large discoid foraminifera (25). Some intracellular algae show intracellular displacements. For example, Foraminifera are testaceous protozoa characterized by the possession of an extra-test fine extension of the cytoplasm forming a system of anasthomized pseudopodia (*reticulopodium*), and an intra-test cytoplasm or *endoplasm*. The dinoflagellate symbionts of *Globigerinoides* are dispersed into the reticulopodium during the day to exploit a greater surface for photosynthesis, and then regrouped into the endoplasm

during the night. This type of displacement is governed by the host via cytoplasmic fluxes. In other foraminiferan-dinoflagellate symbioses, it is the alga that moves via conserved flagella into the cytoplasm of the host. A bathymetric stratification of some planktonic protist species may be also observed, in function of the different optimal values of wavelength and luminosity of the specific alga symbiont. For example, the foraminiferans *Globigerinoides ruber*, *Orbulina universalis*, and *Globigerinella siphoniphera*, which host different types of algae, live at different levels in the water column, at the surface, at a median, and at a deeper level, respectively (25).

Some cases of extracellular symbiosis exist: for example, the dinoflagellates, which are endocytobionts in several marine animals, but are hosted extracellularly in the mantle in branched ends of a tubular system originating at the stomach, of the giant clams tridacnids (26). The intracellular algae are generally located in a perialgal vacuole, a symbiosome, into the cytoplasm of the host cell. But in some associations, the alga has been observed free into the cytoplasm. In endosymbiosis, the algae show some simplification in comparison to the free-living relatives or even to the isolated organism. For example, zooxanthellae in corals and *Chlamydomonas* in foraminifera are nonflagellated in the host but become flagellated when isolated in culture. Pennate diatoms do not form frustules when harbored within foraminifera, and similarly the thecate four-flagellate green alga *Tetraselmis* lose these structures when establishing symbiosis (the intra- or extracellular localization is still disputed) with the acoel worm *Convoluta*.

In some cases some anatomical modifications of the multicellular host may have evolved. For example, some octocorals show a reduced digestive mesenteron and the loss of the nematocyts, and depend on their zooxanthellae for nutrition (e.g., some species of the family Xeniidae). However, an efficient carnivorous ability is present in other zooxanthella-harboring cnidarians, like sea anemones and stony corals; in these symbioses organic N and P and/or vitamins from the digested prey are probably utilized by the alga (24).

Several modes of transmission of the alga to the offspring host exist. Generally the algae multiply and then are distributed in each offspring host originating by asexual reproduction both in multicellular animals (e.g., fission or budding in sponges and cnidarians) and protists. When the sexual reproduction takes place, the algae may be externally associated with the eggs or may be placed within the cytoplasm of the egg prior to fertilization. For several species of cnidarians the larva must acquire the symbiont from the environment, so lineage recombinations of host and symbiont are allowed. Similarly, the algae are vertically inherited by the protist cells originating from asexual reproduction, whereas they are lost by the gametes and then the new generation originating from the sexual reproduction acquires the algae from the environment.

The basis of the endosymbiosis of algae is nutritional, the algal photosynthate being passed, in some associations up to 90%, to the host that often lives in oligotrophic waters. The release of the photosynthate seems to be controlled by a "host factor," because the alga isolated in culture does not release it. In some associations, it has been shown that the alga is also involved in recycling organic N and/or P released as wastes by the host. For some flatworm-chlorophyte associations, where the worm inhabits O_2-poor waters, there is evidence that the host utilizes the oxygen produced photosynthetically by the alga for its respiration. However, oxygen production often results in the accumulation of excess O_2 in host tissues. This leads to the production in the host tissues of elevated levels of enzymes protecting against oxygen radicals, like superoxide dismutase. Periodic digestion of the symbiont may be another source of nutrients for the host and/or a mechanism to control the symbiont population. The algal population may then be reintegrated either by the multiplication of the surviving symbionts or by acquiring new algae from the environment. In several cases in both animals and protists the plastids were digested more slowly in comparison to the rest of the alga. The host may then exploit the production of photosynthate for some days more, and then it will periodically ingest new algae to replace the no more functional plastids.

For several species, the endosymbiotic algae may be isolated in culture where they regain normal features, such as flagella or shells, and in some instances the alga does not seem to be essential to the survival of the host. However, a range of occasional-to-obligate symbiophotoautotrophies has been described. For example, the photoautotrophy in marine planktonic ciliates and foraminiferans may be based either on strictly endosymbiotic algae or on occasionally/periodically engulfed algae. In some cases only the algal plastids are retained to perform a temporary photosynthesis (25,27). Nudibranch molluscs prey upon several sessile animals (e.g., sponges, cnidarians, bryozoans), some of which harbor endosymbiotic algae. Some species of nudibranchs are able to retain zooxanthellae, either extracellularly in their gut or intracellularly in the digestive diverticula, and algae continue to multiply and to release photosynthate. Some species of nudibranchs have developed densely branched digestive diverticula to harbor intracellular zooxanthellae originating from the ingested prey. Similarly, another group of molluscs, the Saccoglossa, contains several species that live by sucking the cell contents of multicellular algae; some saccoglossans retain the plastids intracellularly in their branched digestive diverticula (1).

Another way by which the algal symbionts seem to play a key role in the life of their host, is that they contribute in some ways to the calcification of the host structures, favoring the deposition of calcium carbonate. Examples are the shell formation of foraminiferan hyaline testes (25) and the improvement of the skeletogenesis in reef-building species of corals, called *hermatypic corals*. The coral reefs are the most diverse aquatic ecosystems, and often they flourish in nutrient-poor shallow waters, where the primary production is assured by endosymbiotic zooxanthellae. Water temperature and light penetration are major limiting factors. Reef-building corals are dominated by zooxanthella-harboring stony corals (Scleractinia, Hexacorallia, Anthozoa), but important in the reef formation are also other hexacorals, octocorals, and hydrocorals (Anthomedusa, Hydrozoa).

Coral species lacking zooxanthellae can live in deep and cold waters, and generally they cannot produce reefs (*ahermatypic corals*), even if some species build significant constructions. In tropical reef corals, the rapid loss of zooxanthellae (*coral bleaching*) results often in a mass coral mortality. Coral bleaching events may be caused by several factors, the most evoked being the global warming and the increased ultraviolet radiation. Bacterial infections may also be a cause of bleaching, for example, *Vibrio shiloi* that infects intracellularly the Mediterranean Sea coral *Oculina patagonica* and produces a toxin that inhibits zooxanthella photosynthesis (28 and references therein). However, such events of bleaching may be an occasion for the coral to be repopulated by a different type of zooxanthella, perhaps more resistant. Zooxanthellae show a high diversity within corals (29), and a single coral colony may harbor several types of zooxanthellae and may also change the algal type composition in response to a bleaching event, for example, some species of the genus *Montastraea*, which dominate the Caribbean corals (30). Such multispecies dynamic communities of zooxanthellae hosted by a same coral colony may be an evolutionary adaptation to environmental stresses.

Endosymbiotic associations have also additional advantages. For example, in the *Paramecium-Chlorella* symbiosis the alga is protected against viral infections (31), and the ciliate seems to acquire a stronger resistance to microbial infections and to the attack by predatory protists (1). Several marine invertebrates (e.g., sponges, cnidarians, bryozoans, and tunicates) not only harbor endosymbiotic algae and cyanobacteria but also a high variety of heterotrophic bacteria playing a possible nutritional role [(32), for endosymbiotic bacteria of sponges]. These animals may be sources of a variety of peculiar bioactive metabolites. Such compounds may play a role in the defense of the host against predators and/or infectious microorganisms, and some of these molecules have showed to possess antitumoral, antiviral and/or immunosuppressive activities (33–35). In some cases it has been possible to ascribe the origin of some of these compounds to the endosymbionts. For example, zoocyanellae have been implicated in the chemical defense of sponges (36) and tunicates (35). Similarly, some marine invertebrates may prove toxic to a potential predator, including humans, because they may accumulate toxic algae, like dinoflagellates and diatoms (37).

Symbiotrophic Systems in Sulfur- and Methane-Rich Waters

Deep-sea hydrothermal vents on midocean ridges and other marine environments like sediments, some shallow waters, and also whale falls (38) are rich in reduced compounds like hydrogen sulfide and methane, of geothermal or biological origin, respectively. Such habitats present anoxic-to-oxygenated gradients, where a rich bacterial biota develops. Bacteria obtain energy through the oxidization of reduced sulfur and fix carbon dioxide through the Calvin-Benson pathway (thioautotrophy by sulfur-oxidizing bacteria), or by using methane as source of both energy and carbon (methanotrophs). These habitats also harbor a rich invertebrate fauna, based on symbiotrophy with such types of bacteria, hosted either as epibionts or as extra- or intracytobionts (Fig. 3). Animal groups involved in such symbiotrotrophy include Porifera, Bivalvia, Anellida, Pogonophora, Vestimentifera, Nematoda, and Crustacea. In addition, epibiont bacteria are present also on the colonial ciliate *Zoothamnium*, which lives on decaying plant material in mangrove forests (39).

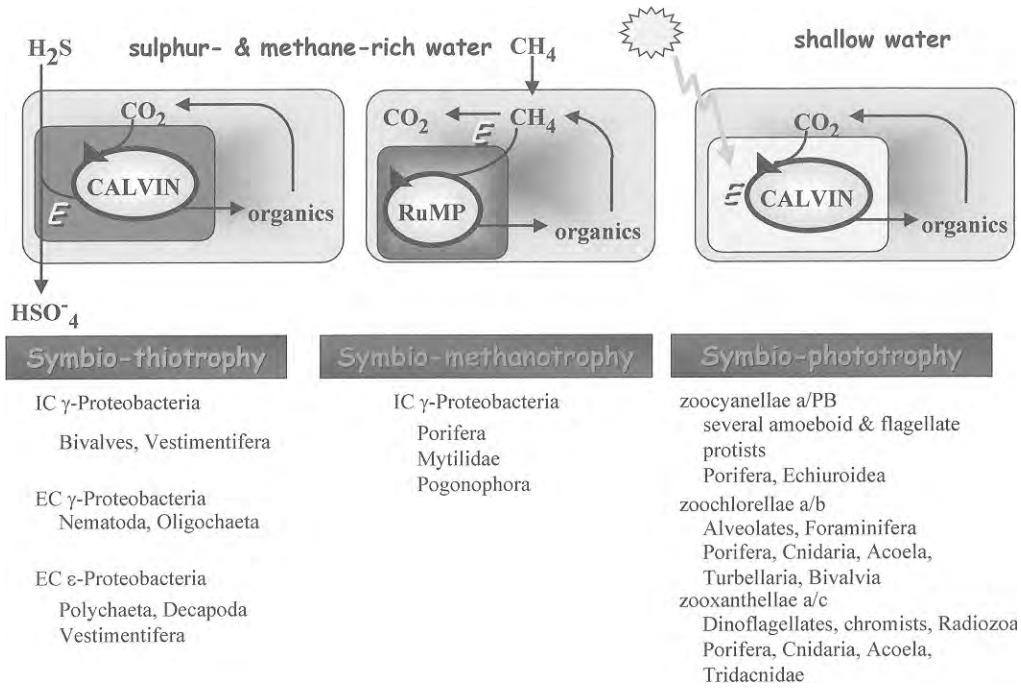

Figure 3. Symbiotrophic animals. See color insert.

Sulfur-oxidizing symbionts are mostly γ-Proteobacteria, harbored as epibionts and/or subcuticular extracytobionts by sediment-inhabiting nematodes (subfamily Stilbonematinae, e.g., *Laxus*) (40) and inter/subtidal calcareous coral reefs sands oligochaete annelids (e.g., *Inanidrilus*) (41). However epibiotic ε-Proteobacteria are also present, harbored by the hydrothermal vent-inhabiting polychaete *Alvinella* (42,43), and the shrimp *Rimicaris* (39). At least five bivalve families and the vestimentiferans (e.g., *Riftia*) harbor intracellular γ-proteobacterial thiotrophic symbionts, located within bacteriocytes in the gills or in the trophosome, respectively. Reduction or total disappearance of mouth and gut may be observed in some bivalve families and their fossils (44). The transmission of the symbiont from one generation to the next may occur via the egg if the ovary of the female is infected. The embryo becomes infected by the symbiont, and this type of transmission is called *transovarial*. A *horizontal* or *environmental* transmission of the symbiont occurs when the new generation of the host acquires the symbiont from an extracellular, free-living population of such a symbiont. Transovarial transmission has been reported for several species of bivalves, as well as an acquisition from the environment for other ones (42,45). Symbiont transmission in vestimentiferans occurs horizontally, the worm acquiring the symbiont from the environment at very earliest stages of its life when a transient digestive tract is present. Molecular analyses indicated that a significant strain-level variation between endosymbionts exists, depending on both the type of site (i.e., vent- or seep-dwelling) and on the geographic area (46).

The symbiothiotrophy seems to be very ancient. A rich fossil hydrothermal vent community has been reported from the Silurian (400 mya), including taxa, such as brachiopods and monoplacophorans, unreported in modern communities (47). In addition, the distinctive morphology of the trilobites of the family Olenidae, from the Late Cambrian to Early Ordovician (505 mya), coupled with a sulfur-rich lithology, has been interpreted as evidence for symbio-thioautotrophy (48).

Methanotrophs are a polyphyletic group of Proteobacteria able to utilize methane as the sole source of energy and carbon (49). The strains found as intracellular symbionts of invertebrates form a separate cluster closely related to the type Ia γ-Proteobacteria, within the family Methylococcaceae (50). The symbionts have been found in mytilid bivalves, a pogonophoran and a sponge. Interestingly a hydrothermal vent mytilid harbors in the same gill bacteriocyte both methanotrophic and thiotrophic endosymbionts (51).

Recently an "endosymbiotic" sulfur cycle has been described in an oligochaete worm inhabiting sediments at 6 to 8 m water depth in the Mediterranean Sea (52). In fact, a sulfur-oxidizing γ-proteobacterium, closely related to the other thioautotrophic endosymbionts, and a sulfate-reducing δ-proteobacterium, closely related to the free-living sulfate-reducing *Desulfosarcina-Desulfococcus*, occur in the immediate proximity, extracellularly, in the subcuticular space of the worm. Sulfide produced by the δ-symbiont is used by the γ-symbiont as electron donor for the autotrophic fixation of carbon dioxide. Organic carbon is then passed to the worm, which via anaerobic metabolism provides succinate and fatty acids as electron donors to the δ-symbiont.

Nitrogen Fixation

Biological nitrogen fixation is an essential process supporting life on Earth. The process is lacking in eukaryotes, but is performed by a wide range of prokaryotes, called diazotrophs or nitrogen-fixing. Several nitrogen-fixing prokaryotes are free-living, whereas others have evolved more or less strict symbiotic associations, generally with plants, such as the epiphytic *Azospirillum*, several intra- or extracellular cyanobacteria, and the endosymbiotic bacteria rhizobia and *Frankia* (Fig. 4). Nitrogen fixation is generally performed under anaerobic or microaerobic conditions, because the enzyme nitrogenase, coded by the *nifHDK* genes, is rapidly inactivated by O_2. Symbiotic diazotrophs can develop anaerobic structures, such as the heterocysts of cyanobacteria or the vesicles of *Frankia*. Nitrogenase converts N_2 into ammonia, which is generally assimilated by the host and then fixed as amino group in glutamic acid via the glutamine synthase (GS). A by-product of nitrogenase activity is H_2, consuming about 25% of the energy utilized by the enzyme. However, some diazotrophs, including also the symbiotic *Frankia* and some rhizobial strains, possess a hydrogenase ($H_2 + O_2 \rightarrow H_2O + ATP$). By oxidizing H_2 to H_2O with production of ATP, the hydrogenase recovers energy and gives additional protection to nitrogenase from the O_2.

Intestinal Symbionts of Termites. A rich bacterial flora able to fix N_2 is hosted in the intestine of termites, a group of insects living on diets of cellulose. *Citrobacter* and *Enterobacter* species are intestinal symbionts known since the 1970s. However, molecular phylogenetic analyses based on the research of the nitrogenase reductase gene (*nifH*) have revealed that termites host a richer flora of N_2-fixing bacteria, composed mainly by yet-uncultivated species belonging to several lineages like γ-Proteobacteria, *Clostridium* group, spirochetes and methanogenic archaebacteria (53,54).

Cyanobacteria. Cyanobacteria may perform N_2 fixation in the specialized heterocyst, and several eukaryotes may enter in symbiosis with them to get nitrogen compounds (1,55). Intracellular N_2-fixing cyanobacteria have been reported in some marine and freshwater diatom algae (Heterokonta), in all known species of the eudicot *Gunnera* (Angiosperms), occasionally in some species of *Sphagnum* (mossess), in the zygomycete *Geosiphon pyriforme* (Fungi), and also in a coral reef sponge. In addition, extracellular cyanobionts are present in several fungi and landplants.

In their association with fungi, cyanobacteria form bipartite (mycobiont + cyanobiont) or tripartite (mycobiont + cyanobiont + phycobiont) lichens. In *Geosiphon* and bipartite cyanolichens, the cyanobiont supplies the fungus with both ammonia and photosynthates, whereas in tripartite lichens, the fungus receives ammonia from

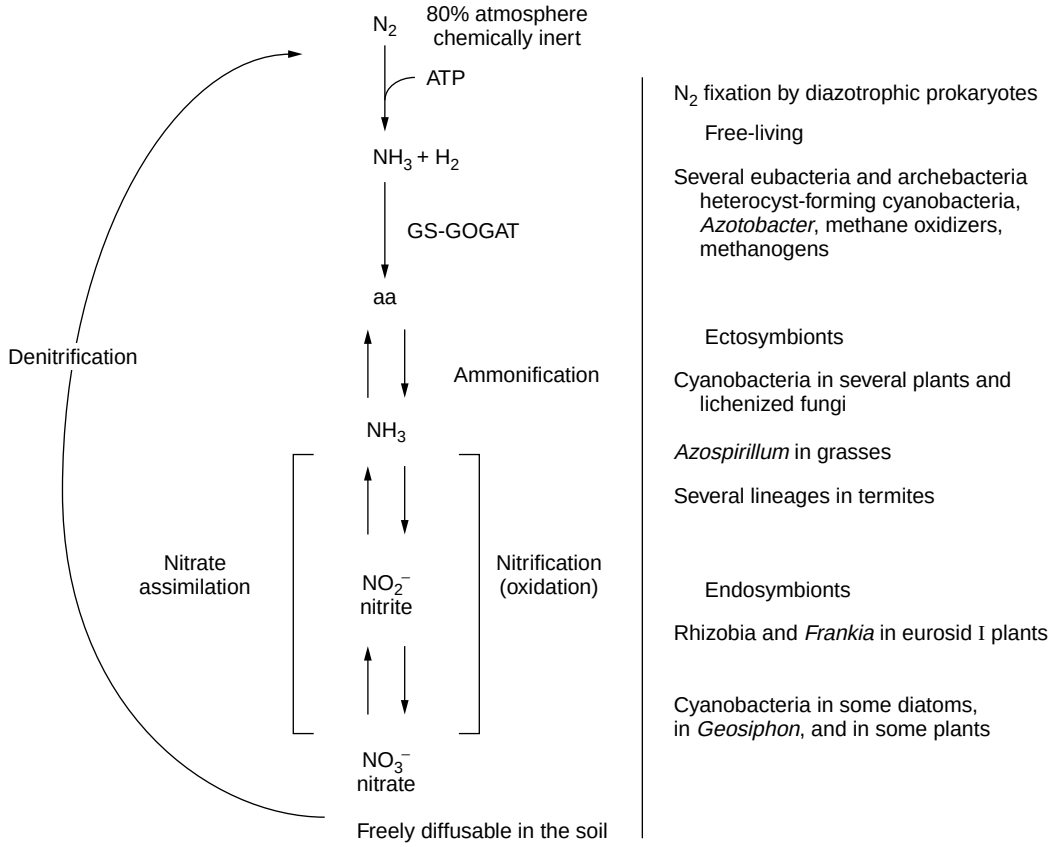

Figure 4. Nitrogen cycle. Nitrogen (N_2) constitutes 80% of the atmosphere and is a chemically inert gas. Diazotrophic prokaryotes, both free-living and symbiotic (listed at the right side of the figure) are able to fix N_2 to ammonia, which is assimilated into amino acids (aa) via the GS-GOGAT pathway. Organic nitrogen returns into the environment in the form of ammonia (ammonification), and then it is oxidized first to nitrite, and then to nitrate (nitrification) by chemoautotrophic bacteria. Nitrate is very soluble and is the main nitrogenous form available in soil for plant growth (nitrate assimilation). Under anaerobic conditions a variety of bacteria may use nitrate as a final electron acceptor in place of O_2, releasing then N_2 into the atmosphere (denitrification).

the cyanobiont and photosynthates (polyols) from the phycobiont (a green alga).

Many plant species within the landplants harbor associated cyanobionts (55): four out six genera of hornworts, but only two out the over 300 genera of liverworts, all the species of the water fern *Azolla*, and all the known cycads. In both intra- and extracellular associations with plants, the photosynthetic activity is restricted to the plant host (Table 2). Some photosynthate is provided by the plant to the symbiont, which in return supplies the host with ammonia. By contrast, in the association with the diatoms the photosynthetic activity is present in both the cyanobiont and the alga. Intracellular cyanobionts within sponges generally provide the host with the photosynthate, but the possibility of nitrogen fixation has been reported for some marine coral sponges.

Rhizobium-Legume Symbiosis and Actinorhizal Plants. Within the angiosperms, legumes and some other eudicot families have the capacity to enter in symbiosis with some Proteobacteria collectively called rhizobacteria or rhizobia, and with the actinomycete *Frankia*. Rhizobia interact with legumes (family Leguminosae or Fabaceae) and *Parasponia*, a nonleguminous genus within the family Celtidaceae, whereas *Frankia* interact with several species belonging to other eight eurosid families also called actinorhizal plants (families Betulaceae, Casuarinaceae, Coriariaceae, Datiscaceae, Elaeagnaceae, Myricacaee, Rhamnacaee, and Rosacaee) (56). The bacteria are hosted in a modified plant structure, called a nodule, where they fix N_2 and supply ammonia to the host plant. Recent molecular phylogenetic analyses have shown that such plant families are included, along other nonsymbiotic families, in a well-supported clade within the eurosid I group of the eudicot plants (56), suggesting that an unique genetic architecture has evolved within a definite lineage of plants to support symbiotic nitrogen fixation.

Nodulation genes are present in all the rhizobacteria. They code for Nod factors, that are lipochitooligosaccharides, which act as morphogenetic signals for the specific legume host to induce bacterial infection and plant nodulation (57–60).

Table 2. Cyanobacterial Symbioses

Host	Cyanobiont	N_2 Fixation	Photosynthesis		GS Activity[a]	
			Cyanobiont	Host	Cyanobiont	Host
Diatoms	IC	+	+	+	−	+
Plants						
Liverwort	EC	+	−	+	⇓	+
Hornwort	EC	+	−	+	⇓	+
Mosses (*Sphagnum*)	IC	+	−	+	⇓	+
Pteridophyte (*Azolla*)	EC	+	−	+	−	+
Cycadophyta	EC	+	−	+	+	−
Angiosperms (*Gunnera*)	IC	+	−	+	⇓	+
Fungi						
Lichens	EC	+	+	−	−	+
Geosiphon	IC	+	+	−	−	+
Animals						
Sponges	IC	(+)	+	−	?	?+

Note: Cyanobacteria may form symbioses with a wide range of eukaryotic hosts. In the table are listed the localizations of the cyanobiont: extracellular = EC, intracellular = IC. The cyanobiont performs nitrogen fixation, and the glutamine synthetase (GS) activity is performed by the host, with the exception of cycads. The cyanobiont also performs the photosynthesis, with transfer of photosynthate to the host, when the host is heterotrophic (fungi [in tripartite lichens (cyanobiont + fungus + green alga), the photosynthates derive from the phycobiont] and animals). Metabolic activities: + = present; − = absent; ⇓= decreased; (+) = activity possible but not confirmed; ? = unknown.

[a]Cycads receive amino acids synthesized via cyanobiont GS.

Rhizobacteria comprise six genera of related but distinct α-2 Proteobacteria (*Allorhizobium*, *Azorhizobium*, *Bradyrhizobium*, *Mesorhizobium*, *Rhizobium*, and *Sinorhizobium*), a unique species from the genus *Methylobacterium* (α-2 Proteobacteria), and also two members from the genus *Burkholderia* (β-Proteobacteria) (61–63). As only around 10% of the legume genera have been characterized until now, new rhizobial lineages may probably be found in the future. Each symbiotic genus has nonsymbiotic bacteria as closest relatives, as inferred from 16S rDNA-based phylogeny. Phylogenetic trees based on nodulation genes indicate a common origin of such genes, and are incongruent with 16S rDNA-based phylogenies. Assuming that the 16S rDNA is always vertically transmitted, there is strong evidence in favor of a lateral transfer of nodulation genes, often carried by large plasmids, as "symbiogenetic islands" (61,64,65).

The host ranges of rhizobia vary from very narrow, as for *Azorhirobium caulinodans*, which nodulates only legumes of the genus *Sesbania*, to very broad, as for the strain NGR234 of *Rhizobium* sp., which nodulates several species from almost all the legume tribes.

Bacteria respond to plant secreted flavonoids by producing Nod factors, which induce the curling of the root hairs. There is a local hydrolysis of the cell wall of the root cells, and bacteria penetrate within a tubelike structure called an infection thread. Such a structure grows intracellularly and penetrates several layers of the root cortical cells to reach the centrally located primordial cells. The infected primordial cells then develop into a nodule. Actinorhizal nodules have a rootlike anatomy, that is, they are constituted by several lateral structures called lobes, having a central vascular bundle and peripheral infected cells. By contrast, legume nodules are stemlike, that is, vascular bundles are peripheral and infected cells central. Specialized plant cells form a diffusion barrier into the nodule, which generates a microaerobic habitat within the tissue hosting the rhizobia. In addition, the microaerobiosis at the nodule level is also maintained by the leghaemoglobins (legume hemoglobins) that bind O_2 and release it slowly. Even if *Parasponia* nodules are infected by rhizobia and activated by Nod factors, their anatomy is similar to the actinorhizal nodule, then indicating that the plant host has a control in the nodule development. Nodulations in legumes and actinorhizal plants are related processes, yet giving different structures. Nodule-specific gene transcription has also been detected in other organs of the plant host, and interestingly some homologous genes have recently been found also in non-nodulating plant species distantly related to the eurosids. In addition, it has been demonstrated with nodulation mutant plants that a common set of host genes is essential to both nodulation with rhizobia and to endomycorrhiza formation, an endosymbiotic association with glomalean fungi present in almost all the landplants. It has been then hypothesized that the nodulation process may have originated in the eurosids by recruiting some of the apparatus evolved in landplants to form the endomycorrhiza (66).

Endomycorrhizal Burkholderia Symbiont. Another potential N_2-fixing endosymbiont is the intracellular symbiont of some endomycorrhyzal fungi. This endosymbiont belongs to the genus *Burkholderia* of the β-Proteobacteria (67) and possesses transcriptionally active *nifHDK* genes (68).

REPRODUCTIVE PARASITES

Reproductive parasites (69) form a diverse group of endosymbionts belonging to different eubacterial lineages and to the eukaryotic microsporidia, able to manipulate

the reproduction of the host, generally an arthropod. Generally these parasites cause a benign infection of the female host, and exploit the cytoplasmic transovarial passage in the next generations as a mechanism for its survival. Being then maternally transmitted, these parasites tend to promote a female-biased sex ratio of the host. Manifestations of such type of parasitism are various, ranging from the killing of the male progeny, to the feminization of the genetic male and to the induction of parthenogenesis (Table 3). Whereas the male killing phenotype has evolved several times in distantly related bacteria (70), some other reproductive disorders seem to be caused only by some specific organisms (71). *Wolbachia* is the most studied of such parasites, and may display all the manifestations of the reproductive disorders.

Wolbachia

Wolbachia belongs to the order Rickettsiales (α-Proteobacteria) characterized by an obligate intracellular life. Four wolbachial phylogenetic lineages, A to D, have been identified, infecting a wide range of arthropods (A and B lineages in several species of insects, mites and isopods) and several filarial nematodes (C and D lineages) (72,73). *Wolbachia* resides in a phagosome, mainly in cells of the reproductive organs of the host. In arthropods it is able to modify the normal chromosome kinetics, resulting in a variety of reproductive disorders. In wasps, some *Wolbachia* strains induce parthenogenesis by aborting the first mitotic phase in unfertilized eggs. The resulting diploid egg develops in a normal female, as hymenopterans have a haplodiploid system of sex determination (male is haploid, female is diploid) (thelytochous parthenogenesis). In parasitoid wasps a horizontal transfer of *Wolbachia* from infected to uninfected larvae within a same parasitized host is a possibility (20). Similarly, natural horizontal transfers of *Wolbachia* between distinct insect species have been reported, namely from the parasitized *Drosophila* host to the parasitoid wasp *Leptopilina* (74). Horizontal transfers between different parasitoid species have not been reported yet, but theoretically such events could be possible as the same food source, that is, the parasitized insect, may be shared by different species, some being occasional or obligate hyperparasitoid (19). Recently, a case of "mutualistic" symbiosis of *Wolbachia* with a parasitoid wasp has been reported, as the oogenesis of the wasp is specifically inhibited by the remotion of the bacterium (75).

In a larger range of arthropods, the most common effect of *Wolbachia* infection is cytoplasmic incompatibility (CI), that is, the production of haploid embryos from fertilized eggs by blocking the syngamy of both the paternal and maternal chromosomes, with the elimination of the paternal pronucleus. In haplodiploid insects the haploid embryo develops in normal males, and CI results then in a male-biased sex ratio. In diploid species, CI results in the death of the embryo. In haplodiploid mites the holokinetic nature of the chromosomes probably does not allow a complete elimination of the paternal chromosomes. This leads to aneuploid nuclei showing several phenotypes ranging from aborted embryos to sterile females. CI is governed by a modification/rescue (mod/res) mechanism:

Table 3. Reproductive Parasites

Parasite	Male-Killing		Feminization	Parthenogenesis	Cytoplasmic Incompatibility
	Embryo	Larva			
Rickettsiales					
Orientia				*Leptotrombidium* (Acari)	
Rickettsia	Coleoptera				
Wolbachia[a]	Coleoptera, Lepidoptera		Isopods, Lepidoptera	Hymenoptera	Insects, mites, isopods
γ-Proteobacteria					
Arsenophonus[b]	Hymenoptera				
Mollicutes					
Spiroplasma	Coleoptera, Diptera, Lepidoptera				
CFB lineage[c]	Coleoptera		*Brevipalpus phoenicis*[d] (Acari)		
Verrucomicrobia					
Xiphinematobacter				*Xiphinema* (Nematoda)	
Microsporidia[e]		Mosquitoes	Marine amphipods		

Note: Microorganisms causing a variety of reproductive disorders in their hosts. All but Microsporidia (eukaryotes) are eubacteria.
[a] *Wolbachia* causes reproductive disorders in arthropods (A and B lineages), but it is essential to the normal development of filariae (C and D lineages), and in one case of a parasitoid wasp.
[b] *Arsenophonus triatominarum* in the reduviid bug seems to be not associated to reproductive disorders.
[c] CFB, *Cytophaga-Flavobacterium-Bacteroides* lineage.
[d] Populations of this mite species are constituted entirely by haploid females. Closely related symbionts are found also in parasitoid wasps (associated to parthenogenesis) and in the tick *Ixodes scapularis*.
[e] Several species.

infected males do not transmit *Wolbachia*, but produce "modified" sperm that can be rescued only if the egg is infected by the same strain of *Wolbachia*. Several mod/res alleles exist. Other factors are involved, like a dose effect of infection density, the possibility of a double infection by different *Wolbachia* strains, the age and phenotype of the host, the temperature, etc. CI may cause reproductive isolation between different populations of a same species. If gene flow is interrupted long enough to allow the appearance of nuclear incompatibility, an event of sympatric infectious speciation may arise. Evidence in favor of the possibility of such an infectious speciation exists in the parasitoid wasps of the genus *Nasonia*. Natural populations of the three species *N. vitripennis*, *N. giraulti*, and *N. longicornis* showed bidirectional CI. Aposymbiotic interspecific crosses with *N. vitripennis* resulted in F1 hybrids, which however showed other isolation barriers, such as high lethality or abnormal behaviors of F2 hybrids. But aposymbiotic crosses between *N. giraulti* and *N. longicornis* resulted in viable and fertile F1 and F2 hybrids (76). This indicates that the hybrid incompatibility between these two latter species is mainly caused by the *Wolbachia*-induced CI, which then would precede the evolution of other isolation mechanisms.

In terrestrial isopods *Wolbachia* seem to have played a central role in the evolution of sex determination, possibly as source of a genetic element that has transformed an original male chromosome in a female one (77). Males develop because of the effects of the male hormone produced by the androgenic gland. Females emerge if the product of a "female gene" inhibits the development of the androgenic gland or the secretion of the male hormone. Sex determination in isopods is mainly heterochromosomal, that is, there are male- or female-specific chromosomes (XY/XX or ZZ/WZ, respectively). Sex chromosomes are very homologous (lack of heteromorphy), and it seems that the female chromosome is a male chromosome carrying the "female gene" (f factor). Such f factor has been hypothesized to have derived from a genetic element of *Wolbachia*.

By contrast, in filarial nematodes *Wolbachia* does not seem to be a source of reproductive disorders. The presence of the symbiont seems to be essential to the normal life of the host (78) and also it seems to participate to the inflammatory pathogenesis characterizing the filarial infection in vertebrates (79). A split in the evolution of *Wolbachia* towards the reproductive parasitism in arthropods and the mutualism in filariae, may be hypothesized. The A and B lineages comprise reproductive parasites of arthropods, without a congruency between symbiont and host phylogenies, whereas the C and D lineages are restricted to filariae, with a parallel between the phylogenies of hosts and symbionts. In addition, the filarial symbionts have a reduced genome size, about 30% smaller than those of the arthropod parasites (80), which is consistent with the genome reduction observed in several mutualistic symbionts.

Male-Killing

At present four lineages of bacteria are recognized as being responsible for the killing of the male embryos in several insect orders: the Rickettsiales with the genera *Wolbachia* and *Rickettsia*; *Arsenophonus* within the γ-Proteobacteria; unnamed species within the Flavobacteria, and some strains belonging to the genus *Spiroplasma* within the Mollicutes. The prevalence of infection in natural populations may vary greatly, from less than 1% to more than 80%, depending on several factors, such as host species bioecology (e.g., consumption of dead sibling males by sibling females), efficacy of the parasite transmission, and temperature (70). It is possible that the killer phenotype may have evolved from neutral or beneficial vertically transmitted symbionts by an event of horizontal transmission to a new host. The flavobacterial killer of ladybird beetles is specifically related to *Blattabacterium*, a beneficial symbiont of cockroaches (Dictyoptera, Blattoidea), whereas *Arsenophonus* sp. causes male-killing in wasps but not in triatomine bugs (21,22). Interestingly, all the *Rickettsia* species seem to be slightly or not pathogenic for the arthopod host when the host is a tick, but not when the host is an insect. Whereas some of these agents seem to be strictly vertically transmitted, horizontal transmission is possible and even important for others. Both *Rickettsia* and *Spiroplasma* possess lifecycles involving an animal or a plant as intermediate hosts, and horizontal transmission occurs, even if rarely, for *Wolbachia* also.

Male-killing at the larval stage has been reported for Microsporidia infecting mosquitoes, probably reflecting the ability to exploit both vertical and horizontal transmission. Indeed, whereas the parasite is vertically transmitted in the host female, the delayed death of the male at the larval stage allows it to join its aquatic habitat. The larvae then die, releasing the parasite spores for the horizontal transmission.

Induction of Parthenogenesis

The induction of parthenogenesis seems to be exclusive to *Wolbachia*. However, this mechanism is probably also used by another rickettsia, *Orientia*, the causative agent of the scrub typhus, to cause a very strong female-biased sex ratio in populations of the host, the mite *Leptotrombidium*. Recently the endosymbiotic induction of parthenogenesis has been evoked also for the longidorid nematodes of the *Xiphinema americanum* group. The populations of these worms are composed almost exclusively of females, which harbor transovarially transmitted organisms belonging to the Verrucomicrobia (81) in symbiosomes within the intestinal epitheliocytes of the juvenile and within the ovarial wall cells of the adult.

Recently a very interesting phenomenon has been reported (82) for a parthenogenetic mite species, *Brevipalpus phoenicis*, belonging to the haplodiploid superfamily Tetranychoidea. Caryological analyses surprisingly showed that females of this species are haploid, and harbor an endosymbiotic bacterium belonging to the *Cytophaga-Flavobacterium-Bacteroides* lineage. Aposymbiotic mites produce a progeny of males that are all symbiont-free. This may be a case in which a symbiont has infected the haploid male of a haplodiploid species. As such symbiont induces feminization, then a population of mite species constituted entirely of haploid females originated. Closely

related bacteria (96 to 98% 16S rDNA homology) have also been found in the tick *Ixodes scapularis* and in several species of parasitoid wasps, and in the latter they have been associated to the induction of parthenogenesis.

ENDOSYMBIONTS AND THE ORIGIN OF EMERGING PATHOGENS

As protists harbor diverse intracellular symbionts (83), they may potentially play a role as vector and/or potentiator of virulence for some pathogens as well as agents of selection for emerging parasites. Indeed protozoa may be considered as Trojan horses of the microbial world (84).

Outbreaks of pneumonia caused by *Legionella pneumophila* infection present important morbidity and mortality rates. This bacterium belongs to a rich group of intracellular parasites of several free-living and ubiquitous protozoa, including the loboseans *Acanthamoeba* and *Hartmannella*, the percolozoans *Naegleria* and *Vahlkampfia*, as well as the ciliate *Tetrahymena*. Legionellae are able to multiply within alveolar macrophages avoiding digestion by the phagocyte. Molecular and genetic analyses have shown that the infections of protozoa and macrophages are highly similar. Legionellae illustrate how a pathogen may emerge. Legionellae are naturally parasites of protozoa, in which they multiply blocking the endocytic pathway. The evolution of such a strategy of exploitation of hosts possessing tremendous digestive systems, most of these being indeed bacterivorous, has provided legionellae with the virulence traits allowing to avoid the human phagocytes (85,86). Several bacteria, among which some human pathogens, may reside into, and also multiply within environmental protozoa. New lineages of amoeba symbionts have been recently discovered, some being closely related to known human or animal pathogens. Among those are the acanthamoebal endosymbionts parachlamydiae, belonging to the order Chlamydiales, which show an increasing diversity (87), and the pararickettsiae (88), that are closely related to the rickettsiae.

Another important source of potential emerging pathogens are the arthropods. In fact it is conceivable to speculate that a new animal pathogen may arise from an endosymbiont if the bacterium is horizontally transmitted from a nonbiting arthropod species to a biting one, or if the ancestral host enters in contact with an animal. This is illustrated by the great variety existing in nature of arthropod endosymbionts closely related to well-known animal pathogen species, like *Rickettsia* and *Francisella* (89,90).

SYMBIOSES AND EVOLUTION

Obligate Symbioses

Many types of intracellular organisms exist, which are maintained in their host by either horizontal or vertical transmission. If the transmission is strictly vertical, the symbionts are constituted by small strictly clonal populations. In the absence of recombination, they then accumulate deleterious mutations that will be fixed in the genome. Such a situation results in three main features: (*1*) a higher nonsynonymous mutation rate, that is, the endosymbiont evolves faster than a free-living relative, (*2*) the reduction of the genome size, and (*3*) an increase in A + T base composition of the genome caused by a mutational bias (91). Small genomes with low G + C contents are indeed a common feature of both mutualistic and parasitic intracellular bacteria. Such a genome reduction evolution seems however to be governed to some extent by the peculiar type of intracellular association. For example, the aforementioned three main features of genome evolution have been found in P-symbionts of insects *Buchnera* and *Carsonella* (12,91). *Buchnera* possesses a highly reduced genome of 640 kbp with a G + C content of around 26% (92), but genes for the synthesis of the essential amino acids tryptophan and leucine are often amplified in multicopy plasmids. An even more drastic gene reduction is showed by *Carsonella*, the P-symbiont of psyllids, with the elimination or reduction of intergenic sequences, the reduction of the protein sizes and the modifications of 16S rRNA. In addition *Carsonella* possesses the higher A + T content found so far, that is, G + C less than 20% (93).

Endosymbiotic organisms may evolve as permanent residents of the host cell. Peculiar syntrophic consortia may provide novel metabolic processes, and the extent of host-endosymbiont integration may become highly advanced. Examples are the spirochaetes involved in the motility symbiosis with some protists, as well as the endosymbiotic algae in the symbiophototrophic hosts or the sulfur-oxidizing bacteria endosymbionts of marine invertebrates. Some ciliates possess bacterial epibionts, called *epixenosomes*, that are involved in a defensive response against predators by an extrusive apparatus (94,95). These epibionts may represent a "preorganellar state" toward the subpellicular extrusive organelles found in other protists (trychocysts) that act similarly.

The Origin of the Eukaryote Cell and Its Organelles

The main example of extreme endosymbioses is the eukaryote cell. Almost all the eukaryotic organisms are indeed characterized by harboring at least two types of genomic materials: nuclear and mitochondrial. Mitochondria are derived from highly integrated endosymbiotic bacteria, possibly a unique lineage of α-proteobacteria related to the rickettsiae. A third genome, bacterial derived, is present in photosynthetic eukaryotes, plastids being of cyanobacterial origin. Some authors have proposed a bacterial endosymbiotic origin also for the eukaryotic flagellum and the peroxisomes, a *Spirochaeta*-like and a gram-positive, respectively, but having entirely lost their genomes. Finally the ancestral eukaryote cell also is believed to have originated from an archae-eubacterial merger, several models involving different lineages of both the partners having been proposed. The integration of these bacterial endosymbionts, and perhaps of others, is hypothesized to have occurred by a stepwise manner, the so-called Serial Endosymbiosis Theory (SET). This theory was proposed in the last decades of the nineteenth century, and was reevaluated in the 1970s and it is at present widely accepted (Fig. 5).

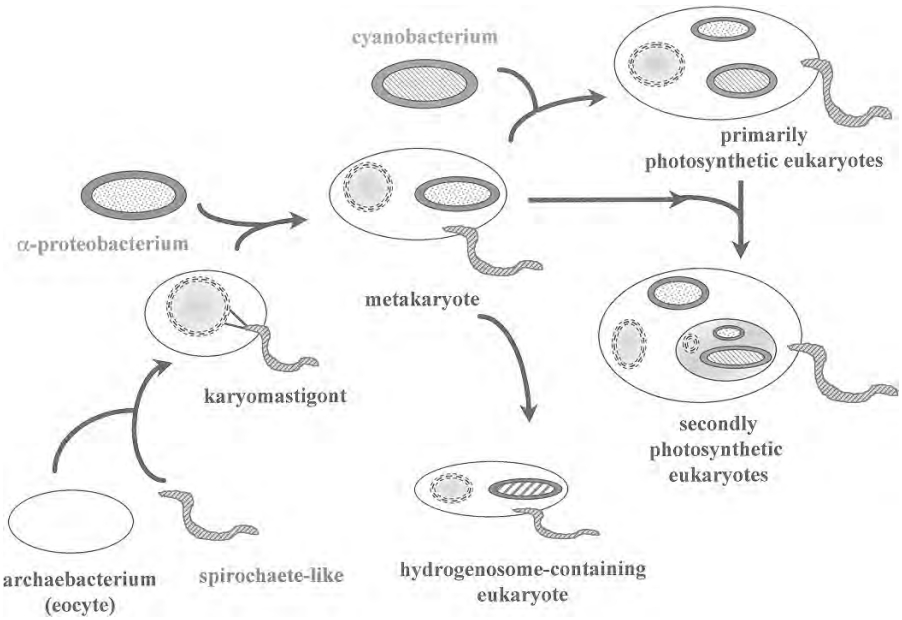

Figure 5. Serial endosymbiotic theory. The ancestral eukaryote cell is supposed to have originated from an archaebacterium (eocyte), perhaps as the result of a merger with an eubacterium (spirochaete), as a motility symbiosis, or as a failed predation. A system of internal membranes has been developed to include all the genetic materials, giving rise to the nucleus, whereas the motility symbiosis reached a high integration, giving rise to the eukaryotic flagellum. The cell at this step is called a *kariomastigont*. At one moment a novel episode of endosymbiosis with an α-proteobacterium appears, giving rise to the mitochondrion. The cell at this step is called a *metakaryote*. Some metakaryotes adapt several times and independently to anaerobic habitats changing the mitochondrion into a hydrogenosome. Endosymbiosis with a cyanobacterium has allowed the emergence of photosynthetic eukaryotes, that form at the present the kingdom of Plantae. Successive episodes of secondary symbioses between a plant and a phagotrophic metakaryote originate the secondarily photosynthetic eukaryotes (euglenoids, chlorarachniophytes, chromist algae and some alveolates). Whereas the first steps of the evolution of the eukaryotic cell are still disputed, several theories have been proposed, the origin and evolution of mitochondria and plastids are now widely accepted. See color insert.

The Karyomastigont. In the model proposed by Margulis (96,97), eukaryote cell originated from a merger between a thermoacidophil archaebacterium *Thermoplasma*-like and a heterotrophic swimmer eubacterium *Spirochaeta*-like. Both partners live in acidic environments, in which the *Thermoplasma*-like produce hydrogen sulfide that is oxidized by the *Spirochaeta* -like to ferment carbohydrates. Organic carbon is then utilized by the *Thermoplasma* -like. In addition the *Spirochaeta* -like provides motility. Such a sulfur syntrophic motility symbiosis is supported by the existence of extant *Thiodendron*, which is in reality a sulfur syntrophic consortium of spirochaetes and *Desulfobacter*. Other examples of motility symbiosis include some anaerobic flagellates, such as *Mixotricha paradoxa* (Parabasala) and *Pyrsonympha* (Metamonada), gut endosymbionts of termites, where small and large epibiontic spirochaetes are important in the motility of the protist. It should be noted that the two lineages to which these motility symbiosis flagellates belong are considered to be among the most ancestral (Archeprotista). The strict association between the epibiont spirochaete and the thermoplasmal nucleoid has originated an attachment system, called a *karyomastigont*, which assures stability to the chimera allowing the integration of the spirochetal (mastigont) DNA to the thermoplasmal genome, with the formation of the nucleus. The formation of nuclear membrane may have originated from the membrane hypertrophy induced as a defensive response to the invasive attached spirochaeta. Moreover, nucleoid membranes exist in some planctomycetes, which are peptidoglycan-less eubacteria. There are some evidences that a centriole-kinetosome DNA is still present. In Margulis's model, the karyomastigont, identifiable in some extant protists, resulted in the first microtubule-organizing center (MTOC), from which originated the 9[2] + 2 eukaryotic flagellum and the 9[3] + 0 microtubule spindle apparatus. Some extant anaerobic, mitochondria-free protists, like the Archamoeba (e.g., *Mastigamoeba*), Metamonada (e.g., *Giardia*), and Parabasalia (e.g., *Trichomonas*) are believed to be the descendants of this primitive eukaryote cell. These organisms are referred as the Archeprotista by Margulis (96), or Archezoa by Cavalier-Smith (98), or Hypochondria by Patterson and Sogin (99). Successively the endosymbiosis with an aerobe α-proteobacterium has originated the mitochondrion, and then the emerging of the aerobic, mitochondriate eukaryotes. Some of these have successively integrated a cyanobiont, which evolved in the plastid.

The Archezoa Hypothesis. In the early formulation, then, the amitochondriate Archezoa are direct descendants of the eukaryote cell, before the integration of the protomitochondrial bacterial symbiont. Phylogenetic analyses performed on the small subunit (SSU) of the

rRNA, as well as simplified cytological features (98) seem to confirm the early derivation of archezoa. But this scenario has recently been challenged by the recovery in some archezoa, namely in *Giardia* and in *Trichomonas*, of mitochondrial-derived genes. The human pathogen *Entamoeba hystolytica*, previously removed from the Archezoa owing to the presence of "advanced" features like spliceosomal introns and dictyosomes, possesses a small organelle targeted by nucleus-encoded mitochondrial-specific proteins. This organelle, termed the mitosome or crypton, contains a genome, and is considered to be a reduced mitochondrion (100). In addition, revaluations of phylogenetic affiliations based on protein-coding genes indicate that the early branching of archezoa in SSU rRNA trees may be the result of a long-branch attraction, which is the placement of highly divergent sequences toward the root of the tree because artificially affiliated to the distantly related prokaryotic ones. At present the Microsporidia are believed to be a highly derived, and then simplified, lineage of parasitic fungi, whereas trichomonads possess hydrogenosomes, which are believed to be derived from mitochondria.

The α-Proteobacteria, Rickettsiae, and Mitochondrial Origins. Members of the α-Proteobacteria are characterized by a strict association with eukaryotic cells, and several are facultative or obligate intracellular microorganisms, either symbiont or pathogens.

Rickettsia prowazekii, for which the complete genome sequence is available (101), is an aerobic obligate intracellular parasite representing at present the closest relative of the eukaryotic mitochondria. This bacterium lacks genes for the glycolysis but possesses a complete system for the utilization of the pyruvate produced by the host cell. This system is composed of three-enzyme complex for the pyruvate dehydrogenase, the tricarboxylic acid (TCA) cycle or Krebs cycle, a cytochrome-based electron transport chain, and the cytochrome oxidase, and a F_1F_0 ATPase pump. An ATP/ADP translocase allows the acquiring of ATP from the cytoplasm of the host. Molecular phylogenetic analyses of the products of all but the translocase genes showed a strong homology with those of the mitochondria. ATP/ADP translocase complex is present in mitochondria and plastids and, among prokaryotes, only in rickettsiae and chlamydiae, another group of obligate intracellular parasites. In phylogenetic analyses rickettsial ATP/ADP translocases group with the translocases of chlamydiae and of plastids, and all import ATP from the cytoplasm of the host and release ADP. The mitochondrial translocases act inversely, acquiring ADP from the cytoplasm of the cell and releasing ATP, and, in molecular analyses, form an ancient monophyletic lineage independent from the translocases of plastids, rickettsiae and chlamydiae. However, the analysis of protein-coding genome (proteome) of mitochondria reveals that of about 400 proteins only 50 are of α-proteobacteria origin. Indeed, about 200 proteins cluster exclusively as eukaryotic homologs. This suggests that the mitochondrial proteome is not the descendant of the ancestral symbiont proteome exclusively (102).

The presence of eubacterial-like sequences also in archezoan genomes has led to the proposal of an early emerging of mitochondria, perhaps contemporarily to the emergence of the same eukaryote cell. One of such models is the "hydrogen hypothesis," in which the origin of the eukaryote cell takes place on the syntrophy between an anaerobic methanogen (nucleocytoplasm) and a facultative anaerobic H_2-producing eubacterium (103). The ancestral organelle has then functioned as a modern hydrogenosome, evolving in the aerobic mitochondrion in the O_2-adapting eukaryote lineages. This hypothesis found a strong support in the extant syntrophies between methanogens (both free-living and epi/intracytobiont) and protists, which are widespread in anaerobic habitats, such as anoxic sediments and gastrointestinal tracts of animals. The protists are mitochondria-free but possess hydrogenosomes: for example, archaeamoebae inhabiting the organic-rich stagnant water sediments (sapropel) of the genera *Mastigella* and *Pelomyxa*, and several ciliates and other protists either free-living (104) or gut symbiont of ruminants (105). The H_2 produced by the hydrogenosome is then exploited by the methanogen to reduce carbon dioxide to methane. In some protists, for instance, the sapropelic ciliate *Metopus contortus*, the methanogen endosymbiont may also have morphological alterations, like partial loss of the cell wall, allowing a stricter contact with the organelle.

Another model based on methanogen syntrophy invokes a myxobacterium as the eubacterial symbiont, with a successive acquisition of the mitochondria. Anaerobic mitochondria also exist, producing ATP through pathways present in extant anaerobic bacteria but not in *Rickettsia*, an obligate aerobe. Among these anaerobic mitochondria are the denitrifying mitochondria of some fungi and ciliates, and the fumarate-reducing mitochondrion of trypanosomes and some worms. *Euglena* mitochondria utilize enzymes similar to those of hydrogenosomes. Finally, hydrogenosomes oxidize pyruvate to acetate and H_2 via pyruvate ferrodoxin oxidoreductase and hydrogenase, which are enzymes found in anaerobes. These organelles share a common ancestor with mitochondria, and at least one has been found possessing DNA (106). It is probable that the common ancestor of mitochondria and rickettsiae possessed genes for the different pathways of ATP production. As other intracytobionts, such an ancestor has undergone genome reduction with the loss of useless genes. Whereas the obligate aerobic and parasitic rickettsiae have retained only genes for aerobic metabolism, mitochondria have transferred most of their genes to the nucleus.

Whereas the genes for metabolism show eubacterial origins, the genes for replication, transcriptation and translation of DNA are archaebacterial-like. Such a situation seems to confirm an archaebacterial derivation for the nucleocytoplasm, as inferred previously from phylogenetic analyses of some protein-coding genes that showed a sister-group relationship between archaebacteria and eukaryotes. However, as sequence and sample data accumulate, a more complex situation appears. In fact eubacterial metabolic genes, and in a minor feature archeal informational genes, seem to have different origins, as showed by different roots and branching topologies on phylogenetic trees. This is consistent with the hypothesis

that lateral gene transfers (LGT) from different bacteria to the eukaryote genome have occurred repeatedly. Such LGT may have originated from bacterial endosymbionts, as it is the case for mitochondrial and plastid genes, but also from engulfed or parasite bacteria digested by the cell.

Cyanobacteria and Plastid Origins

Plastid Types and the Kingdom Plantae, the Primary Symbiosis-Derived Algae. The photosynthesis in eukaryotes is based on an oxygenic reduction of carbon dioxide performed by an intracellular organelle, called a *plastid*, which originates from an extreme endosymbiosis of a cyanobacterium (Fig. 6). All the plastids possess chlorophyll *a* (Chl. *a*) as the principal pigment, but they vary in their accessory pigments. This allows us to recognize three main types: green, containing Chl. *a* and *b* (*a*/*b*); red, containing Chl. *a* and phycobilins (*a*/PB); and yellow-brown, containing Chl. *a* and Chl. *c* (*a*/*c*). Data suggest that all the plastids are derived from a unique cyanobacterial protoplastid, which had given rise to the different types of green, red, and brown plastids by changing the composition of the pigments (107). It is probable that such a protoplastid derived from a cyanobacterium possessing all the main pigments, that is, an *a*/*b*/PB organism. Whereas the great majority of known cyanobacteria have Chl. *a* and PB (*a*/PB), some others, called *prochlorophytes*, but not representing a monophyletic lineage, have Chl. *a* and *b* (*a*/*b*). However, one prochlorophyte, *Prochlorococcus*, contains both Chl. *a* and *b* and PB. Phylogenetic analysis of the chlorophyll *a* oxygenase, the enzyme that converts Chl. *a* into Chl. *b*, shows that the enzyme sequences in the prochlorophytes and the *a*/*b* plants originated from a unique ancestor (108). It is then conceivable that a differential loss of different pigments has taken place, originating the *a*/PB cyanobacteria, the different lineages of *a*/*b* prochlorophytes within the cyanobacteria, and an *a*/*b*/PB protoplastidial cyanobacterium. The latter has changed the light-harvesting complex proteins, which in cyanobacteria and plastids belong to two different protein families. Then it has given rise to the *a*/PB plastids of the glaucophytes and the rhodophytes by losing Chl. *b*, and to the *a*/*b* plastid of the chlorophytes (green algae and lanplants) by losing PB. The evolutionary history of plastids comprises in addition several gene loss and/or transfer to the nucleus (109), leading to high integrated host-plastid systems among the different lineages of eukaryotic algae. Glaucophytes, rhodophytes, and chlorophytes form a monophyletic lineage, the kingdom Plantae (109,110). They are diagnosed (111) as having plastids enveloped by only two membranes, believed to be derived from the two membranes of the symbiotic cyanobacterium (primary symbiosis). Such an event has been ancestral to the emergence of the kingdom Plantae, the nonphotosynthetic members being so secondary.

The Secondary Symbiosis-Derived Algae. The other photosynthetic eukaryotes belong to independent lineages and possess plastids enveloped by three or four membranes (Fig. 6). These plastids are believed to have originated from secondary symbiosis between a phagotrophic protist and (*1*) an engulfed chlorophyte: the three-membraned plastid of the euglenophytes and the four-membraned plastid of the chlorarachniophytes; or (*2*) an engulfed rhodophyte: the three-membraned plastid of the pyrrophytes, or dinoflagellates, and the four-membraned plastid of the chromist yellow-brown algae. In addition a non-photosynthetic, four-membraned plastid is present in Apicomplexa, probably deriving from an independent secondary symbiosis with a green alga, but their origin by an extreme reduction of the red plastid present in a common ancestor of Apicomplexa and dinoflagellates may not be excluded. However, dinoflagellates may harbor both chlorophytes and chromist algae. In some cases the symbiosis with chromist algae seems to be highly integrated, so some dinoflagellates may represent cases of tertiary symbioses. All but the chromistan algae belong to larger protist groups probably including primitively non-photosynthetic lineages. Euglenophytes belong with the parasitic kinetoplasts (e.g., *Leishmania*, *Trypanosoma*) to the Euglenozoa, which are believed to be related to the Percolozoa (e.g., *Naegleria*), and then they are included together in the taxon Discicristata, for the discoid cristae of mitochondria. Chlorarachniophytes form an independent lineage within the Cercozoa, which also comprises monadofilosans (*Cercomonas*) and the plasmodiophorans. Dinoflagellates are included in the well-defined group of Alveolates, which comprises the ciliates and the parasitic apicomplexa (*Plasmodium*). It is interesting to note that ciliates harbor frequently endosymbiotic algae, and that Apicomplexa (e.g. *Plasmodium*) possess a relict plastid, without pigments, of uncertain derivation.

Dinoflagellates, and chromist algae contain *a*/*c* plastids, where PB have been probably substituted by Chl. *c*, but some members of both the algal groups contain *a*/*c*/PB plastids (e.g., the dinoflagellate *Amphidinium*, and the chromistan algal eustigmatophytes). Additionally, the fourth outermost periplastid membrane in the yellow-brown algae is continuous with the rough endoplasmic reticulum. Such a character has been considered as diagnostic for this group of algae, for which Cavalier-Smith has proposed the elevation to the rank of kingdom, as kingdom Chromista (111). This kingdom comprises the Cryptophyta, the Heterokonta, and the Haptophyta, and members of both cryptophytes (*Goniomonas*) and heterokonts (e.g., the oomycetes) are nonphotosynthetic, having secondarily lost the plastid.

Evidences of transitional events of primary and secondary symbioses may be found in some extant algae. Glaucophytes (*Cyanophora paradoxa*) are characterized by possessing an *a*/PB plastid that includes peptidoglycan (PG), then often called *cyanelle*. However, both the genome structure and the gene content reduction indicate that it is an organelle, not an endosymbiotic cyanobacterium. Such a plastid may represent the ancestral form of the plastid, when a genome reduction of the symbiont and a strong integration took place, but some features, such as the PG were retained. It is interesting to note that glaucophytes form the most basal lineage of the kingdom Plantae, which seems to be the unique lineage to have originated by primary symbiosis.

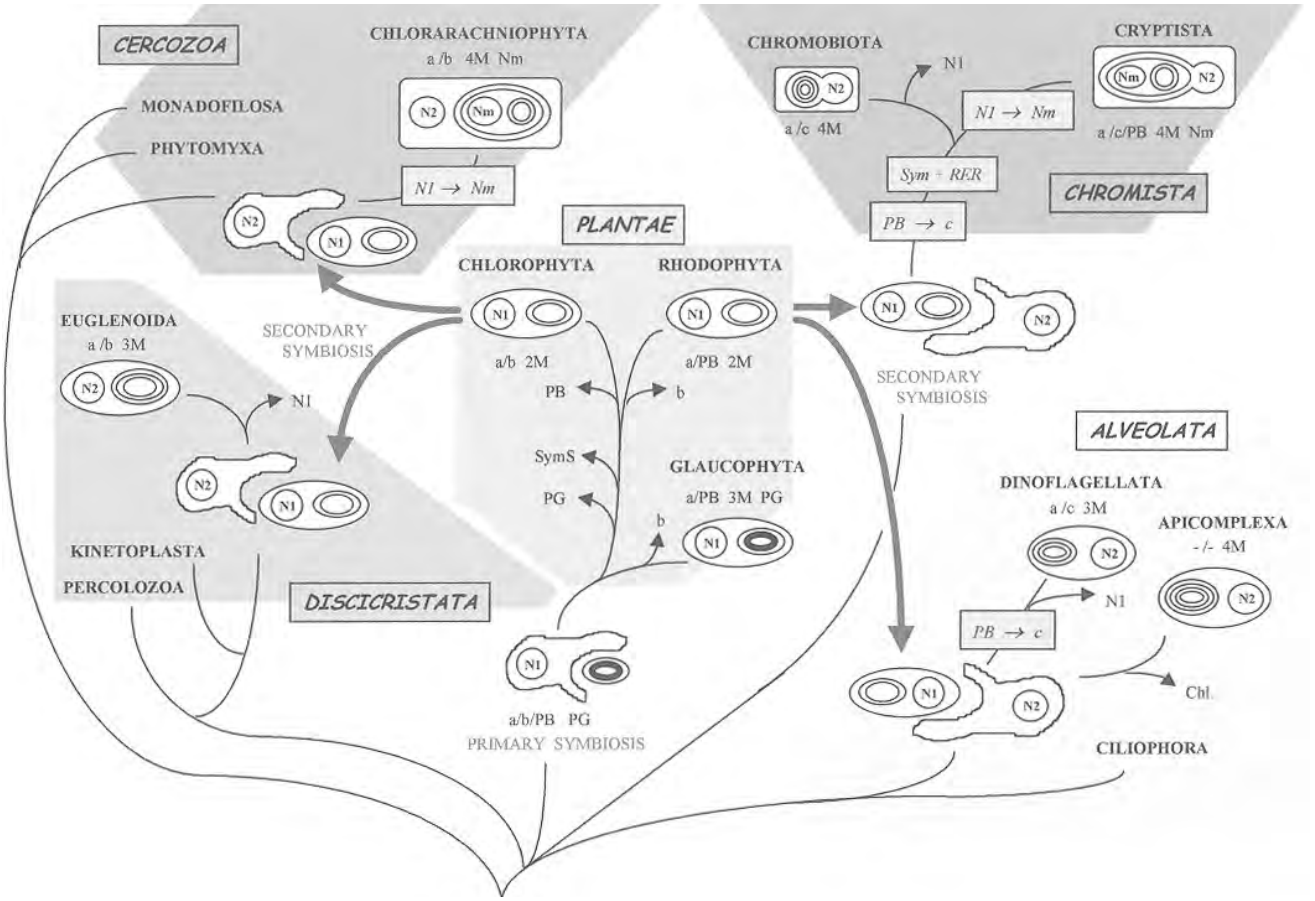

Figure 6. Origin and evolution of the eukaryotic algae. The five lineages of eukaryotes containing photosynthetic members are indicated: Alveolata, Cercozoa, Chromista, Discicristata, and Plantae (according to Cavalier-Smith 1998 (111)), with the pigment composition (a, b, c and PB, for chlorophylls *a*, *b*, *c*, and phycobilins, respectively). The number of plastid membranes is also indicated (2 M, 3 M, 4 M, for two, three, or four membranes), as well as the eventual presence of peptidoglycan (PG), and the retention of the nucleus of the primary alga as nucleomorph (Nm). N1 = nucleus of the primary alga; N2 = nucleus of the secondary alga. In squares are indicated the major transitions: substitution of phycobilins with chlorophyll *c* (PB → c), degeneration of the primary alga nucleus N1 into a nucleomorph (N1 → Nm), fusion of the symbiosome membrane with the rough endoplasmic reticulum (Sym + RER). A single event of primary symbiosis between a phagotrophic eukaryote and a cyanobacterium has led to the establishment of the kingdom of Plantae, the only primarily photosynthetic eukaryotes. Lineages within the kingdom Plantae then diverged by differential losses of plastid pigments. Episodes of secondary symbioses (large arrows in bold) between a green alga or a red alga and some phagotrophic protists, have led to the euglenophytes and chlorarachniophytes, and to the dinoflagellates and chromist algae, respectively. The nonphotosynthetic apicoplast of Apicomplexa seems to have originated from a green alga. In the Chromista, both Cryptista and Chromobiota harbor members without plastids, probably because of secondary loss. Cryptista and some Chromobiota (e.g., Eustigmatophycea) also possess phycobilins. See color insert.

Chlorarachniophytes and Cryptophytes are unrelated photosynthetic eukaryotes believed to have originated by secondary symbioses of heterotrophic protists with a chlorophyte and a rhodophyte, respectively (Fig. 6). Their plastids are enveloped by four membranes, the first two being the membranes of the plastid. The third derives from the cytoplasmic membrane of the primary host, and the outermost originates from the symbiosome membrane of the secondary host, fused with the RER in the case of the cryptophytes. These algae are very interesting because they have retained within the third membrane that is within the cytoplasm of the primary host, the nucleus of the primary host. Such nuclei, called *nucleomorphs* (Nm), contain a genome greatly reduced (three chromosomes for a total of 400 to 600 kb) with a high A + T content (60 to 70%), but they are transcriptionally active (112). The gene density as a result is very high, with that of cryptomonal Nm being the highest for an eukaryotic genome (1 gene per 0.8 kb). Spliceosomal introns are very squeezed, less then 20 bases in length in chlorarachniophyte Nm, or totally absent, in cryptophyte Nm (113). Recently the entire

551 kb genome of the nucleomorph of a cryptophyte has been sequenced (114).

CONCLUSION

Endosymbioses are widespread in nature, including both extracellular and intracellular microorganisms, prevalently prokaryotes, which have developed a mutualistic association with a larger organism, the host, that is generally an eukaryote, either unicellular or multicellular.

An endosymbiotic association is the result of a long-time adaptation process between two organisms, which may have originated from a virulent-to-avirulent evolution of an invading pathogen, or from the integration by the host of either a new metabolic process (syntrophy) or another property (e.g., chemical defense) possessed by an ingested prey. For example, the extant rhizobium-plant symbiosis may have originated from a failed plant infection by a pathogen able to infect the plant through the prevention of the hypersensitive response of the host. The localization of the genetic apparatus for both the nodulation and the nitrogen fixation on symbiogenetic plasmids has allowed its diffusion to other bacterial genera. Also, endosymbiotic algae may have originated as retained engulfed preys in many phagotrophic protists and invertebrate animals. In these types of associations some mechanisms of recognition and of regulation must have evolved. The recognition between symbiont and host is essential, for example, for the transmission of the symbiont to the next generation of the host, and for the localization of the endosymbiont in specific organs or cells of the host. The regulation of the association is essential, for example, to control the syntrophic process, and to prevent the defensive systems of the host destroying the invading endosymbiont and/or the endosymbiont causing disease to the host. The highly developed immune system of vertebrates seems to be the main cause for the extreme rarity of endosymbionts in this group of animals. In fact microbial infections in vertebrates are performed by microorganisms possessing the ability to avoid the immune response of the host at both the levels of cell and organism.

Ecological impact of endosymbiosis is particularly important. For example, the entire coral reef ecosystem in tropical, oligotrophic seas, one of the more species-rich on the Earth, is based on the endosymbiosis with zooxanthellae. There is also an endosymbiotic association between invertebrate animals and sulfur-oxidizing bacteria that characterizes the hydrothermal vent fauna, a photosynthesis-independent ecosystem. Fossil evidences indicate that such types of symbiotrophies have appeared early in the evolutionary history of invertebrate animals.

Finally, endosymbioses play also a key role in the evolution, resulting a way to create evolutionary novelties. For example, the terrestrial ecosystems dominated by the land plants from the Early Paleozoic, more than 400 mya, have originated from a lineage of green algae that acquired the ability to colonize the mainland by forming symbiosis with fungi of the order Glomales. In addition, the intracellular endosymbiosis has played a more important role in the evolution of life on the Earth, being at the origin of the eukaryotic cell and some of its organelles.

ENHANCED DETECTION OF AIRBORNE MICROBIAL CONTAMINANTS

LINDA D. STETZENBACH
University of Nevada, Las Vegas
Las Vegas, Nevada

Numerous methodologies currently are available for the detection of airborne microorganisms. Traditional detection of airborne microorganisms and microbial by-products is performed using microscopy and culture techniques (1). Microscopy generally is used to detect total microbial populations in a given sample without regard to the physiological state of the organism; both viable and nonviable organisms can be observed. Culture-based assay is limited to measurement of those organisms that proliferate under the growth conditions provided in the laboratory. Organisms that are difficult to culture because of nutrient (e.g., xerophilic fungi such as *Wallemia* spp. and *Eurotium* spp.) or temperature (e.g., thermophiles such as *Aspergillus fumigatus* and *Mycopolyspora faeni*) requirements often are not isolated. Identification of fungi to the species level based on culture and subsequent microscopy is highly subjective and difficult to perform. Direct counting methods for fungal monitoring that rely on classical microscopic features for identification cannot distinguish between the spores of some fungal genera (e.g., *Aspergillus* and *Penicillium*) or between species. Generally, the traditional detection methods of culture and microscopy are tedious and time-consuming, and generally have low sensitivity and specificity. Culture and microscopic assays also are inherently subjective making intralaboratory comparisons difficult.

Methods for enhanced detection of airborne microorganisms and by-products using bioassay, immunoassay, analytical instrumentation, and biotechnology-based technologies have been developed that increase the sensitivity and specificity of identification and reduce processing time. Traditionally, biochemical assays have been used in the microbiology laboratory to identify culturable organisms based on substrate utilization. Recently, biological and biochemical assays have been developed to detect the presence of microbial toxins and indicators of microbial biomass without the need for culture. Immunoassays involve antigen-antibody recognition between a surface antigen on the microorganism and a laboratory-prepared antibody. The use of analytical chemistry instrumentation to detect biological components in a sample and that of biotechnology-based assay methods for the detection of genetic elements unique to the microorganisms of interest are rapidly developing technologies. Categories of these detection technologies that are potentially applicable to monitoring of airborne microbial contaminants (Table 1) are discussed in the following sections, although use of the following techniques for bioaerosol detection to date has been limited.

BIOASSAYS

The limulus amebocyte lysate assay (LAL) is an in vitro biological assay used to detect endotoxin, the lipopolysaccharide in the outer membrane of gram-negative bacteria (2). The chemically distinct lipid A fraction of the lipopolysaccharide of the molecule is the toxigenic component. The 3-hydroxy fatty acids of the lipid A fraction are used as chemical markers for endotoxin in air and water samples (3). Underreporting of cell-bound endotoxin using LAL methods has been minimized by sonication of the samples, optimization of processing buffer, and extraction of samples (4,5). Commercially available kits for LAL assay are available and approved for use in the pharmaceutical industry, but they were not designed

Table 1. Listing of Selected Traditional and Enhanced Detection Technologies Applicable to Bioaerosol Monitoring

Method		Principle	Advantages	Disadvantages and Interferences
		Traditional Methods		
Culture		Growth of culturable organisms on selected media and temperatures	Simultaneous assay of many contaminants, inexpensive	Organism of interest may require special growth conditions; overcrowding on agar surface; inhibition by other organisms
Microscopy		Morphology	Rapid	Subjective; debris may obscure viewing
		Enhanced Methods		
Bioassay	LAL	Measurement of LPS as indicator of microbial presence	Used to measure endotoxin and glucans without requirement of culture	Specificity; underreporting of cell-bound endotoxin
	FISH	Fluorescent in situ hybridization and measurement of light scatter	Detection of bacterial cells	Currently high detection limits
	GC-MS-MS	Analytical instrumentation to detect muramic acid; 3-OH fatty acids; endotoxin; biopolymers	Measurement of endotoxin and glucans without requirement of culture	Reference library and fingerprints needed for identification
Biotechnology-based	PCR	Amplification of specific, unique gene sequences	Increased specificity and sensitivity	Requirement for known unique sequences; Inhibition by other nucleic acids and abiotic substances
	Microchip PCR	PCR on microscale	Decreased PCR analysis time and reagents	Currently higher detection limits than PCR; inhibition by other nucleic acids and abiotic substances
	Molecular beacons	Detection of nucleic acid	Specificity	Inhibition by other nucleic acids and abiotic substances

for use in aerobiological investigations (3). Some of the problems with use of LAL for environmental samples are because of inconsistency among the lysate preparations and storage of the samples before analysis (3). The kinetic limulus assay with resistant-parallel-line estimation (KLARE) method was developed as a kinetic LAL assay with regression analysis to measure endotoxin in environmental samples (6). The improvement in detection using the KLARE method included an ability to correct for the presence of interfering substances.

The LAL assay also has been used to detect β-(1 $\rightarrow$ 3)-D-glucans, glucose polymers that are structural components of fungal cell walls (7). Glucans have been associated with sensory irritation (7) and the inflammation-regulating capacity of airway macrophages (3). A LAL assay has been used to detect airborne β-(1 $\rightarrow$ 3)-D-glucans (7) and this assay method may be the most sensitive of the currently available methods for glucan. However, the LAL does not differentiate between β-(1 $\rightarrow$ 3)-D-glucans and β-(1 $\rightarrow$ 6)-D-glucans (8).

IMMUNOASSAYS

Enzyme Immunoassay

Enhanced detection of microbial components using immunoassays relies on the specific interaction of antigens with their respective antibodies. The enzyme-linked immunosorbent assay (ELISA) uses an enzyme to signal the presence of an antigen or antibody reaction. ELISA has been adapted to detect antigenic sites of environmental contaminants in house dust and air samples (9,10). ELISA also has been used to assay for Alternaria antigens Alt a I and GP70 using impingement air samplers (11). An inhibition enzyme immunoassay (EIA) has been developed for the detection and quantification of fungal cell wall β-(1 $\rightarrow$ 3)-D-glucans in indoor environments with a lower limit of detection in air and dust samples reported as 0.2 $\mu g/m^3$ and 0.3 $\mu g/m^3$ of air, respectively (8). The EIA also was performed on inhalable dust collected with glass fiber filters and settled dust collected with paper filters. The samples were heat-extracted and then stored at $-20\,^{\circ}C$ until analyzed in a microtiter plate format.

Electrochemiluminescence

An integration of equilibrium immunoassay with electrochemiluminescense involves a biotinylated antibody sandwich for detection of allergens. A labeled *N*-hydroxysuccinimide ester of a ruthenium (II) trisbipyridine chelate and streptavidin-coated paramagnetic beads capture the antibody-antigen-antibody sandwich complex. Detection ranges from 2.5 ng/ml to 2,000 ng/ml have been reported (12). This methodology has application for bioaerosol monitoring of allergenic constituents of microbial contaminants.

Biosensors

Detection using immunoassay in conjunction with a sensor membrane has been developed for the detection of bacteria by the food industry, medicine, biotechnology, and environmental microbiology (13). These biosensors also have been used to detect staphylococcal enterotoxin B, a matter of concern to biological warfare (14), although current detection limits are relatively high (3.0×10^5 to 6.2×10^7 cells/ml). The incorporation of a 20-MHz piezoelectric quartz crystal sensor in a flow injection system with a polyclonal antibody detected 0.1 ug/ml of staphylococcal enterotoxin B. However, inhibition was noted at concentrations greater than equal to 10 ug/ml (14).

ANALYTICAL INSTRUMENTATION ASSAYS

Mass Spectrophotometry

Gas chromatography-ion trap tandem mass spectrometry (GC-MS-MS) and conventional quadrupole GC-MS have been used to detect indicators of the presence of microbial contamination (15) and endotoxin (3). However, the GC-MS procedure for detection of endotoxin's 3-hydroxy fatty acids is approximately 1,000-fold less sensitive than the LAL assay (3). Monitoring of airborne bacteria in a stable and a dairy environment has been performed using GC-MS-MS (16). Airborne dust samples were collected with Teflon filters and analyzed for muramic acid and 3-hydroxy fatty acids as indicators of peptidoglycan in gram-positive and gram-negative bacterial cells, and endotoxin from bacterial lipopolysaccharide in gram-negative cells, respectively. Matrix-assisted laser desorption ionization (MALDI) mass spectrometry can identify gene sequences that are not readable using gel electrophoresis (17). It also has been used for the detection of quasimolecular ions of large organic molecules (up to several hundred kDa molecular mass) such as biopolymers (peptides, proteins, oligosaccharides, and nucleotides in the subpicomolar range) with an accuracy of 0.1 to 0.01% (18).

Flow Cytometery

Flow cytometry (FCM) uses simultaneous measurements of light scatter to determine cell size and structure. Incorporation of fluorescence increases the capabilities to include quantitation of cellular components, antigen detection, and estimations of cell physiology (19). Instrumentation permits the measurement of 500–5,000 objects/sec; the results are displayed in bivariate histograms. Indirect quantitation of cells is conducted using the addition of fluorescent polystyrene beads.

Staining techniques used with FCM include the use of fluorescent brighteners. An ultraviolet-excited fluorescent whitening agent (Tinopal CBS-X) with ethanol has been used as a stain for both vegetative cells and endospores in the presence of high biological background (20). FCM analysis with nucleic acid staining [e.g., 4′,6-diamidino-2 phenylindole (DAPI)] permitted the discrimination of *Pseudomonas aeruginosa* from debris and beads, and comparison with other methods of analysis (21). When comparing FCM with culture and microscopy for air samples with impingement sampling in a barn, the culture method underestimated concentrations by 2 orders of magnitude (21). The combination of FCM and fluorescent in situ hybridization (FISH) has been reported for log-phase cultures of *Escherichia coli* and *P. aeruginosa* aerosolized in exposure chambers and collected with an impingement sampling method (21). FISH also was used to detect bacteria in air samples collected in a barn. Although the FISH assay technique was reliable with the exposure chamber aerosols, difficulties were noted with the complex agricultural dust samples. Improvements to increase the permeability of the staining, to increase the sensitivity to detect cells at various stages of growth, and to enhance the detection of contaminants at lower concentrations (e.g., 10^2 cells/m^3) are in development. Advancement in detector design also will broaden the use of this technology for bioaerosol monitoring.

Immunomagnetic separation with fluorescent antibody-labeled beads and FCM is also used to detect microbial contaminants (22). This methodology has shown a detection of less than 10^3 colony-forming units for pure culture suspensions and 10^3 to 10^4 colonies of *E. coli*/ml in a mixed suspension with a one hour analysis time. Analysis can be completed in two hours and only a single antibody is required, but detection limits can be high (10^5 cells/ml) (23).

BIOTECHNOLOGY-BASED ASSAYS

Polymerase Chain Reaction Amplification

Polymerase chain reaction (PCR) amplification is an in vitro enzymatic reaction that uses amplification of specific DNA sequences for identification of a specific microorganism or group of organisms (24,25). The repetitive cycles of amplification in which specific gene sequences are copied increases the amount of DNA in the sample so that it can be detected. This technology is not dependent on the physiological state of the organism and therefore can be used to detect viable (culturable) and nonviable (nonculturable) organisms. However, the gene sequences specific to the targeted contaminant must be known. Although PCR has been used successfully to enhance the detection of microorganisms in other matrices such as clinical samples (26), food (27), water (28–30), and soil (31,32), the use of this method for monitoring airborne microorganisms is a more recent concept (33). PCR was shown to offer an increase in sensitivity over traditional culture methods for airborne bacteria (34–36) and viruses (37), and it is

possible to obtain results from air samples within hours of sample collection using PCR, compared with days or weeks for culture (35). PCR will also be useful when monitoring for airborne microbial contaminants that are difficult to culture such as *Mycobacterium tuberculosis* (38) and *Stachybotrys chartarum*.

Standard PCR involves the use of two unique primers to produce a single-amplification DNA product. To increase sensitivity when low concentrations of organisms are present in the sample, some investigators attempt reamplification (40) or the use of nested primers (41,42). Reamplification involves reassay of negative-amplification products with fresh reaction mixtures in an attempt to improve exponential amplification. When a PCR sample is amplified a second time using an inner primer set, the assay is termed *nested*. Amplification of a 208-bp fragment within a 1,247-bp product using nested PCR resulted in detection of a single plasmid copy per PCR and two *Bacillus anthracis* spores per PCR rather than the 10^3 plasmid copies and 10^4 spores detected using a standard PCR (41). Nested PCR also has been useful in detecting *B. anthracis* in tissue samples to discriminate the source of exposure (43). Multiplex PCR can be used to detect multiple contaminants by using several sets of primers to yield multiple amplification products (24). Tracking the release of fermentation products from biotechnology facilities or agricultural spraying of microbial pest control agents are potential uses for multiplex PCR in monitoring bioaerosols. Subtractive hybridization to remove homologous sequences of different strains so that unique sequences can be detected has been shown to improve PCR detection in samples containing mixed populations of similar organisms (44,45). This technique may improve the specificity of bioaerosol monitoring when a particular species within a genus is of interest. Reverse transcriptase (RT) PCR is used to detect RNA by generating a cDNA copy of the nucleic acids in a single-stranded RNA during the first cycle. The cDNA is used as the template for successive PCR cycles. RT-PCR has been shown to detect rapidly 1–10 virus particles (46).

Difficulties with the use of PCR for detection of airborne microbial contaminants includes the lack of known unique gene sequences for the organisms of interest. Selection of candidate gene sequences and the determination of likely PCR primer and probe locations using computer software have been developed. The sensitivity of the primers and probes then must be determined and the specificity tested using standard strains in laboratory experiments.

Liquid impingement and filtration sampling have been suggested for collection of air samples to be analyzed using PCR (47). Several commercially available impingement samplers and filtration devices have been used for bioaerosol collection (1), and these methods are discussed in the chapter on sampling for airborne microorganisms.

As with other environmental samples, an efficient yet simple nucleic acid extraction and purification procedure is needed before PCR can be performed on air samples. An optimized extraction and purification method will maximize yield and minimize processing time. A variety of techniques for DNA extraction have been developed, including hot detergent treatment, freeze-thaw, and bead mill homogenization. These methods have been used to detect and enumerate a variety of microorganisms including Varicella-Zoster virus (37), endospore-forming bacilli (48,49), vegetative bacterial cells (34,49), and fungal conidia (39,49–51). Six DNA-extraction methods for *Aspergillus fumigatus*, an important airborne fungal contaminant, were evaluated recently for samples from the mycelial mat of liquid fungal cultures with the highest genomic DNA yields obtained using glass bead pulverization with vortexing (52).

Detection limits using PCR for analysis of bioaerosols are affected by the physical condition and the concentration of the target DNA, and the presence and concentrations of background DNA in the reaction mixture. The presence of other airborne particles can interfere with successful detection using PCR amplification. Alvarez and coworkers (35) demonstrated interference in detection of *E. coli* with background airborne gram-negative bacilli concentrations of 10^4 CFU m^{-3}. Dilution of the sample resulted in successful amplification by diluting out the inhibitors but this procedure raises the lower limits of detection. Pretreatment of samples may be necessary to minimize interferences from biotic and abiotic material in the sample matrix and to improve detection limits. The separation of bacterial cells from PCR inhibitors by buoyant density centrifugation was tested with two vegetative gram-negative bacteria, *Shigella flexneri* and *Yersinia enterocolitica*, in food products, resulting in a detection limit of 10^4/g of blue cheese and 500/ml of milk (53), and this method may prove useful for preprocessing of air samples. Buoyant density centrifugation is performed with the sample containing target cells layered on top of Percoll media and subjected to centrifugation. Target cells are harvested from below the lighter Percoll layer while the PCR inhibitors remain in the upper layer. Sample purification using Sephadex or Chelex columns removes environmental inhibitors, and commercial kits are available. Additionally, purification of the DNA following extraction can be used to minimize interferences.

Although not yet reported for detection of bioaerosols, increasing the number of PCR samples by processing with a 864-well microwell plate has been reported. High-throughput PCR has demonstrated in 30 nine-minute cycles the analysis of more than 3,000 samples in less than 4.5 hours with simultaneous target amplification (54).

PCR does not provide information as to the viability or infectivity of the microbial contaminant. The addition of an enrichment step in sample processing can assist in discriminating infectivity of the microbial contaminant (55) or in analyzing for mRNA (24). Messenger RNA is produced before protein synthesis and has a half-life of only a few minutes. Therefore, mRNA can be used in sample analysis to estimate metabolic activity. However, mRNA is not specific to a single organism. Therefore the use of this technique for monitoring airborne viable organisms in clean–room-type environments (e.g., pharmaceutical and medical facilities) may be useful, but that in environments with mixed bioaerosol populations would be problematic.

The incubation of a sample with the appropriate host cells before extraction also can be used to establish the infectivity of viral contaminants. Integrated cell culture PCR (ICC-PCR) methodology differs from conventional PCR in that only viruses that have attached to host cells (the first step for viral infectivity) are amplified and detected, and inhibition by contaminant substances (e.g., humic acids, protease and transcriptase inhibitors) that may be present in environmental samples is minimized. Although ICC-PCR methodology has been used for detection of microbial contaminants in water (56), the application of ICC-PCR to bioaerosols has not been reported.

Until recently, post-PCR manipulation was required to detect the presence of amplified sequences, often by gel electrophoresis. The authenticity of the amplified DNA was confirmed by sequencing, restriction analysis, or nucleic acid hybridization using an oligonucleotide probe complementary to a specific internal DNA sequence within the product. Newly developed techniques have eliminated post-PCR processing with the incorporation of specific fluorescent-labeled probes that indicate amplification. The use of fluorescence correlation spectroscopy with PCR in microtiter plates combines reagents for amplification and detection in a single tube or well (57). Double-stranded target DNA is detected by two amplification primers that are 5′-tagged with two different fluorophores, resulting in a detection limit of 10–25 initial copy numbers of template. The ABI Prism 7700 Sequence Detection System (Perkin Elmer, Applied Biosystems, Foster City, California) uses TaqMan™ technology and incorporates a fluorogenic probe and the TaqMan™ PCR reagent kit (Perkin Elmer) with a 96-well microtiter format. The release of an internal fluorescent probe (cleaved during amplification) to indicate amplification provides rapid detection and quantitation of target gene sequences. The system has demonstrated reliability over several orders of magnitude and provides quantitation without the exhaustive and elaborate experimental manipulation previously described for quantitative PCR (58). Quantitative measurement of spores of a toxigenic fungus *Stachybotrys chartarum* from culture stocks (50,51) and air samples (51) has been reported using TaqMan™ technology. These investigators used reference sequences of a yeast to normalize the data for accuracy and precision of DNA extraction.

Combining PCR with immunological techniques has resulted in a rapid and efficient solution-phase hybridization of labeled targets and biotinylated capture probes. Target-probe hybrids containing biotin are captured onto streptavidin-coated microwells while other PCR components are washed away. This chemiluminescent microtiter PCR methodology uses digoxigenin-labeled amplified target detected by anti-digoxigenin-alkaline phosphatase conjugates and a chemiluminescent substrate. Although this method has not been used for bioaerosol detection, results were reported in two hours with a detection limit of 10 targets (59).

Additional PCR formats include the use of surface plasmon resonance to measure secondary structure of amplified DNA following asymmetric PCR (60) and the addition of peptide nucleic acid applied to the DNA probe with surface plasmon resonance (61). The use of rapid thermal cycling of microliter volumes inside capillary tubes containing indium-tin oxide offers additional decrease in analysis time and greater control over PCR temperature cycling (62).

Microchip-Based PCR

Integrating microchip technology and PCR can decrease the analysis time required for detection of microbial contaminants. A microchip PCR array with 10 silicon reaction chambers, thin-film heaters, and solid-state optics has been developed that provides real-time monitoring with low power requirements and no moving parts (63). Detection of *Erwinea herbicola* (vegetative cells), *Bacillus subtilis* (endospores), and MS2 (RNA virus) with a detection limit of 10^2–10^4 organisms/ml within 16 minutes has been reported (63). The simultaneous analysis of several samples can be accomplished by hybridization of fluorescent-labeled DNA on a microchip. An array of oligonucleotide probes are immobilized into gel elements fixed on a glass plate. Analysis then is performed with a two-wavelength fluorescent microscope equipped with a charge-coupled camera (64). Micro-machined silicon high efficiency reaction chambers (miniature thermal cycling chamber, MATCI) with integrated heaters and simple electronics to control temperatures provide solid-state, diode-based detection for real-time fluorescence monitoring of product DNA. The MATCI, a briefcase-sized instrument with rechargeable batteries (65), has detected single base pair substitutions in orthopoxviruses (monkeypox, cowpox, camelpox, and vaccinia viruses), human genomic DNA, and viral DNA (66). Combining cell lysis, multiplex PCR amplification, and electrophoretic sizing on a monolithic microchip has resulted in the analysis of amplified products using a sieving medium for size separation and an intercalating dye for fluorescence detection. This electrophoretic analysis has resulted in data available in less than three minutes after PCR (67). A 4.5-μl silicon microchip containing a series of 3.5-μm "weir-type" filters spanning the flow chamber was developed to minimize interference by separating the target from the background (68).

Molecular Beacons

The technology of sample analysis using nucleic acid probes that spontaneously undergo a fluorogenic conformational change when they hybridize with target fluorescent probes has been termed *molecular beacons* (69). These beacons are specific because they fluoresce only in the presence of complementary target. The reactions are carried out in a sealed tube minimizing manipulation. Application of this methodology to monitoring of bioaerosols may provide a means to screen rapidly a large number of samples with minimal analysis time.

CONCLUSION

The detection of airborne microorganisms is a difficult task confounded by the heterogeneous and highly variable composition and concentration of bioaerosols. Except

in pharmaceutical clean room-type environments, the presence of airborne microorganisms is highly variable over time and space, often fluctuating over several orders of magnitude. Enhanced methods of analysis have been reported and additional technologies are being adapted or are in development. Bioassays, immunoassays, analytical instrumentation assays, and biotechnology-based methods do not depend on viability of the organism; so culturable and nonculturable microorganisms, and cellular fragments can be detected. These techniques also demonstrate improved accuracy and precision, and provide quantitative data. Another advantage to these methods is interlaboratory comparability because the data generated are objective rather than the subjective determinations. Detection and enumeration with enhanced methods will improve the monitoring of airborne biocontaminants in indoor and outdoor environments.

ENTAMOEBA HISTOLYTICA/ENTAMOEBA DISPAR

ANA MARIA P. DE MERIDA
BEATRIZ LOPEZ
MARICRUZ ALVAREZ DE MEJIA
ROBERT E. KLEIN
American Embassy/Guatemala
Miami, Florida

Entamoeba histolytica is one of six parasitic amebas of the genus *Entamoeba* that are known to infect humans. *Entamoeba histolytica*, a protozoan parasite, is the organism responsible for the disease defined as *amebiasis*; the other amebas (*Entamoeba coli*, *Entamoeba hartmani*, *Iodamoeba butchlii*, *Endolimax nana*, and *Entamoeba polecki*) are not human disease causing organisms. Amebiasis is one of the great parasitic diseases of human kind; it predominantly affects individuals of lower socioeconomic status who live in developing countries where contaminated food and water, crowding, and inadequate hygiene are associated with disease transmission. Currently, there is a good understanding of the biology of *E. histolytica* and the mechanisms that account for its virulence and pathogenicity. Vaccines for amebiasis or reliable chemoprophylaxis, however, are not available, and the diagnosis still rests on microscopy and physician acumen in developing countries, where the disease is endemic.

HISTORY

The organism known as *E. histolytica* was first described 125 years ago by Losh (1) who named it *Amoeba coli*. Schaudinn (2) did not formally name the organism itself until 1903. After that, the taxonomy of the parasite became confused with several organisms that were morphologically similar to each other and are nonpathogenic parasites of the human intestine. These nonpathogenic organisms, as well as *E. histolytica*/*E. dispar*, have each different morphological characteristics. Differences are found in the structure of the cytoplasm, types of inclusions, motility, and size. According to the species, the nuclear peripheral chromatin is distributed in a different way or it may be absent, the karyosome may be central or eccentric and may vary in size. The morphology of the mature cyst and the number of nuclei are characteristic of the species (Tables 1 and 2). These differences can be detected if the organisms are stained, but in wet preparations, the organisms can be confused with one another.

The simple life cycle (Fig. 1) of parasitic amebas is identical in all species. The presence of nonpathogenic amebas in feces of humans is indicative of the subject having ingested contaminated foods.

In 1919, Dobell (1) published the monograph *The Ameba Living in Man*, in which he concluded that there was only one species of *Entamoeba* that produced cysts with four nuclei and the name *E. histolytica* was retained. In 1925, Brumpt (3) described *E. dispar* as an organism identical to *E. histolytica* but never causing disease in the host. Brumpt (3) based his argument on an eight-year follow-up of a patient who never developed symptoms, and on epidemiological surveys. These surveys revealed significant infection rates with what appeared to be *E. histolytica* in countries where invasive disease was almost unknown. He concluded that most infections in temperate countries were due to a distinct species, not easily differentiable from *E. histolytica*, which he named *E. dispar*. Brumpt's theory (3) was not accepted at the time, in part, because of evidence for the existence of asymptomatic carriers of ameba that were capable of causing invasive disease in others and also because these organisms could not be differentiated with the light microscope.

The name *E. dispar* disappeared from the literature for more than 50 years until 1978, when it was revealed that *E. histolytica* could be divided into two groups using isoenzyme electrophoresis. This evidence was supported by studies in several thousand isolates from all over the world and followed by a number of studies using molecular and immunological techniques (4–8). A well-documented article was published stating that *E. histolytica* was a complex of species (9), and subsequently differences between the two groups were confirmed (10). By 1993, Diamond and Clark (11) redescribed the two groups of

Table 2. Differential Morphology of Protozoa Found in Stool Specimens of Humans: Amebae-Trophozoites

Species	Size (Length)	Motility	Nucleus			Cytoplasm	
			Number	Peripheral Chromatin	Karyosomal Chromatin	Appearance	Inclusions
Entamoeba histolytica	10–60 μm Usual range, 15–20 μm commensal form[1] More than 20-μm invasive form[2]	Progressive with hyaline, finger-like pseudopods	1 Not visible in unstained preparations	Fine granules Usually evenly distributed and uniform in size	Small, discrete Usually centrally located, but occasionally is eccentric	Finely granular	Red blood cells occasionally Noninvasive organisms may contain bacteria
Entamoeba Hartmani	5–12 μm Usual range, 8–10 μm	Usually nonprogressive but may be progressive occasionally	1 Not visible in unstained preparations	Similar to *E. histolytica*	Small, discrete, often eccentric	Finely granular	Bacteria
Entamoeba coli	15–50 μm Usual range, 20–25 μm	Sluggish, nonprogressives, with blunt pseudopods	1 Often visible in unstained preparations	Coarse granules, irregular in size and distribution	Large, discrete, usually eccentric	Coarse, often vacuolated	Bacteria, yeasts, other materials
Entamoeba polecki	10–25 μm Usual range, 15–20 μm	Usually sluggish, similar to *E. coli* Occasionally, in diarrheic specimens, motility may be progressive	1 May be slightly visible in unstained preparations Occasionally may be irregularly distorted by pressure from vacuoles in cytoplasm	Usually fine granules evenly distributed Occasionally granules may be irregularly arranged Chromatin sometimes in plaques or crescents	Small, discrete, eccentric Occasionally large, diffuse, or irregular	Coarsely, granular, may resemble *E. coli* Contains numerous vacuoles	Bacteria, yeasts

Table 2. (*Continued*)

Species	Size (Length)	Motility	Nucleus			Cytoplasm	
			Number	Peripheral Chromatin	Karyosomal Chromatin	Appearance	Inclusions
Endolimax nana	6–12 μm Usual range, 8–10 μm	Sluggish, usually nonprogressive with blunt pseudopods	1 Visible occasionally in unstained preparations	None	Large, irregularly shaped, blotlike	Granular, vacuolated	Bacteria
	8–20 μm Usual range, 12–15 μm	Sluggish, usually nonprogressive	1 Not usually visible in unstained preparations	None	Large, usually central Surrounded by refractile, achromatic granules These granules are often not distinct even in stained slides	Coarsely granular, vacuolated	Bacteria, yeasts, or other material
Dientamoeba fragilis[3]	5–15 μm Usual range, 9–12 μm	Pseudopods are angular, serrated, or broad lobed, and hyaline, almost transparent	2 (In approximately 20% of organisms only 1 nucleus is present) Nuclei invisible in unstained preparations	None	Large cluster of 4–8 granules	Finely, granular	Bacteria: occasionally red blood cells

[1]Commensal form — usually found in asymptomatic or chronic cases; may contain bacteria.
[2]Invasive form — usually found in acute cases: often remain red blood cells.
[3]Flagellate — included with amebae for diagnostic purposes.

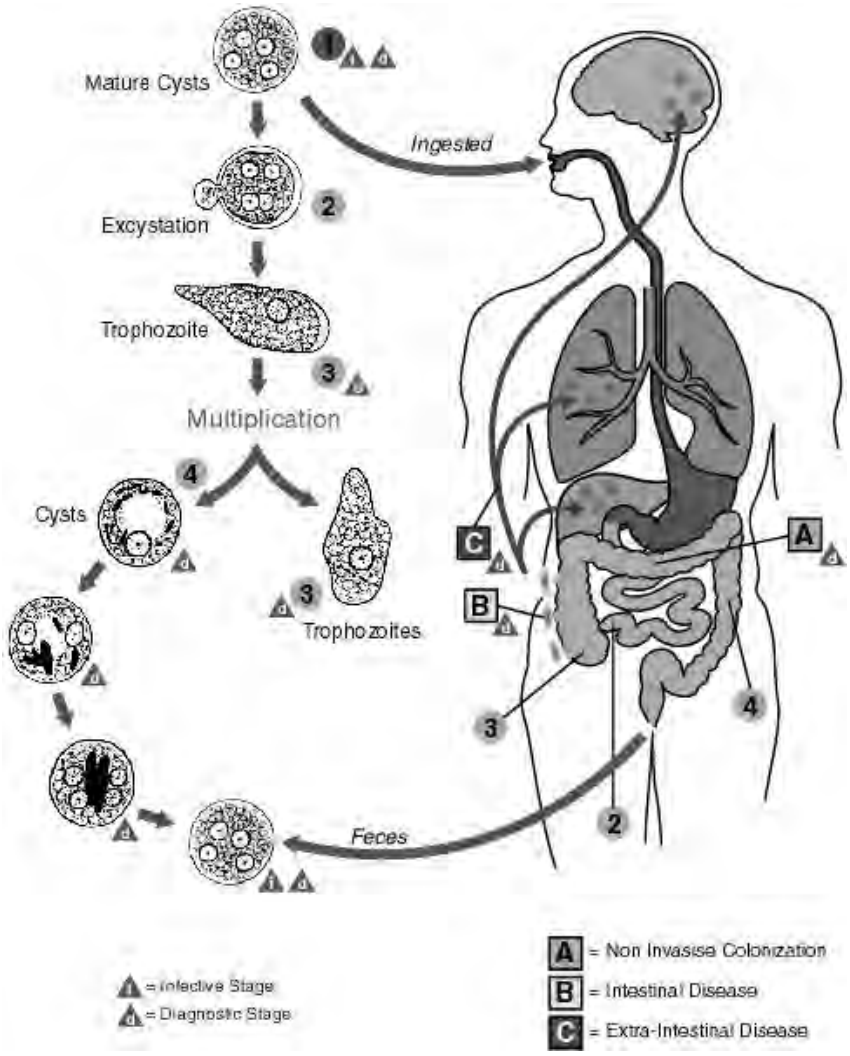

Figure 1. Life cycle of *Entamoeba histolytica*/*E. dispar*. *Source*: DPDX, the CDC web site for parasitology diagnosis. *www.cdc.gov/dpdx*. See color insert.

E. histolytica, the pathogenic and the nonpathogenic, as two different species, *E. histolytica* and *E. dispar*.

The two species present immunological differences like a 96-kDa antigen is present in pathogenic (P) strains and is absent in nonpathogenic (NP) isolates, a 30-kDa surface antigen is absent in NP isolates, a monoclonal antibody against electron-dense granules (EDG) was absent in NP isolates, finally, a monoclonal antibody detecting a 81/84 intracellular antigen was not present in NP isolates (11). Among the genetic evidence between the two species is selective hybridization of two DNA probes; cDNA encoding the 29-kDa antigen isolated from P and NP isolates showed a 4.5% difference between the two, differences in structure and expression of cysteine proteinase genes was found between P and NP isolates, the genomic organization of the actin genes appears to differ between the two forms (11).

In 1997, a World Health Organization (WHO) expert committee met in Mexico to consider the status of *E. histolytica*/*E. dispar* nomenclature, and officially recognized the existence of the two species. The growing list of differences between the two species, identical in morphology, include differences in every gene sequence examined (12–16) and differences in the cell surface scanned with light and electron microscopy (17–19). The acceptance of *E. dispar* and comparisons between the two species may provide insight into why *E. histolytica* is pathogenic (20).

LIFE CYCLE

The life cycle of *E. histolytica*/*E. dispar* was described extensively (1) and includes the description of the different stages of the parasite; trophozoite, precyst, and cyst.

Trophozoite

Trophozoites vary from 10 to 60 μm in diameter (usual range 20–30) depending on the environmental conditions. Motility and pseudopod formation is rapid and unidirectional, rarely occurring in a straight line. In wet preparations, the trophozoites have hyaline pseudopods that are fingerlike. The ectoplasm is clear and the endoplasm is finely granular and may contain bacteria and/or erythrocytes in various stages of digestion. In stained slides, the trophozoite nucleus is spherical, comprises one fifth of the trophozoite, and is difficult to see in wet preparations. The peripheral chromatin with fine granules is

usually evenly distributed in the nucleus wall. It contains a small and compact karyosome located near the center.

Precyst

In the precyst stage, the trophozoite becomes approximately the same size as the cyst. The cytoplasm is cleared of food inclusions, and occasional chromatoid bodies are present. The precystic form is uninucleated, and the enlarged nucleus contains a karyosome that is more or less central.

Cyst

A cell wall develops around the precystic form. There may be two types of inclusions within this immature cyst: a glycogen mass and highly refractile chromatoidal bars with smooth rounded edges (other species have chromatoidal bars with brushlike edges). As the cyst matures, there is nuclear division with the production of four nuclei to become the mature formed cyst. As the cyst matures, glycogen and chromatoidal material disappear. On stained slides cyst size ranges from 8.5 to 19 μm in diameter (usual range 11–14). Because of dehydration in the process of staining, cyst size may be 1 to 1.5 micrometers smaller. The mature cysts are usually spherical and contain four nuclei. The immature cysts contain one or two nuclei. The nuclear membrane is uniformly lined with peripheral chromatin. The karyosome is small, compact, and is usually located within the nucleus at the center. Cyst formation occurs only within the intestinal tract; once the stool has left the body, cyst formation does not occur. The one, two, and four nucleated cysts are infective and represent the mode of transmission from one host to another (21)

The life cycle is described in Figure 1. The infection with *E. histolytica*/*E. dispar* occurs following ingestion of a mature cyst in fecally contaminated food or water. The excystation occurs in the small intestine and trophozoites are released to migrate to the large intestine. During the process of excystation, the encysted ameba become very active, separating from the cyst wall. The ameba escapes from the cyst wall through a tiny pore and the nuclei clump together. Outside the cyst, the nuclei begin to separate from the cytoplasm and undergo division to form eight uninucleate metacystic trophozoites that continue to feed and grow, and produce cysts that are passed in the feces.

Entamoeba histolytica inhabits primarily the large intestine, where the trophozoites, or active forms, live in the intestinal lumen and on occasion may invade the mucosal crypts, where they feed upon red blood cells and form ulcers, and this gives rise to symptomatic infection with tissue invasion. The exact form of invasion is not known, but it has been suggested that amebae have enzymes that lyse host tissue, possibly from lysosomes on the surface of the ameba or from ruptured organisms. Ulceration of the intestinal wall may give rise to amebic dysentery. The majority of human infections are usually asymptomatic. Such individuals will have a negative or weak serologic response and negative stools for occult blood. They will primarily pass cysts in their stool, but if trophozoites are found, they will not show erythrocytes ingested. Isoenzyme analysis of organisms isolated from asymptomatic individuals, generally indicate that the isolates belong to nonpathogenic zymodemes (22). Asymptomatic patients infected with *E. histolytica*/*E. dispar* never become symptomatic (11). About 10% of the individuals infected have clinical symptoms presenting abdominal pain, and may eventually present dysentery. The incubation period varies from a few days to up to several months. Symptoms of amebic dysentery include diarrhea with cramping, lower abdominal pain, low-grade fever, and the presence of blood and mucus in stool. The ulcers produced by intestinal invasion of trophozoites start as superficial localized lesions that deepen into the classic flask-shaped ulcers of amebic colitis. The ulcers are separated by segments of normal tissue but can coalesce. Ameba may be found at the advancing edges of the ulcer usually not in the necrotic areas. Abdominal perforation and peritonitis are rare, but are serious complications. A more chronic presentation occurs with amebic colitis. It is characterized by intermittent diarrhea over a long period of time and can be misdiagnosed as ulcerative colitis or irritable bowel syndrome. Ameboma, a localized tumor like lesion, results from chronic ulceration and may be mistaken for malignancy. Histologically, it consists of granulomatous tissue. The ameba may find their way into capillaries, to be transported via the blood stream to the liver and other organs where abscess formation may occur. It can occur with or without previous symptomatic intestinal infection. The liver is the most common site of extraintestinal disease, followed by the lungs, pericardium, brain, and other organs. Symptoms can be acute or gradual and may include low-grade fever, right upper quadrant pain, and weight loss. Up to 5% of individuals with intestinal symptoms develop liver abscess. However, up to 50% of individuals with liver abscess have no previous history of gastrointestinal disease (22) Although the proportion of individuals infected with *E. histolytica*/*E. dispar* is small in terms of morbidity and mortality, the disease represents a major public health problem in Third World countries, where the disease is endemic.

EPIDEMIOLOGY

Entamoeba histolytica infections are well known worldwide, especially in developing countries where disease incidence is high. In 1913 (23), Walker and Sellard in their controlled experiments in the Philippines, noted that: (*1*) transmission was accomplished by cysts not trophozoites, (*2*) asymptomatic carriers were often possible reservoirs and responsible for transmission, (*3*) there are differences in the risk of infection among individuals, and (*4*) there are differences in the virulence of the strains. The acceptance of the existence of two morphologically identical species has profound implications for understanding the complex epidemiology of this parasite.

Infections by *E. histolytica*/*E. dispar* are worldwide, but are more prevalent in the tropics. It is estimated that 480 million people or 12% of the world population are infected and that the annual mortality is 40,000 to 110,000

persons (24). High rates of infection occur in the Indian subcontinent, in Southern and Western Africa, in the Far East, and in areas of South and Central America. The prevalence of the infection is related to cultural habits, age (higher among school children), level of sanitation, crowding, and socioeconomic status (25). High-risk groups include people who travel constantly, such as immigrants, and working immigrants, immunocompromised individuals, individuals in mental institutions, and homosexual men in North America (26). It is of special interest that very little invasive disease is found in patients with AIDS. The majority of strains isolated from patients positive for the immunodeficiency virus, analyzed with isoenzyme patterns, are nonpathogenic (27). Prevalence of infection varies from one area to another, as does severity of the illness from one patient to another (28). Differences in prevalence, however, are also associated with detection methods and the number of samples examined. An important limitation in epidemiological studies is that many surveys use nonrepresentative samples of the population in question (24). Approximately 10% of the people infected each year have symptoms (24). Of the 48 million with clinical symptoms, 80 to 90% have symptoms related to the intestinal mucosa (diarrhea or dysentery); however, from 2 to 20% of the population have clinical symptoms, associated with invasion through the intestinal mucosa (24).

Humans are the only reservoir of *E. histolytica*/*E. dispar* infection. Ingestion of food or drink contaminated with cysts from stool and direct oral-fecal contact are the most common ways of acquiring the infection. Transmission of *E. histolytica* by contaminated water is common in developing countries, where drinking water is not treated (24). The use of human excreta as fertilizer is also an important source of infection. Only cysts are infective, and transmission is principally from asymptomatic carriers. Depending on the environmental conditions, cysts may remain viable up to three months, in the water; however, viable cysts can be destroyed by hyperchlorination or iodization (26).

TRANSMISSION

The infective form of *E. histolytica*/*E. dispar* is the quadrinucleated mature cyst. Unlike trophozoites, cysts may remain viable for prolonged periods of time under different environmental conditions. They are resistant to gastric juice and digestive enzymes. Amebic cysts conserve their infective capacity in stools, in water and in the soil. They are resistant to chlorine in quantities normally used to purify water and thus, this procedure does not prevent epidemics caused by fecal contamination of drinking water. Cysts are very resistant to environmental conditions and can remain viable in the soil for eight days at 28 to 34 °C, 40 days at 2 to 6 °C, and 60 days at 0 °C. Cysts are destroyed by exposing them to iodine (200 ppm), 5 to 10% acetic acid, and temperatures more than 68 °C, and can be removed by filtration with sand (29).

Risk of infection is related to poor hygiene education and environmental sanitation, especially water distribution, elimination of excreta, food safety, crowding, and hygiene habits. It has been demonstrated that the frequency of cyst carriers is higher among individuals of low socioeconomic status (30). In Mexico, it was found that the frequency of cyst carriers was significantly higher in slum areas where illiteracy, the proportion of homes with dirt floors without purified drinking water or drainage was high (31). The duration of the carrier state is variable and can last from several months to two years. Carriers can heal spontaneously, which means they can stop shedding cysts in a few months (32) and they do not need to be treated.

Contamination of drinking water distribution systems with stools that contain viable cysts can cause serious epidemic outbreaks, not recorded in the literature (33), especially in developing countries where water distribution systems are deficient, and where water for human consumption is taken from rivers, wells, and other sources. Water from these sources as well as that used for irrigating crops, are frequently contaminated with fecal material (34). Contamination of food by this and other mechanisms such as unhygienic food handling and the use of feces as fertilizer are undoubtedly the main mechanisms of transmission in developing countries.

Not all individuals who ingest cysts will become carriers. This variation may be related to the size of the inoculum, characteristics of the strain of the parasite, the susceptibility of the individual, and environmental factors (33).

Because of limitations in the published literature, accurate generalizations on prevalence, incidence, morbidity, and mortality of amebiasis are difficult to make. Intestinal ameba is universal, but their geographic location marks the prevalence of the infection and the incidence of the disease. Probably the most complete information available from both serologic and stool surveys, comes from Mexico, where it is estimated that 5% of the population suffers a severe episode of invasive amebiasis annually (30).

Table 1 shows the percentage of people with diarrhea related to *E. histolytica* according to the WHO (35).

In summary, in 1981, approximately 480 million people carried this protozoan parasite in their intestinal tract, 36 million developed severe colitis, and at least 40,000 died. This infection deserves more attention and greater effort to develop control strategies, including research on better methods for prevention, diagnosis, and treatment (24).

DIAGNOSIS

The appropriate diagnosis for *E. histolytica* is accomplished by identifying the microorganisms in stools, biopsy material, liver aspirates for extraintestinal infection, and by some immunological tests. Identification of the organism can be done microscopically, but differentiation of *E. histolytica* and *E. dispar* requires other methods. The presence of red blood cells (RBC) in trophozoites found in stool samples and finding trophozoites in tissue is diagnostic of *E. histolytica* infection (36).

The collection of samples should be done in appropriate wide mouth containers, labeled with all the information about the patient, time of collection, date, and for stools,

consistency of the sample. Samples should be transported immediately to the laboratory and should be processed within half an hour after the stool is taken. Fresh samples are preferred in the laboratory to enable technicians to see moving organisms. If the sample is not processed immediately, it should be preserved in buffered formalin and polyvinyl alcohol PVA for concentration and staining respectively. It is recommended that at least three samples should be taken from the patient within 10 days, preferably every other day for a better recovery of the parasite (22,36–38).

Microscopic diagnosis should be done by trained personnel with knowledge of the morphological characteristics of the parasite (22,39) because it may be confused with white blood cells (40,41). The sample should be screened for both trophozoites and cysts in a wet mount. Permanent staining with trichrome or iron haematoxylin is mandatory to confirm diagnosis by observing morphological characteristics (22,37,39,42). Trophozoites and cysts should be differentiated from other nonpathogenic ameba (Tables 2 and 3). Biopsy specimens should be taken from the edge of ulcers. Periodic-acid-Schiff stains the parasite a magenta color, increasing the ease of detection in biopsies (43).

Microscopic techniques cannot differentiate between *E. histolytica* and *E. dispar*, other methods are needed to differentiate these species. Culture techniques have been used to cultivate the organisms and further differentiate pathogenic and nonpathogenic strains with isoenzyme electrophoresis (44). The strains were named *invasive* and *noninvasive* and three enzymes were used to differentiate them: glucose phosphate isomerase, phosphoglucomutase, and L-malate : NADP oxidoreductase (oxaloacetate decarboxylating), electrophoretic patterns were compared and analyzed by distance analysis (9). Further studies of this type and the use of an additional enzyme, hexokinase, have revealed differences, not only between strains of *E. histolytica*, but within the whole histolytica group (9,45).

Differentiation of species can be done using immunological and genetic methods. Antigen detection may be useful as a complement to microscopic diagnosis in detecting parasites and to distinguish between pathogenic and nonpathogenic strains. Antibody detection is most useful in patients with extraintestinal disease that is amebic liver abscess when organisms are not found in stool examinations. Because *E. dispar* is not pathogenic, it should not elicit a detectable antibody response and therefore patients with *E. dispar* will be negative in *E. histolytica* detection tests. Kits for antibody detection, including indirect hemagglutination (IHA), enzyme immunoassay (EIA), and immunodiffusion (ID) are commercially available in the U.S. (22,46).

The IHA was the standard for routine serodiagnosis of amebiasis for a long time. The IHA test detects antibodies specific for *E. histolytica* at titers of $>1:256$ in approximately 95% of the patients with extraintestinal amebiasis, 70% of patients with active intestinal infection, and 10% of asymptomatic persons who are passing of *E. histolytica* cysts. The EIA test has been found to be as sensitive and specific as the IHA and has now replaced the IHA in most laboratories. The immunodiffusion test is specific, but it is slightly less sensitive than the IHA and requires a minimum of 24 hours to obtain results, in contrast to two hours for the IHA and EIA tests (22,46).

Monoclonal antibodies to the galactose specific adherence lectin (GIAP) mediates amebic attachment to colonic mucins, epithelial cells, and host inflammatory cells, were screened to recognize epitopes specific to pathogenic and nonpathogenic strains (10,47). Epitope 1 and 2 Mabs bind to the lectins of both species, whereas epitope 3 to 6 Mabs recognize only the *E. histolytica* lectin. These monoclonal antibodies against GIAP of *E. histolytica* have been extensively tested (48–51). The first field test of a commercial antigen detection kit was reported in 1995 (52). Recent studies indicate improved specificity and sensitivity of fecal antigen assays. Atleast one commercial kit is available, which detects only pathogenic *E. histolytica* infections in stool, whereas several kits are available, which detect *E. histolytica* in stool but do not exclude *E. dispar* (CDC web site for parasitology diagnosis *www.cdc.gov/dpdx*).

GENITIVE EVIDENCE

Differentiation of the two species has been tested at the molecular level. DNA probes have been developed from the pathogenic and nonpathogenic strains (53,54). Amplification of the fragments differentiating the strains has been accomplished by designing specific primers for both *E. histolytica* and *E. dispar* (55,56). The primer construction was based on the pathogenic and nonpathogenic sequences of a small subunit of ribosomal RNA (rRNA) that revealed a genetic distance of 2.2% greater than that between humans and mice (5). Polymerase chain reaction (PCR) developed by Aguirre and coworkers (57), called the SHELA method uses DNA extracted directly from stool samples and allows extraction from trophozoites and cysts. PCR products are detected using a colorimetric method based on enzyme linked immunoabsorbent assay (ELISA) to read by spectrophotometry, or by eye. An improvement of the DNA extraction and changes in the primer design in the SHELA method has made it possible to analyze multiple primers within one day (58). Later in 1997 another PCR method that uses fresh stool samples concentrated in acetate-acetic acid-formalin (SAF) was developed and used digestion with proteinase K. A 0.88 kb sequence of multicopy 16S rRNA gene served as target for the amplification (59). Storage in SAF fixative before testing, resulted in decreased sensitivity after two days.

Several studies have evaluated and compared immunological and molecular methods of differentiation of the two species (60–62). The Techlab (Blacksburg, VA.) kit did not cross react with *E. dispar* antigens, but was 100 times less sensitive than PCR in detection and differentiation between the two species. The use of PCR in epidemiological studies is recommended (60). Others recommend the Techlab kit because they consider PCR too time-consuming, cumbersome, and expensive and therefore not suited for developing countries where the infection is endemic (61). Both, epidemiological studies and detection of extraintestinal amebiasis have been done at the molecular level (62–65).

Table 3. Differential Morphology of Protozoa Found in Stool Specimens of Humans: Amebae-Cysts

Species	Size (Diameter or Length)	Shape	Nucleus			Cytoplasm	
			Number	Peripheral Chromatin	Karyosomal Chromatin	Chromatoid Bodies	Glycogen
Entamoeba histolytica	10–20 μm Usual range, 12–15 μm	Usually spherical	4 in mature cyst Immature cysts with 1 or 2 occasionally seen	Peripheral chromatin present. Fine, uniform granules, evenly distributed	Small, discrete, usually centrally located	Present. Elongated bars with bluntly rounded ends	Usually diffuse. Concentrated mass often present in young cysts. Stains reddish brown with iodine
Entamoeba hartmanni	5–10 μm Usual range, 6–8 μm	Usually spherical.	4 in mature cyst Immature cysts with 1 or 2 often seen	Similar to *E. histolytica*	Similar to *E. histolytica*	Present. Elongated bars with bluntly rounded ends	Similar to *E. histolytica*
Entamoeba coli	10–35 μm Usual range, 15–25 μm	Usually spherical. Occasionally oval, triangular, or other shapes	8 in mature cyst Occasionally super-nucleated cysts with 16 or more are seen. Immature cysts with 2 or more occasionally seen	Peripheral chromatin present. Coarse granules irregular in size and distribution, but often appear more uniform than in trophozoites	Large, discrete, usually eccentric but occasionally centrally located	Present, but less frequently seen than in *E. histolytica*. Usually splinter-like with pointed ends	Usually diffuse, but, occasionally well defined mass in immature cysts. Stain reddish brown with iodine
Entamoeba polecki	9–18 μm Usual range, 11–15 μm	Spherical or oval	1 rarely 2. Occasionally visible in unstained preparations	Usually fine granules evenly distributed	Usually small and eccentric	Present. Many small bodies with angular or pointed ends, or few large ones. May be oval, rod-like, or irregular	Usually small, diffuse masses stain reddish brown with iodine. A dark area called an “inclusion mass” (possibly concentrated cytoplasm) is often also present. Mass does not stain with iodine

Table 3. (*Continued*)

Species	Size (Diameter or Length)	Shape	Nucleus			Cytoplasm	
			Number	Peripheral Chromatin	Karyosomal Chromatin	Chromatoid Bodies	Glycogen
Endolimax nana	5–10 μm Usual range, 6–8 μm	Spherical, ovoidal, or ellipsoidal	4 immature cysts Immature cysts with less than 4 rarely seen	None	Large (blotlike), usually central	Occasionally granules or small oval masses seen, but bodies as seen in *Entamoeba* spp. are not present	Usually diffuse Concentrated mass seen occasionally in young cysts. Stains reddish brown with iodine
Iodamoeba butschlii	5–20 μm Usual range, 10–12 μm	Ovoidal, ellipsoidal, triangular, or other shapes	1 in mature cyst	None	Large, usually eccentric Refractile, achromatic granules on one side of karyosome. Indistinct in iodine preparations	Occasionally granules present, but chromatoid bodies as seen in *Entamoeba* spp. are not present	Compact well-defined mass; stains dark brown with iodine

CONCLUSION

Entamoeba histolytica and *Entamoeba dispar* are now two well-defined organisms. More and more research in being done to define detailed biological, biochemical, and genetic characteristics of each organism and to specify the biological and diagnostic differences between the two organisms. Information on differences and similarities between the two organisms, however, is not conclusive (66–71). Diagnostic procedures are still being evaluated to differentiate the two organisms (72,73). Epidemiologically, the discovery or redefinition of *E. dispar* has given insight into why *E. histolytica* is pathogenic and elucidated questions about the epidemiological behavior of the species once believed to be only one organism. More research will take place until finally, all questions will be answered, or maybe more questions will be asked. This is a challenge to our capacity to decide when sufficient questions have been asked. International agencies have taken action in resolving the public health problem that diarrheal disease imposes on humanity. Especially in children, there is still much to be done.

ENTEROVIRUSES: BASIC BIOLOGY AND DISEASES

CHARLES P. GERBA
University of Arizona
Tucson, Arizona

The enteroviruses have been the most-studied waterborne enteric viruses. This was the result of their ability to be easily grown in cell culture and the occurrence of poliovirus epidemics in the first half of the twentieth century. Although almost always present in sewage and feces of infected persons, they have been seldom associated with water and food-borne outbreaks. This may be because they often cause mild or asymptomatic infections and because of lack of diagnosis. Still, they are associated with a number of common and serious infections worldwide. The development of molecular epidemiology has increased our understanding of the potential role of these viruses in heart disease and diabetes, and helps to fully understand their routes of transmission in the environment.

GENERAL PROPERTIES

Enteroviruses are a genus of the Picornaviridae family, which are among the smallest ribonucleic acid (RNA) viruses. "Picorna" means small RNA virus. The Picornaviridae family also includes the closely related rhinoviruses and hepatitis A virus (which was once classified as enterovirus type 72). Enteroviruses are subdivided into four groups, namely, polioviruses, Coxsackieviruses, echoviruses, and enteroviruses 68–71 (Table 1). Echovirus 22 and 23 have now been separated from the echoviruses as a separate genus, the parechoviruses, based on significant differences in their genome from the other echoviruses (1). They are now referred to as parechoviruses 1 and 2.

Table 1. Human Enterovirus Types

Number of Serotypes	Members
3	Polioviruses 1, 2, 3
22	Coxsackieviruses A1-22, 24 (A23 is echovirus 9)
6	Coxsackieviruses B1-6 (swine vesicular disease virus is very similar to coxsackie B5 virus)
26	Echoviruses 1–7, 9, 11–27, 29–34 echo 8 is echo 1 echo 10 is reovirus, type 1 echo 28 is human rhinovirus 1A echo 22 and 23 are now parechoviruses 1 and 2
4	Enteroviruses 68–71

Table 2. Biophysical Properties of Poliovirus

Physiochemical Characteristics of the Major Virus-Particle Population	Poliovirus Type 1
Morphology	
Diameter	28 nm
Envelope	none
Symmetry	isosahedral
Sedimentation Rate	156 S
Density (CsC1)	1.34 g/ml
Nucleic Acid	
Type	single-stranded RNA
Length	2.3 Fm
Molecular weight	2.6×10^6
Number of base pairs	7,441*
Polypetides (major)-molecular weights	24,000 25,000 34,000
Viron Mass**	8.43×10^6
% RNA (as K salt)	31.6
% Protein	68.4
Viron/mg	7.07×10^{13}

**Computed from complete nucleotide sequence

Enteroviruses are nonenveloped, icosahedral in shape, and 25 to 30 nm in diameter (Table 2). They contain a genome of single-stranded RNA of the positive sense, which acts like messenger RNA and is polyadenylated at the 3′ terminus. The RNA from all the sequenced enteroviruses are similar in length, about 7,400 base pairs. The viral capsid contains sixty subunits, each subunit containing four polypeptides. The four peptides are referred to as VP1, VP2, VP3, and VP4. In addition, one small noncapsid protein, Vpg, is covalently attached to the 5′ end of the virion RNA.

Soon after an enterovirus attaches to a cell, it is delivered into the cytoplasm as viral RNA freed from its protein shell. The single-strand genome RNA then serves as its own mRNA, which is translated to form a single large polypeptide that is subsequently cleaved to produce the various viral capsid polypeptides. Completion of encapsidation produces mature viral particles, which are then released when the cell lysis. The time required from initiation of infection to completion of virus assembly ranges from 5 to 10 hours, depending on pH, temperature, host cell, and number of particles to which the cell is exposed (2). Yields may be up to 100,000 particles per cell, but in a single passage only 1 in 1,000 or 1 in 100 may be infectious in cell culture. This has led to the assumption that most of the particles are defective, that is, lacking a complete genome or protein capsid. However, the apparent low ratio of infective to noninfective particles actually results from poor assay efficiency in cell culture. Optimizing attachment of virus to the cell and the use of different cell lines can enhance infectively of the virus in cell culture 2 to more than 10-fold (1a,1b,1c).

Enteroviruses have a buoyant density of 1.34 g/mL in cesium chloride. A characteristic of the enteroviruses is their resistance to high and low pH levels. They are stable at pH 3 to 5 for one to three hours and can tolerate pH 10 to 11 for several minutes. They are resistant to antibiotics, 70% alcohol, 5% Lysol, 1% quaternary ammonium compounds (Roccal),and insensitive to ether, deoxycholate, and most detergents. Treatment with 0.3% formaldehyde, 0.1 N HCl, or a free residual chlorine level of 0.5 mg/L will cause their rapid inactivation.

Enteroviruses are fairly stable at room temperature (days), but are rapidly inactivated at 50 °C. However, in the presence of molar magnesium chloride, only partial inactivation occurs in one hour at 50 °C (3). They are stable at 4 °C for weeks, and for years at −20 °C and −70 °C. They are rapidly inactivated by drying.

HISTORY

Poliovirus was the first enterovirus to be recognized, although it was not classified as an enterovirus until 50 years after its discovery. Poliomyelitis, the crippling disease caused by the polioviruses, has been known for centuries, but the basic studies began in 1908 when Landsteiner transmitted the disease to monkeys. In the 1930s, Paul and Trask (3) recovered the virus in feces of patients and the concept of poliomyelitis as an enteric infection became established. The first strains of what are now known as Coxsackievirus subgroup A were isolated by inoculation of infant mice with fecal material from two children during an epidemic of poliomyelitis in 1948 in Coxsackie, New York (4). Additional types of subgroup Coxsackie B were discovered shortly thereafter (5). As soon as cell culture became available in the late 1940s, other enteroviruses were isolated from the stools of both healthy and ill children. Because the viruses in the healthy children were not immediately associated with a disease they were called “orphan” viruses and later became known as ECHO (enteric cytopathogenic human orphan) viruses. As new enterovirus members were recognized, they were given sequential numbers as enterovirus 68–71.

EPIDEMIOLOGY

In the prevaccine era, epidemics of poliomyelitis occurred with great frequency among the developed countries of

the world. In the period 1951 to 1955, an average of almost 38,000 cases of poliomyelitis (approximately 21,000 of them paralytic) were reported annually in the United States. Only eight to nine cases now occur annually in the United States, and these all have been vaccine associated (i.e., conversion of the live vaccine to wild type after infection) (6). Nonpolio enteroviruses are estimated to cause 10 to 15 million symptomatic infections in the United States annually (7).

The fecal-oral route is believed to be the main route of transmission, although respiratory transmission may also be significant for some types (8). It is believed that the fecal-oral route can transmit almost all enteroviruses (except possibly enterovirus type 70, which causes eye infections). Incubation periods vary greatly with the type of virus and may be as short as 12 hours for Coxsackievirus A24 (eye infections) to as long as 35 days for poliovirus. Because of their antigenic inexperience, children are the primary targets of enterovirus infections, and thus serve as the main vehicle for their spread, which is chiefly by the fecal-oral route. These viruses are easily spread within family settings and closed institutional populations, where the rate of infection among nonimmune members may reach as high as 80%. Where unsanitary and poor socioeconomic conditions prevail, the rate of infection among infants and children may exceed 50%. As personal and community hygiene improve in a population, spread of enteroviruses becomes limited, so that increasing numbers of individuals reach later childhood, or even adulthood, without having been infected and immunized by the common serotypes. By two years of age, regardless of climate, geography, or socioeconomic conditions, most children have already experienced several asymptomatic or mildly symptomatic enterovirus infections. One set of enterovirus serotypes may be predominant for a time in some areas, or even worldwide, to be succeeded by other types.

A number of different Coxsackievirus and echovirus serotypes have been involved in sizable epidemics, and enteroviruses 70 and 71 have also been responsible for outbreaks in various parts of the world. These outbreaks have been mostly localized to one area, although one epidemic of echovirus 9 infections in the late 1950s had almost worldwide distribution, and enterovirus 70 spread explosively in Asia and Africa during 1969 to 1973. In 1981, enterovirus 70 epidemics reappeared in Asia and Africa, and also spread to the Western hemisphere. Enterovirus 71 has been involved in several outbreaks affecting large numbers of patients in several different nations, but pandemic spread has not been observed (6).

GROWTH IN CELL CULTURE

Most of the enteroviruses grow very well in human and monkey cell lines. They grow best in primary cell lines (kidney cells). Coxsackievirus A viruses do not grow in most cell lines, but can be isolated by inoculation of newborn mice. The buffalo green monkey cell (BGM) line of African green monkey kidney cells has been reported as being more sensitive than primary rhesus or green monkey kidney cells for titration of certain enteroviruses, and for recovery of plaque-forming enteric viruses from sewage and water (9,10). The BGM cell line is the cell line most commonly used today for the isolation of enteroviruses from the environment. The RD cell line, derived from a human rhabdomyosarcoma, has been shown to support the growth of the Coxsackievirus A group. A second passage in cell lines is often necessary, to obtain cytopathogenic effects (CPE) with enteroviruses isolated from environmental samples (11).

In monolayers of cultured cells, the growth of enteroviruses is generally associated with a characteristic CPE. Infected cells round up, shrink, and show marked nuclear pyknosis, become refractile, and eventually degenerate and falloff the plastic or glass surface. The time for the appearance of CPE is dependent on the concentration of virus in the inoculum, the type of virus, and if it has been repeatedly passed in the cell line. In the case of laboratory grown poliovirus, CPE can be observed usually within 48 hours.

Most enteroviruses are inhibited from propagating in cell cultures by two-(alpha-hydroxybenzyl)-benzimidazole and guanidine (12). The susceptibility of cells to a number of enteroviruses may be increased by treating with 5-iodeoxyuridine at 50 fg/mL for three days before exposing the cells to the virus (13).

IDENTIFICATION

Although isolation of enteroviruses in cell culture is fairly simple, identification of the serotype may be slow and expensive. Traditionally, specific identification tests using serum neutralization were utilized. Using specific antisera for each virus makes this a very time consuming process. However, identification is simplified with the use of antisera pools, each containing antisera to several types of enteroviruses. These pools are constituted in a pattern in such a way that, a given antiserum appears in one pool, two pools, or three pools. An unknown enterovirus may be identified by its pattern of neutralization by the pool or pools containing its homotypic antiserum (14).

Application of recombinant DNA procedures and the polymerase chain reaction (PCR) through the use of specific primers have led to the use of methods for the identification of enteroviruses in both clinical and environmental samples. These methods can be used directly on the samples, or to identify the enteroviruses after isolation in cell culture (14).

HOST RANGE

Human enteroviruses are believed to have no known natural reservoirs. They have been occasionally isolated from the feces of dogs in developing countries and rural areas (15,16). Serologically distinct enteroviruses have been found in many animals; however, humans do not usually have recognizable infections with "Animal" enteroviruses. Some laboratory animals, however, are susceptible to infection with human enteroviruses, including primates and neonatal mice. Most strains of poliovirus infect and cause paralysis in monkeys and

chimpanzees. Coxsackie A viruses, characteristically produce widespread stretching of the muscle in the skeletal muscles of new born mice, resulting in paralysis.

INFECTIVITY

The only dose-response data available are those obtained from studies conducted with vaccine strains of poliovirus or echovirus 12. Lepow and coworkers (17) conducted studies on newborn infants less than five-days old, infected with poliovirus Sabin type 1 (LSc-2ab). Minor and coworkers (18) exposed two-month-old infants, via the oral route using a syringe, to a vaccine strain of polio type 1. Plotkin and coworkers (19) and Katz and Plotkin, (20) orally exposed premature infants to an attenuated strain of poliovirus type 3 (Fox strain). Schiff and coworkers (20) studied the infectivity of echovirus 12 in adults. The virus was from stools of previously infected individuals. Teunis and coworkers assessed the probability of being infected by ingesting one virus in these studies (21). They found that the probability ranged from 7.14×10^{-4} to 1.90×10^{-1}. The range probably reflects the type of virus and method of administration.

IMMUNITY

Immunity to the enteroviruses is believed to be permanent. Immunity is generally specific to the enterovirus serotype. Virus-neutralizing antibody develops within a few days after exposure to the virus, usually before the onset of illness, and may persist for life (22). Infection of the intestinal tract results in the production of a secretory nasal and duodenal IgA antibody.

PATHOGENESIS

The portal of entry of the enteroviruses is the alimentary tract via the month. The incubation period is usually 7 to 14 days, but may range from 2 to 35 days. After initial and continuing multiplication, probably in the lymphoid tissue of the pharynx and gut, viremia may occur, and in turn lead to further growth and multiplication in other organs, namely, spinal cord, brain, meninges, heart, and skin. Usually, the virus is excreted in the stool for several weeks and is present in the throat for one to two weeks after infection in clinical or asymptomatic cases. Enteroviruses have been isolated from the feces, pharyngeal washing, cerebrospinal fluid, spinal cord, brain, heart, eye, and skin. The reported average concentration of enteroviruses in stools is about 10^6 tissue culture infectious units (23) per gram of feces.

ASYMPTOMATIC INFECTIONS

A striking future of most enterovirus infections is the large variation in asymptomatic infections seen with this group of viruses. This may vary by both the type and strain of enterovirus (24). Within each group of the major enteroviruses, a wide range of asymptomatic infection rates may be observed. For example, there is approximately a 15% asymptomatic infection rate for echovirus 9 versus 67% for echovirus 11 (25,26). As a rule of the thumb, asymptomatic infection is apparently most common for the poliovirus (90–95%), followed by the echoviruses and coxsackieviruses (about 50%). About 4 to 8% of the poliovirus infections are associated with minor illness such as upper respiratory tract infection, gastroenteritis, and influenza-like illness (8). Another 1 to 2% may develop aseptic meningitis accompanied by back pain and muscle spasms. Only 0.1 to 2% may develop paralytic poliomyelitis.

SECONDARY TRANSMISSION

Transmission within households has been well studied for the enteroviruses. Household secondary attack rates in susceptible members may be greatest for enterovirus type 70, which causes eye infections, and for the polioviruses. In some studies, the secondary attack rates may be 90% or more, although they are typically lower (24). In a study of New York families, on the transmission of viral disease, the secondary transmission rate for Coxsackievirus in susceptible persons was 76% and for echoviruses 43% (27). Enterovirus infections, often spread more frequently among children than adults, and secondary coxsackievirus infections were more frequent in mothers (78%) than in fathers (47%). The greater spread of poliovirus and Coxsackievirus may derive from longer periods of viral excretion (24). Secondary transmission rates may vary with the type and strain of enterovirus.

ILLNESSES CAUSED BY ENTEROVIRUSES

Enteroviruses cause a wide spectrum of diseases that involve almost any organ (Table 3). Disease severity can range from life-threatening with significant morbidity, to mild or subclinical. The more common syndromes include nonspecific febrile illness, aseptic meningitis, herpangina, hand-foot-mouth syndrome, and exanthems (skin infections). The clinical manifestations of infection in the neonate can be distinct and discussed separately.

Currently, there are no vaccines (except poliovirus) or treatment of enterovirus infections, except those supportive of clinical symptoms.

PARALYSIS

Before the advent of vaccination, poliovirus was a major cause of permanent paralysis in the United States. Vaccination has eliminated poliomyelitis in the United States, and no indigenous wild viruses have been detected there since 1979 (8). Most infections are asymptomatic (90–95%) with only 0.1 to 2% resulting in paralytic poliomyelitis. Most poliovirus infections occur in children under four to five years of age, but the older the age of infection, the greater the severity of the outcome. Mortality in children averages 2.5% for symptomatic infections and 30% in adults (8).

Table 3. Common Clinical Syndromes Associated with Enterovirus Infections in Children

Syndrome	Predominant Virus	Clinical Features
Nonspecific febrile illness	All types	Febrile illness (fever), with nonspecific upper respiratory and gastrointestinal tract symptoms
Aseptic meningitis	Echovirus, group B Coxsackieviruses, and polioviruses	Fever, meningeal signs with mild cerebrospinal fluid (CSF) pleocytosis, usually normal CSF glucose and protein, and absence of bacteria
Herpangina	Group A Coxsackieviruses	Fever, painful oral vesicles on tonsils and posterior pharynx
Hand-foot-mouth disease	Coxsackievirus A16	Fever, vesicles on buccal mucosa and tongue and on interdigital surfaces of hands and feet
Nonspecific exanthems	Echoviruses	Variable rash (usually rubelliform but may be petechial or vesicular), with or without fever
Pleurodynia	Coxsackievirus B3, B5	Uncommon, epidemic, fever, and severe muscle pain of chest and abdomen
Myocarditis	Group B Coxsackieviruses	Uncommon, myocarditis/pericarditis, which can present with heart failure or dysrhythmia
Acute hemorrhagic conjunctivitis	Enterovirus 70	Epidemic cause of conjunctivities with lid swelling, subconjunctival hemorrhage, and eye pain without systemic symptoms
Paralytic disease	Poliovirus, Enterovirus 71, Echoviruses, and Coxsackieviruses	Paralysis

Nonpolio enteroviruses have been associated with paralysis, but this is uncommon compared to poliovirus (28,29). Coxsackievirus A7 has been associated with outbreaks of paralytic disease (30), and outbreaks of enterovirus 71 have been involved in several outbreaks of central nervous system involvement, with most fatal cases in children (31).

PERINATAL AND NEONATAL INFECTIONS

Neonates represent a population at great risk from several enteroviral diseases. Adverse effects to the fetus are caused by enteroviral infection during pregnancy. In the prevaccine era, paralytic poliomyelitis occurred during pregnancy in apparent excess of age-adjusted expected rates, suggesting predisposition among pregnant women (32). Infections of pregnant women by the nonpoliovirus enteroviruses occur frequently. In a seroepidemiologic study, Brown and Karunas (33) found a 42% rate of infection during pregnancy, in a population evaluated prospectively over a 10-year period. In a review of Coxsackie B infections, Modlin and Rotbart (34) suggested that greater viral replication and prolonged maternal enterovirus excretion occurring in late pregnancy may well enhance the risk of infection of the newborn infant in the perinatal period.

Neonatal nonpolio enteroviral infections are common. Estimated attack rates indicate that disease in newborns and young infants is comparable or exceeds symptomatic neonatal infections caused by herpes simplex virus and cytomegalovirus (35–37). Enteroviruses were responsible for the majority (65%) of greater than three-month-old infant admissions to a hospital in one community for suspected sepsis (36–38). In another study, enteroviruses were the most frequently identified pathogens between days 8 and 29 of life, accounting for at least one-third of all cases of neonatal meningitis (36–39).

Age is the most important determinant of the outcome of enterovirus infections. Different age groups have different susceptibilities to infection, different clinical manifestations and degrees of severity, and different prognoses following enteroviral infection. Young children have higher attack rates. In one study, echovirus 9 disease attack rates in children were found to be 50 to 70% compared with 17 to 33% in adult age groups (40). Age-specific attack rates for echovirus 30 per 1,000 persons in an outbreak in the United Kingdom ranged from 19.7 (Children age 0 to 9 years) to 7.11, 4.82, 4.73, 1.5, and 0 for the succeeding 10-year age cohorts, respectively (41).

Severity of illness may also be age dependent. With poliovirus infection, adults are more likely to be severely affected, tending to acquire paralytic poliomyelitis rather than nonparalytic poliomyelitis (i.e., aseptic meningitis) or asymptomatic infection. On the other hand, Coxsackie B virus infection is clearly more severe in newborns than in older children and adults, often, causing myocarditis, encephalitis, hepatitis, and death (42,43). Coxsackievirus and echovirus encephalitis and aseptic meningitis are most frequent among those 5 to 14 years old (44,45), while myocarditis is most common in adults and neonates. In another study (46), the mean age among patients with Coxsackievirus B, meningitis was 7.7 years, pericarditis was 9.9 years, and gastroenteritis was 1.3 years.

HERPANGINA

Herpangina is characterized by a painful vesicular eruption of the oral mucosa associated with fever, sore throat, and pain on swallowing. It is seen most commonly in children ages 3 to 10 years (8). Group A coxsackieviruses are the most common etiologic agents, but group B coxsackieviruses and echoviruses also have been isolated form patients. Fever, usually mild, develops suddenly, but higher temperatures up to 41°C

(105.8 °F) can be seen, particularly in younger patients. Nonspecific early symptoms may include headache, vomiting, and myalgia. Sore throat and pain with swallowing are the most prominent symptoms and precede the characteristic exanthems (eruption of mucous membranes) by, approximately, one day. Herpangina is self-limited and symptoms resolve within one week.

ASEPTIC MENINGITIS

Nonpolio enteroviruses are the leading causes of aseptic meningitis, accounting for 70% to 90% of all cases for which an etiologic agent is identified (7,47). The most common enterovirus types associated with aseptic meningitis are Coxsackievirus B5 and echovirus 4, 6, 9, and 11. These have occurred in epidemic outbreaks, as well as sporadic cases being most common in the 5 to 15 year age group (8).

The course of enteroviral meningitis usually is self-limited and benign, but there has been an ongoing debate about the occurrence of long-term neurological, cognitive, or developmental abnormalities from this infection in older children (48). However, several investigations have documented that 10% of children younger than three months of age who have aseptic meningitis may suffer long-term sequelae, especially speech and language delay (49).

NONSPECIFIC FEBRILE ILLNESS

The most common clinical presentation of nonpolio enterovirus infection is a nonspecific febrile illness (fever). Typically, fever develops suddenly and temperatures range from 38.5 °C to 40 °C (101 °F–104 °F) and last for an average of three days. Occasionally, a biphasic pattern of symptoms can be seen, with an initial fever for one day, followed by two to three days of normal temperatures and recurrences of fever for an additional two to four days.

Studies have found that enteroviruses are the major cause of hospitalization for young infants (younger than two to three months of age) for suspected fever caused by septicemia during the summer and fall (50). A recent study of infants less than 90 days of age found that nonpolio enteroviruses were the most common cause of fever in infants requiring hospitalization (51). Greater than 25% of the infants were infected. The average length of stay was three days with average medical costs of $4,500.

EXANTHEMS (ERUPTION OF THE SKIN)

Nonpolio enteroviruses are the leading cause of exanthems in children during the summer and fall months. The most common serotype causing exanthems is echovirus 9. The classic enteroviral exanthems consist of a pink, macular, rubelliform rash. The rash may be the sole manifestation of infection, or may be present in association with febrile illness, or aseptic meningitis. Enteroviral exanthems are seen most commonly in children younger than five years of age and decrease in prevalence with age. The rash is self-limited and disappears in three to five days (7). Most infections occur in infants and young children 3 to 10 years of age (median, 4 years) (8).

The best-known enteroviral exanthem is the hand-foot-mouth disease. It is commonly associated with Coxsackievirus A16, but may also be caused by Coxsackievirus A5 and several other enteroviruses including enterovirus 71 (52). Children usually have a fever, with multiple discrete red macular lesions of about 4 mm appearing on the palms, soles, fingers, and toes. The infection is usually self-limited, lasting one to two weeks.

Complications associated with hand-foot-mouth (HFM) disease caused by enterovirus type 71 include encephalitis, meningitis, hemorrhage, acute flaccid paralysis, and myocarditis. During a large outbreak of HFM disease in Taiwan in 1990, of enterovirus type 71, 129,000 cases were estimated resulting in 405 hospitalizations and 78 deaths (53). Almost all of the severe cases and deaths were in children less than five years of age.

RESPIRATORY ILLNESS

Worldwide enteroviruses appear to account for 2% to 15% of all viruses that cause upper and lower respiratory tract diseases (54). The illness is most commonly associated with coxsackie A10, A21, A24 and B2 (8). Both children and adults are affected with infections lasting only a few days. Pneumonia associated with enteroviral infection has been reported in both outbreaks and individuals (54). Fatal pneumonia has been associated with Coxsackievirus and echovirus infections in infants and children (55–57).

ACUTE HEMORRHAGIC CONJUNCTIVITIS (AHC)

This explosive epidemic enterovirus conjunctivitis, first described in 1969 in Africa and Asia, is now found worldwide. It is common in tropical and densely populated regions. The majority of outbreaks have been caused by enterovirus serotype 70, but recently coxsackievirus A24 has been isolated during the outbreaks (8). AHC is characterized by a sudden onset of severe eye pain, photophobia, and blurred vision. Subconjunctival hemorrhages, erythema, edema of lids, and eye discharge are characteristic of infections. Recovery occurs within 7 to 10 days. Spread is by the eye-hand-fomite route in contrast to the fecal-oral route seen with most enteroviral infections. Overall, it is more common in adults, but it also does affect school-aged children. Some enterovirus outbreaks have been associated with poliomyelitis-like paralysis.

DIABETES

Insulin-dependent diabetes mellitus (IDDM) is the most common severe chronic childhood illness, affecting an estimated 123,000 children in the United States (58). More than 11,000 new cases are diagnosed annually. The disease is the leading cause of renal failure, blindness, and amputation, and a major cause of cardiovascular disease and premature death in developed countries (59). IDDM occurs most frequently at the ages of 2, 4 to 6, and 10

to 14 years, perhaps because of physiological increases in sex hormone levels and insulin resistance or because of alterations in the pattern of childhood infections. Season and latitude affect incidence, suggesting an infectious etiology (59). The infectious agents most commonly linked to IDDM have been the enteroviruses.

To date, epidemiological studies have failed to prove or disprove the association of enteroviruses with IDMM (60). This may be because the nature of the disease may involve both genetic factors of the host and environmental exposure, with the development of clinical symptoms taking years to develop. Autoimmunity, potentially induced by a preceding enterovirus infection, could play a role in human IDDM (59). Recent studies continued to support some association with enterovirus infections and IDDM (61–64).

PLEURODYNIA (BORNHOLM DISEASE)

Pleurodynia or epidemic myalgia is characterized by an acute onset of severe muscular pain in the chest and abdomen accompanied by fever. Coxsackieviruses B3 and B5 are the major causes of this epidemic disease; sporadic cases have been described with other nonpolio enteroviruses.

The muscular pain is sharp and spasmodic, with episodes typically lasting 15 to 30 minutes, although they can last up to several hours. During spasms, patients may develop signs of respiratory distress or appear shocklike with diffused sweating and pallor. Pain localized to the abdomen in young children may falsely suggest appendicitis. The illness usually lasts one to two days, but frequent recurrences are possible several weeks after the initial episode. Associated signs and symptoms include anorexia, headache, nausea, and vomiting. In contrast to many other enteroviral syndromes, pleurodynia is more common in older children and adolescents.

Cases are recognized mostly in school-aged children and adults, with the peak age being in children two to nine years old (8). However, older boys have also been reported to develop orchitis, namely, inflammation of the testes (8). It has not been established whether involvement of the ovaries occurs.

MYOCARDITIS

Coxsackievirus B infections are increasingly being recognized as a cause of primary myocardial disease in adults as well as children (2). In some studies, up to 39% of persons infected with coxsackievirus B5 developed cardiac abnormalities. Coxsackieviruses of group A and echoviruses have also been implicated, but to a lesser degree. The illness is common in neonates and adults. Older adults represent the vast majority of cases, with patients aged 40 and older, composing 69% of the cases (65). While the incidence is less in neonates, the outcome is potentially more severe with mortality among infants reported to be 30 to 50% (34). Symptoms usually begin within the tenth day of birth with fatigue, poor feeding, or mild respiratory distress.

Most children and adults recover; however, one or more recrudescences several weeks to more than a year later have been reported in approximately 20% of the cases after the initial illness (66). Persistent electrocardiographic abnormalities (10–20%), cardiomegaly (5–10%) and chronic congestive heart failure indicate that permanent heart damage occurs due to this illness.

DISEASES ASSOCIATED WITH THE IMMUNOCOMPROMISED

Enteroviruses are not prominent among the microorganisms that cause serious morbidity and mortality among the immunocompromised. In childhood, serious enterovirus infection does not appear to be particularly common in the T cell immunodeficiency syndromes (8). However, enteroviral infections pose significant risk to children who have defects in B lymphocyte functions, the most common of which is X-linked agammaglobulinemia (67). Unlike other viruses that are combated by cellular immune mechanisms, enteroviruses are eliminated from the host by humoral immune mechanisms. An intact B-cell response is believed to be necessary to block viral entry into the central nervous system. Children who have agammaglobulinemia may develop chronic enteroviral infection, most commonly meningoencephalitis. Patients experience headache, lethargy, seizures, motor dysfunction, and altered sensorium. Symptoms may wax and wane for years, but there is an overall progressive deterioration in central nervous system function. Infections are fatal in most children who are immunodeficient. Echovirus 11 has been the most common cause of chronic infection, but cases caused by other echoviruses and Coxsackieviruses have been reported (8).

Enterovirus infections in infants who have received organ transplants can result in serious complications (68). Serious life-threatening infections of both echovirus and Coxsackievirus have been documented in infants receiving both bone marrow and liver transplants. Cancer patients receiving chemotherapy may also suffer from severe illness when infected with a Coxsackievirus (69).

OTHER ILLNESSES

Enteroviruses have been associated with a number of other illnesses including juvenile rheumatoid arthritis (70) and gastroenteritis (71) (Table 4). Case reports have also linked enteroviruses to short-term mental impairment in children and other illnesses or symptoms in children (Tables 3–5). Other studies have suggested relationships between enterovirus infections and sudden infant death syndrome or SIDS (72), risk of schizophrenia from infections early in childhood (73), amyotrophic lateral sclerosis (Lou Gehrig's disease) (74), vertigo (75) and chronic fatigue syndrome (76). These studies have been limited in scope or speculation.

INCIDENCE OF ENTEROVIRUS INFECTIONS

In two studies on virus occurrence in solid waste, Peterson (85,86) isolated enteroviruses in 10% of the

Table 4. Less Common Illnesses Associated with Enterovirus Infections

3 Fox	2.66×10^{-1}	5.0	20

*The number of viruses required to cause infection in 50% of the individuals exposed (77)

fecally soiled diapers that she examined. The excretion rate of enteroviruses has been found to vary by the month, with the greatest percentage from May to October in the United States. The incidence in children over the entire year ranges from 2.4% to 13.3%, with the higher excretion rate in the lower socioeconomic group (6). The most extensive work done on virus excretion was during the "Virus Watch" studies in which the incidence of virus illness and excretion was conducted in families, for many years in several locations across the United States. (6). In Seattle and New York, stools samples were collected from family members regularly (usually at monthly intervals), whether illness was present or not. Over a three-year period, the incidence of excretion of any enteric virus in children (<15 years of age) was found to range from about 10% in the winter to almost 40% during the summer. During the summer and autumn months (June through October), over one-third of the healthy children were excreting some virus in the feces, as detected by cell culture. Overall, the frequency of illness associated with echovirus infections was 44%. However, symptomatic infections were greater for children under four years of age; 78% for four-year-olds, and 12% for children, five years of age and older. The rate of symptomatic infections among the adults was 28% for both Coxsackievirus and echovirus versus 42% for children under four years of age.

ECONOMIC IMPACT

Studies on the economic cost of nonpolio enterovirus infections have only recently been attempted. Pichichero and coworkers (87) conducted a study on children older than four years to assess the economic impact of enterovirus infection. Some 380 children in two clinics, over a period of four months, in different regions of the United States, were involved in the study. The children were followed for two weeks to document absenteeism and follow-up medical care. The majority of the illnesses were mild and no hospitalizations were required. Most of the illnesses occurred in children 4 years to 12 years of age. The duration of illness in most children was prolonged, lasting 9.5 days on average. The total of direct medical care costs and indirect costs per case ranged from $132 for hand-foot-and-mouth disease to $1,193 for meningitis.

In 1991, a large outbreak of echovirus 30 meningitis occurred in New England, affecting more than 1,500 individuals (88). A cost analysis of the hospital billing for the inpatient/outpatient care of 103 patients involved in the outbreak, was performed at a hospital serving the region. The average inpatient management cost of a patient with enterovirus meningitis, in this outbreak, was $1,757 + $198 and the outpatient management costs was $477 + $63. Indirect costs were not determined.

WATER AND FOOD-BORNE OUTBREAKS

A search for instances of waterborne poliomyelitis began about 1937, and continued through much of the 1940s. The search yielded only eight likely outbreaks in which a relationship to contaminated drinking was presumed by the investigator (89). However, the epidemiological evidence was not conclusive in any of these outbreaks. Only the outbreak near Lincoln, Nebraska, has sufficient data to suggest that contaminated water was involved (90). This outbreak occurred in 1952, among families living in a cluster of temporary houses facing a number of serious difficulties with the water distribution system, fluctuations in pressure, and toilet bowl water that may have siphoned back into the water main. The most convincing outbreak linking poliomyelitis to drinking water occurred in Taiwan in 1982 (91). Having been free of the disease for seven years, 1,031 cases of poliomyelitis were reported within a five-month period. An intensive epidemiological study concluded that inadequate vaccination and receipt of a nonmunicipal water supply were significant risk factors.

Several recreational outbreaks of nonpolio enterovirus infections have been documented among children. An outbreak of Coxsackievirus B4 or B5 meningitis occurred at a boy's summer camp linked to swimming in a lake (92). Another outbreak of meningitis, this time caused by Coxsackievirus A16, occurred due to exposure to lake water (93). An epidemiological study among bathers, swimming in nondisinfected lake waters, demonstrated an association with increased risk of enterovirus infection. D'Alessio and coworkers (94) surveyed children of ages 1 to 15 at a pediatric clinic to determine where they had been swimming and the location and frequency of the swimming during the prior two weeks. Children swimming in a pool (with a chlorine residual) had a statistically significant increase in the relative risk of having an enterovirus illness. Of the 134 viruses isolated from the patients, 119 (90%) were nonpolio

enteroviruses and 33.6% were Coxsackievirus type A. Echovirus 30 transmission to children has also been associated with a community swimming pool (95). The risk of echovirus 30 was greatest among those who swallowed pool water.

A raw milk–associated outbreak of poliomyelitis in 1914 is believed to be the first recorded food-borne outbreak of a viral disease (96). Consumption of raw milk was implicated in 10 more such outbreaks in the United States and United Kingdom by 1949 (97). Combined effects of pasteurization and immunization made this a rare event after the 1950s (98). Only two outbreaks associated with foods have been reported. The first of these was in 1976 when 80 cases of aspectic meningitis were recorded among those who ate coleslaw served at a picnic; echovirus type 4 was identified as the causative agent but the actual source of the virus could not be determined (99). The other outbreak occurred in 1988 and led to 161 cases of an unspecified illness. The causative agent proved to be echovirus type 5, but the specific food and the actual source of the virus remained undetermined (100). The sole source of a food-borne outbreak due to the Coxsackievirus B subgroup comes from the former Soviet Union (101). A day care center was the site of the outbreak and Coxsackievirus types B1, B3, and B5 were reported to have been isolated from certain items of food, surfaces in food preparation areas, as well as the infected individuals.

CONCLUSION

Enteroviruses are the most studied waterborne viruses, although rarely associated with documented waterborne disease. They have been used as a model for the study of all enteric viruses in the environment. Methods are readily available for their detection in the environment and they are very stable in the environment. They are a very common cause of illness in man, causing an amazingly wide variety of illnesses, from mild to life-threatening. The impact of enteroviruses on human health is still not fully understood.

ENTEROVIRUSES IN WATER: CONCENTRATION AND DETECTION

SAGAR M. GOYAL
University of Minnesota
St. Paul, Minnesota

Human and/or animal enteroviruses may be present in raw and treated municipal wastewater, animal manure, biosolids, groundwater, rivers, lakes, and drinking water. With the possible exception of raw sewage and sludge, the number of enteroviruses present in contaminated water is too small to be detected by methods used routinely in clinical virology (e.g., without sample concentration). To determine the presence of viruses in water, therefore, a large sample volume (100 to 1,000 L) needs to be concentrated to a smaller volume, which can then be processed by various methods for virus detection. Although progress has been made over the years for the concentration and detection of viruses from large volumes of water and wastewater (1), a "perfect" method does not exist that can concentrate and detect all types of viruses from all types of water.

The quest for methods to detect the presence of viruses in the water environment started around the 1950s, with scientists attempting to detect poliovirus in water samples (2). Since then, attention has also been focused on the concentration and detection of other enteric viruses, for example, enteroviruses, hepatitis A virus, and Norwalk (NV), and Norwalk-like viruses (NLV). Adsorption of viruses from water matrix to a solid surface and their subsequent elution in small amounts of buffer remain the basis of all concentration methods. The method is termed appropriately as *virus adsorption-elution* (Viradel) method. Surfaces that have been used for virus adsorption include microporous filters, granulated coal, organic polymers, glass powder, and polyethylene glycol (Table 1). However, methods using virus-adsorbing filters are preferred because they are simple to use and large quantities of water can be processed.

In short, a virus concentration procedure consists of the following steps: (*1*) filtration of large quantities of water or wastewater through a virus-adsorbing filter, (*2*) elution of adsorbed virus in 1 to 2 L of an eluent (usually 3% beef extract-glycine, pH 9.0 or 0.05 M glycine, pH 10.5), (*3*) further reduction in the volume of the eluate by a second-step reconcentration method (usually by organic flocculation or aluminum hydroxide-hydroextraction method), and (*4*) virus detection by inoculation in cell cultures or by molecular means. A number of excellent reviews are available that describe methods for the concentration and detection of enteric viruses from water and wastewater (1,16,17). The purpose of this review is to describe methods that have been used extensively in the field, namely, the viradel method using membrane filters.

Table 1. Media Used for Concentration of Viruses

Media	Reference
Electronegative filters	3
Electropositive filters	4
Bituminous coal sandwich	5
Glass powder, glass wool	6–8
Organic polymers	9
Erythrocyte ghost cells	10
Yeast cells	11
Inorganic salts ($CaHPO_4$)	12
Active aluminum oxide	13
Diatomaceous earth modified with metallic hydroxides	14
Animal cells growing on filters	15

ELECTRONEGATIVE FILTERS

Negatively charged pleated cartridge (25.4 cm) filters (Filterite filters) were found to readily adsorb poliovirus from water that had been adjusted to acidic pH and to which small amounts of trivalent cations (e.g., aluminum chloride) had been added (3). Adsorbed virus was eluted by treating the filter with glycine buffer at high pH. Using these epoxy-fiberglass pleated filters, approximately 70% of the poliovirus added to 400 L of estuarine water was eluted in 2 to 3 L of filter eluate, which was further concentrated by adsorbing the virus to aluminum hydroxide flocs and then recovering it in 150 mL of buffered fetal calf serum. Additional reductions in volume were achieved by hydroextraction (aluminum hydroxide hydroextraction method). By using these procedures, 60 to 80% of the virus in filter eluate could be recovered in a final volume of 10 to 40 mL. In a subsequent study, it was shown that these filters could be regenerated by autoclaving or by treating them with 0.1 N NaOH. The regenerated filters were found to retain their ability to concentrate viruses from water (18).

In another study, pleated membrane filters (Filterite filters) were used for the concentration of poliovirus from large volumes of tap water (ca. 1,000 L) by conditioning the water with small amounts of aluminum chloride to enhance virus removal by membrane filters (19). Tap water treated with 2×10^{-5} M aluminum chloride showed slight decreases in pH and turbidity and enhanced removal of poliovirus by membrane filters. The virus was quantitatively recovered by treating the filters with a basic buffer, and the eluate was reconcentrated to a small volume by adsorption to aluminum hydroxide flocs. Using these procedures, virus from 1,000 L of tap water was obtained in a final volume of 20 to 80 mL with a mean recovery of 70%. Before these studies, most of the virus concentration methods were limited to the use of flat filters that could process relatively small volumes of water.

The Viradel technique was modified for the concentration and detection of rotavirus from seawater using simian rotavirus SA-11 as a model virus for human rotavirus (20). The virus adsorbed optimally to filterite filters when seawater was adjusted to pH 3.5 and 1.0 mM aluminum chloride (Fig. 1). Adsorbed virus was eluted

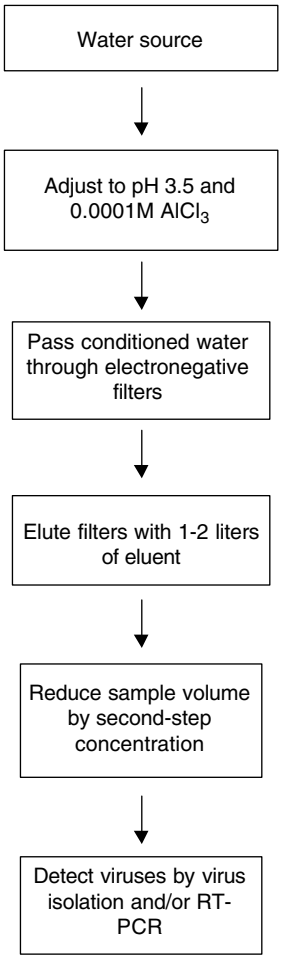

Figure 1. Schematic diagram of a virus adsorption-elution method using electronegative filters.

with 6% beef extract at pH 10.5 and was further concentrated to a smaller volume by using a modification of the organic flocculation method. When this method was used in conjunction with an indirect immunofluorescence test, rotaviruses were detected in sewage-contaminated seawater.

To enhance the virus-adsorbing capacity of electronegative microporous filters, Preston and coworkers (21) soaked epoxy-fiberglass (filterite) filters in an aqueous solution of a cationic polymer (polyethyleneimine; PEI) for two hours at room temperature and then allowed the filters to air-dry overnight on absorbent paper towels. Filters thus treated were evaluated for adsorption of coliphages (MS2, T2, ϕX174) and enteroviruses (poliovirus type 1 and coxsackievirus type B5) and were found to adsorb more viruses than untreated filters.

To determine the ability of pleated filters to adsorb bacteria, viruses, and protozoa, Payment and coworkers (22) used 3- and 1-μm wound electronegative fiberglass cartridge filters in series for the simultaneous concentration of poliovirus, coliphages, *Giardia lamblia* cysts, *Clostridium perfringens* spores, and *Legionella pneumophila* from large volumes of drinking water (Table 2). Filtration was performed at pH 3.5 in the presence of 0.001 M aluminum

Table 2. Studies on Electronegative Filters

Reference	Filter Type	Usage
3	Filterite	Concentration of viruses from estuarine water
18	Filterite	Regeneration of filters for reuse
23	Filterite	Concentration of poliovirus from tap water
20	Filterite	Concentration of rotavirus from seawater
21	Filterite	Enhanced viral adsorption by treating filter with a cationic polymer
22	Wound fiberglass depth cartridge	Simultaneous concentration of bacteria, viruses, and protozoa
24	Balston	Concentration of four different enteroviruses from water and wastewater

chloride to enhance adsorption. Elution of microorganisms entrapped or adsorbed to the filters was accomplished by a slow backwash elution with 1.5% beef extract solution containing 0.5% Tween 80 (pH 9.75). Tween 80 was shown to enhance the elution of all microorganisms tested. To further reduce the volume of the primary eluate, different second-step procedures were used. Giardia cysts were reconcentrated by low-speed centrifugation and purified by sucrose-density gradient flotation at a final recovery of 52%. *Legionella pneumophila* was reconcentrated by low-speed centrifugation at an overall recovery of 55%. *Clostridium perfringens* spores and coliphages were concentrated by a detergent—protein flotation method. Poliovirus was eluted at 93% and reconcentrated at 78% efficiency by organic flocculation.

Another negatively charged filter (grade C Balston filter, Balston, Inc., Lexington, Massachusetts) was evaluated by Guttman-Bass and Nasser (24). They used selective antibody neutralization to recover four different enteroviruses (poliovirus 1, coxsackievirus A9, coxsackievirus B1, and echovirus 7) from water and wastewater. Organic flocculation was used as second-step reconcentration procedure. The average recovery was 68% with wastewater and 97% with tap water, lake water, and seawater.

COMPARATIVE STUDIES

In subsequent years, many different investigators conducted comparative studies in which different types of filters, adsorption-elution conditions, and second-step reconcentration procedures were compared (Table 3). Beef extract (3% solution at pH 9.0) and 0.1 M glycine buffer (pH 11.5) were compared for the elution of poliovirus

Table 3. Comparative Studies on Electronegative Filters

Reference	Filters Compared
25	Fiberglass cartridge (K27); epoxy-fiberglass-asbestos (M780); Epoxy-fiberglass (filterite)
26	Johns-Manville D39, D49, and D79; Filterite 0.25-μm and 0.45-μm; Millipore AP20 and 0.45-μm; Whatman GF-D and GF-F; Gelman A-E
27	Round-robin comparison of Filterite filter in six different laboratories
28	Wound fiberglass depth cartridge filters
29	Filters from Sartorius, Millipore, Gelman, and Cuno companies
6	Macroporous glass (MPG-1000 VGKh and SO1); Nitrocellulose PNT 0.45-μm; Millipore HAWP 0.45-μm; Synpor 0.45-μm; polycapromide (Pall 0.2-μm); and FMPA 0.55-μm

adsorbed to fiberglass cartridge filters (K27), epoxy-fiberglass-asbestos filters (M780), and filterite filters (25). Poliovirus type 1 (strain LSc) was seeded into 20- to 25-gallon (ca. 75.6–95.6 L) samples of treated sewage effluent and concentrated by filter adsorption-elution technique. Adsorbed virus was eluted by using either two 600-mL portions of 3% beef extract (pH 9.0) or two 1-L portions of 0.1 M glycine, pH 11.5 (Table 4). In all experiments, beef extract elution followed by organic flocculation was found to be superior, yielding a mean viral recovery of 85% (range of recovery = 68–100%). Elution with 0.1 M glycine (pH 11.5) followed by inorganic flocculation resulted in a mean recovery efficiency of 36%. The variable range of viral recoveries with beef extract could not be improved by varying the type of beef extract or by extending the elution time to 30 minutes.

Payment and Trudel (26) compared fiberglass filters from five different sources for virus adsorption, flow rate, clogging resistance, and virus concentration efficiency. Johns-Manville D39, Filterite (0.25-μm), Filterite (0.45-μm), and Millipore (0.45-μm) filters were the most efficient for virus adsorption, retaining more than 99% of the added virus in water at pH 3.5 and 0.0005 M aluminum chloride. The Johns-Manville D79 and D49 filters retained 92 and 96% of the virus, respectively, whereas the Whatman GF-D, Whatman GF-F, Gelman A-E, and Millipore AP-20 filters retained only 28 to 78% of added virus. The best flow rate and the least clogging were seen with Johns-Manville D79 filter (or with this filter acting as a prefilter to the Johns-Manville D49, Johns-Manville D39, or Filterite 0.45-μm filters). Recovery efficiency was 87% when 20 L of tap water seeded with poliovirus was concentrated with a combination of Johns-Manville D79-Johns-Manville D39 or with Johns-Manville D79-Filterite 0.45-μm filters.

Table 4. Common Eluents Used

Eluent	Reference
Glycine buffer (0.05–0.1 M) at pH 9.5–11.5	3,23,25,27
Beef extract (3%–6%) at pH 9.5–10.5	20,25,27
Slow backwash of filters	22
4 M urea-0.05 M lysine (pH 9.0) as eluent	30
Urea-arginine-phosphate buffer as eluent	31
Inclusion of Tween 80 in eluent	22,32

To evaluate the Viradel method using Filterite filters, six laboratories actively involved in water virology research participated in a methods-evaluation study under the auspices of the American Society for Testing and Materials (27). Low (350–860 PFU) and high (1,837–4,689 PFU) doses of a vaccine strain of poliovirus type 1 were seeded in 100-L samples of dechlorinated tap water at each laboratory. The water was adjusted to pH 3.5 and 0.0005 M $AlCl_3$. The filters were eluted with 1,600 mL of 3% beef extract-glycine (pH 9.0) or 0.05 M glycine (pH 10.5) and the eluate reconcentrated to smaller volumes by either organic flocculation (33) or by aluminum hydroxide hydroextraction method (3). All test samples were assayed in a single laboratory, where titers were also determined for the virus seed. With Viradel-organic flocculation method, the average virus recovery for low- and high-input experiments were 66% and 26%, respectively. With the Viradel aluminum hydroxide-hydroextraction procedure, the average recoveries were 20% and 11%. Considerable variation was noted in virus recovery from different laboratories, which may have been due to the length of experience of the people doing the test in a particular laboratory, water quality at different locations, and quality of the eluent used in different laboratories.

Wound fiberglass depth cartridge filters with a nominal porosity of 1 μm were evaluated as an inexpensive alternative to the 0.2-μm pleated cartridge filters (28). More than 99% of experimentally seeded poliovirus was adsorbed to these filters when the water was adjusted to pH 3.5 and 0.001 M aluminum chloride. In another study, Divizia and coworkers (29) compared filters from four different manufacturers (Sartorius, Millipore, Gelman, and Cuno) for the absorption elution of a cytopathic strain of hepatitis A virus (HAV) and found that both electronegative HAWP (Millipore) and electropositive (Cuno) filters absorbed HAV with high efficiency.

Macroporous glass (MPG-1,000 VGKh from Russia and SO1 from Czechoslovakia) and membrane filters (MF) (nitrocellulose PNT 0.45 from Russia, Millipore HAWP 0.45, Synpor 0.45 from Czechoslovakia, polycapromide MF Pall 0.2 from Germany, and FMPA 0.55 from Russia) were compared for the concentration of polio and SA-11 viruses (6). Radioactively labeled poliovirus and rabbit γ-globulin were used. Nitrocellulose filters (Millipore and PNT) proved to be superior in providing 64 to 90% virus sorption and 20 to 24% protein sorption. Elution experiments were conducted using solutions of different chemicals, for example, protein solutions (tryptosophosphate broth and beef extract), amino acid mixture (glycine + arginine), and chaotropic salts (sodium

trichloroacetate + lysine). Protein solutions were found to better elute rotavirus SA-11 from nitrocellulose filters and macroporous glass (MPG). The use of nitrocellulose filters and MPG as sorbents enabled 10 to 40-fold concentration of enteroviruses depending on the eluent used.

ELECTROPOSITIVE FILTERS

The use of electronegative filters requires the conditioning of test water to low pH and $AlCl_3$. To determine if viruses can be adsorbed on electropositive filters without the necessity of conditioning the test water, Sobsey and Jones (4) evaluated Zeta Plus filters (ZP60S) composed of diatomaceous earth-cellulose-"charge-modified" resin mixtures and having a net positive charge at pH 5.0 to 6.0. These filters efficiently adsorbed poliovirus from tap water at ambient pH levels (7.0 to 7.5) without added multivalent cation salts. The adsorbed viruses were eluted with glycine-NaOH, pH 9.5 to 11.5. Similarly, electropositive asbestos-cellulose filters were able to adsorb poliovirus from tap water in the absence of salts and at pH 3.5 to 9.0. However, the adsorbed virus could be eluted with 3% beef extract (pH 9.0) but not with glycine-NaOH (pH 9.5 to 11.5). Virus recoveries with Zeta Plus filters averaged 64 and 23% for one- and two-stage concentration procedures, respectively.

In a subsequent study, Sobsey and Glass (34) described the development of an electropositive pleated cartridge filter (Virozorb 1-MDS). Virus adsorption to these filters occurred in the absence of polyvalent cations and at pH 3.5 to 7.5. Beef extract in glycine (pH 9.5) was a more efficient eluent than glycine-NaOH (pH 11.0). Although poliovirus recovery from 1,000 L of tap water was similar (ca. 30%) to either Virozorb 1-MDS or with Filterite filters (adsorption at pH 3.5 and added $MgCl_2$), the former was much simpler to use (Fig. 2). In addition, electropositive filters gave less variable virus concentration efficiencies than did Filterite filters. Clearly, electropositive filters offer distinct advantages over conventional negatively charged filters for concentrating enteric viruses from water in that they are simple to use without sacrificing viral recovery.

In another study, both electronegative and electropositive filters were compared for the recovery of indigenous bacteriophages from water samples (35). Fiberglass and diatomaceous earth filters displayed low adsorption and recovery, but when treated with cationic polymers, these filters showed approximately 99% virus adsorption. For virus elution, the eluent was passed slowly through the filter, thus increasing the contact time between the eluent and the adsorbed virus. This elution method allowed a maximum phage recovery of 71% as compared with the 47% recovery obtained with the standard elution procedure.

In most of the studies, the 1-MDS filter was found to be efficient for virus concentration, except in a study by Alonso and coworkers (32), in which coliphages were concentrated from drinking water at a recovery rate of only 2%. However, the rate of coliphage recovery could be increased by including Tween 80 in the eluent. This is in agreement with the results obtained by Payment and coworkers (28) in which Tween 80 was shown to enhance the recovery of bacteriophages, bacteria, and parasites.

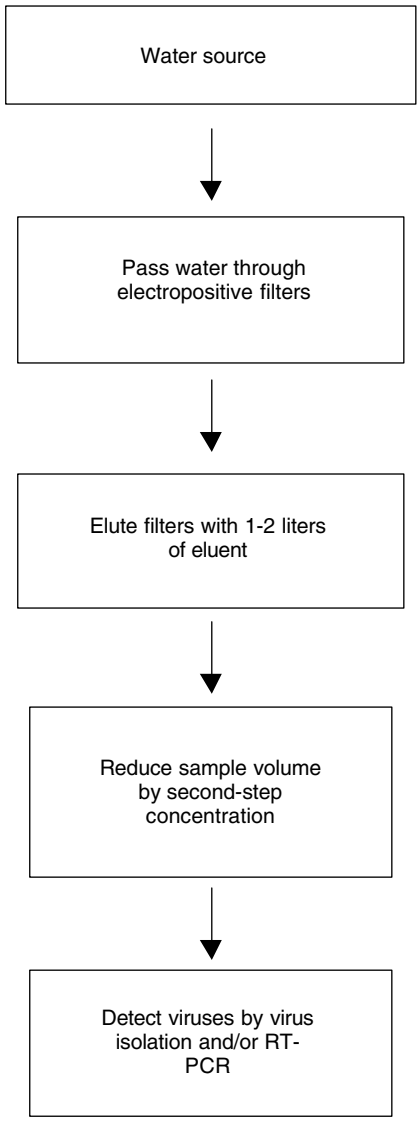

Figure 2. Schematic diagram of a virus adsorption-elution method using electropositive filters.

Another electropositively charged filter (MK filter) was evaluated against the 1-MDS filter to concentrate poliovirus type 1 (PV1) and coxsackievirus B3 (CB3) from 378-L samples of water (36). Adsorbed viruses were eluted from the filters with 3% beef extract buffered with 0.05 M glycine (pH 9.5) and reconcentrated via organic flocculation. At high virus inputs (10^6 PFU), the overall recovery of PV1 and CB3 from tap water with the MK filter was less than that achieved with the 1-MDS filter ($P < 0.05$). The average recoveries of PV1 with MK and 1-MDS filters in five trials were $73\% \pm 26\%$ and $90\% \pm 6\%$, respectively. The recoveries of CB3 in four trials were $33\% \pm 35\%$ and $96\% \pm 12\%$, respectively. Although the MK filter is less expensive than the 1-MDS filter, its use cannot be recommended because of consistently lower viral recovery.

In an effort to increase viral recovery rates, different eluents have been tested by different investigators (Table 4). Positively charged Zeta Plus filters were used to concentrate enteroviruses from 19 L of activated sludge effluent without the addition of salts and/or acidification of the effluent (30). Adsorbed viruses were eluted by treating the filters with a solution of 4 M urea buffered at pH 9 with 0.05 M lysine. The eluate was further concentrated into final volume of 1 to 2 mL by using a two-step reconcentration procedure that employed inorganic and organic flocculation. Approximately 50% of the viruses added to effluents could be recovered in the final sample. Jothikumar and Cliver (31) described the use of urea-arginine phosphate buffer (UAPB) for elution of coliphages adsorbed to positively charged filters. This method compared favorably with the beef extract elution-reconcentration procedure. The success of this method was attributed to testing the whole volume of concentrated sample, rather than partial analysis of the sample as described in standard methods for the examination of water and wastewater.

The use of Virozorb 1-MDS filters is not limited to enteroviruses alone. They have also been used for the concentration of infectious pancreatic necrosis virus from fish hatchery waters (37). The method consists of passing 100 L of hatchery water through 1-MDS filter followed by the elution of the adsorbed virus using a high pH buffer. The virus adsorbed efficiently to 1-MDS filters when the pH of the water was 5.5 and was eluted optimally with 3% beef-extract solution (pH 10). This procedure permitted the processing of 100 L of hatchery water that resulted in a 300-fold reduction in the volume of water and greater than 90% recovery of the seeded virus.

Rotaviruses were concentrated from 8 L samples of raw sewage and sewage-polluted creek water in Brazil using positively charged Zeta Plus filters (38), followed by ultracentrifugation of the filter eluate as second-step reconcentration. Rotaviruses were detected in the final sample by indirect immunofluorescence and direct immunoperoxidase assays. Using this method, rotavirus was detected in 6 of 29 sewage samples and in 19 of 55 creek-water samples. Samples examined during autumn and winter months showed a higher rate of rotavirus detection than those collected in spring and summer, corresponding to the seasonal variation of rotaviral diarrhea in the city of Sao Paulo.

Myrmel and coworkers (39) concentrated small round-structured viruses (SRSV), common cause of gastroenteritis worldwide, from 500 mL of deionized water. SRSV-containing fecal extracts were added to water and virus was recovered by filter adsorption-elution followed by organic flocculation. RNA was extracted and SRSV were detected by the use of reverse transcription-polymerase chain (RT-PCR) reaction. The sensitivity of the method corresponded to a positive SRSV detection at an estimated concentration of 0.5 to 5 virus particles per millimeter.

OTHER MEDIA

Many other media have been evaluated in an effort to find inexpensive alternatives to membrane filters (Table 1). Some of the more promising ones are pig erythrocyte membranes (erythrocyte ghost cells) (10), yeast cells (11), and inorganic salts ($CaHPO_4$) (12). Although large sample volumes cannot be processed by these methods, they may be useful as second-step reconcentration procedures. For example, erythrocyte ghost cells were used for the concentration of bacteriophages (ϕX174, MS-2, and f2) from 5 mL of saline solution (10). The adsorption and elution were carried out at pH 3.5 and 7.0, respectively. Bacteriophage adsorption on ghost cells was 93 to 100% and elution was 92 to 100%. With poliovirus, the rates of adsorption and elution were 100% and 91 to 129%, respectively.

Dahling and coworkers (5) placed a bituminous coal preparation between two prefilters and used this sandwich to recover viruses from large volumes of water. This filter was effective over a pH range of 3.0 to 7.0, and poliovirus recovery from 100 L volumes of tap water and domestic raw sewage was found to be similar to that obtained with Filterite and Millipore filters. Active aluminum oxide was used as an adsorbent for poliomyelitis virus type 3 and simian rotavirus SA-11 from sewage and drinking water (13). Optimum concentrations for effective adsorption of both rota- and polioviruses were 1.5 and 1 g/L, respectively, at ambient pH (pH 7.0 to 8.5) and at contact time of 30 minutes. Elution with 3% beef-extract solution (pH 8.5 to 9.5) was optimum for both viruses.

Farrah and coworkers (14) modified diatomaceous earth by in situ precipitation of metallic hydroxides, thereby decreasing the negative charge on the earth and increasing its ability to adsorb viruses. Filters containing diatomaceous earth modified by in situ precipitation of ferric chloride and aluminum chloride adsorbed greater than 80% of enteroviruses (poliovirus 1, echovirus 5, and coxsackievirus B5) and coliphage MS2 present in tap water at ambient pH (7.8 to 8.3), even after filtration of 100 L of tap water. Viruses adsorbed to the filters were recovered by mixing the earth with 3% beef extract containing 1 M NaCl (pH 9.0).

Papageorgiou and coworkers (15) developed a simple method in which there was no need for virus elution following adsorption to filters. They optimized conditions for the growth of Buffalo green monkey kidney (BGMK) cells on the entire surface of cellulose nitrate membrane filters in such a manner that the cells penetrated through the pores of the filter. When such conditions were used, poliovirus that had previously been adsorbed on the membranes infected the cells and replicated. In addition, this approach allowed plaque hybridization either directly on cellulose nitrate membranes or on Hybond N+ membranes after the preparations were transferred.

FACTORS INFLUENCING VIRUS CONCENTRATION

It is obvious from the preceding text that there is a high degree of variability from laboratory to laboratory when using membrane filters for the concentration and detection of enteroviruses from water and wastewater. Sobsey and Glass (40) studied the effect of various factors on virus concentration by both electropositive

and electronegative microporous filters. They seeded 1.3 L volumes of raw, finished, and activated carbon-treated waters with poliovirus type 1, echovirus type 1, reovirus type 3, and simian adenovirus SV-11. The samples were filtered through 47-mm diameter electropositive (Virosorb 1-MDS) filters at pH 7.5 or electronegative (Filterite) filters at pH 3.5 with and without 5 mM $MgCl_2$. The adsorbed viruses were eluted with 0.3% beef extract in 50 mM glycine of pH 9.5.

Prefiltration to remove particulate matter had no effect on virus recovery, but the presence of soluble organic compounds in raw and finished water was found to reduce virus adsorption to both types of filters. In the case of electronegative filters, this interference could be overcome by the addition of $MgCl_2$ to the sample being filtered. Elution of poliovirus and echovirus was much more efficient than that of reo- and adenoviruses. It was concluded that virus and water types play a significant role in recovery efficiency of any concentration scheme (40).

Lukasik and coworkers (41) studied the effects of different salts (NaCl, $MgCl_2$, and $AlCl_3$) on the adsorption of different viruses (MS2, PRD-1, ϕX174, and poliovirus 1) to commonly used microporous filters, for example, Millipore HA (nitrocellulose), Filterite (fiberglass), Whatman (cellulose), and 1-MDS filters. Both direct and indirect effects (changes in pH value of solutions following salt addition and the formation of insoluble precipitates that could adsorb viruses and be removed by filtration) were studied. The direct effects of added salts consisted of increase, decrease, or no effect on virus adsorption depending on filter type, virus type, and salt type. As reported in previous studies (3), the addition of aluminum chloride to water did enhance virus adsorption to microporous filters. However, this enhancement was due to indirect effects of salts (decrease in pH of water following the addition of aluminum chloride) rather than the direct effects (42). Increase in virus adsorption with aluminum chloride at pH 7.0 was considered to be due to flocculation of aluminum because prior removal of aluminum flocs by filtration did not enhance viral adsorption. The addition of multivalent salt and a compound that interfered with hydrophobic interactions (0.1% Tween 80 or 4 M urea) resulted in a drastic decrease in virus adsorption indicating that hydrophobic interactions are important in virus adsorption to filters. The type of water to be filtered and the possible release of toxic substances from the membrane matrix during filtration should also be considered (43) when evaluating a particular concentration method.

Table 5. Common Methods Used for Second-Step Concentration

Eluent Used	Reconcentration Method	Reference
Glycine	Aluminum hydroxide flocculation hydroextraction	3
Beef extract	Organic flocculation	33
Beef extract	Modified organic flocculation	20

SECOND-STEP CONCENTRATION

Many different methods have been evaluated for the reconcentration of filter eluates (Table 5). Kashkina and coworkers (9) described a two-phase system of water-soluble polymers for the concentration of measles virus. One of the polymers was polyethylene glycol (PEG) (MW 6,000), which was used with either dextran sulfate (DS; MW 500,000) or with dextran (D; MW 500,000). Virus concentration was found to occur in the interphase and lower phase. The concentration factors were 300 and 60 to 100 for PEG-DS and PEG-D system, respectively. Preformed magnesium hydroxide precipitate has been used for second-step concentration of viruses present in the first eluate (performed with 50 mM glycine buffer, pH 11.5)(44). The viruses were adsorbed on a preformed magnesium hydroxide precipitate. After low-speed centrifugation, the viruses were eluted (desorbed) with McIlvaine citrate-phosphate buffer. Under these conditions, 90% of the viruses present in the 300 mL of the first eluate were reconcentrated in a final volume of 40 mL. The recovery efficiency was independent of either virus concentration or water quality.

Enteroviruses added to 114 L of dechlorinated tap water were recovered in a 16 mL sample by a two-stage concentration procedure in which different types of membrane filters were used in each concentration stage. Viruses in tap water at pH 3.5 were first adsorbed to Filterite filters and then eluted with 0.2 M sodium trichloroacetate solution buffered at pH 9 with 0.2 M lysine. Viruses in this solution were adsorbed to 47-mm asbestos filters (Seitz) without pH adjustment or other modification of the solution. Viruses were recovered from the Seitz filters with 16 mL of either Casitone or fetal calf serum at pH 9. With these procedures, approximately 45% of several types of enteroviruses added to 114 L of tap water could be recovered in the final 16-mL sample (45).

A second-step concentration procedure using iron oxide was developed for the detection of rotaviruses in water (46). Samples (378-L) of estuarine water adjusted to pH 3.5 and 0.001 M $AlCl_3$ were filtered through Filterite filters of 3.0- and 0.45-μm porosity. Adsorbed virus was eluted with 1 L of 10% tryptose phosphate broth, at pH 9.5. Primary eluates were reconcentrated to a final volume of 10 to 20 mL by magnetic iron oxide adsorption and elution procedure. A 2% solution of casein at pH 8.5 effectively eluted rotavirus from iron oxide. Using this method, rotaviruses were detected in water, suspended solids, fluffy sediments, and compact sediments at different locations within the Galveston Bay, Texas.

A modification of the organic flocculation was described (47) in which bacteriophages and enteroviruses in water were adsorbed to positively charged 1-MDS filters or Seitz S filters. Adsorbed viruses were eluted with 10% beef extract, at pH 9. Organic flocculation of the beef extract at pH 3.5 permitted recovery of more than 40% of the enteroviruses but less than 15% of the bacteriophages. A method was developed that used salts at pH 7 to flocculate beef extract. Two volumes of saturated ammonium sulfate were added to beef extract, and both enteroviruses and bacteriophages were adsorbed to the flocs that formed.

More than 70% of the enteroviruses and bacteriophages were recovered by centrifuging the sample and suspending the flocs in a small volume of distilled water.

Addition of Tween 80 to a 1.5% solution of beef extract was found to enhance the elution of bacteriophages adsorbed to electronegative filters (48). When reconcentration of the eluate was attempted by ammonium sulfate precipitation, a floating layer containing most of the viruses was formed. This floating layer could be obtained with several nonionic detergents including Tween 80 and, under a salt saturation of 55%, with ammonium sulfate, potassium tartrate, and sodium phosphate. Virus recovery ranged from 91 to 103% and was obtained with several bacteriophage strains. With poliovirus type 1, coxsackievirus B-4, and rotavirus SA-11, the recoveries were 100%, 20%, and 80%, respectively, but toxicity to cell culture was encountered. After removal of the detergent by a second floating-layer method, the recovery was 32% for poliovirus. Compared with organic flocculation, this method provided improved recovery for bacteriophages.

Hollow-fiber ultrafilters have been used to remove viral contaminants from fluids. During ultrafiltration, virus concentration in the feed continues to increase because the retentate is returned to the input reservoir, although the permeate is removed to a separate vessel. Wallnerova and Simkova (12) suggested the use of the Amicon apparatus for ultrafiltration of water samples. Later, Divizia and coworkers (49) evaluated a molecular filtration system for recovering hepatitis A (HAV) and polioviruses seeded into 1 L of dechlorinated tap water. A polysulfonate membrane of 10,000 molecular weight was used. Under these conditions, HAV recovery was 100% of the input, but the percentage was reduced dramatically when the inflow pressure was increased. In contrast, poliovirus recovery was low under standard conditions, but improved when membranes were pretreated with different buffers. The best recovery was obtained using beef extract at neutral pH.

Recently, Oshima and coworkers (50) tested hollow-fiber ultrafilters with different molecular weight cutoffs to remove and detect poliovirus and phages T1 and PP7 from ultrapure water. Ultrafilters with molecular weight cutoffs of 13,000 and 6,000 were found to be very effective in removing small virus particles (25 to 30 nm) by size exclusion. In a subsequent study, they developed modified polyvinylidene fluoride (PVDF) membrane filters and tested them for the removal of different viruses from ultrapure water (51). Small volume (10 mL) filtration experiments were conducted with 47-mm disks, whereas larger volume experiments (1 L) were conducted with cartridge filters (surface area of 1.63 m2). Influenza A virus and phage T1 were removed to less than detectable limits with titer reductions of grater than 2.0×10^6 and greater than 5.8×10^8, respectively. The results of cartridge filter experiments were similar to those of 47-mm disks. Efficient virus retention suggests potential applications of this filter for second-step reconcentration of filter eluates.

A method consisting of a concentration step by tangential flow filtration (TFF) system, ultrafiltration by centrifugal concentrator, and visualization by transmission electron microscopy (TEM) has been described (52). With this method, 2 L volumes of seawater were reduced to 10 to 20 μL, which could then be dispensed on electron microscopy grids to count total viral particles. Recovery rates varied depending on both the viral morphology and flow rate. At low flow, 117% and 61% of T6 and φX174, respectively, were recovered.

Vortex flow filtration (VFF) was used to concentrate viruses and dissolved DNA from freshwater and seawater samples (53). Recoveries of T2 phage and calf thymus DNA added to artificial seawater and concentrated by VFF were 73% and 80%, respectively. Virus concentrations determined by transmission electron microscopy of VFF-concentrated samples ranged from 3.4×10^7/mL for a eutrophic Tampa Bay sample to 2.4×10^5 for an oligotrophic oceanic surface sample from the southeastern Gulf of Mexico. Viruslike particles were also observed in a sample taken from a depth of 1,500 m in the subtropical North Atlantic Ocean. Filtration of samples through Nucleopore or Durapore filters (pore size 0.2 μm) before VFF resulted in a reduction of phage counts.

MOLECULAR METHODS OF VIRUS DETECTION

Until recently, virus detection was done by virus isolation in cell cultures. The problems with this approach are that some sample concentrates are cytotoxic, not all viruses grow in cell cultures and the method is time consuming and costly. To overcome these problems, molecular diagnostic techniques have been introduced in environmental virology laboratories, the method of choice being the reverse transcription-polymerase-chain reaction (RT-PCR). Even fastidious viruses that do not grow in cell cultures, can be detected by this technology. The drawbacks of this technique are that sample concentrates may sometimes contain inhibitors of PCR reaction, PCR is unable to differentiate between infectious and noninfectious viruses, and its use is limited to sophisticated laboratories.

The development of a nucleic acid hybridization test for the detection of hepatitis A virus (HAV) in estuarine samples was described (54). The sensitivity was limited to approximately 10^4 physical particles of HAV per dot and was affected by hybridization stringency, ^{32}P energy level, probe concentration, presence of humic acid, and nucleic acid binding to filters. No cross-hybridization with other enteroviruses and unrelated nucleic acids was observed. Potential false-positive reactions between bacterial DNA in samples and residual vector DNA contamination of purified nucleotide sequences in probes were eliminated by DNase treatment of samples. Similarly, interference by organic components of virus-containing eluates was removed by proteinase K digestion, followed by phenol extraction and ethanol precipitation.

A major advance in the use of molecular techniques was made by the development of a reverse transcriptase (RT)-polymerase chain reaction (PCR)-oligoprobe (OP) or (RT-PCR-OP) method for the detection of Norwalk virus (55) that has the potential of being used for the detection of this virus in both clinical and environmental samples. Primers

were used for the amplification of RNA polymerase (260-bp product) and a putative immunogenic protein (224-bp product). The resulting DNA fragments (amplicons) were hybridized to a digoxigenin-labeled internal OP specific to each amplicon. This method was 100-fold more sensitive than radioimmunoassay (RIA). In addition, this method was specific for Norwalk virus and did not detect human and animal caliciviruses, hepatitis E virus, Snow Mountain agent, astroviruses, 16 human enteroviruses, and 5 human rotaviruses. Norwalk virus was detected in 4 of 21 coded fecal specimens that were also positive by enzyme immunoassay.

The RT-PCR technique was later used to detect hepatitis E virus (HEV) in sewage (56). HEV in sewage samples was concentrated through adsorption to membrane filters, elution with urea-arginine phosphate buffer, and subsequent reconcentration with magnesium chloride. HEV-specific cDNA was prepared by reverse transcription of the total RNA extracted from samples. Specific DNA amplification by PCR in combination with slot-blot hybridization was used to demonstrate the presence of HEV in sewage samples from the inlets and outlets of three sewage treatment plants. The assay was specific for HEV, and a 240-bp amplified product was visualized by ethidium bromide fluorescence. Sewage samples adjusted to pH 5.0 for adsorption of viruses to membrane filters were PCR positive, whereas samples adjusted to pH 3.5 were PCR negative.

Puig and coworkers (57) described the use of a nested PCR for the detection of entero- and adenoviruses and found that extraction by adsorption of nucleic acids to silica particles was the most efficient. Using this procedure, they were able to detect 24 different enteroviruses and 47 human adenovirus serotypes with a sensitivity of 1 to 10 virus particles. When 25 samples of sewage and polluted river water were analyzed, nested PCR detected more positive samples than virus isolation in cell cultures.

To determine RT-PCR compatibility of sample concentrates obtained by conventional filter adsorption-elution methods, Schwab and coworkers (58) used beef extract-glycine eluates, with or without humic acid, and seeded them with poliovirus type 1. These mock eluates were further processed by polyethylene glycol precipitation, Pro-Cipitate precipitation, a second polyethylene glycol precipitation, spin column chromatography, and ultrafiltration. The sample volumes were reduced from 1 L to 20 to 50 μL. Detection by RT-PCR was compared with cell culture infectivity procedures. As little as 3 PFU of poliovirus in an initial 1 L of mock eluate was detected by RT-PCR.

To increase the sensitivity of enteric virus detection in tap water concentrates, poliovirus 1 and coxsackievirus B3 were seeded into 378 L of tap water, concentrated with 1-MDS filters, and reconcentrated by organic flocculation (59). RT-PCR was successful in detecting viral nucleic acid following the removal of PCR inhibitory substances from water concentrate. Direct phenol-chloroform-isoamyl alcohol (PCI) extraction of viral RNA was found to be sufficient to remove inhibitory substances for RT-seminested PCR with a sensitivity of 0.2 plaque-forming units per 10 μL (0.2 PFU/L tap water).

Nucleic acid amplification by RT-PCR and confirmation by oligonucleotide probe hybridization was evaluated for the detection of poliovirus type 1 (PV1) or hepatitis A virus (HAV) in oyster extracts (60). For this purpose, seeded viruses in oyster extracts were purified by fluorocarbon extraction and concentrated by polyethylene glycol (PEG) precipitation and elution. A protein-precipitating agent, Pro-Cipitate (Affinity Technology, Brunswick, N.J.), was used in an adsorption-elution precipitation scheme to reduce sample volume to 100 μl. Virus detection by RT-PCR and cell culture propagation were comparable and correlated well with replicate samples and at different virus titers.

Schwab and coworkers (61) developed a broad-spectrum immunocapture method for indirect antibody capture (AbCap) of intact viruses, release of virion genomic RNA, RT-PCR for RNA amplification, and oligoprobe hybridization for virus detection. Enteric viruses were concentrated from large volumes of water by standard filtration-elution techniques using 1-MDS filters and 1 L of 1% beef extract-0.05 M glycine as an eluate. The eluate was concentrated and purified by polyethylene glycol (PEG) precipitation, Pro-Cipitate precipitation, and a second PEG precipitation to a volume of approximately 500 μL. Aliquots of the second PEG precipitate were further processed by RNA extraction, AbCap, or cell culture analysis for infectious viruses. The AbCap method was applied to 11 field samples of fecally contaminated surface water. Of the 11 samples, 9 were positive for enteric viruses by AbCap method, 4 were positive by direct RNA extraction of a small aliquot of the second PEG concentrate, and 4 samples were positive in cell cultures.

The PCR technique was also evaluated for the detection of enteric viruses in groundwater (62). An improved sample processing technique and a large-volume amplification protocol were used. Viruses were detected after concentration from 1,512 L of water by a filter adsorption-elution method. When 150 samples were analyzed, only 13 (8.7%) were positive in cell cultures, whereas 40 (30.1%) tested positive by RT-PCR. The authors believed that their sample-processing technique and large-volume PCR protocol (reaction volume, 300 μL) were responsible for removal or dilution of inhibitors so that more than 95% of the samples could be assayed by PCR.

Greening and coworkers (63) developed a sensitive, nonisotopic microtiter plate hybridization assay for the detection of enteroviruses in environmental samples. Following reverse transcription, viral cDNA was labeled with digoxigenin (DIG)-dUTP during the PCR amplification step. The labeled PCR products were hybridized with enterovirus-specific biotinylated oligonucleotide probe and captured in streptavidin-coated microtiter wells. Hybridized enteroviral PCR products were detected by an antidigoxigenin peroxidase conjugate using either a colorimetric or a chemiluminescent substrate and automated measurement. The chemiluminescent assay was found to be more sensitive than the colorimetric assay for the detection of poliovirus, and was specific to enteroviruses.

A multicentric study was conducted in three laboratories to evaluate the efficiency of a standardized kit for

the detection of enterovirus genome in wastewater (64). Twenty-one samples of 20 L of wastewater were analyzed before and after concentration through glass wool. Each sample was analyzed with the Amplicor kit and with techniques developed independently in each laboratory. The results showed that the Amplicor kit was well-suited for the detection of the enterovirus genome in treated wastewater and that the results were comparable to those obtained with seminested RT-PCR. In one study, Grabow and coworkers (65) compared three different cell types (L20B mouse cells, PLC/PRF/5 human liver cells and BGM cells) and RT-PCR for the detection of human enteric viruses in environmental samples. Of the 319 samples tested, 263 failed to produce cytopathic effects in either of the three cell lines but were positive by RT-PCR.

Chapron and coworkers (66) collected 29 surface-water samples using the Information Collection Rule method consisting of filter adsorption-beef extract elution and organic flocculation. Two methods were compared for virus detection in these concentrates, for example, (*1*) an integrated cell culture-RT-PCR (ICC-RT-PCR) coupled with nested PCR to detect human astroviruses, enteroviruses, and adenovirus types 40 and 41 and (*2*) total culturable virus assay-most-probable-number (TCVA-MPN) method as recommended by the U.S. Environmental Protection Agency. Twenty-seven of the 29 samples (93%) were positive by the ICC-RT-PCR method, whereas only 5 samples were positive by the TCVA-MPN method. Primers based on the helicase region of the genome of the small round-structured viruses (SRSVs) (Norwalk-like viruses) were found to be useful in detecting SRSVs in water (67).

INHIBITORS OF RT-PCR

From the foregoing account, it is clear that RT-PCR is more sensitive than virus isolation. However, it does suffer from the disadvantage that sample concentrates may sometimes contain substances that inhibit PCR amplification of target RNA. Several investigators have addressed this issue. Sephadex G-200 gel chromatography has often been used to remove PCR inhibitors (55,68). Virus concentration by adsorption onto glass powder or glass wool has been used to detect viral genomes in treated wastewater by seminested PCR (7). No enterovirus genome was detected directly in 25 samples of treated wastewater by seminested PCR but 48% and 56% of the samples concentrated by adsorption onto glass wool or glass powder, respectively, were positive for viral genome. Secondary concentration by organic flocculation of samples concentrated by glass wool resulted in a decrease in the number of RT-PCR positive samples (from 48–20%). Secondary concentration of glass wool concentrates, on the other hand, resulted in an increased recovery (from 56–72%).

Myrmel and coworkers (69) described a simple method for the preparation of Norwalk-like virus (NLV) RNA from environmental samples. They coated magnetic beads with polyclonal antibodies against a recombinant capsid protein of genogroup I NLV and used these beads for immunomagnetic separation (IMS) of NLV. Viral RNA was heat released and detected by RT-PCR. The combination of IMS and heat release was found to be more efficient than organic extraction of RNA from water contaminated with humic acids.

Lewis and coworkers (70) investigated the effects of clay, humic acid, ultraviolet light, and shellfish tissue residues on the detection of poliovirus type 2 by cell culture and RT-PCR. The latter technique was found to be 10 to 100 times more sensitive than culture in the absence of sample contaminants. The addition of 100 to 1,000 mg/L of bentonite clay and shellfish tissue residues reduced virus detection by plaque assay. Similarly, bentonite clay, humic acid (5 to 150 mg/L) and mussel tissue reduced virus detection by RT-PCR (between 1 and 8 logs), although this was mitigated in part by elution and Sephadex filtration of extracts. As expected, the exposure of virus in water to ultraviolet light reduced culturability of the virus but not detection by RT-PCR.

CONCLUSION

It is clear from this and other reviews that membrane filters are the media of choice for adsorption-elution of viruses from large quantities of water. Electropositive filters are simple and easy-to-use because preconditioning of water with acid and salt is not necessary. Molecular methods of virus detection in concentrated samples have proven useful and more progress is being made in this area. However, the problems associated with molecular methods (detection of infectious and noninfectious viruses, presence of RT-PCR inhibitors in the sample concentrates) will need to be worked out before these methods become even more popular for virus detection.

ENTEROVIRUSES: OCCURRENCE AND PERSISTENCE IN THE ENVIRONMENT

C. GANTZER
L. SCHWARTZBROD
Faculté de Pharmacie
Nancy, France

Evaluation of the viral contamination in the environment is subject to many variations inherent in the analysis methodology, relating particularly to the techniques used for virus concentration and to the virus material to be tested. *Enteroviruses* can be detected in the stools of patients, in environmental samples by isolating infectious virus particles on cell cultures and also by detecting the viral genome using molecular biological techniques such as the reverse transcription-polymerase chain reaction RT-PCR.

The use of RT-PCR to detect *Enterovirus* in water has several benefits over cell culture technique. It has the potential to improve detection limits as well as reducing processing times and cost. It is a sensitive and specific method but a number of outstanding problems can seriously affect its performance. For example, the enzymes used during the RT-PCR reaction can be inhibited by a number of environmental contaminants such as humic acid. Furthermore, the great sensitivity of PCR makes it susceptible to false-positive results because of contamination. Finally the detection of *Enterovirus* genome using RT-PCR is not the proof of the presence of infectious *Enterovirus*.

If attempts are made to detect infectious virus particles in cell cultures or their genome by molecular biological techniques like RT-PCR, the results for the same sample of water may differ substantially. For example, Puig and coworkers (1) found 31% of the samples to be positive when detecting infectious *Enterovirus* particles and 75% of the samples to be positive when testing for the enteroviral genome.

Viral contamination of the environment is a natural phenomenon associated with the discharge of human and animal feces, particularly into water systems. An individual infected with an *Enterovirus* whether or not he has symptoms, may excrete up to 10^6 cell culture infectious units per gram of feces. Nevertheless, the stool probably contains 10 to 100 times more viral particles (2). Given that humans produce a mean of 100 to 200 g of feces per day, approximately 10^8 *Enterovirus* particles may be released per day by an infected individual. It is logical for the enteroviral concentration to be very high in the raw wastewater that constitutes the natural receptacle for feces. However, it is important to bear in mind that the density of *Enterovirus* in wastewater varies as a function of many geographic, socioeconomic, seasonal, and, particularly, sanitary factors. Thus, the lower the level of hygiene and the larger the proportion of children in a community, the larger the number of *Enteroviruses* found in the wastewater. Indeed, children are a preferred target for these viruses. Dahling and coworkers (3) observed that the level of *Enterovirus* contamination of wastewaters was higher in Puerto Rico (a region with a very high population density and a low socioeconomic level) than in other locations in the United States, with peak concentrations of *Enterovirus* reaching more than 10^5 plaque forming units (pfu) per liter.

Similarly, the effects of other geographic and climatic factors are not negligible and it has long been known that *Enterovirus* infections show a predominance in summer and autumn in countries with temperate climates.

The diagram of the enteroviral transmission in the environment is given Figure 1.

Studies have been published concerning the level of contamination of raw wastewater (4,5). On average, 90 to 100% of raw wastewater samples contain infectious *Enterovirus*, at a mean concentration of 10^2 to 10^3 pfu/L.

In many parts of the world, these waters are discharged into the natural environment without treatment. However, in industrialized countries, they receive physicochemical or biological treatment. This treatment has two practical consequences: it improves the microbiological quality of the water discharged and reduces the amount of biologically degradable organic matter, unfortunately it also leads to the production of large quantities of residual sludge that must be disposed.

The residual sludge resulting from the treatment of wastewater contains significant numbers of *Enteroviruses* because wastewater results in their transfer to the sludge. The density of these viruses in sludge depends on the nature of the treatment process. The mean virus content of sludge is very variable, but primary sludge generally contains 10^3 to 10^4 pfu/kg of dry matter. This sludge may be used as agricultural fertilizer, discharged, or incinerated.

Viral contamination of treated wastewater has also been extensively described in the literature (6,7). Clearly, the concentration of *Enteroviruses* depends on the type of treatment applied to the raw wastewater and the initial level of contamination. The mean concentration of *Enteroviruses* following biological treatment by activated sludge is generally 0 to 10^2 pfu/L. On release from treatment plants, the number of viruses discharged into surface waters is therefore far from negligible.

In surface waters, as a result of dilution, viral concentrations rarely exceed 10 pfu/L and the frequency of samples in which infectious *Enteroviruses* may be detected is between 0 and 50%. In contrast, the enteroviral genome may be detected in as many as 30 to 100% of samples. However, in these waters, as in the environment as a whole, the presence of the *Enterovirus* genome does not constitute proof of the presence of infectious *Enteroviruses*. For example, Pallin and coworkers (8) detected the *Enterovirus* genome in 25 to 92% of seawater samples whereas no infectious *Enteroviruses* (cell culture) were isolated from the same samples.

It is also worth pointing out that most of these studies were carried out in areas likely to be polluted by waste from human activity and that these percentages therefore are not representative of surface waters as a whole. In any case, the majority of the *Enteroviruses* may be adsorbed to suspended matter and are therefore likely to sediment or to be deposited in fluvial or marine sediments.

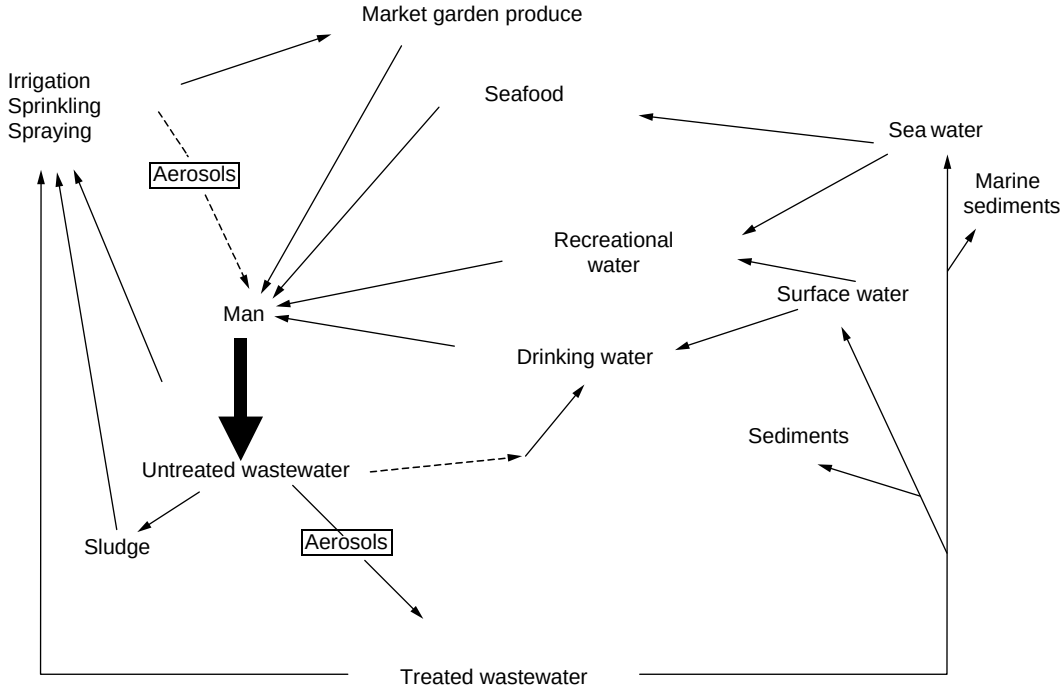

Figure 1. Diagram of the enteroviral transmission in the environment.

The superficial layer of very light readily resuspended sediments constitutes a potential source of contamination remote from the source (Fig. 2).

Viruses usually isolated in larger numbers from sediments than from the overlaying water, and values of 10^2 pfu/kg are not unusual (7,10).

If shellfish-producing areas become contaminated, the shellfish, which feed by filtering large quantities of water, may retain, and even concentrate, the virus in their digestive tract. This bioaccumulation occurs very rapidly (within a few hours) and is very efficient. Digirolamo and coworkers (11) have reported factors of concentration of up to 32 for *Poliovirus 1* in oysters. The extent of this bioaccumulation depends on the type of shellfish, its physiological state, the temperature of seawater, the type of virus, its concentration in seawater, and above all, its state, free or adsorbed. In fact, viral adsorption onto supports (feces, kaolinite, unicellular algae and so on) increases the rate of accumulation (12). In most cases, the contamination of shellfish is correlated with the discharge of raw or treated wastewater in the shellfish-producing zone. For example, infectious *Enteroviruses* and the enteroviral genome have been detected in shellfish raised in seawater into which raw wastewater, primary treated wastewater,

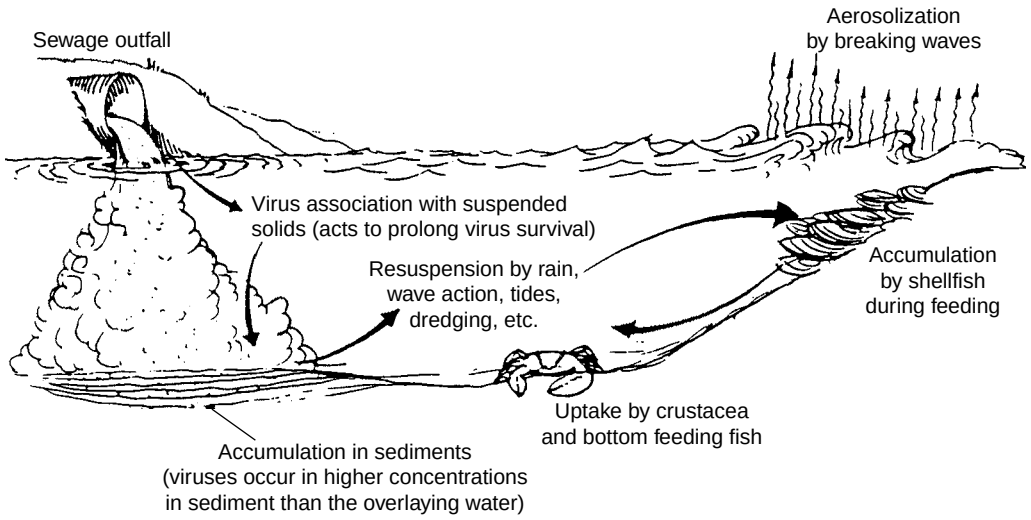

Figure 2. Fate of viruses in coastal systems (from 9).

and secondary treated wastewater have been discharged. The mean concentration in shellfish was 12 pfu, 0.3 pfu, and below the detection threshold, respectively, per 10 g of shellfish (13). But even in the last case when no infectious *Enteroviruses* were isolated, the enteroviral genome was detected in 100% of the samples. The *Enterovirus* genome has been reported to be present in molluscs on numerous occasions (7,10,14), often in the absence of infectious *Enteroviruses*. It should also be pointed out that in some cases, infectious *Enterovirus* and, more frequently, the *Enterovirus* genome, have been detected in shellfish meeting bacteriological standards for shellfish growing areas.

Wastewater (raw or treated) may be used for land irrigation and sludge spreading on fields. Infectious *Enteroviruses* and their genome have been detected in fields to which sewage sludge has been applied. Viruses have been isolated from groundwater situated vertically below fields irrigated with wastewater. Goyal and coworkers (15) isolated *Enteroviruses* in wells, at a depth of 27.5 m. In contrast, Moore and coworkers (16) did not isolate any viruses in well water while observing a site irrigated with wastewater but found *Enteroviruses* in the water of a lysimeter, at a depth of 1.37 m.

Infectious *Enterovirus* and enteroviral genome were recovered, respectively, from 3.4% and 9.2% from 303 groundwater samples (1,700 l) (17). Abbaszadegan and coworkers isolated infectious *Enteroviruses* from 8.7% of groundwater samples (1,512 l) while 30.1%, 8.6%, and 13.8% of these samples were positive for the genomes (RT-PCR) of *Enteroviruses* hepatitis A virus, and *Rotaviruses* (18), respectively.

Aerosols can form while wastewater is being treated, particularly during the activated sludge phase and when irrigation is carried out using spraying techniques. When spraying is carried out with a sprinkler, 0.05 to 1% of the liquid is transformed into aerosols. It is generally thought that 30% of the particles suspended in the aerosol could be inhaled because their size varies between 0.2 μm and 5 μm. It is therefore possible that after inhalation these particles penetrate the respiratory system and that the largest (2 μm) are evacuated by ciliary action and pass into the digestive system. If these particles contain viruses, the latter can cause infection. *Enteroviruses* have been detected in air samples taken near an activated sludge treatment plant (19). Teltsch and Katzenelson (20) found *Enteroviruses* between 40 and 100 m downwind from fields irrigated by spraying with wastewater. Similarly, Shuval and coworkers (21) have observed that 12.5% of air samples taken 730 m downwind from land irrigated by lagooned wastewater contained concentrations of *Enteroviruses* varying between 0.03 pfu and 1.94 pfu/m^3.

Finally, very little information exists on the contamination of market garden produce irrigated with wastewater. However, Bagdassaryan (22) has reported the isolation of *Enteroviruses* on irrigated vegetables but the quality of the wastewater was not indicated.

PERSISTENCE OF THE VIRUS IN THE ENVIRONMENT

Enteroviruses are obligatory intracellular parasites, and as such they can only multiply within the host cells. In the environment, the concentration of *Enteroviruses* can therefore only decrease, or at worst, remain constant. The fate of viruses therefore depends on the effects of physicochemical (temperature, adsorption onto suspended matter, salinity, pH...) and biological (inactivating substances of microbial origin...) factors in the environment. All of these factors may act separately or in conjunction and it is difficult to separate the various factors in complex environments.

Influence of Physicochemical Factors

Temperature. In the environment, viruses are inactivated by the combined effects of various environmental factors. However, many studies carried out on natural surface water (e.g., sea, river, lake) and on soils have shown that high temperatures are of primary importance in viral inactivation. An increase in temperature leads to a change in the capsid conformation and thus loses the ability to interact with the receptors of the target cell. Furthermore, it is well known that the attachment of the virus to the target cell via these receptors is the first step in viral infection and is essential for all viral infections.

Thus, increase in temperature initially affects the infectivity of the virus without causing lesions in the viral genome. This is supported by studies showing that the *Poliovirus 1* genome can be detected in the phosphate buffer after heating to 75 °C for 15 minutes, whereas infectious virus particles are no longer detected after 15 minutes at only 56 °C (23). Similarly, but at a much lower temperature (37 °C), Enriquez and coworkers (24) observed a large decrease in the infectivity of *Poliovirus 1* (5 log) after incubation in the phosphate buffer for 21 days, whereas in the same conditions a decrease of only 1.5 log was recorded for the genome after 75 days.

Adsorption. Viral adsorption also has an significant effect on the fate of viruses in the environment. Generally, viruses behave like colloidal particles with a large capacity for adsorption to surfaces of all kinds. There are many potential adsorbents in the environment including clays, suspended solids and other colloids present in the water, microorganisms, soils (in cases of wastewater irrigation), shellfish and so on. In the environment, viral adsorption depends on many factors including the nature and concentration of the salts and adsorbents present, the viral serotype, the nature and concentration of the organic matter present and so on (25,26). For example, pH plays a fundamental role. The surfaces of viruses are covered with ionizable groups, the charge of which may be modified as a function of pH. The overall charge is positive if the pH is below the pH_i (the isoelectric pH at which the overall charge of the virus is zero) and negative if the pH is above the pH_i. Most *Enteroviruses* have a pH_i between 4 and 8.2. These electrical charges, which vary with pH, enable the virus to adsorb to surfaces of opposite charge or to desorb from supports with the same charge.

The effect of salts on adsorption is also important and it has been clearly shown that both the nature and concentration of salts in solution play key roles in

determining the level of interaction between the virus and the surface. Salts may reduce the surface potential of the virus and of the adsorbent surface, thereby decreasing the repulsion between these two entities. This makes it possible for the virus particles to approach one another and to create hydrophobic and electrostatic interactions (27). It is generally accepted that when viruses come into contact with an adsorbent support, adsorption occurs rapidly and extensively. For example, 30 to 50% of *Poliovirus 1* particles adsorb to montmorillonite clay in deionized water in less than 30 minutes, but more than 99% were adsorbed in the presence of salts or in seawater (28,29). In most environmental conditions, a very large proportion of *Enteroviruses* may be adsorbed or aggregated.

This capacity for adsorption is extremely important because it enables the virus to accumulate in sediments, shellfish, and soils and may protect the *Enterovirus* against inactivating environmental factors. However, against heat, it only provides significant protection in the presence of high concentrations of suspended matter or if the temperature increase is very significant. Thus, Quignon and coworkers (29) and Gantzer and coworkers (28) reported that the presence of less than 500 mg/L of suspended matter did not affect the survival of *Poliovirus 1* at temperatures below 35 °C in sterile media. In contrast, Liew and Gerba (30) observed 1 log inactivation after 30 minutes in artificial seawater at 50 °C in the presence of marine sediments (8 g/L), whereas they observed 3 log inactivation in the absence of sediments. In fact this protection is only observed at temperature $\geq$35 °C; the temperature rarely exceeds 30°C in the environment. Protection from the inactivating of biological and other physical and chemical factors may be more important in natural waters (i.e., sunlight).

pH. The effect of pH on the survival of the virus depends largely on the type of virus. *Enteroviruses* are stable over a large range of pH, from 3 to 9, and possibly even higher, for short periods. Piirainen and coworkers (31) demonstrated that *Poliovirus* remains infectious after treatment for two hours at pH 2 at 37 °C but is inactivated after 24 hours by the same treatment. Most *Enteroviruses* are inactivated by pH greater than 11 (32).

However, in the environment, it is very difficult to demonstrate a correlation between pH and the level of inactivation because certain molecules affect both the pH and the survival of the virus. For example, ammonia, which increases pH, is toxic to *Enteroviruses* disrupting their nucleic acids (33).

Salts. The effect of salinity on the survival of viruses has been demonstrated only in very precise temperature conditions. Wetz and Kucinski (34) showed that *Poliovirus 1* was stable for one hour at 20 °C in an hypotonic buffer but was rapidly degraded at 37 °C. However, at temperatures below 34 °C, closer to those in the environment, Quignon and coworkers (35) demonstrated that neither the nature (KCl, CaCl2, or FeCl3) nor the concentration of salts affected the survival of *Poliovirus 1*. The observed effect thus results from the combined action of high temperature and low salt concentration, destabilizing the viral capsid.

Conflicting results have been obtained concerning the possible correlation between salinity or conductivity and the inactivation of the virus in the environment because of the differences in the type of salt present and because some salts may have a negative effect on the virus (virucidal), whereas others may have a positive effect (e.g., protective effect by increasing adsorption or aggregation, or by thermostabilization).

Many studies have investigated the effects of seawater salinity on the survival of *Enteroviruses* and their conclusions differ. Katzenelson (36) and Babich and Stotzky (37) found that salinity affected the inactivation of *Enteroviruses* whereas the authors found that salinity (14, 24 and 33 NaCl g/l) had no effect on the inactivation of *Poliovirus 1* in sterile water containing no suspended solids (38).

Sunlight. Since viruses are sensitive to inactivation by ultraviolet light they are more readily inactivated in the presence of sunlight. Hurst (39) reported that, in the absence of sunlight, the level of inactivation was between 0.7 and 0.8 log per day, whereas in sunlight, the level ranged from 1.3 log per day in very turbid water to 2.4 log per day in water that was only slightly turbid. Thus, sunlight inactivates viruses but this inactivation is less efficient if the water contains suspended solids as such solids both protect the adsorbed virus particles and hinder the penetration of ultraviolet light in the water column.

Influence of Biological Factors

Biological factors seem to affect the persistence of Enteroviruses in natural waters, but their nature and mode of action are not clear. Overall, it has been clearly demonstrated that more Enteroviruses survive in sterile water than in natural water. This difference in survival may be due, in particular, to the presence of biological factors that have demonstrated virucidal activity. Girones and coworkers (40) isolated marine bacteria belonging to the genus Moraxella, which had antiviral activity against *Poliovirus 1*. Similarly, Ward and coworkers. (41) isolated 27 bacterial strains with virucidal activity, notably against Enterovirus, from surface waters. Some of these virucidal biological factors are heat-sensitive. Enriquez and coworkers (24) observed a 4 log reduction in the concentration of *Poliovirus 1* in wellwater after 13 days at 37 °C, however, 19 days at this temperature were required to achieve the same level of inactivation in autoclaved water. It has also been shown that *Poliovirus* genome (RNA) is less stable in natural water than in the same water that has been autoclaved (120 °C, 20 minutes). Ward and coworkers (41) also showed that the addition of a protease inhibitor markedly decreased the virucidal activity of bacterial origin in water. This suggested that enzymes, particularly proteases (degrading the capsidal proteins) and ribonucleases (degrading the genome), may play a role in inactivating viruses in the environment. The factors that may influence persistence in soil and in water are summarized in Table 1.

Table 1. Factors That May Influence *Enterovirus* Survival in Water and Soil (from 42)

Factors	Comments
Temperature	Survival decreases with increasing temperature
Desiccation	One of the most detrimental factors; increased virus reduction in drying soils
Sunlight	May be detrimental at the soil and water surface because of ultraviolet (UV) light
pH	May indirectly affect virus survival by controlling their adsorption to soils and to suspended matter
Cations	Certain cations have a thermal stabilizing effect on viruses; may also indirectly influence virus survival by increasing their adsorption to soil (viruses appear to survive better in the sorbed state) and to suspended matter
Soil texture	Clay minerals and humic substances increase water retention by soil and thus have an impact on desiccation
Biological factors	No clear trend with regard to the effect of soil microflora on viruses; some evidence of virucidal activity by water microflora

Taking into account all these parameters it is obvious that the survival of *Enteroviruses* is largely variable in environment. Some example of T90 (time in which the initial viral concentration decreases by 90%) for infectious *Enterovirus* are given in Table 2 but it should be kept in mind that even in similar media, *Enterovirus* survival is dependant on the physicochemical and biological characteristics of each environment.

Table 2. *Enterovirus* Survival in Environment

Environmental Media	Temperature	T90 (days)	References
Raw wastewater	25 °C	30 days*	43
Primary effluent	4 °C	20 days**	
	15 °C	17 days**	44
Secondary effluent	4 °C	23 days**

Influence of Wastewater Treatment

Wastewater contains large numbers of *Enteroviruses* and other pathogenic microorganisms. Therefore, in industrialized countries, they are subjected to treatment aimed at reducing their level of contamination before discharge into the environment.

Wastewater may be treated using various processes aimed at eliminating chemical (e.g., phosphate, nitrate) or biological (e.g. organic pollutants), but also pathogenic microorganisms. Some procedures involve a simple physical treatment but the most commonly used process involves four steps (Fig. 3):

The elimination of *Enteroviruses* during the treatment of wastewater clearly depends on the type of treatment. It is generally recognized that preliminary treatments have only a small impact on the concentration of viruses in wastewater, whereas the primary, secondary, and tertiary treatments have greater effects.

Primary Treatment

Primary treatment makes the reduction possible by simple sedimentation of "settleable solids," thereby also eliminating the *Enteroviruses* absorbed onto them. The reduction in virus concentration achieved by such treatments is very variable (10 to 80%), but is always less than one logarithmic unit (54). The magnitude of the decrease depends on the level of adsorption of the viruses onto settleable solids.

Biological Treatments

Biological treatments of wastewater were not originally designed specifically to eliminate pathogenic microorganisms, their original goal being the degradation of organic matter. The activated sludge process is based on stimulation of the degradation of organic matter by the bacterial biomass. Wastewater rich in nutrients and bacteria is subjected to forced aeration, which enables the bacterial population to multiply more rapidly. This bacterial population then consumes the carbon- and phosphorus-containing nutrients present in the wastewater. In a second step, bacteria flocs are eliminated from the liquid phase by sedimentation.

During this treatment, there is a transfer of viruses, from the water phase to a solid phase. The *Enteroviruses* present adsorb onto the formed flocs and sediment with them to constitute the sludge. The adsorption of viruses onto bacterial flocs is rapid and substantial. Farrah and coworkers (55) estimated that in the presence of activated sludge, between 0.7 and 1.8 log of *Enteroviruses* are adsorbed. However, *Enteroviruses* are also inactivated by substances with virucidal activity produced by the bacterial flora. It is in this environment that virucidal biological factors have most frequently been identified. The theoretical rate of inactivation of *Enteroviruses* in activated sludge is between 0 and 2 log in 48 hours (56). However, as the time spent in an activated sludge basin is on the order of 6 to 12 hours, the true level of inactivation is low.

Some studies have shown that protozoans and metazoans play a significant role in the elimination of viruses

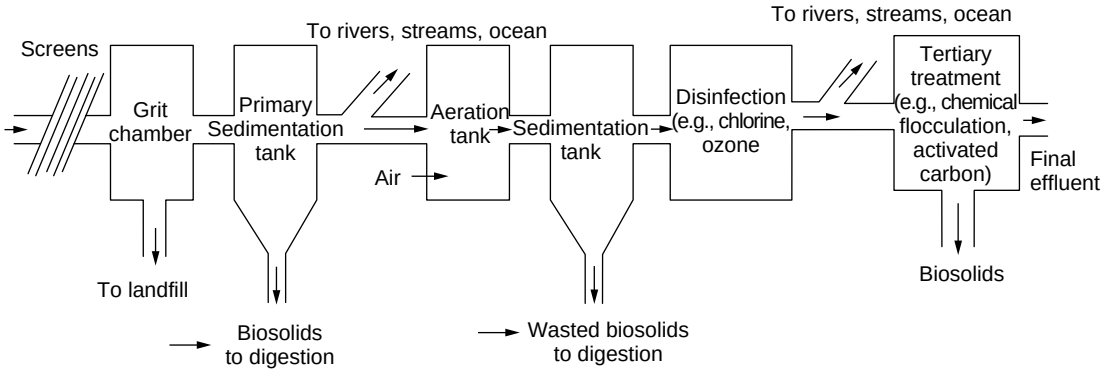

Figure 3. Flowchart of a wastewater treatment plant (from 53).

— Preliminary treatment to remove oils, sands, and large debris
— Primary treatment, generally involving simple sedimentation of suspended solids
— Secondary treatment such as activated sludge, trickling filters, oxidation ponds...
— Tertiary treatment that usually involves some type of physical and chemical treatment and disinfection.

by predation (57), but the real impact of this factor is, however, difficult to quantify.

Finally, during this type of treatment the combination of adsorption, inactivation, and predation may result in a 90 to 99% decrease in the number of *Enteroviruses* initially present in raw wastewater. The same is true for treatments involving biological filters and oxidation tanks.

The efficiency of water purification by lagooning varies from 0 to 99.9% and depends in particular on the duration of the treatment and of temperature (58).

Disinfection

In some cases, the decrease in the levels of pathogenic microorganisms achieved by biological treatment is not sufficient to satisfy current standards required for shellfish production area, bathing zones, or in case of agricultural water reuse. Then specific treatments that mostly involve disinfection are implemented (59).

Disinfection generally involves the use of chlorine (60), ozone (61), and ultraviolet irradiation (61). The inactivation of *Enteroviruses* by oxidants is a complex phenomenon, the efficiency of which depends on many factors including the aggregation or adsorption state of the virus, the nature of the oxidant, the pH, and the oxidant demands of the suspending medium. This last factor is very important because the medium itself reacts with oxidants as a result of the presence of organic matter and reduces the quantity of free disinfectant that can act on the viruses. It is therefore necessary to distinguish between the theoretical disinfecting capacity in buffered water, with no oxidant demand, and actual disinfecting capacity in wastewater.

Chlorine. Three types of chlorine compounds are generally used: free chlorine (Cl_2), chloramines (NH_2Cl), and chlorine dioxide (ClO_2).

The results obtained with buffered solutions with no oxidant demand clearly show that chlorine is an effective virucidal agent. In the presence of 1 mg/L of free chlorine, 99 to 99.9% of *Poliovirus 1* particles are inactivated within 1 minute (43,62).

In wastewater, the organic matter present reduces the virucidal capacity of chlorine because it is rapidly transformed into monochloramines (or other organic and inorganic chloramines) by reaction with ammonia and other nitrogenous compounds. In these conditions, it is not surprising that Behac and coworkers (60) obtained an inactivation of only 50% of *Poliovirus 1* in wastewater in 15 minutes, with 6.6 mg/L residual chlorine.

Chloramines have a much lower level of virucidal activity than free chlorine. In the presence of 2 mg/L of monochloramines, it requires almost three hours to reduce the level of *Poliovirus 1* to 90% in a medium with no oxidant demand (63).

Chlorine dioxide is a much more powerful oxidant. In a buffered medium, 99% of *Poliovirus 1* is inactivated in 10 minutes in the presence of 1 mg/L of chlorine dioxide. However, in effluent, it is necessary to almost double the dose to obtain the same decrease (64).

In the case of free chlorine and chloramines, inactivation is greatest at pH 6, the predominant form being HOCl. With chlorine dioxide, inactivation is maximal at high pH (around 10).

The effects of chlorine are all given with respect to infectious *Enteroviruses*. If detection of the viral genome is taken into account, significant differences are observed with respect to the results obtained by detection of infectious viruses. For example, in the presence of 1 mg/L free chlorine in water without oxidant demand, the reduction of infectious *Poliovirus 1* is between 2 and 3 log in one minute, whereas it is only 0 to 1 log for the genome (43,65). The same phenomenon is observed with chlorine dioxide and chloramines (63).

Ozone. Ozone is an excellent virucidal agent. In general, in sterile buffered media, more than 99% of Enteroviruses are inactivated in less than one minute (66,67) in the presence of 0.05 to 0.15 mg/L

residual ozone. However, as for chlorine, the presence of organic matter or suspended matter interferes with disinfection. In addition, the disinfectant action of ozone is affected by the pH of the medium. Roy and coworkers (68) showed that *Poliovirus 1* was inactivated more rapidly at pH 7.2 than at pH 4.3.

In wastewater, ozone is naturally less virucidal and thus the reduction of virus is smaller. For example, Harakeh and Butler (69) observed 80% inactivation in 10 to 15 minutes in the presence of 0.2 mg/L ozone.

Comparison of the decrease in levels of infectious *Poliovirus 1* and of its genome shows, as for chlorine, a great difference in behavior between the two entities. The infectivity of the virus is destroyed much more rapidly than the viral genome. Moore and Margolin (70) reported the total inactivation of *Poliovirus 1* in deionized water within 10 minutes of ozone treatment, whereas a significant decrease in the level of the viral genome was not detected until after 60 minutes.

Ultraviolet Irradiation. Photoinactivation is a natural phenomenon that has been known for some time to affect suspensions of Enterovirus exposed to sunlight. In phosphate buffer, Battigelli and coworkers (71) observed that a dose of 25 $mW\,s^{-1}\,cm^{-2}$ reduced the concentration of Coxsackie B5 virus by at least 3 log. In natural water samples, the efficiency of UV irradiation for disinfection depends on suspended matter content. They protect microorganisms and act as a barrier against UV irradiation.

A clear difference is observed if the fate of infectious *Poliovirus* and of their genome are compared following UV treatment. In distilled water, for a dose of 22 $mW\,s^{-1}\,cm^{-2}$, a reduction of 5 log is observed for infectious virus and only of 1 log for the viral genome (62). These results suggest that UV irradiation has an effect on the viral genome and does not prevent detection of the genome by RT-PCR.

Influence of Sludge Treatment

Wastewater treatment always produces very large quantities of sludge (i.e., biosolids), which normally undergoes physical (dewatering, heating...), chemical (lime treatment...), and microbiological (aerobic or anaerobic stabilization, composting...) treatments. In most countries, most of the treated sludge is applied to agricultural land. Therefore, to avoid any transmission to humans, it is important to understand the fate of *Enteroviruses* during sludge treatment and disposal.

Aerobic and Anaerobic Digestion. Aerobic and anaerobic digestion can be carried out at psychrophilic (low temperature), mesophilic (25 °C to 45 °C), and thermophilic (>45 °C) temperatures. The differences in viral inactivation achieved by such processes are linked essentially to differences in temperature. The level of viral reduction is greatest for thermophilic digestion, followed by mesophilic digestion and psychrophilic digestion.

Other parameters, such as the concentration of oxygen or ammonia, water content, and the presence of proteolytic enzymes may also affect viral inactivation. Psychrophilic digestion is little used and the reductions in viral contamination reported for this technique are small. For example, Martin and coworkers (72) obtained a 0.7 log reduction after 20 days of treatment at 8 °C.

Mesophilic stabilization should generally continue for at least 15 to 20 days. Nevertheless, very diverse results have been reported because it is necessary to take into account climatic data and the large variations in temperature associated with them. Reductions in contamination of between 0.5 and 3 log units have been reported for anaerobic digestion at 35 °C for 15 to 20 days (73,74,75). During aerobic digestion, Martin and coworkers (72) used a regression model to estimate that the reduction achieved in 20 days was 1 log at 18 °C, 1.1 log at 24 °C, 1.3 log at 26 °C, and greater than 3.2 log at 38 °C.

Finally, thermophilic stabilization can be considered to be an effective treatment to eliminate all *Enteroviruses* (76) provided that the sludge is continually mixed in the presence of air or oxygen, for 10 days at 55 to 60 °C. The reduction in contamination obtained is smaller if lower temperatures or shorter treatment times are used. There is generally little difference in the reduction of viral contamination obtained with aerobic and anaerobic thermophilic treatments at identical temperatures. At temperatures above 50 °C, heat is the principal inactivating factor. Generally speaking, 2 to 4 log *Enterovirus* reduction is obtained using these processes.

During anaerobic digestion at 49 °C for 20 days the reduction of *Enteroviruses* is 2.5 log (75), but if it is a two stage process (55 °C for two days and 37 °C for 10 days), the reduction is 4 log (77). In aerobic conditions, 4 log reduction is obtained at 55 °C for 28 days (78).

Composting. American legislation considers that composting as a treatment is able to eliminate *Enteroviruses* from sludge if the temperature is maintained at over 55 °C for three days with forced aeration, or at more than 55 °C for 15 days if successive turning techniques are used. The principal problem with this process is heterogeneity, particularly in terms of the temperature within the compost. This may result in the preservation of zones at a lower temperature in which the virus is able to survive. It is therefore not surprising that the results obtained are very variable (1.2 log to >4 log) despite theoretical temperatures of 60 to 70 °C for seven days (79).

Lime Treatment

Lime treatment is usually realized by addition of lime to the sludge. Such treatment increases both pH (quick and slaked lime) and temperature (quick lime). The increase in pH depends on the quantity of lime added to the sludge. The decrease of viral density is about 0.3 log at pH 8.3, 3 log at pH 10.8, and may be as much as 7 log at pH 12.5 (79,80). Finally, Hurst (58) reported reductions in contamination of 1 log in 0.47 days, four days, and seven days for the addition of 5, 3, and 1.5 kg of lime/m^3, respectively. The increase in temperature seems to be

highly variable depending on moisture and the quantity and quality of lime added.

Dehydration and Heat Treatment

Dehydration techniques are used to reduce the humidity of the sludge to various degrees and it was demonstrated there is a loss of viral infectivity proportional to the level of dehydration (81).

To conclude, heating to high temperatures (130 to 180 °C for 30 minutes) guarantees that the resulting sludge is free of *Enterovirus*.

CONCLUSION

Enteroviruses, which are excreted in large numbers in infected human stools, are currently detected in all raw wastewater.

The application of classical biological treatments significantly decreases the level of viral contamination, but, depending on the initial concentration in raw wastewater, the number of *Enteroviruses* released into the environment may be far from negligible. Therefore, in some cases, a tertiary disinfection treatment (chlorine, UV, ozone) may help to protect some environmental areas from pathogen contamination.

However, whether or not wastewater is treated, enteroviral contamination should naturally decrease from surface to seawater as a result of simple dilution. The persistence of these viruses in the environment depends on the physical and chemical characteristics of the medium.

Thus, the diversity of potential viral reservoirs in the environment, constituted not only by water (wastewater, river water, seawater, and, possibly, groundwater) but also by shellfish, which concentrate the virus in their tissues, and high levels of viral persistence, clearly result in a large potential for human contamination by *Enteroviruses*.

While perhaps the most visible and profound consequence of the biotechnology revolution has been our increased knowledge of fundamental life processes and the development of novel medicines, the most pervasive use of recombinant DNA (rDNA) technology has been in the production of manufactured goods. Everyday you are using, wearing, or eating something that has been touched by industrial enzymes produced using biotechnology. For example, have you had a soft drink or a piece of candy or cake made with high-fructose corn syrup? Have you worn any denim garments today? Have you washed your clothes with laundry detergent this week? All of these products have been made possible by the advent of modern biotechnology through the use of biotechnologically derived industrial enzymes. The increasing use of enzymes to replace more traditional chemical transformation processes in these and many other industries is driven by a desire for better production economics, new product functionalities, improved workplace safety, and an increasing desire by companies to reduce the environmental impact of their operations. Often chemical transformations produce nonspecific reactions that may result in poor product yields and by-products that may prove difficult and costly to dispose. High temperatures and/or pressures needed to drive reactions lead to high energy costs and may require large volumes of cooling water downstream. Harsh and hazardous processes involving organic solvents and acidity or alkalinity at high temperatures and pressures need expensive, specially designed equipment and control systems. All of these drawbacks can potentially be eliminated using enzymes. Public, regulatory, and private industrial forces are all fueling a conversion to greener alternatives. Industrial enzymes fit this category, as enzymes do their work, become inactive, and break down into simple, nontoxic, natural components. They are increasingly being used in industrial process development and manufacturing, thereby circumventing the harsh chemical and toxic loads often put into the environment by older manufacturing methods. To meet this increasing demand for enzymes, most new enzymes are produced from genetically engineered fungal or bacterial organisms grown in large-scale fermenters. In this article, the current art of industrial enzyme production and the application of those enzymes to manufacturing processes are described.

INDUSTRIAL ENZYME PRODUCTION

Biotechnology of Enzyme Production

Historically, industrial enzymes have been made by simply fermenting an organism and recovering the fermentation broth (Fig. 1). In fact, the world's first commercialized extremophile enzyme, Esperase® (Novo Nordisk A/S), a detergent protease with pH activity range from pH 7 to 12, was developed in 1974 as a fermented *Bacillus* sp. product. Simply fermenting organisms is still done in selected cases today, as it is the mixture of enzymes in the final product that holds the desired activities. For example, a mixture of endoglucanases, cellobiohydrolases, xylanases, and hemicellulases in a product called Novozyme 342® (Novo Nordisk A/S), which is a fermented broth from *Humicola insolens*, is used in the de-inking process in paper recycling; a mixture of endo- and exoproteases in a product called Flavourzyme® (Novo Nordisk A/S), which is a fermented broth from *Aspergillus oryzae*, is used for protein hydrolysis, debittering, and flavor enhancements in vegetable and animal protein hydrolysis. In the future, this approach of "just fermenting" the organism and using the fermentation broth is expected to continue as a minor contributor to the overall source of industrial enzymes.

Today it is recombinant DNA technology that is the rule rather than the exception when it comes to producing industrial enzymes (Fig. 2). It is estimated that approximately 80% of the turnover of industrial enzymes comes from genetically modified organisms (1). Recombinant enzymes are derived primarily from extracting the gene of interest from the prokaryotic or eukaryotic source, using DNA probes based on the genetic code from primary amino acid sequence information of the purified enzyme. Alternatively, the gene encoding the desired enzyme may be chemically synthesized. In either case, the enzyme-encoding gene is then inserted into a recombinant host, such as the widely used fungal strains *Aspergillus oryzae* or *A. niger* or *Bacillus* sp. for bacterially derived enzymes (2,3). Using a wide variety of DNA expression vectors tailored for high-level expression, the active enzymes are secreted into the growth media when these organisms are fermented.

A number of techniques have been developed and are utilized to tailor enzymes for specific industrial applications. Random mutagenesis, in which the gene encoding the enzyme is mutated without regard to any structural information, results in enzyme mutants with a wide variety of amino acid substitutions, some of which may prove beneficial in a given application. When an enzyme structure is known, this information can be used to target specific amino acids using site-directed mutagenesis to improve enzyme performance in a process called protein engineering. Both approaches are typically done in an iterative manner, combining steps of mutation and screening; at each round, screening and selecting out the best protein-engineered variant for a given application and using it as a starting point for another round of mutagenesis. More recently, an improved method termed *directed evolution* has been developed that more closely resembles natural protein evolution. In this process, improved mutants selected from screening a naturally occurring or mutated pool of enzyme genes are recombined to create random chimeras that "shuffle" mutations between different enzyme mutants. This is superior to iterative mutagenesis techniques because it

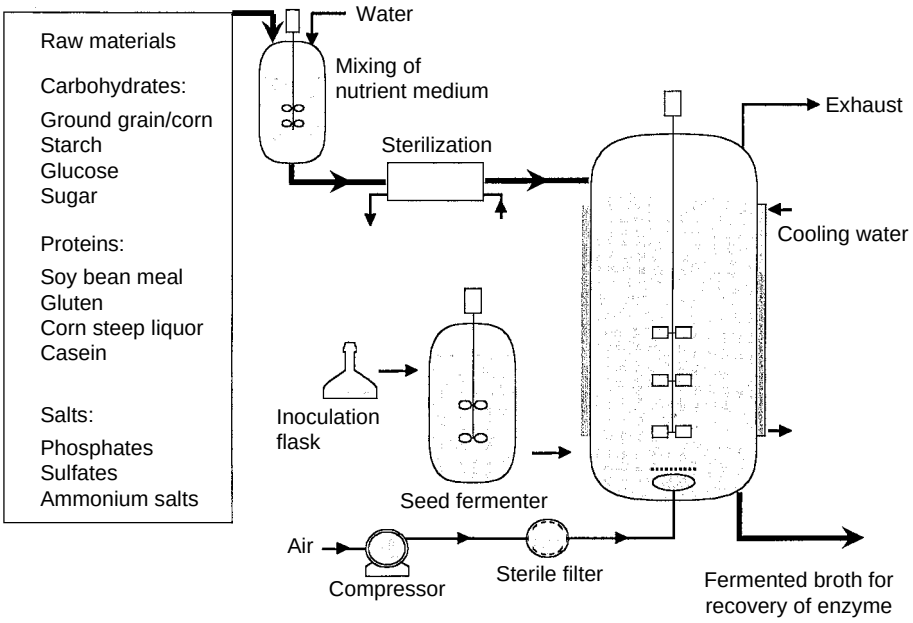

Figure 1. Schematic of large-scale industrial fermentation for enzyme production.

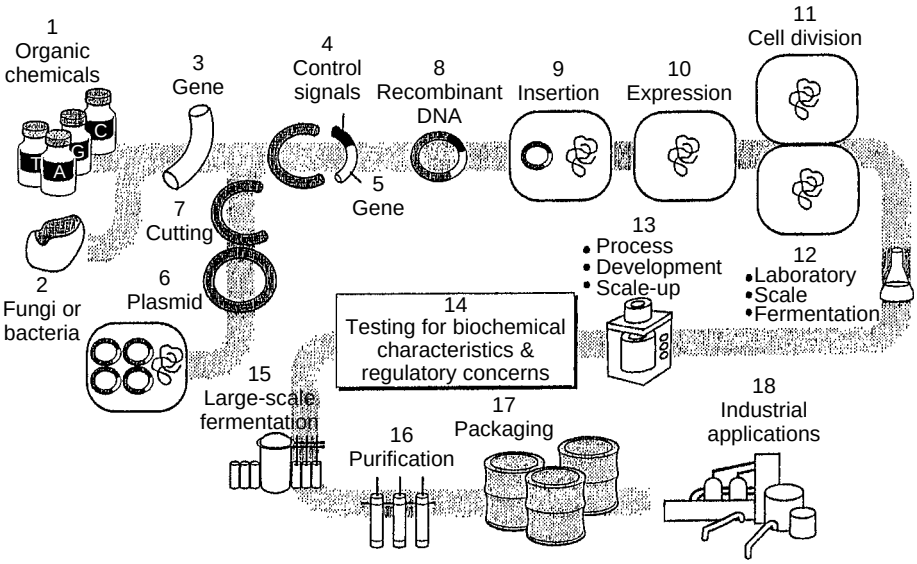

Figure 2. Flowchart of recombinant protein production showing steps in the synthesis, cloning, and expression of a heterologous gene into a production bacteria or fungus.

provides a mechanism to randomly separate beneficial and deleterious mutations (4–6). Screening is then used to identify those mutants with the optimum combination of beneficial mutations.

There are numerous examples of protein-engineered lipase, protease, amylase, glucose isomerase, cellulase, and other enzyme variants produced in small quantities by academic laboratories (7). There are a smaller, but growing number of protein-engineered and protein-evolved enzymes commercially produced (Table 1). As techniques for generating and screening mutants become more advanced, enzymes capable of catalyzing nearly any reaction under nearly any condition will be developed, the limitation being only the ability to set up a relevant screening system for the desired activity. Using such techniques, one may supplant the need for extensive environmental screening for the desired enzyme with the "proper" or "optimal" characteristics.

Enzyme Fermentation

The vast majority of industrial enzymes are produced by large-scale submerged fermentation. This involves growing a selected microorganism in closed vessles in which all the conditions critical for growth are carefully controlled: pH, temperature, feed in the form of carbon and nitrogen sources, and oxygen. The selected microorganisms are either bacteria (typically *Bacillus* sp.) or fungal (typically *Aspergillus* or *Trichoderma* sp.) that have been carefully chosen and optimized for secreted protein production. Almost all enzymes of any commercial consequence are secreted directly from these organisms into the growth medium, where they can be readily

Table 1. Commercially Produced Protein Engineered Industrial Enzymes

Enzyme	Mutagenesis Method	Advantages
Durazyme® protease	Site-specific	Enhanced storage stability in laundry detergents
Lipase Ultra®, Lipase	Site-specific	Enhanced fat-removing in laundry detergents
Guardzyme® peroxidase variants	Random, site-specific, directed evolution	Enhanced thermal and oxidative stability
Amylase	Site-specific	Reduced calcium dependence in laundry detergents

Note: The examples given are all products of Novo Nordisk A/S, Bagsvaerd, Denmark.

recovered by removal of the organism using filtration or centrifugation. As an example of the extreme productivity of this method of producing proteins, *T. reesei* has been reported to secrete some cellulase-degrading enzymes at up to 40 g/L of fermentation broth (8).

Formulation

Formulation often is a critical step in commercial production because it can stabilize the enzyme, create time-release characteristics, and allow for improved safety and ease in handling. Enzymes recovered from fermentation broth are usually concentrated by evaporation, membrane filtration, or crystallization, depending on the enzyme and its intended application. Crude enzyme can then be formulated into granulate powders or liquids, or immobilized on an inert support. As an example, enzymes used in the last step of high-fructose corn syrup production, converting glucose to fructose, are immobilized and packed in a column that can function effectively for over a year. To provide a stable, nondusting enzyme for the detergent industry, enzyme granulation is a critical step. A number of methods have been developed and patented over the years, but most granule production today is performed either in a fluidized bed or in a high-speed mixer followed by a controlled drying process. Normally, both these types of granules will also be coated by a wax or polymer to reduce dust release from the product and to protect the enzyme from other detergent components such as bleaching compounds.

THE ENZYME MARKET

The estimated worldwide industrial enzyme market in 2000 is valued at approximately $1.5 billion (1) and is traditionally divided into three segments: the largest at 73% of sales, technical enzymes include enzymes used in the detergent, starch, textile, leather, pulp and paper, and personal care industries; food enzymes, the second largest segment at 22% of the market, include dairy, brewing, wine and juice, fats and oils, and baking industries; and feed enzymes, covering enzymes used in animal feeds, contribute approximately 5% of the market (Table 2). Proteases comprise the largest selling and largest volume enzyme currently sold, primarily to the detergent industry as a stain-removing additive.

While enzymes are widely used in industry, they make up only a small percentage of the overall chemical market. This is due to a number of factors including, (*1*) the economics of the enzyme manufacture — where price competition with the competing chemical technology requires enzymes to be made in the multigram per liter amounts in the fermentation process; (*2*) the lack of understanding in many industry segments of enzymology — knowledge about basic chemical mechanisms and how enzymes might be used to solve problems is limiting in many applications-oriented fields; (*3*) the difficulties in incorporating the enzyme into many "older" manufacturing processes — capital intensive equipment and the "old way of doing things" prevents a transition to enzyme use; and, (*4*) finding the right enzyme — each industrial process has its own conditions for operation and it is important to find the best enzyme for each application. With this background, several examples are discussed where enzymes are being used, and where they might be used in the near future, to provide a more environmentally friendly solution to industrial processes.

TECHNICAL ENZYMES

Laundry Detergents

Detergents represent the single largest industry segment for the use of today's enzymes, representing about 38% of the total enzyme market. Enzymes used in detergents today include both bacterial- and fungal-derived proteases, amylases, cellulases, lipases (9,10), and the newly introduced mannanase (11); others are in the R&D pipeline. The single largest selling industrial enzymes are the detergent proteases. These bacterial, subtilisin-type proteases are one of the basic workhorses in detergents today and are considered indispensable in formulating efficient laundry detergents worldwide. As catalysts, each molecule of enzyme cuts the protein components of laundry stains thousands of times during a wash cycle, making them very space-efficient ingredients that are excellent at removing blood, grass, milk, and various foods containing proteins. In addition to the wild-type enzyme, a number of protein-engineered variants of subtilisins have entered the marketplace, with such properties as increased stability toward oxidation and increased cleaning performance.

Alpha-amylases have proven useful in catalyzing the degradation of starch stains and in improving overall soil removal by hydrolyzing the starch that binds particulate soil to the fabric. Using both proteases and amylases,

Table 2. Enzymes Sold Commercially in the Three Industry Segments, with a Short Summary of What Function the Enzyme Performs in the Process or Product

Industry Segment	Enzymes	Enzyme Function
	1. Technical Enzymes	
• Detergents	• Lipases, proteases, cellulases, amylases, mannanases	• Degradation of protein, starch, and fatty stains in laundry • Color clarification and softening of cotton laundry • Automatic dishwashing • Surfactant production • Deep cleaning
• Starch and sugar	• Amylases, pullulanases, glucose isomerase, xylanases • Cyclodextrin glucanotransferases	• Liquefaction and saccharification for the production of dextrose, fructose and special syrups for the baking, confectionery, and soft drink industries, among others • Cyclodextrin production
• Textile	• Amylases, cellulases, catalases, laccases	• Polishing of cotton fabrics • Stonewashing of denim garments • Degumming of silk • Bleach cleanup • Removal of starch from woven materials • Bleaching of denim
• Leather	• Proteases, lipases	• Soaking of hides and skins, unhairing, bating and defatting
• Pulp and paper	• Xylanases, mannanases	• Control of pitch problems caused by the use of mechanical pulps • Reduction of chlorine consumption in pulp bleaching process • Viscosity control in starch-based coatings
• Fiberboard production	• Laccases	• Free radical crosslinking of wood fibers
• Personal care	• Protease, lipases • Catalase • Lactoperoxidase, glucose oxidase, and glucoamylase • Laccases	• Removal of protein and oils from dentures, contact lenses • Removal of residual H_2O_2 from contact lenses • Oligosaccharide removal in toothpaste • Oxidation of aromatics for hair dying • Antimicrobial activity in toothpaste
• Organic chemical synthesis	• Isomerases, lipases, reductases, acylases	• Biocatalysis under mild conditions
• Alcohol	• Amylases, pullulanases, proteases, cellulases	• Degradation of starch or cellulose into sugars which are converted to alcohol through fermentation
	2. Food Enzymes	
• Baking	• Amylases, xylanases, lipases, proteases, glucose oxidases	• Reduction in bread staling • Starch, pentosan and protein modification for improvement of the baking properties. • Improvement of crust color, dough handling, stability and quality
• Dairy	• Proteases, lipases, lactases	• Cheese production, curdling of milk • Conversion of lactose in milk and whey into sweeter, more easily digestible sugars • Flavor development in specialty cheeses
• Brewing	• Amylases, beta-glucanases, alpha-acetolactate decarboxylases, proteases, pullulanases	• Degradation of starch, protein, and glucans when brewing with a combination of malt and unmalted raw materials, e.g., barley, corn, and rice • Shorten beer production time • Production of low carbohydrate beer

Table 2. (*Continued*)

Industry Segment	Enzymes	Enzyme Function
• Wine and Juice	• Pectinases, beta-glucanses, cellulases, hemi-cellulases, pullulanases, amylases, alpha-acetolactate decarboxylases, laccases	• Degradation of pectin when manufacturing fruit juices, wine, etc. • Clarification • Improved filtration • Viscosity reduction • Enzymatic peeling • Inhibition of taints in corks
• Fats and oils	• Lipases, phospholipase	• Modifications of fats and lecithins and synthesis of esters
• Food functionality	• Endoproteases, exoproteases, carbohydrases, cellulases, hemi-cellulases, phospholipases	• Improvement of nutritional and functional properties of animal and vegetable proteins • Flavor and texture improvements • Process of optimization, e.g., energy savings by lowering of viscosity • Hydrolysis of phospholipids • Reduction of starch viscosity
	3. Feed Enzymes	
• Animal feed	• Endoproteases, exoproteases, lipases, phytases, cellulases	• Degradation of feed components for improvement of feed utilization and nutrient digestion • Improved palatability

the overall performance of the detergents is increased at lower washing temperatures and there is a decrease in the detergent's overall chemical makeup.

Cellulases can be used in lieu of cationic surfactants (fabric softeners) because they improve the softness of cotton fabrics. Cellulases are also active in removal of particulate soil by removing microfibrils from the cotton fibers. As a result, there is a color-brightening effect of the cellulase treatment. Lipases catalyze the hydrolysis of triacylglycerides present in fatty stains, making them more hydrophilic and more easily removable during the wash.

Enzymes used in detergents have a positive environmental impact because they save energy by reducing washing temperatures; allow the content of undesirable chemicals in detergents to be reduced; are totally biodegradable, leaving no harmful residue; have no negative impact on sewage treatment processes; and, most importantly, do not present a risk to aquatic life. Chemicals eliminated or reduced by the use of enzymes in detergents include phosphates, surfactants, carbonates, silicates, and chlorine bleach.

Automatic Dishwashing

Automatic dishwashing detergents have traditionally contained high concentrations of silicates (sodium metasilicate) as high pH buffers, phosphate builders (sodium tripolyphosphate), and chlorine (sodium dichloroisocyanurate) as bleach. Safety, environmental factors, and performance concerns have shifted manufacturers to begin using enzymes in automatic dishwashing detergents (12). Phosphates were causing eutrophication of surface water; silicates, while being added to minimize corrosion of metals and ceramic dish surfaces, were too alkaline and posed a health threat in some European countries if ingested; and chlorine-based chemicals were reacting with organic compounds. Enzyme use, such as with proteases, lipases, and amylases, has thus lowered the requirement of these chemicals, generating "greener," safer, and higher performing automatic dishwashing detergents.

Starch

One of the most well-known applications of enzymes is in the starch processing industry for the production of high-fructose corn syrup (Fig. 3) (13). Maize starch is the most widely used raw material used, followed by wheat, tapioca (cassava), and potatoes. Starch is composed of long linear polymers of α-1,4 linked glucose with a minor number of oligoglucose branches linked α-1,6. To make the starch contained in these feedstocks available for enzymatic hydrolysis by amylase, it is pressure-cooked until a gel is formed. Liquefaction of the starch is accomplished by the addition of thermostable alpha-amylases, most of which are protein-engineered, that are added before the gelatinization. The resulting solubilized starch, composed of short glucose polymers, are then saccharified to glucose by the action glucoamylase, an exocarbohydrase specific for α-1,4 linkages, and pullulanase, an enzyme that specifically attacks α-1,6 branch points in the starch molecule. The resulting glucose syrup is then converted to the sweeter isomer fructose by the action of an enzyme called glucose isomerase.

Enzymes replaced acids and heat as processing aids in starch liquefaction and saccharification about 50 years ago. In the 1970s enzymes also replaced alkali in the isomerization of glucose to fructose. Converting starch to dextrose, in the traditional process, was achieved by acid treatment at pH 2, followed by a 140 °C heat treatment (Fig. 3).

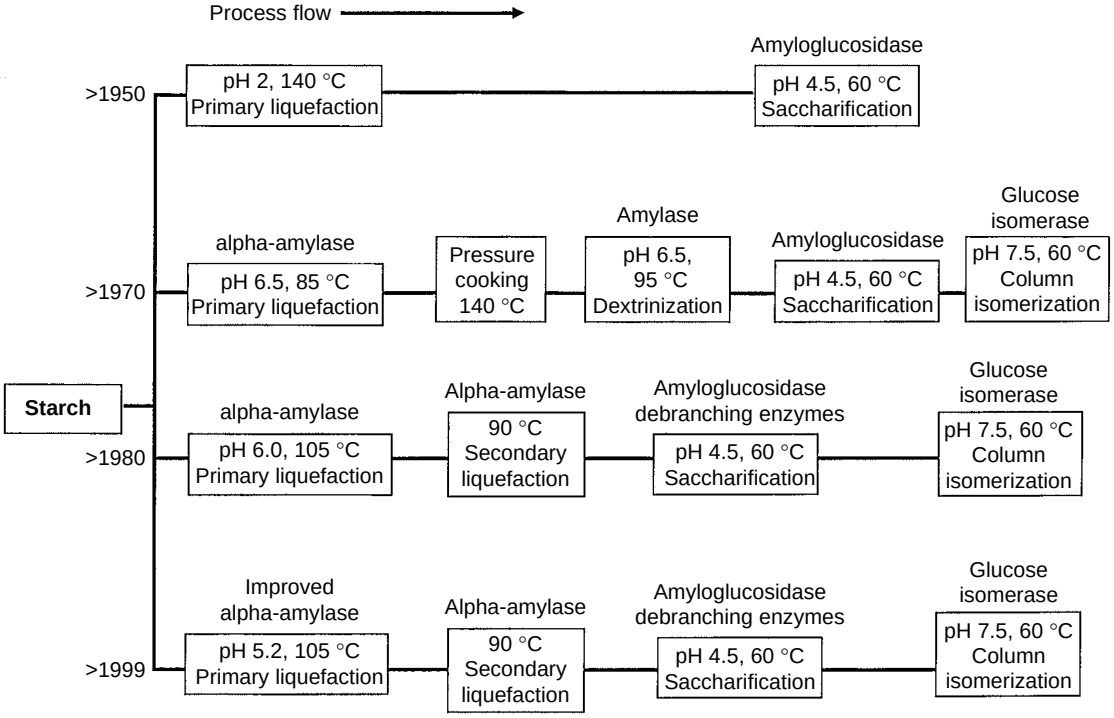

Figure 3. Enzyme-mediated improvements in the production of high-fructose corn syrup over time.

A heat-stable alpha-amylase (Novo BAN®, a bacterial amylase), operating at up to 90 °C was first used to replace the acid treatment. This enzyme, which acts randomly on α-1,4 linkages in amylose and amylopectin, required multiple dosing as the enzyme was inactivated at the higher temperatures. Later developments included the use of even more thermostable amylases (Novo Termamyl®) derived from *B. licheniformis* enabling reaction temperatures to reach 110 °C for short periods. In 1999 a Termamyl® variant called Termamyl Supra® (Novo) was introduced that allows the process to be performed at pH 5.2 rather than pH 6, dramatically reducing the cost of pH adjustment by ion exchange. Today the process may involve several different enzymes, depending on the final starch product required, including fungal and bacterial amyloglucosidases and debranching enzymes, such as pullulanase, which acts on α-1,6 linkages in the branched dextrin chain. The end result is a higher yield coupled with a more energy-efficient process and less toxic waste stream.

Textiles

Enzymes are extensively used in the textile industry for improving production methods and fabric finishing, often replacing hazardous methods with simpler, more environmentally benign alternatives. In the textile and fashion industries, product appearance is everything, so fabric dyeing must be done right. Before textile dyeing, cotton fibers are bleached to provide a uniform whiteness. The bleach must then be completely removed from the fabric or it will interfere with subsequent dyeing steps. Bleach removal is achieved either by several rinses in water or by neutralization of the bleaching chemical by a reducing agent, followed by rinsing in water. For example, in some situations approximately 40 liters of water are needed to rinse the bleach from one kilogram of fabric. When an enzyme such as catalase is used, the fabric requires no rinsing with water at all (14). The enzyme can be added and after about 15 minutes the dye can be added to the fabric. In the case of the nonenzymatic reaction, the textile manufacturer will often overdose the reducing agents, such as sodium thiosulfate or sodium bisulfate, to be sure of neutralizing the bleach. These reducing agents can also interfere with the subsequent dyeing steps and must also be rinsed away. In the traditional process, energy consumption is also required as high temperatures are needed in order for the reducing agents to react efficiently with the hydrogen peroxide. Catalase treatment therefore has a number of environmental advantages, including lower water and energy consumption, elimination of sulfate and nitrogen salt compounds in effluents, and the breakdown of hydrogen peroxide into its natural components of water and oxygen. In addition, the process is more controllable and shorter in duration.

Starch usually is coated onto cotton to give it strength in the mechanical weaving process. The starch must be removed before finishing the fabric, and this has traditionally been carried out using acid treatment. Enzymatic desizing using amylases, eliminating the acid reaction, dates back to the early 1900s. Amylases work efficiently in the desizing process and without the environmentally hazardous waste treatment problems associated with harsh chemicals such as acids, bases, and oxidizing agents.

Before dying of cotton fabric, the cotton must be "scoured" using high temperatures and highly alkaline

chemicals such as lye to remove waxes that prevent the fabric from being evently wetted. This process requires the handling of caustic chemicals, corrosion-resistant reaction vessels, and considerable inputs of energy for extensive hot water rinsing. A recently introduced alkaline pectate lyase, BioPrep™ from Novo Nordisk, is a recombinantly produced enzyme than can effectively remove these waxes under relatively mild conditions with minimal washing. The process saves energy because it can be performed at a lower temperature (50–60 °C) than the traditional process (90–100 °C) and reduces the quantity and toxicity of rinse water previously required to remove the lye from the cotton by up to twofold (Table 3). In addition, unlike the lye treatment, the specificity of the enzyme leaves the cellulose fibers in the cotton intact, resulting in increased fabric strength and weight. Enzymatic scouring of cotton therefore offers advantages in economy of production, product quality, and environmental impact over older, more traditional processes in large textile mills.

About 1.2 billion pairs of denim jeans are produced each year, as well as a significant number of other denim garments (shirts, jackets). A large percentage of these denim garments are abraded and faded, previously by such methods as stonewashing, to give a "washed out" and/or softer look to the garment. Stonewashing has traditionally involved "beating up" the garments in large washing machines in the presence of pumice stones, typically one to two kilograms of stones per pair of jeans. Bleach is often added when a lighter color is the intent. Neutral or acid cellulases have been an excellent replacement for stonewashing of denim garments, a process referred to as "biostoning" (15,16). A cupful of enzyme can replace about 100 times its weight of pumice stones, thereby preventing pumice particle dust in the manufacturing plant and preventing clogged drains by spent pumice sand.

Using cellulases as a substitute for pumice stones also prevents damage to washing machines and the garments, eliminates the need for disposal of the used stones, improves the quality of the wastewater, and eliminates the need for labor-intensive removal of dust from the finished garments. Without the use of stones, the garment load can be increased by as much as 50%, thereby increasing throughput. Neutral cellulases have an advantage in the process of biostoning because of the reduction in backstaining and its broader pH profile. Backstaining is a result of the released indigo dye from the denim being redeposited onto the surface of the fibers.

Table 3. Comparison of Enzymatic and Traditional Alkaline Cotton Scouring in a Jet Dryer Process

Measurement	Biopreparation	Alkaline Treatment
pH	8–9.5	13–14
Process Temperature	50–60 °C.	90–100 °C.
Residual Pectin	22–30%	10–15%
Weight Loss	<1.5%	3–8%
Wettability, drop test	<1 second	<1 second
Rinse water consumption	40–50%	100%
Burst Strength, % of start	95–100	90–97

Laccases (1.10.3.2), also known as polyphenol oxidases, are a new entrant to the industrial enzyme marketplace. Laccase, in a product called Denilite® (Novo Nordisk A/S), was first launched in 1998 for the process of denim bleaching and abrasion. Laccases are a family of multicopper proteins with broad specificity toward inorganic and aromatic compounds, particularly phenols and anilines. These enzymes catalyze oxidations by molecular oxygen, often creating free radicals in the process. Recently several laccases were cloned, expressed (17,18), and biochemically characterized (19–21). The first laccase X-ray crystal structure has also been recently published (22).

The process of bleaching or abrading denim garments to give a "softer" or "worn-out" look involves the removal of the blue indigo dye. To remove the indigo dye from the garment, the conjugated double bonds between indigo's two carbonyl groups must be broken. The oxidative cleavage of these double bonds in the denim bleaching process typically has been carried out using hypochlorite as the bleaching agent. For enzymatic bleaching, an oxidoreductase enzyme, such as laccase, is needed. However, since the indigo dye on the garment is not accessible as a substrate to the laccase, a small organic mediator, such as *propionic acid phenothiazine* (PPT), is added. Figure 4 outlines the mechanism behind laccase denim bleaching. The technology is based on laccase using molecular oxygen as an electron acceptor being oxidized (with the concomitant reduction of oxygen to water), which then creates a mediator radical (PPT+) from the mediator itself, PPT. The PPT+ radical then reacts in a catalytic cycle in which the oxidized cation radical oxidizes solid indigo on the denim surface under simultaneous reduction back to the natural mediator. One of the advantages of this technology is that a side reaction occurs in which the PPT radical disproportionates to form an oxide (PPT-O), which depletes the catalytic cycle, thereby ending the bleaching cycle. In this way, the level of bleaching can be predefined and controlled by the amount of mediator added at the beginning of the process. In addition to the denim bleaching process, the enzyme/mediator mixture can also be used for abrasion enhancement in a totally stone-free process for obtaining highly abraded denim (24).

Other textile materials, such as wool and silk, can also use enzymes for surface modification. Selected proteases can be used to reduce pilling in wool garments by specifically hydrolyzing surface fibers. Silk normally requires a highly alkaline degumming step to remove sericin, a sticky protein that adheres tightly to the fibrin that makes up the silk fiber. Although this process is effective, it is hazardous and causes some damage to the fibrin, weakening the fiber. Certain proteolytic enzymes specifically remove the sericin without cleaving the fibrin.

A recently introduced product from Bayer, Baysolex, contains a recombinant peroxidase that effectively oxidizes residual reactive dyes on cotton after the dying process. This procedure not only reduces the amount of water and

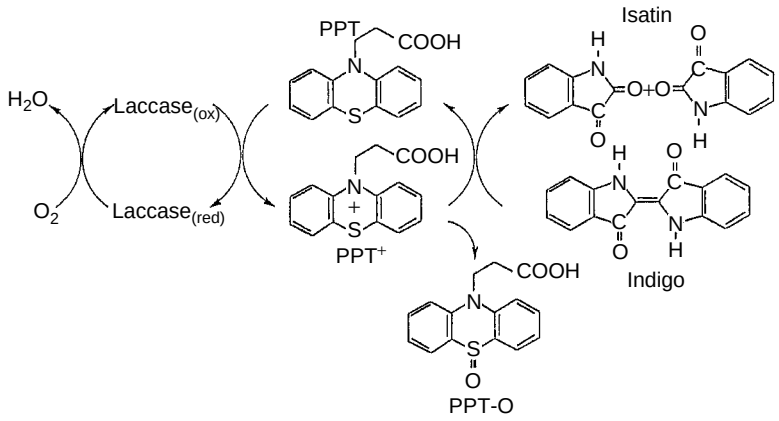

Figure 4. Outlined mechanism behind Denilite® laccase/mediator bleaching technology.

energy required for rinsing but also yields a more colorfast fabric (23).

Leather

The production of leather is one of the oldest applications of industrial enzymes. Traditionally, steps include curing, soaking, dehairing and dewooling, bating, and tanning. The process involves the use of numerous chemicals and unpleasant working environments to remove hair, fat, and unwanted protein such as elastin, keratin, albumins, and globulins, leaving the collagen fibers intact before the tanning of the hides and skins. Traditionally, dog or pigeon feces were used in the early bating steps to make the leather more pliable. The feces bating owed its softening effect to the action of proteases. In 1908 the first standardized enzymatic bating process was patented and was based on using animal pancreatic enzymes. Today bacterial and fungal proteases, mammalian trypsin (a by-product of insulin production), and lipases are used in leather processing (24). The results are a reduction in the use of sulfides, lime, nonionic surfactant compounds and organic solvents. The benefits are in a more standardized, well-defined process, with advantages with respect to the final characteristics and properties of the leather itself.

Pulp and Paper

Paper comprises wood fibers derived from pulp produced by chemical and/or mechanical means. The worldwide production of pulp raw materials is approximately 70 million tons per year, corresponding to a market value of pulp and paper chemicals of more than $5 billion. In the manufacture of white paper derived from pulp there is a strong desire to reduce (and eliminate) the use of chlorine and other chlorinated organic compounds as bleaching agents. This desire stems from intensified federal, state, and local regulatory and public environmental pressure to create fewer pollutants (25,26). A key concern in the reduction of chemical use is to provide the same high quality of brightness of the final paper product without losing paper strength. Enzymes are being used to enhance the bleachability of the chemically derived pulp.

The purpose of processing wood and bleaching the pulp is to remove lignin (delignification). Lignin is a natural resinous adhesive, which causes the yellow-brownish color. The goal is to reduce wood to cellulose fibers and to do so with as little damage as possible to the other wood constituents such as hemicellulose and, most importantly, the cellulose itself. Pulp production begins with debarking and chipping wood logs (Fig. 5). This is followed by a caustic sodium hydroxide cooking wherein the main part of the lignin is dissolved and then washed away. The result is a darkly colored pulp that has to be bleached in order to obtain white pulp for paper production. Chlorine and chlorine dioxide are the most common bleaching chemicals used in multiple stages of pulp bleaching coupled with alkaline extraction of the dissolved lignin.

Environmental pressures have been mounting over the past 15 years on the control of toxic dioxins and chlorinated organic compounds in paper mill effluents. Regulators have been pressuring industry to move away from using chlorine-based chemicals and toward other alternatives, such as the use of hydrogen peroxide, oxygen, ozone, and more recently the use of enzymes. Hydrogen peroxide, oxygen, and ozone have the disadvantages of being too expensive, requiring costly capital investments and resulting in the loss of paper strength. Considerable effort has been devoted to finding alternative bleaching agents, and alternatives have been examined to supplement the delignification stage. The application of xylanases and mannanases has turned out to be useful in removing part of the lignin after the alkaline cooking process and before the bleaching step (27,28).

In a typical xylanase procedure, a pH adjustment of the pulp from 10–11 to 7–9 is necessary. (The temperature is about 55–65 °C). After the pH adjustment, xylanase is mixed into the pulp, which is then kept in a holding tank for about two hours. Mannanases may also be added in some cases for additional bleach-boosting effects. As a result of the significant lignin removal by the enzyme treatment, much lower consumption of chlorine (10–50% reduction) is required to bleach the pulp further (depending on the type of wood and particular enzyme(s)). In addition, the enzyme treatment offers improved bleachability, reduction in the bleaching costs, less chlorinated organic compounds in the effluent, and higher brightness in the paper. The economic benefits include very simple equipment needs and savings in chlorine compounds. These benefits can easily pay for the enzyme treatment, not to mention the supplementary beneficial

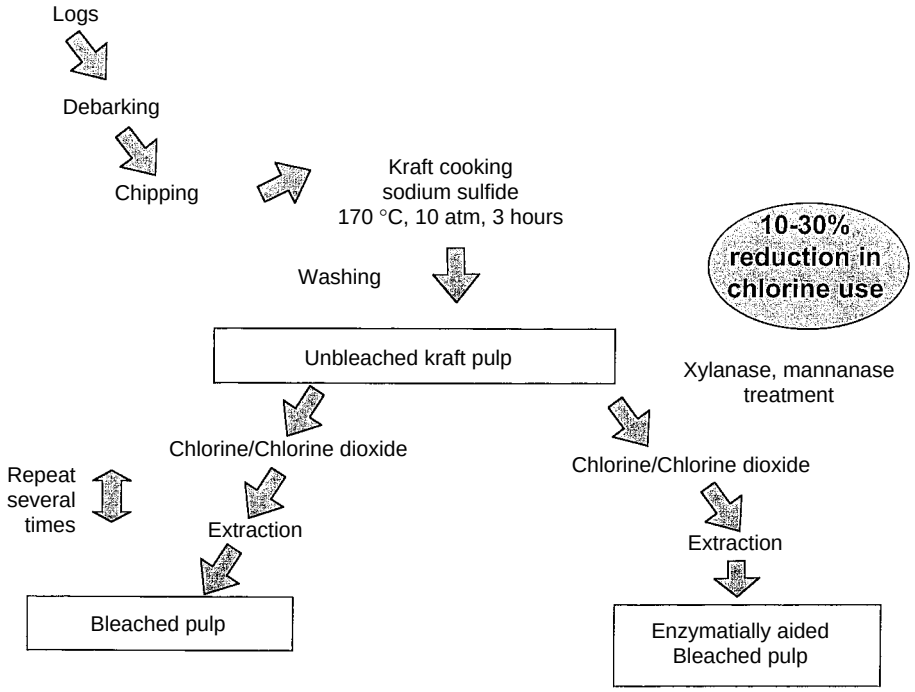

Figure 5. Enzymatic and chemical pulping flow diagram.

effect on the environment. New xylanases introduced into the market are able to withstand higher pH pulp processes without the need for neutralization and are more thermostable, further improving the attractiveness of enzymatic pulp treatment (29).

Although the mechanism of enzymatic bleach-boosting is not fully understood, it appears that xylan is solubilized during the pressurized alkaline cooking process. As the pressure, temperature, and pH drop, xylan precipitates on the wood fiber surfaces. Some lignin is chemically bound to the xylan, which may become released by the action of the xylanase. The precipitated xylan may create a physical barrier for the bleaching chemicals to get into the fibers and block the extraction of lignin and other chromophores. The paper fibers become more susceptible to bleaching after xylanases selectively remove xylan from the surface and the pores of the fibers, releasing the darkly colored chromophores.

In addition to pulp treatment, enzymes are used in the papermaking process. Residual tree resin in pulp can adhere to rollers and cause the pressed paper to be stained or tear, necessitating work stoppage and laborious cleaning. Addition of lipase before the rolling of the paper can reduce the occurrence of these resin-related problems in production. High-quality paper is often coated with starch to improve gloss, smoothness, and printing properties. The starch used in this process must be low in viscosity and was previously treated with aggressive oxidizing agents. Amylases that cleave the starch result in starch solutions with appropriately reduced viscosity and can be produced on-site at paper mills using batch or continuous processes.

Paper recycling is increasing rapidly on a worldwide basis (30), and enzymes may play a significant part in making this an economically viable alternative to new paper production. Recycled paper represents about 30% of total paper consumption and is growing yearly. Of the paper that is recycled, 60% represents old newspaper and 40% represents mixed office wastepaper and tissue paper. Since municipal waste comprises of about 35 to 40% paper, the shrinking availability of land for waste burial could be significantly alleviated with a reduction in disposed paper. Efficient ink removal is a critical requirement before paper can be effectively recycled.

Current de-inking methods involve a highly alkaline solution containing sodium hydroxide, sodium silicates, hydrogen peroxide, chelating agents, and synthetic surfactants (31). These chemicals provide fiber swelling, ink removal, and the disaggregation of the paper into fibers. As the de-inking process starts, the paper has a tendency to darken, necessitating the addition of large amounts of hydrogen peroxide to keep the pulp white. Often harsh chlorine-based bleaching chemicals are used as a final whitening step. In addition to the chemicals, the process involves a combination of thermal and mechanical energy.

Pilot plant de-inking trials using enzymes have shown that fungal cellulases are effective in de-inking newspaper (32) and, most importantly, in aiding toner removal from xerographic and laser-printed paper, largely comprising mixed office wastepaper (33,34). Toners used in office copiers are made of resilient plastic polymers that are tightly bound to the paper fibers. Their removal is difficult with the chemical process, but cellulases are able to release toners from fiber surfaces, presumably by the enzymatic removal of the tiny strands of cellulose that protrude from the surface of the paper fibers, dislodging the cellulose that holds the particle of ink to the paper. De-inking mixed office wastepaper can be achieved using low doses of alkaline cellulases without any added sodium

hydroxide. The alkaline cellulases are required because the pulp already has a high pH due to calcium carbonate used as a filler in the initial paper product. It is expected that enzyme technology will be used on a commercial scale in the near future to modify and/or replace the current de-inking methods.

Fiberboards

During the processes of making wood composites such as fiberboards, particle boards, cardboards, and the like the wood is first disintegrated into small pieces, which are afterward put together into larger boards using high energy and petrochemical adhesives such as urea-formaldehyde and phenol-formaldehyde glues. There is a growing interest in eliminating the use of such toxic and carcinogenic chemicals in the process. In addition, boards made with these adhesives give off small emissions of formaldehyde for months after manufacture.

Enzyme technology may provide a natural alternative to formaldehyde glues for board manufacturers. Lignin, a heterogeneous polyaromatic polymer, is a naturally resinous adhesive material. Nonsulfonated and sulfonated lignin can be polymerized by oxidase reaction. Enzymatic treatment of the wood particles with oxidases, such as peroxidases and laccases, leads to a rough surface of the fiber, rendering them very susceptible to interfibrous bonding. Fiberboards prepared from enzymatically treated fibers by simple pressing under normal production conditions have shown in preliminary trials to have very good technical properties (35). Both the tensile strength and the swelling properties met the required technical standards without the use of the formaldehyde-based adhesives. While a commercial process is still being developed, it should be possible to completely avoid the use of the hazardous formaldehyde-based adhesives. Enzymatic gluing of wood could significantly reduce the worldwide consumption of the approximately 300,000 tons of phenol-formaldehyde and the 2,500,000 tons of urea-formaldehyde used in the manufacture of today's fiber- and chipboards.

Personal Care

The use of enzymes in the personal care industry holds great potential, although there are only a few examples of products that contain enzymes thus far. Some brands of toothpaste and mouthwash incorporate glucoamylase, glucose oxidase, and lactoperoxidase. Although only present in the mouth for a few minutes, the solubilized enzymes attack oligosaccharides adhered to teeth and other mouth surfaces, producing hydrogen peroxide. The low levels of peroxide then effectively inhibit the formation of bacterial plaque that causes tooth decay and bad breath.

Another novel application of enzymes is a new system for hair dyeing using a laccase. The enzyme utilizes oxygen and a common hair dyeing intermediate that is oxidized, resulting in colored hair. Because of the specificity of the enzyme for the intermediate and the use of neutral pH conditions, the oxidative damage that normally occurs with hair dyeing using hydrogen peroxide and ammonia is avoided. There is also no smell of ammonia, no risk of skin irritation, with a broader precursor specificity (and a larger range of colors) (36).

Enzyme applications are also established in the field of contact lens cleaning. Contact lenses are cleaned using solutions containing proteases, lipases, or both. Methods using hydrogen peroxide as a disinfectant require complete removal of the peroxide before replacement in the eye. Catalase, which converts hydrogen peroxide to water, is used to remove residue of this oxidant before final rinsing.

Organic Chemical Synthesis

The role of enzymes in the manufacture of organic chemicals is becoming more established (37). Examples include the isomerization of glucose to fructose by glucose isomerase, beta-cyclodextrin production using cyclodextrin glucanotransferase, carnitine production using beta-ketoreductase, and aspartame production using the protease, thermolysin. The use of enzymes is particularly important when chiral molecules must be distinguished. In the production of amino acids, the conversion of racemic mixtures to the chirally pure desired product is being carried out using amidohydrolases and hydantoinases. The production processes of medically important antibiotics, penicillin and ampicillin, both benefit from enzymatically aided synthesis in lowered chemicals (inorganic and organic solvents) usage, waste, and reduction in energy. Biocatalysis offers significant advantages over equivalent chemical processes in allowing more benign pHs, temperatures, and pressures to be used. In addition, the enzymatic route of synthesis results in fewer undesirable by-products and less waste.

Oil and Gas Drilling

Oil and gas drilling requires the pressurized injection of drilling mud into the well for cooling the drilling head, transporting stone and grit up to the surface, and controlling the pressure underground. This mud often contains injected biopolymers such as guar gum to aid in stabilization and fracturing and to create a "filter cake" that prevents fluid loss. This filter cake can become impermeable, reducing field yield and well productivity. Enzymes specific for degrading the polymeric glue are currently sold to the drilling industry as replacements for strong acids and oxidants that have been traditionally used to degrade the filter cake.

More recently, enzymes have been developed that produce organic acids during the drilling process, dramatically reducing the need to interrupt drilling to degrade the filter cake. In addition, the acids produced allow the in situ generation of minerals, gels, and resins that can act to consolidate sandy drilling fractures and reduce mineral contamination in the product (38).

Fuel Alcohol

Many countries with excess agricultural capacity have a strong economic impetus to reduce their dependence on fossil fuels by production of alcohol from biomass. In a process similar to that described for the production

of high-fructose corn syrup and distilled liquor, complex starch must be converted from sugar polymer to monomer form to make the sugars fermentable by yeast. This requires liquefaction, the conversion of the solid polysaccharides into a liquid form by hydrolysis into shorter oligosaccharides, followed by a saccharification step producing fermentable monomeric sugars. The ethanol resulting from the fermentation is then recovered by distillation. In this industry, where low price is the only means of competition, reduction in capital costs, energy inputs, and efficient conversion are critical. Although the equipment and process for making fuel ethanol and distilled liquor are different, the principle of using enzymes to create fermentable sugars is exactly the same.

More recent efforts in the fuel ethanol industry are centered on converting biomass waste such as corn stover (leaves, husks, and stems), wood pulp, and sugarcane leaves and stems (bagasse) to fuel. In this case, the glucose is derived from cellulose, a β-1,4 polymer of glucose, rather than from starch. Combinations of cellulolytic enzymes capable of hydrolyzing the β-1,4 bonds such as cellobiohydrolases, endoglucanases, and cellobiases are required for this process. Research efforts aimed at reducing the cost of these enzymes are being investigated with funding from the U.S. Department of Energy.

FOOD ENZYMES

Baking

Six billion loaves of bread are baked in the United States alone each year. Approximately 600 million to over 1 billion of these loaves become unsaleable as a result of staling and mold spoilage. Research into bread staling has had a long history, with no good answers, until recent developments in the use of enzymes, such as amylases, to retard the process. Several theories exist regarding why bread stales. Bread is comprised primarily of starch (amylose and amylopectin) and a heterogeneous mixture of gluten proteins. In fresh bread, starch is mostly in an amorphous state. A modification in starch structure plays a major role in the staling of bread (39). Starch molecules tend to revert from an amorphous state to a less hydrated, crystalline state. As this happens, water is released from the starch and presumably is absorbed by the gluten proteins. Long linear amylose chains, extending through several amorphous regions of the bread, interact with the crystalline regions (which may involve as much as 15% of the starch), making it rigid, affecting the entire bread.

Many bakers employ the use of chemical emulsifiers, such as monoglycerides, to retard staling. The emulsifying agents make a softer bread and reduce the rate at which bread becomes firm (stale). Amylases can be used as natural antistaling baking ingredients because they reduce the need for chemical emulsifier additives (40). Amylases have been shown to significantly increase the freshness of bread compared with results using emulsifying agents. Bread has been shown to retain greater than 80% of its original freshness at the end of 48 hours when the dough was made using Novamyl® (Novo Nordisk A/S), a maltogenic bacterial alpha-amylase. Novamyl® is believed to act on specific regions of the starch fraction in bread that normally crystallize during the staling process (41). In fact, bread made with the Novamyl® is more likely to spoil from mold than as a result of staling. Novamyl® retards the staling process without affecting the handling of the dough, and because its action is very specific, overdosing does not reduce bread quality. Other amylases with less specific hydrolysis characteristics are also effective as antistaling agents but can more easily be over- or underdosed, resulting in sticky dough, collapsed bread, or poor resistance to staling.

A number of other enzymes are also used in the baking industry to modify dough properties for better baking results. Although the true mechanism of carbohydrases such as hemicellulase, pentosanase, or xylanase in bread making has not been clearly elucidated, it is well known that doughs containing optimized doses of these enzymes yield a more flexible, easier to handle dough with improved machinability. The strength of the protein network in dough can also be increased by the addition of lipase that partially degrades the lipid fraction of wheat flour. This ensures a more stable dough, resulting in a larger loaf volume and better bread texture. Chemical oxidants such as bromates, azocarbonamide, and ascorbic acid, widely used to increase the strength of the protein network in dough, can be replaced by the addition of an enzymatic oxidant such as glucose oxidase in some breads. Bread is comprised of starch and gluten proteins. During baking, the gluten proteins orient, align, partially unfold, and interact with one another through hydrophobic bonds and via disulfide linkages. This protein network transforms into a thin film in the bread, entrapping the carbon dioxide produced during rising and baking. The addition of oxidizing agents such as potassium bromate, azodicarbonamide, and ascorbic acid enhance the cohesive structures of hydrated gluten proteins in the bread dough, causing an increase in the toughness and elasticity of the bread. The effect is an overall increase in the volume of the bread, better crumb structure, and improved dough handling properties. Bromates and azocarbonamide have come under regulatory fire for health reasons and are restricted and/or banned in some countries. Animal feeding studies have shown potassium bromate to be carcinogenic (42). In the United Kingdom, potassium bromate as a bread improver was banned in 1990. Oxidases, such as glucose oxidase and sulfhydryl oxidase, have dough-strengthening effects and may become important players in the replacement of these oxidizing chemicals.

Dairy Products

The application of enzymes in the processing of milk has a long tradition. Since ancient times, an extract of calf stomach called rennet was used for coagulation during cheese production. We now know that the active ingredient in rennet is chymosin, a protease that cuts the milk protein casein at a specific place, rendering it insoluble. Today calf chymosin and selected fungal proteases with similar

properties are produced from recombinant hosts and sold to cheese producers to replace the traditional rennet at a fraction of the cost. While chymosin and other proteases are the major enzymes used today in cheese production, recombinant lipase cloned from the fungus *Mucor miehei* is also sold as a cheese ripening aid. As a minor component in rennet, the lipase was a component found to be important to the development of flavor in certain blue and Italian cheeses. Health fears concerning the use of animal extracts such as rennet on production of human food are avoided by the use of recombinant products made in microbial expression systems.

Another use of enzymes in the dairy industry is in the modification of milk for improved digestibility. Although all humans at birth make sufficient lactase to break down the 5% lactose that is found in milk, aging often is accompanied by reduced lactase production. Lactase (β-galactosidase) is sold as a dietary aid, as well as to improve the solubility or sweetness of various dairy products. Finally, highly purified and specific proteases are used to make infant formula from milk that is low-allergenic. The number of protein-sensitive individuals is estimated at 1 to 2% of adults and between 5 and 8% of children (43). By using proteases that cleave regions of the milk proteins that induce allergic responses, safe, highly nutritious replacements for mother's milk can be produced (44).

Brewing and Distilling

Beer is one of the oldest fermented products, resulting from the action of yeast on a cooked extract of barley malt; starchy cereal grains such as maize, sorghum, rice, or barley; and hops called sweet wort (Fig. 6). In sweet wort production, malted barley traditionally contributes an amylase activity that functions to break down the starch into smaller sugars that can be converted to alcohol and carbon dioxide by the fermenting yeast. Variability in the amylase activity present in different batches of malted barley can wreak havoc with beer making, resulting in poor filtration, incomplete conversion to alcohol, and poor flavor. Addition of thermostable alpha-amylase and other carbohydrases, such as β-glucanase, speed the fermentation process and increase the predictability of fermentation. The production of light beer, containing reduced sugar content, is accomplished by the addition of glucoamylase, which converts short sugar chains produced by other carbohydrases into glucose, which can then be easily fermented by the yeast. Finally, protease added during the production of the wort can produce increased nitrogen levels in wort made with low-nitrogen cereals. The increase in available nitrogen in turn aids in yeast growth and complete fermentations.

The production of distilled alcoholic drinks from crops rich in starch is another age-old example of fermentation. The conversion of starch to alcohol has always been an enzymatic process, but the source of enzymes before the 1960s was barley malt or koji, a rice extract containing fermenting organisms. Today the majority of distilleries use purified industrial enzymes. A few liters of carbohydrate-degrading enzymes can replace as much as 100 kg of malt, dramatically reducing the cost of raw materials and greatly simplifying the fermentation process.

Fruit, Juice, Wine, Fats, and Oils

A wide variety of consumer goods produced by processing of plant materials use industrial enzymes, including fruit juices, whole prepared fruit, wine, and oil. Traditional methods of wine and juice making begin with the crushing of the fruit to extract juice but are accompanied by the extraction of other plant cell components that may make further processing difficult. The pectin present in fruits reduces the yield of juice and clogs the filter apparatus used in clarifying juices. Pectin is a complicated polysaccharide composed primarily of linear chains of galacturonic acid with branches composed of a variety of shorter linked polysaccharides. During crushing, the addition of pectinases, capable of hydrolyzing the bonds between linear galacturonic acid chains, as well as other carbohydrase activities (rhamnogalacturonases, xylanases, galactanases, arabinases, etc.) contribute to increased juice yield and reduced filtration times. In juice for wine production, treatment also intensifies the flavor and color of the juice.

Whole citrus fruit can also be treated with a similar mix of enzymes to remove the skin ("enzymatic peeling"),

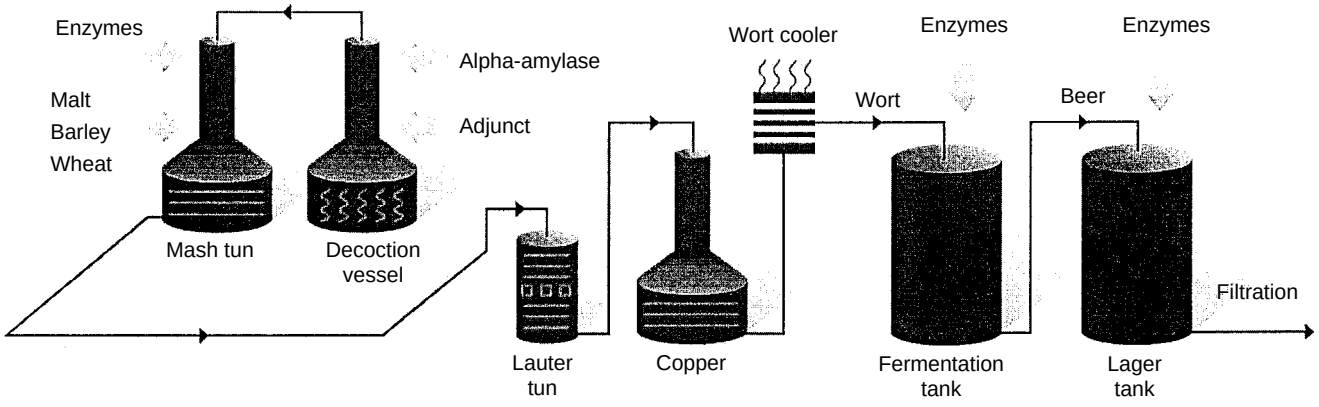

Figure 6. The brewing process.

avoiding the use of caustic soda that is traditionally used. The resulting fruit segments are fresher and no longer have a membrane surrounding them, resulting in better texture and appearance.

Wine making, beyond the production of juice for fermentation, has also been impacted by industrial enzymes. Pectinase treatment after mashing aids in wine clarification, allowing residual pectin to be degraded and reducing the viscosity of the juice.

Oil from coconut, olive, rapeseed, maize germ, sunflower seed, and palm kernels usually is crushed and extracted using an organic solvent such as hexane, an identified air pollutant. Cell wall–degrading enzymes offer a safe and environmentally responsible alternative. The degradation of the cell wall allows aqueous extraction of oil.

FEED ENZYMES

Animals have an inherent inability to digest various types and amounts of plant raw materials in feed. This can be overcome to a significant extent by the addition of enzymes in the feed. Enzymes used in animal feed act as feed enhancers. Enzymes improve the digestibility of feed raw materials, thereby increasing the efficiency of nutrient utilization. The market for animal feed enzymes has grown from about $5 million per year in 1990 to over an estimated $100 million per year today. The market potential for animal feed enzymes is much greater because today only about 6% of the manufactured animal feeds contain enzymes.

Today the primary enzymes used in animal feed are xylanases, beta-glucanases, proteases, and phytases. In addition to improving the overall digestibility of the feed raw materials and increasing the nutrient availability from the feed, there is a concomitant reduction in the production of animal waste. Animals are unable to unlock the energy in various forms of cereal- and vegetable-based non-starch polysaccharides (NSP). The addition of beta-glucanases, xylanases, and proteases will free this NSP, rendering it available to the animal. The removal of NSP also releases starch and protein, which can otherwise be masked by the cell structure in the cereal. This leads to an overall increase in metabolizable energy and in protein utilization.

Between 50 and 80% of the total phosphorus in pig and poultry feeds is present in the form of phytate, the hexaphosphate of myoinnositol, an important phosphate storage compound in plants. Phytate not only is resistant to digestion in these animals but also binds tightly to various proteins and nutritionally important metals such as calcium, zinc, and magnesium. Phytate excreted by animals also negatively impacts the environment since it is readily broken down into free phosphate by soil microorganisms and released into the soil and groundwater. Use of the enzyme phytase as an animal feed supplement therefore has two primary benefits: it increases the nutritional value of the feed by releasing phosphate and bound metals from the phytate, and it reduces the release of free phosphorus in animal waste by as much as 30% (45,46).

CONCLUSION

Enzymes are the most widespread products of biotechnology in use today. As demonstrated by the vast array of industries and applications described here, it is nearly impossible to avoid using, eating, or wearing a commercial product that has not been touched by the action of industrial enzymes. Since enzymes are responsible for the catalysis of chemical reactions in all living things, they provide a natural, biodegradable solution to numerous problems in our industrial society. Their production from fermentation of living organisms uses agricultural products as raw materials and produces only biodegradable wastes. They function specifically, are extremely efficient, and often replace chemical processes that require more energy and produce more wasteful by-products. When all the benefits of using enzymes are taken into consideration, it is not surprising that the number of enzyme applications continues to grow each year.

EUTROPHICATION AND ALGAE

Edward J. Phlips
University of Florida
Gainesville, Florida

The process of eutrophication can have wide-ranging and profound effects on algal communities in aquatic ecosystems. However, the first and by no means trivial challenge in dealing with this topic is to define the meaning of eutrophication. Despite the ubiquitous use of the term in the field of aquatic ecology, it is surprising how many different ways eutrophication is used in the literature. In keeping with the Greek origin of the word eutrophic, meaning well-fed, eutrophication is sometimes used in the context of increases in nutrient loading or concentration in aquatic ecosystems. In contrast, many limnologists and oceanographers use the term in a more reactive context, that is, referring to increases in biological productivity and/or standing crop. Obviously, these two usages are intimately related, but they are not synonymous. Increases in nutrient loading may not result in increased productivity if other factors limit the use of the nutrients. By the same token, increases in productivity may not lead to increased standing crop because of the nature and magnitude of loss functions, such as grazing, death, sedimentation, dilution, and export. For the purpose of this review, the responses of algae to eutrophication will be discussed from the point of view of both gain and loss functions.

The specific response of algae to increases in nutrient concentrations is dependent on the relative availability of the nutrient in question before the increase. If the nutrient

in question is present at growth-limiting concentrations, increases in availability should stimulate productivity, assuming the absence of other limiting factors such as light availability. Alternatively, addition of a nutrient already present at saturating levels may result in little response. The amount, rate, and manner of nutrient addition can also affect the type of algae that responds to the increase. Hence, the impacts of nutrient increases can be both qualitative and quantitative in nature. The structure and abundance of algal populations, resulting from an increase in nutrient concentrations, is further dependent on a host of physical, chemical, and biological characteristics that define particular ecosystems.

All of the aforementioned considerations manifest the need to define the impact of eutrophication on algae within the context of the fundamental spatial, temporal, and system-specific differences that exist in the structure and function of ecosystems.

NUTRIENT CONCENTRATIONS, TROPHIC STATE, AND ALGAL BIOMASS

Historically, phosphorus has been viewed as the most commonly limiting nutrient in freshwater ecosystems. This principle is in large part attributable to two important facts: (*1*) phosphorus is in low supply compared with biological demand (1), and (*2*) unlike nitrogen, which is also in low supply compared with demand, phosphorus cannot be added to an ecosystem from the air through biological fixation. The role of phosphorus in the control of algal productivity and abundance is manifested by the widely reported relationship between phosphorus concentration and chlorophyll *a* (2). For this reason, many of the most commonly used indicators of trophic state include phosphorus and chlorophyll *a* concentrations as main elements (3). A number of researchers (4–6) have proposed ranges for phosphorus and chlorophyll associated with different trophic states (e.g., Table 1). Total nitrogen concentration and Secchi disk depth are also commonly included in trophic state indices (3). Nitrogen has been shown to be a limiting nutrient for algal growth in a number of freshwater ecosystems subject to relatively high phosphorus loading (3,7). Secchi depth is a widely employed measure of light transparency, and is therefore a useful surrogate for phytoplankton abundance, except in ecosystems in which light absorption is dominated by organic color or nonalgal suspended solids (i.e., tripton).

The range of values used here to define specific trophic states must be considered rough estimates of the actual trophic state, because values observed in the field are subject to considerable spatial and temporal variation, even within well-defined ecological boundaries. As a consequence, the task of establishing an accurate measure of trophic status can require extensive sampling efforts. Adding to the complexity is the fact that in some ecosystems, most particularly those of large size and/or spatial heterogeneity, the values for key trophic state indicators can show significant regional variability (9).

More recently, the abundance of submerged aquatic vegetation (SAV) in aquatic ecosystems has been incorporated in to the evaluation of trophic state (10). This new approach has been a useful addition to defining trophic state in shallow water ecosystems in which the dominant primary producers are benthic macrophytes and algae rather than phytoplankton.

Table 1. Range of Values for Key Environmental Indicators Associated with Different Trophic States (After R. G. Wetzel, *Limnology*, 2nd ed., Saunders College Publishing, New York, 1983.). TP, Total Phosphorus ($mg\,m^{-3}$); TN, Total Nitrogen ($mg\,m^{-3}$); Chl, Chlorophyll *a* ($mg\,m^{-3}$); Peak Chl ($mg\,m^{-3}$); SDD, Secchi Disk Depth (m). Mean Values Are Shown along with Range in Parentheses

Parameter	Oligotrophic	Mesotrophic	Eutrophic	Hypereutropic
TP	8.0 (3.0–17.7)	26.7 (10.9–95.6)	84.4 (16.0–386)	— (750–1,200)
TN	661 (307–1,630)	753 (361–1,387)	1,875 (393–6,100)	— —
Chl	1.7 (0.3–4.5)	4.7 (3.0–11.0)	14.3 (3.0–78.0)	— (100–150)
Peak Chl	4.2 (1.3–10.6)	16.1 (4.9–49.5)	42.6 (9.5–275)	— —
SSD	9.9 (5.4–28.3)	4.2 (1.5–8.1)	2.45 (0.5–7.0)	— (0.4–0.5)

TROPHIC STATE AND ALGAL COMMUNITY STRUCTURE

The process of eutrophication is accompanied by profound changes in many aspects of the structure and function of aquatic ecosystems, beyond simply the abundance of algae. It is, therefore, not surprising that ecosystems of differing trophic status are often characterized by different algal assemblages (e.g., Table 2). Some of these differences are directly related to the relative ability of different algal species to compete for essential nutrients (11–13). For example, in oligotrophic lakes and rivers, algal species with a high affinity for limiting nutrients can have a selective advantage. By contrast, hypereutrophic ecosystems can favor species capable of high nutrient uptake capacity and fast growth. In another case, an ecosystem subject to pulsed nutrient loading may be characterized by species of algae capable of storing nutrients for subsequent growth among loading events. In a forth and widely important scenario, ecosystems subject to nitrogen limitation are often dominated by species of cyanobacteria capable of nitrogen fixation. The latter case is an example of how the ratio of nitrogen to phosphorus, and their concentrations, can impact community structure and biomass. Clearly, there are many possible nutrient concentration and loading scenarios. Individual aquatic ecosystems may be subject to a wide range of conditions over time and space, helping to explain the dynamic character of algal communities.

It is also important to recognize that the direct effects of phosphorus and nitrogen concentration and loading characteristics on algal biomass are only a part of the environmental mosaic that defines the impact of changing trophic status. Light availability, temperature, pH, carbon dioxide concentration, organic carbon content, and oxygen tension are just a few of the parameters affected by

Table 2. Examples of Algal Genera Containing Species Associated with Oligotrophic and Eutrophic Conditions (After R. G. Wetzel, *Limnology*, 2nd ed., Saunders College Publishing, New York, 1983, E. changes in trophic status. Changes in these factors can lead to a cascade of alterations in the physical and chemical structure of ecosystems that ultimately affect algal community structure. For example, high phytoplankton standing crops can enhance thermal stratification of the water column, as a result of increased absorption of solar energy. Stratification, subsequently, increases the potential for hypoxia in lower layers of the water column, increases pH in surface layers, and reduces carbon dioxide availability in the upper layers of the water column. The latter conditions favor species of algae capable of buoyancy regulation and able to use bicarbonate as a carbon source for photosynthesis. This example illustrates how changes in algal abundance can in turn shape the structure of aquatic ecosystems, which in turn precipitates further changes in community structure.

Part of the structural changes brought about by elevated trophic status in aquatic ecosystems is the appearance of algal species adapted to eutrophic and hypereutrophic conditions. The selective factors associated with elevated trophic status include; (*1*) reduced light availability in the water column (i.e., caused by light attenuation by phytoplankton), (*2*) reduced carbon dioxide concentrations (i.e., caused by photosynthetic carbon uptake and elevated pH), (*3*) reduced availability of secondary nutrients (e.g., trace metals), (*4*) increased periods of low oxygen concentrations, (*5*) elevated temperatures, and (*6*) increased frequency of nitrogen limitation. Among the various algal groups, the cyanobacteria contain a disproportionately large number of species well-suited to one or more of the aforementioned conditions. It is, therefore, not surprising that several researchers have observed that the relative importance of cyanobacteria in phytoplankton communities increases with trophic status (16,17). This relationship may, in part, be attributed to the long evolutionary history of cyanobacteria, which dates back over three billion years and includes geologic periods characterized by extreme conditions. Another important factor is the ability of many cyanobacteria to fix nitrogen, which provides them with a distinct advantage under nitrogen-limited conditions. Planktonic nitrogen-fixing genera, such as *Anabaena, Aphanizomenon*, and *Cylindrospermopsis* are found in bloom proportions in eutrophic ecosystems throughout the world. A number of non-nitrogen-fixing cyanobacteria are also prominent bloom-forming species on a global basis, including the genera *Microcystis* and *Oscillatoria*.

Despite the widespread success of cyanobacteria in eutrophic environments, there are species in other algal divisions that can dominate algal communities in eutrophic ecosystems. In the planktonic realm, these species include a number of fast-growing green algal and diatom species (Table 2). In the benthic and epiphytic domain, certain species of filamentous green algae and pennate diatoms can form extensive blooms (18,19). In shallow flowing ecosystems, filamentous green algae, frequently, dominate the algal community. The specific species of algae found in individual systems depends not only on trophic level but also on a host of other environmental parameters, such as conductivity, temperature, light, ionic balance, sediment type (20,21).

FACTORS THAT AFFECT THE RELATIONSHIP BETWEEN NUTRIENT CONCENTRATION AND ALGAL ABUNDANCE

Besides the obvious dependence of algal productivity on the availability of the key macronutrients, namely, phosphorus and nitrogen, there are other factors that can affect the specific response of algae biomass to increases in these nutrients. These factors can operate at different stages of the overall process of algal biomass accumulation, from the light reaction of photosynthesis to cell growth. The nature and magnitude of the effects also vary over wide temporal and spatial scales, from the fractions of a second associated with photosynthetic light reactions to geologic timescale shifts in climatic conditions and from subcellular differences in light absorption to latitudinal differences in seasonality. The one unifying element is that all the controlling factors can have profound impacts on the manner and degree to which changes in nutrient loading are expressed in terms of algal biomass. It is, therefore, appropriate to review some of the principal factors that are involved in determining these relationships.

Light Availability

Light is the energy source for oxygenic photosynthesis, and therefore light is the ultimate limiting factor. In the broadest sense, the varied environmental consequences of latitudinal gradients in annual incident irradiation has been shown to be a major contributor to differences in annual primary production in tropical, temperate, and boreal environments (22). Hence, given similar nutrient status, annual primary productions in ecosystems located in lower latitudes often exceed that in higher-latitudes because of differences in annual light availability. Latitudinal differences in primary production also extend to seasonal patterns of algal abundance. Algal abundance in high-latitude ecosystems frequently shows one peak coinciding with summer light maxima. Conversely, in tropical latitudes, algal abundances can exhibit multiple peaks throughout the year, reflecting the year around availability of light. In temperate ecosystems, two annual phytoplankton peaks, one in the spring and one in the fall, are common. Regional differences in weather conditions can also result in disparities in light availability. The latter considerations have led some researchers to propose that peak algal standing crop during the course of a year is a better measure of trophic status than mean annual chlorophyll concentration.

Beyond the question of variations of incident light flux, the availability of photosynthetically active radiation (PAR) in the water column is dictated by the rate and character of light extinction, depth, and vertical stability. There are a growing number of examples of aquatic ecosystems in which light, rather than nutrient availability, is the primary factor that limits primary production (23,24). As an example of one extreme case, the upper limit of phytoplankton standing crop in some hypereutrophic ecosystems can be dictated by the degree of self-shading. In a classic study of hypereutrophic lakes in equatorial Africa, Talling (25) concluded that the upper limit of phytoplankton standing crop in well-mixed shallow lakes is approximately 400 mg chlorophyll *a* m^{-2}. A similar conclusion has been reached for periphyton communities dominated by benthic cyanobacteria and diatoms (26). In contrast, benthic green algal mats in shallow flowing systems have been observed to exceed 1,200 mg chlorophyll *a* m^{-2} (18,27).

In sharp contrast to the latter scenario, there are eutrophic and hypereutrophic ecosystems in which phytoplankton standing crops only reach a small fraction of the potential represented by the concentrations of bioavailable nutrients present. In some of these systems, light absorption is dominated by the presence of high levels of nonalgal suspended solids. For example, phytoplankton standing crops in parts of Lake Okeechobee in Florida average less than 20 μg chlorophyll *a*/L, despite high concentrations of bioavailable phosphorus, because of very high levels of light-absorbing tripton (23). Similarly, high organic color levels in backwater rivers severely limit PAR light availability and can limit phytoplankton standing crops (24,28).

Besides, light extinction properties of the water column, depth, and mixing characteristics play a major role in defining the effect of light availability on algal biomass. In the case of planktonic primary producers, the movement of algal cells through the water column presents a constantly changing light environment. Therefore, primary production over the water column is an integration of photosynthesis over a range of light intensities. Historically, the relationship between mixing depth and light attenuation has been a central focus in defining the productivity of aquatic ecosystems. The two terms most commonly used to define the relationship are mixing depth and critical depth, that is, the depth at which algal respiration in the water column equals photosynthetic oxygen evolution. If mixing depth exceeds critical depth, there is a putative loss in algal standing crop over time, irrespective of the nutrient availability. This assumes that cells are circulating evenly through the mixed-layer, which is not always the case. For example, many cyanobacteria and dinoflagellates exhibit the capacity for buoyancy regulation and motility. The ability to regulate position in the water column provides these algae with a distinct advantage under conditions of light limitation in the water column. It also represents an example of how differing light environments can affect both phytoplankton community structure and abundance.

The productivity, standing crop, and composition of benthic algae are also subject to issues of light limitation, but in a somewhat different way than planktonic algae. The successful colonization of benthic environments by algae depends on the availability of appropriate substrate at depth ranges that provide sufficient light to sustain growth and reproduction. In shallow water ecosystems, benthic algae biomass can increase significantly with eutrophication. However, above a certain threshold of nutrient concentration, increased phytoplankton abundance can result in sufficient shading of benthic habitat to restrict benthic algal development. The latter phenomena can be interpreted in terms of the concept of alternative stable states (29). The latter concept refers to the presence of threshold levels for environmental conditions that once exceeded results in major shifts in community structure. Major increases in the trophic state of ecosystems can fall in this category. The establishment of high-density phytoplankton biomass can make it difficult for benthic plant communities to maintain or establish themselves without a major environmental disturbance, such as sharp reductions in water levels. Conversely, well-established benthic plant and algal communities stabilize benthic substrates and compete with phytoplankton for bioavailable nutrients, thereby reducing the potential for blooms. A major storm event, such as a hurricane, can disrupt benthic plant community structure and result in a shift to phytoplankton domination. The balance between benthic and planktonic plant/algal biomass during the process of eutrophication is a subject of major concern to managers of aquatic ecosystems. Recent decades have seen a growing effort to maintain or reestablish benthic plant/algal communities in an effort to limit the potential for phytoplankton blooms (29).

At the opposite extreme of limiting light levels is the issue of excess irradiance. High solar irradiance

can negatively impact photosynthesis and cell growth in several ways, including the production of damaging superoxides caused by exposure to excessively high amounts of PAR light and cell damage from exposure to ultraviolet light. Both of these phenomena can lead to reduced algal productivity and standing crop.

Secondary Limiting Nutrients

Although nitrogen and phosphorus are the two most frequently limiting nutrients in aquatic ecosystems, there are other elements that can limit primary production. Limitations of secondary elements, although relatively rare, can directly impact the expression of the growth potential represented by the amount of nitrogen and phosphorus present. Trace elements, such as iron, have been shown to be limiting factors in a number of systems. In some cases, the low concentrations of certain elements can have a specific effect on certain algal taxa, thereby impacting the community structure. For example, silica limitation in the Great Lakes of North America has been shown to limit the growth of diatoms resulting in major alterations in phytoplankton structure and dynamics (30). Similarly, the absence of certain vitamins can limit the growth of certain species of algae, but not others (31).

Temperature

Although light availability is the primary physical factor that limits the rate of photosynthesis, there are a number of other environmental parameters that affect photosynthetic and growth potential of algae. Principal among these is temperature that strongly influences the dark reactions of photosynthesis (e.g., Calvin cycle), and other metabolic functions of algal cells. Despite the fact that algae exhibit both genotypic (e.g., species differences in temperature optima) and phenotypic (e.g., adaptive changes in concentrations of rate-limiting enzymes) adaptations to a wide range of temperatures, short-term changes in temperature and broad geographic differences in temperature regimes (e.g., polar versus tropical or high versus low altitude lakes) have an impact on production potential. For example, low temperatures encountered in temperate and boreal ecosystems during winter can reduce the overall rate of primary production. Similarly, the extremely high temperatures associated with hot springs limit the rate of primary production and also exclude all but thermophilic species of algae.

Loss Functions

Beyond the factors that directly affect the photosynthesis and growth of algae, as previously discussed, there are also a number of key biological and physical processes that can control standing crop after growth. Among the biological processes, one of the most fundamental is grazing. Although the impact of eutrophication on algal productivity and standing crop is most often approached from a bottom-up perspective, such as nutrient limitation, standing crops of algae can also be dramatically affected by top-down processes such as grazing, associated with the food web. Grazing can affect biomass potential, and spatial and temporal patterns of abundance and composition (32). Seasonal cycles of phytoplankton standing crop are often tied to patterns of zooplankton population that vary in response to the availability of the algae biomass. Similarly, the standing crop of benthic algae can be kept down to relatively low levels by benthic grazers (i.e., invertebrates and fish), despite high rates of productivity (33).

Physical processes can also play a major role in the loss of algal biomass. One of the most fundamental physical factors is the rate of water turnover. High rates of water turnover or dilution (i.e., flushing rates) can restrict phytoplankton standing crop by limiting the time available for the accumulation of biomass. Most current models of phytoplankton dynamics include terms for dilution or residence time (34). In the case of benthic algae, high water turnover and flow rates can have the opposite effect, by increasing the flow of water across the surface of the algae (35). Flow can help increase benthic productivity and standing crop in several ways, namely, (*1*) by providing a more consistent supply of nutrients, (*2*) by breaking down the boundary layer that inhibits surface nutrient exchange, and (*3*) by enhancing gas exchange, thereby increasing carbon dioxide availability for photosynthesis and reducing inhibitory oxygen supersaturation. High flow rates can, however, also reduce benthic algal standing crop by physical scouring and erosion of mats (35).

Another physical mechanism for biomass reduction is sedimentation. Because the specific gravity of most algae is greater than water, they sink unless acted upon by physical mixing forces. In aquatic ecosystems in which depth exceeds the euphotic zone, sedimentation can significantly limit productivity and standing crop. Even in shallow water ecosystems, settling of algal cells can reduce total productivity by reducing light availability. There are processes that counteract the rate of sedimentation. The primary physical processes that reduce sedimentation are wind-, heat-, and flow-induced mixing. In shallow water ecosystems, wind mixing can also contribute to dramatic short-term temporal variation in phytoplankton standing crop. For example, highly productive shallow lakes, such as Lake Apopka in Florida, are characterized by high concentrations of meroplanktonic algae (i.e., sedimented algae located at the benthic interface) (36). Wind resuspension of the meroplanktonic layer can result in a two- to threefold increase of phytoplankton concentration in a matter of minutes. Conversely, surface scums of algae can be wind-mixed into a deeper water column, thereby reducing surface algae concentrations over short periods of time. These phenomena present added complexities to the task of determining the trophic status in ecosystems subject to vertical stratification of algal abundance.

In addition to physical factors that control the rate of sedimentation, there are biological mechanisms by which cells can adjust their position in the water column. The three primary mechanisms are buoyancy regulation, motility, and structural adaptation. Certain cyanobacterial groups, such as *Anabaena* and *Microcystis* are particularly adept at controlling buoyancy and can be found at distinct vertical layers in the water column.

Similarly, flagellated algae, such as dinoflagellates, are capable of moving within the water column in order to find optimum environmental conditions.

EVOLUTION OF METABOLIC PATHWAYS FOR DEGRADATION OF ENVIRONMENTAL POLLUTANTS

JAN ROELOF VAN DER MEER
Swiss Federal Institute for Environmental Science and Technology (EAWAG)
Dübendorf, Switzerland

ADAPTATION AND ENVIRONMENTAL POLLUTION

It is undisputed that microorganisms can adapt to changes in their environment. One of the types of changes microbial communities are currently exposed to is the release of large quantities and varieties of organic and inorganic substances into the environment. These substances can act as the "triggers" for different kinds of adaptation of microbial communities. Thus, various evolutionary mechanisms at work in adapting bacterial populations can be observed. From an environmental viewpoint, adaptation of microbial communities is beneficial when microorganisms that can completely degrade polluting substances evolve (e.g., natural attenuation).

What are the ways by which environmental pollutants can act as triggers for adaptation and how might microbial communities react? In general, adaptation (in contrast to intoxication) can be discussed when the overall response of the community is "positive." Artificial organic compounds and wastes that enter the environment may represent a significant source of carbon and/or energy for microorganisms, provided their concentrations are sufficiently high. Those bacteria that can use the carbon and/or energy from the pollutant can proliferate and (perhaps) increase in population size. When this occurs, a rapid disappearance of the pollutant is usually observed. This type of reaction is what has been observed in environments polluted with oil

or oil products (1). Microorganisms degrading oil or coal components are probably ubiquitous in the environment and will immediately start to degrade those components from an oil spill, thereby increasing their population size measurably (2–4).

Other pollutants, however, might have an uncommon type of structure or side substituents, which render them nondegradable or very poorly degradable. Typical examples of such xenobiotics are halogen-substituted compounds (5). Some xenobiotics could even in principle be metabolized by existing microorganisms, but are not being degraded because they are not recognized by the pathway regulatory proteins. Therefore, the proper pathways are not expressed when the microorganisms face the compound (e.g., as for chlorobiphenyls) (6). For those poorly degradable compounds, no reaction of the community occurs and the pollutant disappears only by physicochemical and hydrological processes. However, even when nothing much might happen to a pollutant for a long time, microorganisms that can degrade it may "appear all of a sudden" (7–9). Such microorganisms often have acquired one or more genetic changes (see following section). Typical examples of compounds for which adaptation has been observed are listed in Table 1.

Biochemical Adaptation

When adaptation requires expression of a characteristic, which is present in the cell as such, one speaks of biochemical adaptation. This type of adaptation usually involves a particular signal-transduction pathway by means of signal and/or regulatory proteins that interact with the DNA and regulate gene expression. Such regulatory proteins are very common for activating the enzymes for pollutant breakdown (37,38). For example, bacteria capable of using toluene as the sole carbon and energy source will synthesize the enzymes necessary for toluene breakdown whenever they encounter larger amounts of toluene. A specific regulatory protein in the cell (XylR) is capable of recognizing toluene and activating transcription of the *xyl* genes for toluene degradation (39). Cells that suddenly face a change in carbon substrate go through a transition state (40) and adapt their metabolism to the new compound.

Table 1. Examples of Genetic Adaptation to Xenobiotic Compounds

Compound	Sole Carbon and Energy Source	Reference
Chlorobenzene	+	(10,11,12,13)
2,4-Dichlorophenoxyacetic acid	+	(14,15,16,17)
2,4,5-Trichlorophenoxyacetic acid	+	(18,19)
Hexachlorocyclohexane	+	(20)
Nitrilotriacetic acid	+	(21)
EDTA	+	(22,23)
Chlorinated alkanes	+	(24)
Nitrobenzene	+	(25)
Nitrotoluenes	+	(26,27,28)
Atrazine	+/–	(29,30,31)
Perchloroethylene (anaerobically)	+	(32)
Trichloroethylene (aerobically)	–	(e.g., 33)
Polychlorinated biphenyls	–	(e.g., 34)
TNT (trinitrotoluene)	–	(35,36)

Not necessarily complete listing or in all cases genetically "proven."

The question at what concentration a pollutant may lead to induction or selectable growth is not solved satisfactorily (41). If the concentration of the pollution is too low (below 5–10 nM), nothing much may happen. Studies on pathway induction seem to indicate that there are threshold concentrations below which no inductive effects on pathway expression are seen (42). The fact that very low background concentrations (ng/l range) of various pollutants occur in almost all environmental compartments suggests that these are too low for microbial degradation or adaptation.

Genetic Adaptation or Evolution

If the capability to recognize and degrade a pollutant is not immediately present in the cell and one or more genetic changes are required, we can speak of genetic adaptation (or evolution). This is the case when, for example, a particular mutation is needed to activate a silent gene cluster or to change the specificity of an enzyme. The capacity to produce those genetic changes (e.g., the DNA polymerase, DNA repair systems, or recombinases) resides in the cell and the basic DNA content of the cell is the source for the changes.

When the basic DNA content of the cell is not directly sufficient as source for genetic adaptation, adaptation may still occur, but involves acquisition of DNA fragments from other microorganisms (not of the same strain). Collectively, these acquisition processes are named *horizontal gene transfer*. Various ways exist by which DNA fragments can be transferred from one cell to another, can be taken up, or can be excised from the genome of a "donor" and integrated into a "recipient" organism. Some of these mechanisms are confined to a particular subclass of related microorganisms, whereas others have a broader range. The outcome, however, is that microorganisms in a community can profit to a certain extent from the DNA content of each different individual member.

The different mechanisms that can lead to changes in the DNA are described in detail. Many of these mechanisms are known from areas other than biodegradation itself, but will mostly be illustrated with examples from bacteria degrading organic pollutants.

MECHANISMS FOR GENETIC CHANGE

DNA Replication and Repair Systems

In its most elementary form, the base sequence of DNA can change through base pair substitutions, small deletions, or insertions. Some base pair changes may arise "spontaneously" as a result of chemical reactivity (e.g., deamination), whereas others might be caused by interaction with DNA-damaging chemicals or reactive oxygen species or by ultraviolet light. Some mutations, though, are the result of the activity of cellular enzymes acting on the DNA themselves (43). In growing cells, DNA polymerases, DNA repair enzymes, recombinases, and

topoisomerases are among those enzymes leading to base pair substitutions, small deletions, frameshifts, or small duplications. In nongrowing cells, DNA polymerases might not play such an important role; rather, enzymes acting on DNA supercoiling have been implicated in causing base pair mutations (44).

DNA polymerases are the main DNA-replicating enzymes in the cell, copying each DNA strand meticulously into a complementary one. Although proofreading activity is very high, DNA polymerase III makes accidental mistakes either by incorporating false bases or by incorrect exonuclease editing (45). In most cases, mispaired base pairs are corrected by the mismatch repair system of the cell (46,47). With a certain frequency, however, mispaired regions are not repaired to the original sequence but to that of the falsely incorporated bases. One or more base substitutions remain. The mean frequency for base substitutions is extremely low, but measurable, and accounts for between 5.10^{-8} and 10^{-10} per base pair per replicative round (48). The frequency of base pair mutations is not necessarily constant for all DNA templates, and the types of mutations (e.g., substitutions, deletions, frameshifts) depend on the local sequence and structure of the DNA template (44). For instance, short DNA sequence repeats can act as sites for DNA slippage (43,48–50), which may promote the occurrence of larger deletions or the formation of larger noncomplementary regions. Inverted repeats may also be more prone to base pair mutations because of the possibility of forming hairpin loops during replication or transcription. Differences between mutation rates were also found between leading and lagging strands (45).

As a result of this constant (low) rate of mutations, some cells will also suffer from mutations in certain DNA repair enzymes (such as MutS, MutH, or MutT) (47,51), or in the DNA polymerase itself (45). When these mutations cause a decrease in the proofreading activity of the DNA polymerase or of DNA repair enzymes, the cells turn into hypermutable microorganisms with a significantly higher rate of base pair mutations. On an average, hypermutable organisms seem to maintain themselves quite well, although their relative population size does not increase to much more than 2% (52). Only under specific conditions, their relative number may increase dramatically (53).

The following features of catabolic pathways have been shown to be adaptable by relatively simple base pair mutations (substitutions, small deletions, or duplications):

- kinetic properties, substrate range, inhibition characteristics, or temperature stability of catabolic enzymes
- inactivation of enzyme functions that interfere with a catabolic pathway
- effector specificities and other properties of regulatory proteins
- changes in the operator-promoter regions of catabolic pathways.

Alterations of Enzymatic Parameters

This aspect seems rather trivial in the area of in vitro genetic engineering techniques. However, the discussion here is focused on documented spontaneous changes in catabolic pathways. Single base pair changes in the *amiE* gene that encodes acetamide amidase in *Pseudomonas aeruginosa* PAC resulted in expansion of the substrate range and improved the kinetic properties of the amidase toward butyracetamide and phenylacetamide (54). In addition, different types of mutations in the *dhlA* gene for haloalkane dehalogenase of *Xanthobacter autotrophicus* could be retrieved when selecting for growth on 1-chlorohexane (55). The resulting dehalogenases had better kinetic properties than the wild-type enzyme with 1-chlorohexane as substrate (Fig. 1). Various types of mutations could also be isolated in the genes for protocatechuate 3,4-dioxygenase and vanillate demethylase of *Acinetobacter calcoaceticus*, which affected kinetic properties and thermostability (56,57).

Inactivation of Enzyme Functions

Certain enzyme activities may interfere with a catabolic pathway when they result in the formation of a toxic intermediate. In such cases, there is probably a strong selection for mutants in which the genes for these enzymes are inactivated. For example, *A. calcoaceticus* strains that lack part of the enzymes for protocatechuate metabolism produce the toxic intermediate β-carboxymuconate when grown on *p*-hydroxybenzoate. It is easy to obtain mutant strains in which the *pcaGH* genes for protocatechuate 3,4-dioxygenase, which catalyzes the formation of β-carboxymuconate, have been inactivated by base pair mutations (58). Natural isolates of bacteria with catabolic properties also display evidence for inactivation of unfavorable enzyme functions. In the *Burkholderia* sp. strain PS12, a bacterium capable of using chlorobenzenes as the sole carbon and energy substrate, the *tlpE* gene for

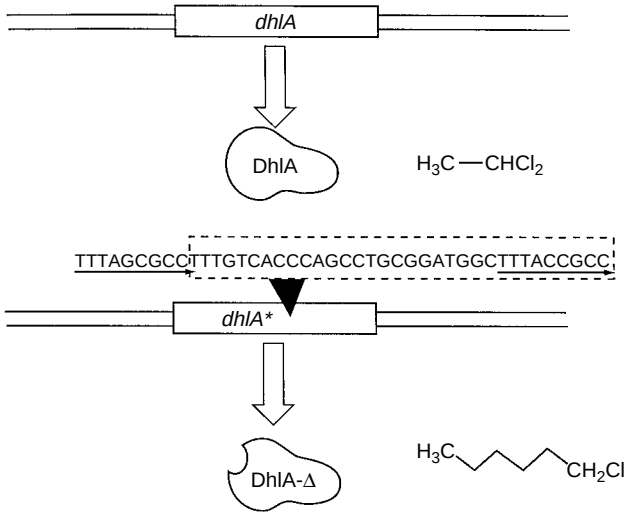

Figure 1. Spontaneous deletion occurring in the *dhlA* gene for dehaloalkane dehalogenase of *Xanthobacter autotrophicus* GJ10 that results in expansion of the substrate range to 1-chlorohexane (55).

catechol 2,3-dioxygenase is inactive, probably because this catechol 2,3-dioxygenase produces a toxic intermediate from chlorocatechols. Three base pair mutations can correct the *tlpE* gene, resulting in the formation of catechol 2,3-dioxygenase activity (10).

Regulatory Functions

Sometimes organic compounds are not used as growth substrates because they do not act as effectors for the regulatory proteins, which activate the catabolic pathway (38). Mutations in the genes for the regulatory proteins or in promoter-operator regions can then lead to pathway activation. For example, *Pseudomonas azelaica* HBP1 is a bacterium capable of growing on 2-hydroxybiphenyl (59). The three enzymes needed for 2-hydroxybiphenyl degradation are capable of converting other types of substituted phenols, such as propylphenol or butylphenol. However, the organism does not grow on these compounds as the main pathway regulatory protein, HbpR, does not recognize them as effectors (60). Mutants of *P. azelaica* can be selected by growing the organisms on isopropylphenol (61). The mutation maps in the *hbpR* gene and causes a constitutive activation of the 2-hydroxybiphenyl pathway (60) (Fig. 2). Such mutations can also be selected in various other catabolic pathways. Mutations in *dmpR* change the effector range of this regulatory protein in phenol catabolism of *Pseudomonas* sp. strain CF600 (62) or result in a constitutive phenotype (63). Similarly, mutations in XylR and XylS, the regulatory proteins of toluene and xylene degradation in *P. putida,* can result in the change of effector specificity (64,65) or in a constitutive phenotype (66,67). Spontaneous mutants of *Comamonas testosteroni* could be retrieved by selection for growth on phenol, in which a silent phenol catabolic pathway had become active. It turned out that mutations had inactivated the *aphS* gene, which normally acts as a factor to repress transcription of the phenol catabolic genes (68).

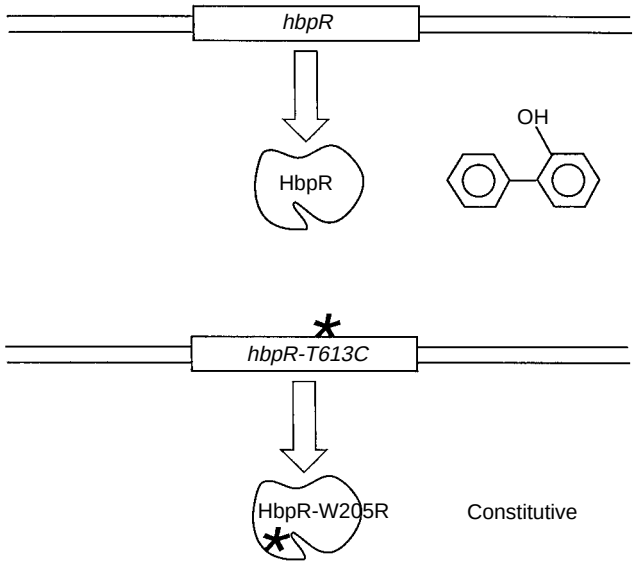

Figure 2. Spontaneous base pair substitution in the *hbpR* gene of *P. azelaica* HBP1. This mutation results in a constitutive activation of the genes for 2-hydroxybiphenyl degradation, which allows the strain to grow on 2-propylphenol (60,61).

Regulation of pathway expression can also be influenced by mutations occurring in the relevant promoter or operator regions. Illustrative in this respect are studies performed with the *pheBA* genes for phenol metabolism. When *P. putida* cells containing the promoterless phenol catabolic gene *pheBA* are incubated in a medium with phenol, mutants growing on phenol can be retrieved. Some of these genes used phenol constitutively and contained base substitutions that created a consensus $\sigma 70$ promoter (69).

Homologous Recombination

Theory. Several enzymes act on the DNA by promoting strand exchange between homologous regions, by cutting and pasting or by inserting foreign DNA. Homologous recombination by RecA and RecBCD, for example, can occur between DNA fragments with sufficient homology (i.e., around 80%) and when the length of the overlapping homologous fragment is at least 15 to 25 nucleotides (70). Because all genomic DNAs analyzed to date contain repeated sequences of this length or more (71–74), it must be assumed that homologous recombination can be important for large-scale rearrangements in genomes. In some long-term laboratory adaptation experiments, recombination between repeated sequences, which resulted in the loss of a particular gene fragment, was demonstrated (75). With a lower frequency, recombination can also occur between sequences with less than 15–25 base pair overlap. This recombination, though, is probably not RecA-dependent but involves activity of DNA gyrase (76). Studies on *A. calcoaceticus* demonstrated that even regions as small as four base pairs were sufficient for DNA recombination (58).

Effects on Catabolic Pathways. The direct effects of homologous recombination in bacteria carrying catabolic pathways are seen mostly in the occurrence of spontaneous deletions between larger homologous regions and the concurrent loss of catabolic functions (77–80). The homologous regions that promoted recombination consisted of different copies of the same insertion element (81), long sequence repeats (82), or different copies of catabolic genes themselves (83). In some cases, recombination occurred between homologous regions on plasmids and on the chromosome. This resulted in integration and excision of a plasmid into and from the chromosome, sometimes accompanied by deletions (84,85). Recombination was also assumed for the formation of hybrid genes, which are sometimes found in catabolic pathways (83,86), or for gene duplications (75,87,88). The different effects of recombinatory mechanisms have been very well studied in *A. calcoaceticus*. *Acinetobacter* can take up linear DNA fragments and the organism is very effective in incorporating such DNAs into the chromosome. It was found that RecA-dependent recombination also plays a role in mutation repair because mutations in a gene from the protocatechuate pathway (*pcaJ*) were very effectively repaired by recombination with a homologous gene (*catJ*) from the catechol pathway (89,90).

Gene Organization. It has to be assumed that recombinatory mechanisms are the general driving forces in structuring catabolic operons. The genetic organization of catabolic gene clusters very often shows blocks of genes with a similar organization, followed or interrupted by other different gene blocks (Fig. 3). For example, the gene order of the so-called *meta*-cleavage pathway cluster is conserved among bacteria using toluene (*xyl* genes), phenol (*dmp* genes), and naphthalene (*nah* genes). However, all three pathways have different upstream genes, which are part of the same operon. For the *xyl* genes they are *xylXYZL* (for toluate dioxygenase and dihydrodiol dehydrogenase), for the phenol pathway they are *dmpKLMNOP* (for a multicomponent phenol hydroxylase),

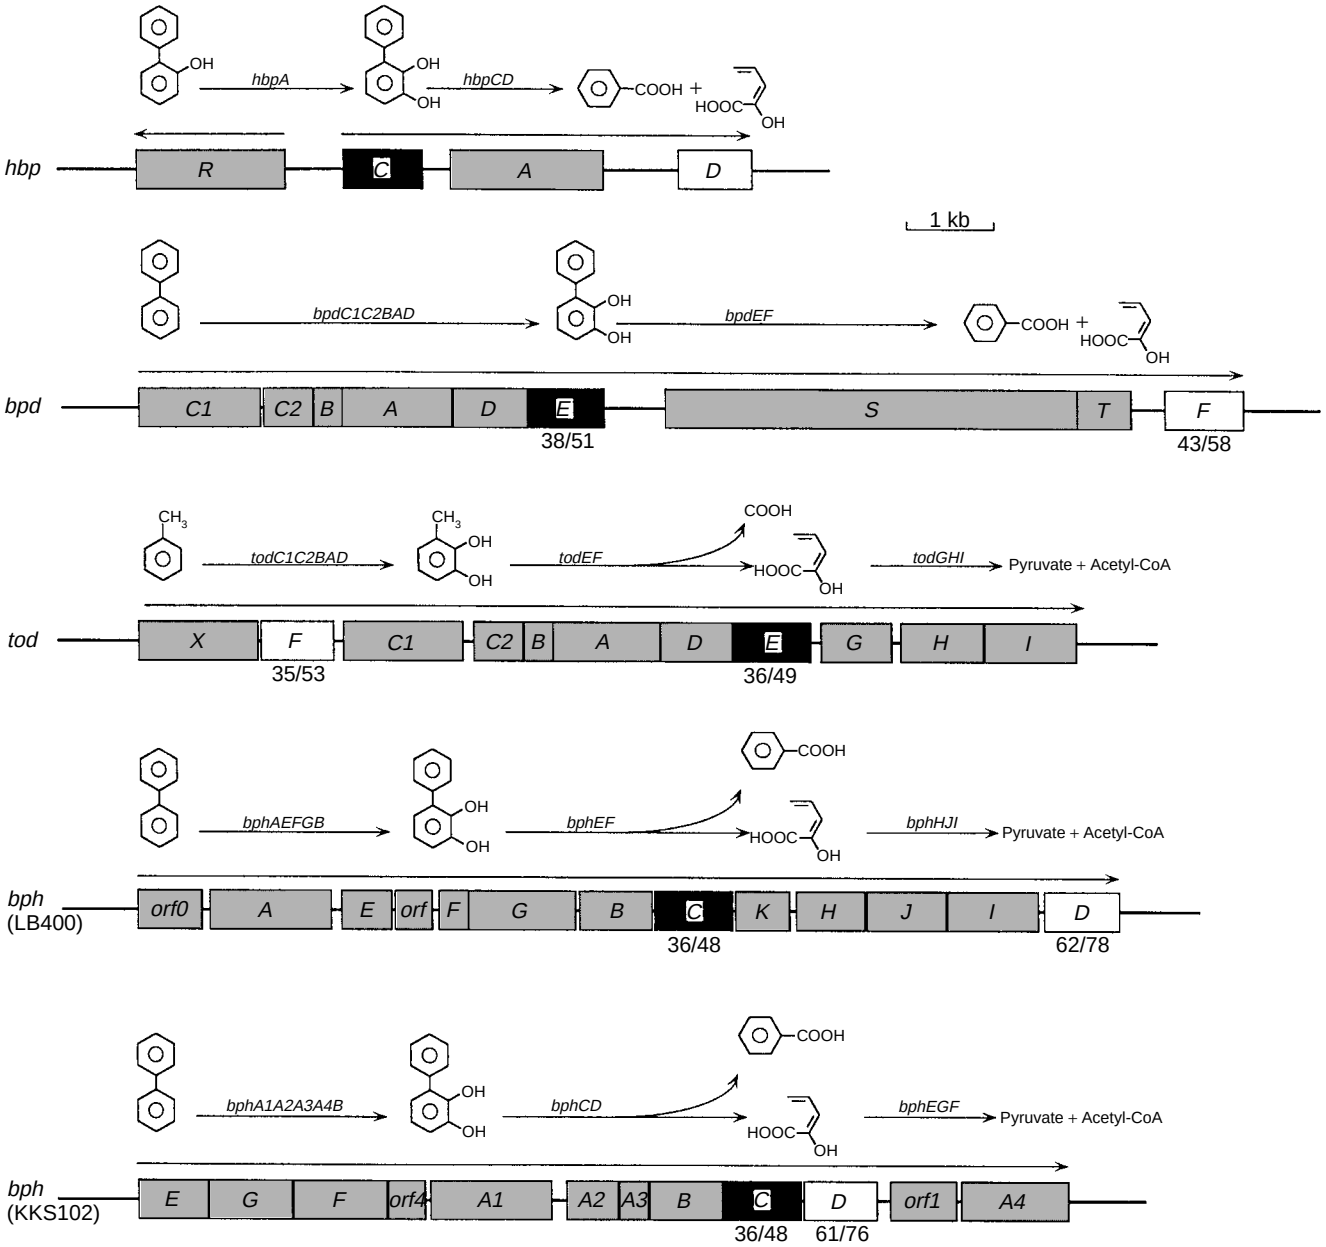

Figure 3. Examples of rearrangements in similar catabolic gene clusters. The focus is on the positions of the gene for extradiol dioxygenase (black bar) and for hydrolase (white bar). Clearly, different gene fragments are found in between those two genes in different catabolic pathways. This might point to a region, which is prone to insertions and/or deletions. Pathways and involved gene functions are summarized above the gene structures. Figures below the black and white bars indicate percentages of identity and similarity, respectively, with the corresponding genes in the *hbp* pathway. References: *hbp*, for 2-hydroxybiphenyl degradation in *P. azelaica* HBP1 (60), *bpd*, for biphenyl degradation in *Rhodococcus* sp. strain M5 (92), *tod*, for toluene degradation in *Pseudomonas* sp. strain F1 (93,94), and *bph*, for biphenyl degradation in *Pseudomonas* sp. strain LB400 (95,96) and in *P. pseudoalcaligenes* strain KKS102 (97–99). Drawing by Marco Jaspers.

and for the naphthalene pathway they are *nahG* (for salicylate hydroxylase) (37). Sometimes, only a single gene seems to have "moved" to a different position (91). Two mechanisms might be responsible for this: (*1*) genes were independently acquired into a gene cluster, but at a different position, or (*2*) gene fragments exchanged their position within a catabolic gene cluster. Interestingly, strong sequence conservation often correlates with conservation of gene organization, which could indicate that rearrangements on the DNA somehow triggered further base pair mutations (37).

Transposition and Integration

A special class of recombinatory enzymes includes transposases, integrases, invertases, or resolvases, which can promote the insertion, reversion, or deletion of discrete DNA fragments at more or less specific recognition sites. Numerous examples of these enzymes have also been found to act on the genes for catabolic pathways or have been associated with them.

Insertion Elements. Insertion elements (also called insertion sequences or IS elements) are relatively small DNA sequences (<2.5 kb) (100) that are capable of inserting themselves into target DNA molecules. The boundaries of IS elements are formed by two more or less specific inverted repeats, mostly of a length between 10 and 40 bp (100). Several hundreds of different IS elements have been described from basically all taxonomic groups of bacteria. They have been grouped in some twenty families with similar characteristics (100). Their capacity to insert into DNA molecules is dependent on a transposase enzyme, which is encoded on the insertion element itself. The transposase cuts both the DNA target and the connection of its own ends with the DNA in which it resides. The inverted repeats thereby function as binding sites for the transposase. If the transposase completely cuts its IS element out of the residing DNA, it is subsequently pasted into the new target by a cut-and-paste mechanism. In this case, no copy of the IS element remains at the original position. Other transposases only break one strand of the residing DNA and connect one strand of each IS end to the target site. The IS element is then replicated and temporarily, two copies arise (replicative mechanism). Both copies may subsequently recombine, either by the recombination system of the host cell or more effectively, by a specific resolvase enzyme (see section "Replicative Transposons").

As a result of their mode of action, IS elements can cause a wide variety of DNA rearrangements and can strongly influence gene transcription in regions near the insertion site. The following effects of insertion element activity were observed in catabolic-pathway evolution:

- gene inactivation, that is, interruption of an open reading frame (ORF)
- gene activation, for example, by deleting from an interrupted ORF
- transcription activation
- rearranging DNA, for example, by serving as targets for DNA recombination between multiple IS copies
- capture and mobilization of DNA fragments.

Gene Inactivation and Activation

Pseudomonas stutzeri strain OX1 contains about 10 copies of a 3-kb IS element (IS*Ps*1), which is involved in activation and inactivation of genes for xylene degradation (101). *Pseudomonas stutzeri* strain OX1 normally grows on *o*-xylene and toluene, but not on *p*- or *m*-xylene. The strain does have the genetic capacity to metabolize *p*- and *m*-xylene, but one of the copies of IS*Ps*1 in strain OX1 is present in front of *xylC*, thereby inhibiting transcription of the genes for *m*- and *p*-xylene degradation. Spontaneous mutants growing on *m*- and *p*-xylene but no longer on *o*-xylene could be obtained. In these bacteria, the IS element had disappeared from its location in front of *xylC*. Instead, one copy was found in the *touA* gene, which encodes *o*-xylene monooxygenase, thus inactivating synthesis of this enzyme. However, spontaneous revertants that could metabolize all xylene isomers could be isolated. In these, neither IS copy was traceable near *xylC* or *touA*.

There is also evidence for insertion inactivation of genes in natural isolates of bacteria with catabolic properties. On the plasmid pJP4 of *Ralstonia eutropha* JMP134, which contains the genes for break down of 2,4-dichlorophenoxyacetic acid, (2,4-D) one copy of an insertion element (IS*JP4*) is present in the coding region for an activator protein of the 2,4-D pathway (Fig. 4). This results in the formation of a truncated regulatory protein, which is not capable of activating *tfd* gene expression (102,103). IS*1236* is an insertion element of *A. calcoaceticus*, which inserts itself preferentially in the gene *pobR* and inactivates the pathway regulator of *p*-hydroxybenzoate degradation (104).

Transcription Activation. The ends of IS elements may contain sequences functioning as promoter-recognition sites. Among others, this was discovered when studying the expression of the *pheBA* genes of *Pseudomonas* sp. strain EST1001. The *pheBA* genes code for a short phenol-degradation pathway, that is, catechol 1,2-dioxygenase and phenol monooxygenase, respectively. When the *pheBA*

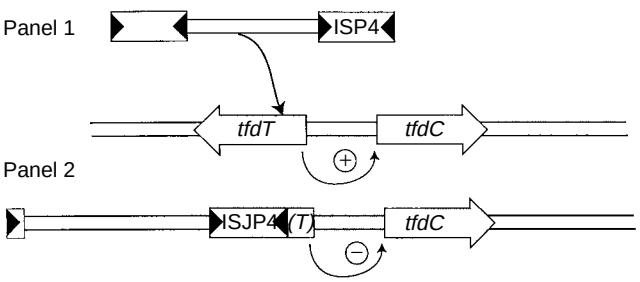

Figure 4. Insertional inactivation of the *tfdT* regulatory gene in the *tfdCDEF* chlorocatechol pathway of *Ralstonia eutropha* JMP134 (pJP4) (103). The *tfdT* gene product positively regulated the expression of *tfdC*. At some point, a transposon formed by two copies of insertion element ISJP4 inserted into the *tfdT*-coding region (panel 1), thereby interrupting the regulatory circuit. The present situation as found on plasmid pJP4 is drawn in panel 2.

genes are introduced into *P. putida* PaW85, transcription activation takes place from a promoter 1.5 kb in front of *pheB* because of cross-regulation by the chromosomally located CatR protein (105). When this region of the plasmid containing the original promoter was removed, the phenol phenotype was not expressed, but spontaneous mutants that grew on phenol could be recovered. In some of these, an IS element (IS*1411*), which is downstream of *pheA* in its original configuration, had inserted another copy of itself directly upstream of *pheB* (106) (Fig. 5). IS*1411* carries a good constitutive promoter at its 3′ end and it could be demonstrated that this promoter drives *pheBA* expression in the new situation (106). In addition, in the 1,2-dichloroethane-degrading organism *X. autotrophicus* GJ10, an insertion element can enhance gene expression. *Xanthobacter autotrophicus* normally does not grow on toxic high (5 mM) concentrations of bromoacetate, but mutants that grow on bromoacetate could be isolated after selection. These mutants could grow as a result of increased expression of the enzyme haloacetate dehalogenase. Genetic analysis demonstrated that insertion of the IS element IS*1247* had occurred at a site upstream of the *dhlB* gene, presumably driving higher constitutive expression from a promoter at the IS end (107).

DNA Rearrangements and Gene Capturing

In numerous catabolic pathways, IS elements are located in or near catabolic genes, which suggests that they have had a role in rearranging DNA fragments and perhaps in bringing new genes together. The insertion sequence IS6100 was implicated in the formation of duplications of the *nyl* genes for nylon degradation in *Flavobacterium* (87). In various natural isolates, strong evidence was found for mechanisms by which IS elements may capture gene fragments and assemble new pathway clusters. For example, two copies of an almost identical IS element (IS*1066* and IS*1067*) were discovered near the *tcbAB* genes for chlorobenzene dioxygenase and chlorobenzene dihydrodiol dehydrogenase (108,109). The structure was shown to be mobile, which made it likely that the IS elements had captured the *tcbAB* genes from another microorganism and grouped them with the genes for chlorocatechol metabolism. Recent analysis of two other chlorobenzene degrading organisms, *Ralstonia* sp. strain JS705 (11) and *Burkholderia* sp. strain PS12 (10),

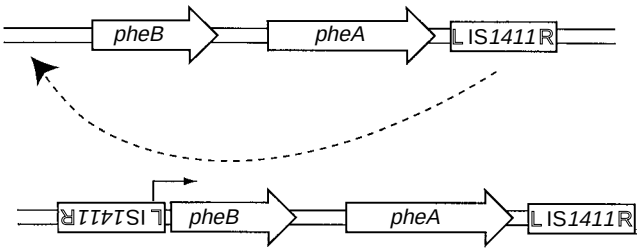

Figure 5. Events that resulted in the spontaneous formation of a constitutive promoter for the *pheBA* genes for phenol degradation (106). Inverted insertion of IS*1411* into a position upstream of *pheB* provided a proper promoter sequence, which is located at the end of the IS element.

reveals that similar events have taken place. Both strains carry gene regions for chlorocatechol degradation combined with those for an aromatic ring dioxygenase and dihydrodiol dehydrogenase, which were surrounded by (putative) IS elements or fragments of IS elements.

IS*1071*

IS*1071* is an unusual insertion element. It is larger than most other IS elements (3.2 kb) and does not produce target site duplication. It has been found in an unusual number of different bacteria as well and is very often associated with catabolic genes. For example, IS*1071* was detected in *Alcaligenes* sp. BR60 plasmid pBRC60 (3-chlorobenzoate degradation), *Achromobacter xylosoxidans* plasmid pEST4011 (2,4-D degradation), *P. pavonaceae* haloalkane dehalogenase gene region, *Ralstonia eutropha* JMP134 plasmid pJP4, *Ralstonia* sp. plasmid pTFD41 (2,4-D degradation), *P. putida* UCC22 plasmid pTDN1 (aniline degradation), *Comamonas testosteroni* T2 plasmid pTSA (toluene sulfonate degradation), and *P. pseudoalcaligenes* POB310 plasmid pPOB (4-carboxydiphenyl ether degradation) (110,111). Convincing evidence that IS*1071* had been independently involved twice in capturing the *cba* genes for 3-chlorobenzoate degradation (112) could be presented.

Composite Transposons

When two IS elements of the same kind are in the vicinity of each other, a composite transposon may be formed, which can mobilize the genetic information located in between the two IS copies. This situation is exemplified by the classic antibiotic-resistant transposons Tn*5* and Tn*10*, but also by several catabolic transposons. For example, transposon Tn*5280* contains two inverted copies of an almost identical IS element (IS*1066* and IS*1067*) and the *tcbAB* genes for chlorobenzene dioxygenase and dihydrodiol dehydrogenase in between (108,109). Both IS copies need not necessarily be intact to achieve transposition. This was shown for a transposable element on plasmid pJP4 in *R. eutropha* JMP134 that contains part of the genes for 2,4-D metabolism (14). The boundaries of the transposable element are formed by one intact and one partial copy of the IS element IS*JP4* (102). It is also not necessary for the transposition to have two copies in inverted orientation. Two copies of IS*1071*, in direct repetition, surround the *cba* genes for 3-chlorobenzoate degradation of *Alcaligenes* sp. strain BR60 and form the composite transposon Tn*5271* (81). However, the frequencies of recombination between two IS copies in direct orientation (with subsequent loss of the transposon structure) are higher than in inverse orientation (81). Not for all composite structures could transposition be demonstrated. For example, Tn*5707* and Tn*5542* are formed by two direct copies of insertion elements IS*1600* and IS1489, respectively. Both IS*1600* copies flank the *cbn* gene cluster for chlorocatechol degradation on plasmid pENH91 in *Alcaligenes eutrophus* NH9 (113), whereas the IS*1489* copies encompass the genes for benzene dioxygenase and dihydrodiol dehydrogenase in *P. putida* ML2 (111).

Replicative Transposons

Replicative transposons (alternative names: class-II transposons or Tn*3* family) do not contain two copies of an IS element. Instead, at one end, the coding regions for the transposase and, often, for a resolvase are found. The transposon boundaries are formed by two inverted repeats with a length of 25 to 100 bp (114). As described earlier (see "Insertion Elements"), the TnpA transposase in replicative transposons makes double-stranded cuts in the target DNA but single-stranded cuts in the residing copy. Only one end at each single strand is connected with the target and the complete transposon is replicated, resulting in two copies. Resolution of these two copies, after which only one transposon remains, is performed by the product of the resolvase gene (*tnpR*), which recognizes a specific resolvase binding site present on the transposon.

Some catabolic transposons belong to this type and often form complex multiple transposable elements. Classical examples are the replicative transposons of the TOL plasmids. Tn*4653* is a 79-kb large transposon that encompasses all of the *xyl* genes (115). The smaller Tn*4651* is 56 kb in size and is contained within Tn*4653*. Tn*4651* is a completely functional transposon, capable of replicative transposition and resolution of the two copies afterward. It is unusual because of the location of the resolvase coding regions and binding sites (82) and because of its transposase (116). Tn*4653* was shown to perform replicative transposition, but resolution was dependent on factors provided by Tn*4651*. A smaller structure of Tn*4651* (Tn*4652*) could arise in which the *xyl* genes had been deleted through recombination at the two direct repeat sequences of 1.4 kb that flank the *xyl* genes (82). The naphthalene plasmid NAH7 bears another (defective) replicative transposon, which contains all of the *nah* and *sal* genes (117). This 37-kb transposon structure, however, only carries a resolvase but lacks its own transposase. It can therefore only be "transposed" by other similar transposases in *trans*.

Integrons

Integrons form a special class of mobile elements, which are involved in inserting and deleting gene fragments into a predefined region contained within the integron (118,119). Integrons consist of so-called 5′- and 3′-elements and an integration site. The 5′-element contains a gene for an integrase and the 3′-element contains two ORFs of unknown function and a gene for sulphonamide resistance. A 59-bp element at the boundary of the 3′ region, or elsewhere between the 5′- and the 3′-element, seems involved in determining the integration site. The 5′- and 3′-elements are highly conserved among integrons known, whereas the 59 bp can differ, but predict a stem-loop-like structure. The recombination site itself is confined to a GTTRRRY-motif, which is common to the right end of the 5′-element and the left end of the 3′-element. Integrated genes in the integron are always transcribed from left to right, possibly from a promoter in the 5′-element. Integrated genes are further inserted very strictly, leaving very few bases upstream and downstream of the actual coding region. Genes can be inserted into integrons in a sequential manner.

Available literature does not indicate integron activity in catabolic gene clusters. In some catabolic gene clusters, however, putative integrase genes were localized near the catabolic genes. Two of these involve gene clusters for haloalkane dehalogenation in the *Mycobacterium* sp. strain GP1 (for 1,2-dibromoethane degradation), and in the *P. pavonaceae* strain 170 (1,3-dichloropropene degradation). Both strains carry an almost identical *dhaA* haloalkane dehalogenase gene, which is also conserved in a third strain *Rhodococcus rhodochrous* NCIMB13064. Comparison of the three *dhaA* gene regions showed remnants of various deletion events. Both *Mycobacterium* and *R. rhodochrous* carried a gene for an invertase upstream of the *dhaA* gene, whereas in both *Mycobacterium* and *P. pavonaceae*, (nonidentical) genes for integrases were found upstream of *dhaA*. A copy of IS*1071* was detected downstream of *dhaA* in *P. pavonaceae*. This suggests that these recombinatory elements were involved in creating the deletions and perhaps insertions (120). Another putative integrase gene was detected near catabolic genes by DNA sequencing of the plasmid pNL1 of *Sphingomonas aromaticivorans* (121).

Horizontal Gene Transfer

Although transposases and integrases promote DNA rearrangements, they do not necessarily promote transfer of genes between different bacteria. It is especially this aspect of gene transfer between different bacteria of a population or in a community between different populations that opens up the true diversity of all genes in a community. However, it is certainly not true that every piece of genetic information in a community is accessible to all others because the host ranges of the transfer mediating elements can be restricted. Generally, one considers three (or four) types of mechanisms for horizontal gene transfer: conjugation by plasmids, phage transduction, conjugative transposons, and transformation (or uptake of naked DNA).

Plasmids. Plasmids are independently replicating units of DNA in bacterial cells. Some plasmids are circularly closed, whereas others may be linear. Some plasmids contain the genetic information for their mobilization and/or transfer, which involves formation of the DNA pore or pilus and transfer of (usually) a single-stranded molecule of the plasmid into the recipient cell. Plasmids seem to be normal residents of bacterial cells and express enormous varieties of host ranges. Numerous plasmids have been described in the literature and almost all catabolic pathways have been associated with the presence of plasmids (although they are not necessarily always encoded on plasmids) (111,122). Classic examples are the TOL plasmids (for toluene degradation), the NAH plasmids (with the naphthalene pathway genes), plasmids for 2,4-D degradation, for alkane, for dichloromethane, for haloalkane, for toluene sulfonate, for chlorobenzoate, or for chlorobenzene degradation. Most of these plasmids were shown to be transmissible in the laboratory. Some plasmids were reported to occasionally give rise to a process called *retrotransfer*, which is the capture of genes

from the recipient organism by the plasmid, rather than donation from the donor to the recipient of the plasmid.

Natural Plasmid Transfer. Considerable efforts have been made to demonstrate natural plasmid transfer or plasmid transfer from introduced donors to indigenous recipient bacteria in the environment. There can hardly be any doubt left that plasmids do play an important role in the dissemination of all kinds of genetic material including catabolic genes, in microbial communities. A few recent examples may illustrate these points. Transfer of a plasmid for 2,4-D degradation to members of the indigenous soil microbial community was achieved by inoculating about 10^6 donor bacteria per gram of soil. Subsequent incubation in the presence of 100-mg/kg 2,4-D probably selected for the appearance of transconjugants, which grew up to population sizes of 10^6/g (123). Transconjugants that were retrieved from the soils were of the genera *Burkholderia* and *Ralstonia* were found to be indigenous members of the soils and contained the intact plasmid of the donor.

Another strong case for plasmid transfer in the natural environment is demonstrated in the following incident: During a major accident with contaminated mine water in 1989 in an Estonian watershed, it was decided to deliberately release phenol-degrading *P. putida* PaW85 bacteria into the river. These bacteria contained a plasmid with the *pheBA* genes for phenol degradation. A few years later, an attempt was made to retrieve the phenol-degrading bacteria from several sites in the watershed. About one-third of the bacteria growing on phenol plates were found to contain the *pheBA* genes; however, these bacteria were of a different species than the original donor strain, which apparently had not survived. It was concluded that they had been transferred from the introduced bacteria into indigenous strains (124) as the *pheBA* genes were not retrieved from any environment before.

On several occasions, circumstantial evidence was provided for gene transfer with catabolic genes in the natural environment. Mostly, this evidence consists of comparisons of isolates with the same catabolic properties from different geographic origins. Incongruent patterns between phylogenetic data obtained on the basis of 16S rDNA sequence comparisons and catabolic gene sequences (e.g., for *nahAc*: naphthalene degradation (125), for *tfdA*; 2,4-D dioxygenase (126), for *dhaA*; haloalkane dehalogenase (127), or for atrazine) (128) was taken as a proof for horizontal transfer of those catabolic genes. This can be viewed as demonstration for natural plasmid transfer as many of those markers are located on plasmids.

Plasmid Sequence Analysis. The near future will not only face a boom in complete genome sequences, but also in plasmid genome sequences. This will provide a very detailed insight into the differences between plasmid incompatibility groups, in conjugative functions, and in acquisition mechanisms. The only catabolic plasmid for which the complete sequence is available is the 184-kb plasmid pNL1 of *S. aromaticivorans* (121). About one-third of this plasmid is catabolic gene region, one-third is involved in conjugative transfer functions, and one-third is attributed to plasmid maintenance. Contrary to the classic large operons that make up single catabolic pathways in *Pseudomonas*, plasmid pNL1 contains multiple transcriptional units seemingly necessary for just one "pathway." In addition, several pathways, for example, for biphenyl and naphthalene, seem genetically intertwined. The conjugative system of pNL1 appeared mostly similar to that of *Escherichia coli's* F-plasmid. Furthermore, many hypothetical proteins were predicted with little homology to anything else known. From this and other work (129) the picture emerges that plasmids can act as collectors of junk, which might be very important for their role in horizontal gene transfer (see later section "Selection Mechanisms").

Phages. Phages are capable of transducing DNA, which means that they accidentally package DNA from the chromosome and transport this to another host cell that the phage infects. Recent genome data indicate that most genomes contain several intact phages or prophages, including a phage integrase, of which only a few phage-type proteins are left on the chromosome. Despite the fact that soils and aquatic systems contain numerous phages (130), no phages have been associated with catabolic gene transport.

Conjugative Transposons. Conjugative transposons combine both phage and plasmid characteristics. They encode the factors for conjugation and harbor a phagelike system to integrate themselves into the genome of the host. In contrast to IS elements and other transposons, conjugative transposition does not cause target-site duplication or replication (131). The integration is mediated by an integrase enzyme, which is encoded on the conjugative transposon itself. During transposition, the conjugative transposon excises and forms a circular intermediate in which both ends are connected in a heterologous hybrid. Integration into a new target proceeds from the circular form. There are a few examples of catabolic genes located on conjugative transposons or elements presumed to be such. The transposon Tn*4371* (132) from *Alcaligenes* encompasses a 60-kb region with a 13-kb region containing the *bph* genes for biphenyl degradation. The element can transpose itself into plasmid RP4, preferentially at two sites (containing the TTTTTCAT motif) and from there into other locations on the chromosome (five sites in *R. eutropha*), in other recipient bacteria or on other plasmids (pSS50). The left end of Tn*4371* locates the integrase gene, facing inward. The integrase has homology to phage P22 and Tn*1545* integrase. The right end contains a second transposon, Tn *bph*. In addition, the biphenyl and salicylate genes from *P. putida* KF715 seem to be located on a 90-kb conjugative transposon (79). The bph-sal element could be transferred from the original strain to *P. putida* AC30 and from this strain to KT2440, thereby always integrating into the chromosome. At present, it is not clear if a specific sequence is targeted by the bph-sal element and which type of integrase is responsible for integration.

The clc-element of *Pseudomonas* sp. strain B13, which carries the genes for 3-chlorobenzoate and chlorocatechol

metabolism, can also be considered as a conjugative transposon, although other features allow it to be called a "gene island" (133). It consists of a region of 105 kb that is integrated in the chromosome of its host. In *Pseudomonas* sp. strain B13, there are two sites of integration, which are formed by genes for a glycine tRNA (Fig. 6) (134). The element itself carries an identical 18-bp sequence as the glycine-tRNA gene. Preferentially, during growth on 3-chlorobenzoate, the element excises and forms a circular intermediate. The integrase of the clc-element is weakly related to that of Tn*4371* but more to phage P4–type integrases. The feature to insert site-specifically into tRNA genes is very typical for pathogenicity islands (135) and bacteriophages.

Uptake of Naked DNA. Transformation or the uptake of naked DNA molecules is also a mechanism by which bacteria can acquire new genetic material, in principle, from any source. Some bacterial strains such as *A. calcoaceticus*, *P. stutzeri*, or *Bacillus subtilis*, develop a state of natural competence (136) during which DNA is taken up preferentially. Some bacteria are also capable of producing larger quantities of extracellular DNA, which can potentially increase the possibility for natural transformation (137). Although several experiments have demonstrated that transformation of naked DNA in the environment can occur (136,138), the contribution of natural transformation to the formation and acquisition of catabolic pathways is not known.

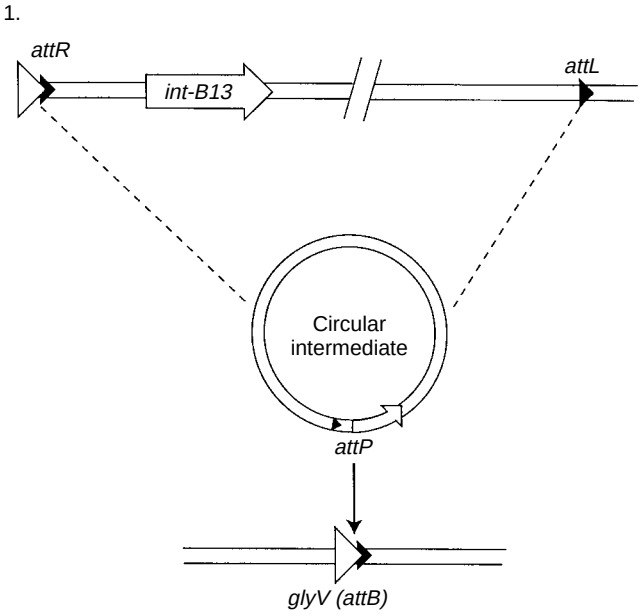

Figure 6. Mechanism of excision and integration of the conjugable clc element in *Pseudomonas* sp. strain B13 (134). The element uses a phage-type integrase (shown here as *int-B13*) to integrate site-specifically in the gene for glycine tRNA (*glyV*). An 18-bp sequence is identical between the *glyV* gene and the element (here indicated as black arrow). Upon insertion, the original *glyV* gene is restored. Attachment-site determinations (*attR*, *attL*, *attP* and *attB*) are according to phage definitions.

Trends in Catabolic Pathway Evolution

Selection of Mechanisms

What is the overall picture that seems to be emerging for the evolution of catabolic pathways in bacteria? As shown earlier, any one genetic mechanism may operate and genetic variation is the sum of all those processes. In this aspect, all the processes creating genetic variation may be considered as the "evolutionary toolbox" of the organisms (139–141). When those pathways that really seem to have been selected for by pollution of the environment with new types of chemical substances (11,18,109,127) are looked into, the most pronounced mechanism for evolution seems acquisition and recombination of sets of genes originating from different organisms, probably by insertion elements. These recombined structures disseminate in a population by conjugative elements, perhaps until the most suitable recipient organism is encountered, which can then proliferate (11). The second step, which perhaps has not yet been observed in real "novel" pathways, is the development of proper regulatory systems (see following section). Secondary mutations and deletions seem to follow the primary rearrangements if the pathway is to establish itself.

For this scenario, it has to be assumed that many of the functions that have been assigned as "typical" for xenobiotic degradation (e.g., dehalogenating enzymes) are found in a suitable form in microbial communities. It seems less likely that those "novel" genes (e.g., the chlorocatechol 1,2-dioxygenase gene) have diverged from normal catabolic genes (e.g., *catA* for catechol 1,2-dioxygenase) since the introduction of large-scale chemical synthesis. Even calculated very optimistically, such divergence times are more on the order of tens of millions of years (142). However, it is possible that the assumptions on rates of base pair substitutions are completely wrong as, for example, the hypermutable state of microorganisms may indicate.

If it is assumed that gene functions are acquired from existing organisms in the environment, then important questions remain. Bacteria with very similar (or even identical) catabolic properties can be found all over the globe, but does this indicate that they have independently picked up the same type of genes (sometimes even with the same type of mechanism)? This seems very unlikely, but might indicate that ignorance still exists on how and which genes are distributed in a microbial community, perhaps constantly, by conjugative elements. Alternatively, bacteria may be transported much more effectively throughout the globe than is thought of and thus cause distribution of bacteria that degrade toxic chemicals as well. For example, birds, wind, clouds, human beings themselves, or goods and products could be vehicles for contaminating microorganisms. Even crude chemicals such as crude oil might be contaminated with microbes degrading them.

It might be concluded that environmental pollution is not only selecting for new rearrangements and new catabolic pathways but also for particular types of genetic mechanisms. As seen earlier, several genetic processes are actually one-step evolutionary mechanisms. Transfer of a

plasmid to a new host is a one-step process, resulting in the acquisition of up to 250 kb of DNA. Activity of transposons or insertion elements is a one-step process, leading to novel DNA structures and combinations. If such genetic structures are favorable and the host carrying them can proliferate, this also means that the "evolutionary elements" themselves proliferate. In this respect, it is surprising that certain IS elements (IS*1071*) are often found near catabolic genes. Perhaps IS elements that carry strong promoters for downstream genes have an evolutionary advantage in catabolic pathway formation. Finally, some genetic adaptive mechanisms may even be directly regulated by environmental signals. It has been known for a long time that conjugation of the *tet* element in *Bacteroides* is triggered by the presence of tetracycline itself (143). In addition, the clc-element of *Pseudomonas* sp. strain B13 specifically excises when grown on 3-chlorobenzoate (144).

Regulation

If horizontal gene transfer and DNA rearrangements are considered as important mechanisms by which rapidly new functions can be acquired and assembled, then a few words should be said about the regulation of expression. Newly arranged DNA or newly incoming DNA may lack the necessary signals for optimum expression. Therefore, it can be expected that some of these DNA are not expressed properly, or are not expressed at all, or are constitutive (as discussed earlier, when insertion elements provide promoter sequences). De Lorenzo and Pérez-Martín proposed how regulatory systems might evolve in front of newly arranged catabolic operons (38). Their first premise was that regulatory genes and structural genes evolve separately. This was concluded from the observation that similar pathways have different regulators (e.g., *xylS* and *nahR*) and different pathways have similar regulators (*xylR* and *dmpR*). Secondly, novel specificities can only develop because the regulatory systems are leaky to some extent. This regulatory noise allows that regulatory proteins bind to other than their cognate operator and may have some affinity to a newly acquired gene region (e.g., activation of the *pheBA* genes by CatR in *P. putida* (105), or activation of the *tfdC*-promoter by TfdR) (103). Further fine-tuning then occurs by acquisition of secondary regulatory factors (e.g., σ^{54} or integration-host factor) or small mutations leading to a more specific effector range of the regulator.

CONCLUSION

Can it be expected that as increasingly taxonomically different bacteria will be isolated and characterized, other types of catabolic gene clusters and evolutionary mechanisms will be found? Most classical studies have been performed with "fast-growing" pseudomonads, which might not represent the true diversity of catabolic pathways in the environment or the true important pollutant-degrading organisms at a site. Some recent studies, employing more sophisticated isolation techniques (145–150) or molecular-detection techniques (4,151–153), seem to suggest that the most important species are not necessarily being looked into. In addition, recent studies on nitroaromatic degradation demonstrated the existence of completely different pathways than previously thought (26,154,155). Genetic analyses of catabolic pathways in some *Sphingomonas* strains (121,156,157) demonstrated that catabolic pathways are not expressed from nicely arranged operons. Rather, intertwined and dispersed multiple operons contribute to a particular pathway. This could indicate very different means for regulation of pathway expression. Studies on chlorocatechol degradation by *Rhodococci* indicated that rhodococcus-type chlorocatechol pathways may have evolved independently from those known in β- or γ-*Proteobacteria* (158). Finally, it may not be surprising to find very different "evolutionary mechanisms" or mechanisms with completely different ranges of activities. Only consider, for example, the very different recombination mechanisms in *Deinococcus radiodurans* (159).

The majority of microorganisms on earth live in microbial aggregates; examples are biofilms attached to solid surfaces (mostly at solid-liquid interfaces), activated sludge flocs in wastewater treatment plants, or associations of microorganisms with inorganic particles and organic detritus in natural surface water (1,2). These microbial assemblages are found ubiquitously in soil and aquatic environments; biofilms are involved in the colonization and infection of plants, animals, and man. They also occur in technical water systems and may sometimes grow on the surfaces of medical devices (3,4). A common feature of all these structures is that the microbial cells are embedded in a hydrated matrix of extracellular polymeric substances (EPS) that are produced by the biofilm organisms. Polysaccharides and proteins are characteristic components of the EPS (5). Polysaccharides have been assigned mainly structural functions in mediating the formation and mechanical stability of the three-dimensional, gel-like matrix of biofilms. In contrast, relatively little is known about the identity and functions of extracellular proteins in biofilms. Different extracellular enzyme activities have been detected in biofilms from diverse environments so that enzymes constitute at least part of the EPS proteins. Heterotrophic bacteria are common biofilm inhabitants, but fungi are also important producers of extracellular enzymes (6).

The majority of natural organic matter is composed of polymeric, high molecular weight compounds that are too large to be transported across microbial membranes into the cell. A main function of extracellular enzymes is seen in the hydrolysis of these compounds to smaller molecules that are readily taken up by the cells and used for cellular metabolism. Natural substrates of extracellular enzymes can be water-soluble polymers (many polysaccharides, proteins, nucleic acids) and water-insoluble substances (e.g., cellulose, chitin, lipids), as well as biogenic particles that are trapped in biofilms. Enzyme-mediated hydrolysis of polymers represents the rate-limiting step in the microbial utilization of dissolved and particulate organic matter in terrestrial and aquatic environments. Enzymes can also be involved in the modification and degradation of structural EPS within biofilms, promoting the detachment of bacteria from biofilms (4). Furthermore, extracellular enzymes are of importance in medical biofilms, because they can function as virulence factors in human infections (7). Some extracellular enzymes from bacteria and fungi are also of commercial interest (6) and are produced on a larger scale industrially. The activity of extracellular enzymes can be exploited in technical processes; as an example, biological wastewater treatment relies on the production of extracellular enzymes by microorganisms in activated sludge flocs and biofilms in fixed-bed reactors, which are used for the removal of organic matter. Extracellular enzymes can also be involved in biodeterioration processes, enzymatically attacking organic and inorganic materials (3). These examples underline the paramount ecological, economic, medical, and technical importance of extracellular enzymes, which strongly influence the physical, chemical, and biological properties of biofilms.

SECRETION MECHANISMS OF ENZYMES

Independent of their final localization in the biofilm, extracellular enzymes can have different sources. They are secreted by intact producer cells within the biofilm, they can be passively released from damaged or lysed biofilm organisms, or they can be trapped from the external environment.

Intact viable cells actively secrete enzymes by transport across the cytoplasmic membrane into the periplasmic space, into the multilayered cell walls of gram-positive bacteria, onto bacterial surfaces, or into the extracellular medium. These enzymes are secretory proteins that, in contrast to intracellular enzymes, only function after their passage through cellular membranes. Various distinct and specific mechanisms of enzyme secretion have been discovered in gram-negative and gram-positive bacteria. A number of recent publications have reviewed the biosynthesis and secretion of bacterial proteins, including enzymes (8–12). So far, mainly planktonic cultures of selected bacterial species were used to study the expression of extracellular enzymes, whereas relatively little work has been done to investigate the secretion of enzymes in biofilms.

Synthesis of secretory enzymes occurs inside the cell at ribosomes that are often directly bound to the cytoplasmic membrane. Secretion involves the transport of these enzyme proteins across the cytoplasmic membrane of gram-positive bacteria or across the inner and outer membranes of gram-negative bacteria. At present,

five main protein secretion pathways have been well characterized, which are designated type I to V secretion systems (Fig. 1).

The type I system is also named the *ATP-binding cassette* (ABC) pathway and involves a one-step protein export, bypassing the periplasm. An ABC exporter machinery consists of three different inner and outer membrane proteins, which form a porelike complex, directly connecting the cytoplasm with the extracellular medium (Fig. 1; 8).

The type II system or general secretory pathway, which is used by gram-negative bacteria, consists of a two-step

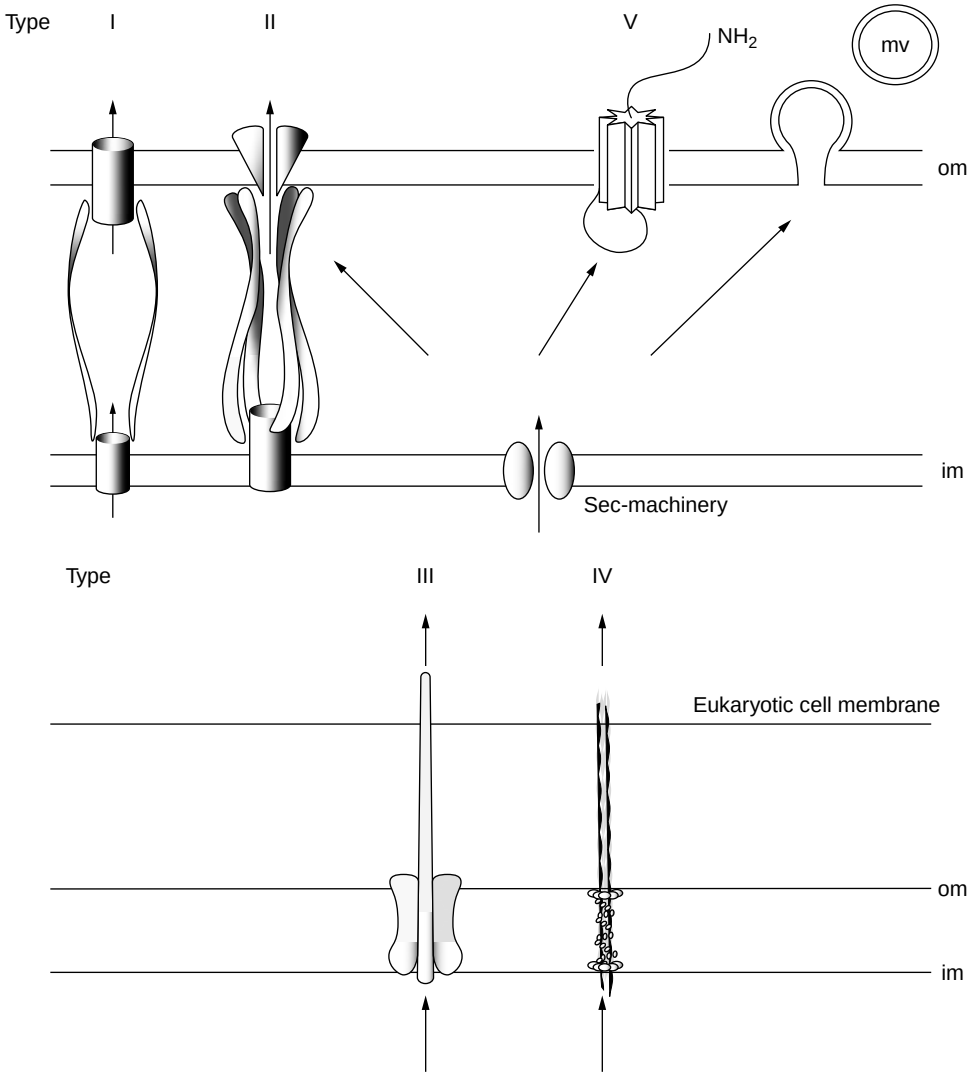

Figure 1. Pathways used by gram-negative bacteria for enzyme secretion (arrows indicate the direction of secretion). Top: The type I secretion system mediates the export of proteins in one step across both the inner membrane (im) and outer membrane (om) and is composed of a cytoplasmatic ABC-protein, a membrane-fusion protein, and a pore-forming outer membrane protein. The type II secretion system is a two-step pathway consisting of the Sec machinery that resides in the bacterial inner membrane and a complex apparatus (secreton); it is composed of 12 to 15 different proteins forming a transport channel that connects the inner and outer membrane. The type V secretion system is also named the *autotransporter pathway*. Autotransporter proteins first cross the inner membrane via the Sec machinery and subsequently insert into the outer membrane with their C-terminal domain that forms a pore through which the N-terminal domain is then secreted. An unspecific secretion pathway (top right) is characterized by the formation of membrane vesicles (mv) that are released from the bacterial cells and may contain various hydrolytic enzymes. Bottom: The type III and type IV pathways are found in many pathogenic bacteria and require contact between the secretion machinery and a eukaryotic target cell. The type III secretion system usually consists of 20 different proteins that form a large inner membrane transport channel and a needlelike structure protruding into the cytoplasm of the eukaryotic cell. The type IV secretion system is used to mobilize DNA and multisubunit proteins across bacterial membranes. About 10 proteins form a piluslike transport complex that spans both the inner and outer membrane.

process: (*1*) the initial signal peptide-mediated transport across the inner membrane and (*2*) the subsequent translocation of the transient periplasmic intermediate across the outer membrane. After translocation of the protein through the inner membrane, the N-terminal signal sequence is cleaved off by a specific signal peptidase, which recognizes a conserved cleavage site usually consisting of the amino acids alanine-x-alanine (13). Secretion proceeds through the so-called *Sec translocase*. In *Escherichia coli*, this is a multisubunit protein complex composed of the soluble dimeric SecA protein and a membrane-embedded complex formed by SecY, E, D, G, and F. The protein to be secreted is kept in a translocation-competent unfolded state by means of the chaperone SecB (14). A similar Sec translocase exists in *Bacillus* species (15). During or after translocation through the cytoplasmic membrane, some proteins additionally require the action of specific foldases to achieve their native conformation. Such foldase proteins that assist correct folding of the enzymes lipase and elastase in the periplasm have been identified in *Pseudomonas* species (16,17). Their main function seems to be helping their cognate enzymes in overcoming a kinetic barrier along their folding pathway. They may also function as temporary competitive inhibitors, preventing enzyme activity inside the bacterial cell. In addition, proteins to be secreted often contain disulfide bonds that are formed in the periplasm. In *E. coli*, a complex system consisting of Dsb proteins mediates disulfide bond formation (18). Recently, a similar system has been identified in *Pseudomonas aeruginosa* and shown to be necessary for the formation of enzymatically active extracellular enzymes (19). After folding in the periplasm, proteins to be secreted are transported through the outer membrane by means of a complex machinery called the *secreton* consisting of up to 15 different proteins forming the so-called main terminal branch of the general secretion pathway (20). In *P. aeruginosa*, lipase is secreted through such a secreton (Xcp machinery; 9,21), here encoded by 12 *xcp* genes organized in two divergently transcribed operons. The Xcp proteins are located both in the inner and the outer membrane, with XcpQ forming a multimeric pore with a diameter of 95 Å (22). Similar multicomponent secretons have been identified in *Pseudomonas putida*, *Klebsiella oxytoca*, *Aeromonas hydrophila*, *Vibrio cholerae*, *E. coli*, and a number of phytopathogenic bacteria (9,20).

The type III or contact site-dependent pathway is used by many animal and plant pathogens, which have developed a complex secretion system consisting of at least 20 different proteins (10). Most of them are located in the inner membrane; however, an outer membrane pore protein analogous to the secretins of the type II secretion machinery is also present. This pathway functions independently from the Sec translocase; the secreted proteins do not contain a signal sequence and no periplasmic intermediates can be isolated. The type III secretion system is designated to deliver bacterial proteins directly into the cytosol of a eukaryotic host cell (Fig. 1), which means that the assembly of the secretion apparatus is regulated by the contact with a eukaryotic target cell.

The type IV protein secretion systems share extensive homology to those systems that transport DNA either from bacteria to bacteria or from bacteria to eukaryotic cells. The classical example is the VirB system of *Agrobacterium tumefaciens* (23). Type IV transporters have also been found in *Bordetella pertussis*, *Legionella pneumophila*, and *Helicobacter pylori*. These consist of about 10 different proteins forming a piluslike structure that bypasses the inner membrane, the periplasm, and the outer membrane (24).

The type V secretion system is also called the *autotransporter pathway*. Autotransporter proteins are virulence factors and have been found in many pathogenic bacteria, including *P. aeruginosa* (25,26). They possess an N-terminal signal sequence and are translocated through the inner membrane via the Sec machinery. As soon as they have reached the periplasm, they mediate their own transport into the extracellular space by virtue of their C-terminal (or β)-domain, which forms a pore in the outer membrane. The N-terminal (or α)-domain is subsequently translocated through this pore to the cell surface (Fig.1).

Several secretion pathways for enzymes can be used by a single species. *Pseudomonas aeruginosa* is an example of a gram-negative bacterium, which is known to employ at least four specific pathways to secrete various enzymes (Table 1). Because this versatile organism typically forms biofilms in diverse environments such as in natural aquatic ecosystems, in technical water systems, on medical devices, and on living tissues of plants, animals, and man (4), it can be expected that extracellular enzymes may be involved in the formation, maintenance, or destruction of biofilms under widely varying conditions. Some of the extracellular enzymes of this opportunistic pathogen are known to be virulence factors; therefore, they may also contribute to the establishment of biofilm-mediated

Table 1. Enzyme Secretion by *Pseudomonas Aeruginosa*

Secretion System	Extracellular Enzyme
Specific Mechanisms	
Type I (ABC pathway)	Alkaline protease
Type II (general secretory pathway)	Elastase B (LasB)
	LasA (staphylolytic protease)
	Exotoxin A
	Alkaline phosphatase
	Phospholipase C
	Lipase
Type III (contact site-dependent pathway)	Exoenzyme S [ExoS] (ADP-ribosyltransferase)
	Exoenzyme T [ExoT] (ADP-ribosyltransferase)
	ExoY (adenylate cyclase)
Type V (autotransporter pathway)	EstA (outer membrane esterase)
Nonspecific Mechanism	
Secretion in membrane vesicles	Alkaline phosphatase
	Protease
	Phospholipase C
	Peptidoglycan hydrolase
	β-lactamase

infection processes. The activities of the *P. aeruginosa* enzymes, alkaline phosphatase, protease, and lipase have been detected in laboratory biofilms and also in the slime formed by this organism (27–30), demonstrating the expression of extracellular enzymes during the biofilm mode of growth.

Secreted enzymes have been categorized according to the final location of the functional enzyme. Here, the term *ectoenzyme* refers to any enzyme that remains associated with its producer cell (31). Examples of the localization of ectoenzymes include the periplasmic space between the cytoplasmic membrane and outer membrane of gram-negative bacteria or the cell wall of gram-positive bacteria, which consists of several peptidoglycan layers intermingled with secondary polymers (teichonic and teichuronic acids); in this wall matrix, the enzymes may be involved in cell-wall synthesis and turnover. Secreted enzymes can be bound to cell-surface structures such as lipopolysaccharide (LPS) molecules as integral parts of the outer membrane of gram-negative bacteria; this has been described for lipase LipA of *P. aeruginosa* (21,32). Enzymes can also be attached to crystalline protein surface layers (S-layers); for example, they have been shown to function as adhesion sites for an amylase of *Bacillus stearothermophilus* (33). The term *extracellular enzyme* is used for any enzyme that has lost contact with its producer cell and occurs in a cell-free form in the surrounding environment, including the EPS matrix of biofilms and/or adsorbed to other living or inert surfaces (31).

Transitions between cell-associated and cell-free states of an enzyme can occur, so that an ectoenzyme may become an extracellular enzyme; examples are alkaline phosphatase (34) and β-lactamase (6) of *Bacillus licheniformis*, amylase of *B. stearothermophilus* (33), or lipase of *P. aeruginosa* (21). The ratios between cell-bound and cell-free enzymes may depend on many factors such as growth phase, nutrient concentration, nutrient composition, association with cell-surface molecules, and accumulation of fungi and gram-positive bacteria within the cell-wall matrix.

A nonspecific mechanism of enzyme secretion, which differs from the specific pathways mentioned earlier, seems to be common among gram-negative bacteria (35,36) and has been intensively studied in *P. aeruginosa* (37,38). This nonspecific enzyme release is mediated through the formation of outer membrane–derived vesicles during normal growth and represents a process by which cellular macromolecules, including periplasmic compounds and membrane components (outer membrane proteins, enzymes, DNA, LPS, phospholipids), are shed into the extracellular space in the form of membrane vesicles (Fig. 1). The formation of membrane vesicles appears to represent an alternative route for enzyme secretion, which functions in parallel to specific secretion processes (Table 1). As an example, substantial proportions of phospholipase C, alkaline phosphatase, and protease activity of *P. aeruginosa* were found to be associated with membrane vesicles, whereas the remaining enzyme activities were localized in the extracellular, vesicle-free medium (37). Using transmission electron microscopy, membrane vesicles have been visualized in pure-culture biofilms of *P. aeruginosa* (38) and in natural freshwater biofilms (36). Membrane vesicles, into which hydrolytic enzymes are packaged (e. g., peptidoglycan hydrolases), may serve to degrade surrounding cells of foreign species in the biofilm ("predatory vesicles") (35), thereby liberating nutrients for the vesicle-forming organisms; this mechanism would be of benefit to vesicle-producing bacteria living in biofilms containing mixed microbial populations. In infection processes, membrane vesicles may facilitate the delivery of those enzymes that function as virulence factors to host tissues colonized by the biofilm bacteria (36).

DETERMINATION OF ENZYME ACTIVITIES IN BIOFILMS

According to enzyme classification, most ectoenzymes and extracellular enzymes analyzed so far in biofilms belong to the class of hydrolases, whereas enzymes belonging to other classes of enzymes (e.g., lyases and oxidoreductases) have been described rarely in biofilms. Hydrolytic biofilm enzymes include polysaccharidases, proteases, lipases, esterases, peptidases, glycosidases, and phosphatases (Table 2).

The selection of the analyzed enzymes reflects the abundance of their substrates in terrestrial and aquatic environments. Particulate and dissolved organic matter introduced into soil or water originates mostly from decaying higher plants, algae, fungi, or animals. Naturally occurring important substrates are polysaccharides (cellulose, hemicelluloses such as xylan, starch, and chitin), proteins, lipids, and lignin (64). Several different enzymes usually cooperate in the microbial degradation of biopolymers to yield successively smaller compounds. First, polymer substrates are degraded to oligomeric products; these are further cleaved to smaller oligomers or to monomeric units, which can easily be taken up and metabolized by the microbial cell. Polymer-degrading enzymes may be endoacting (endolytic), cleaving within the molecule chains and liberating relatively large fragments, or exoacting (exolytic), attacking molecule termini and thus liberating oligomeric or monomeric subunits. Polysaccharides are commonly depolymerized by polysaccharide hydrolases or polysaccharide lyases (eliminases) (65). Proteins and lipids are cleaved by hydrolytic enzymes. The biodegradation of lignin, an abundant structural plant polymer, is catalyzed by various oxidoreductase enzymes (oxidases, peroxidases) (64); the degradation products (phenols, aromatic acids, aromatic alcohols) may repolymerize, a reaction that occurs spontaneously or is catalyzed by microbial phenoloxidases, peroxidases and laccases, giving rise to humic substances (64).

The analysis of enzyme activities in biofilms and flocs is mostly restricted to representative enzymes involved in the degradation of a particular biopolymer. The activities of polymer-degrading enzymes such as cellulases, amylases, or proteases have been studied occasionally in biofilms and flocs; more frequently, oligomer-degrading enzymes involved in later steps of the decomposition of biopolymers have been assayed (Table 2). These enzyme activities are considered as indicators of the microbial

Table 2. Examples of Ectoenzymes and Extracellular Enzymes in Microbial Aggregates from Different Sources

Enzyme	Substrate	Detection Method	Source	Reference
Protein-Degrading Enzymes				
Protease	Hide powder azure	Photometric	Agar-grown biofilm (*P. aeruginosa*)	29
	Azocasein	Photometric	Activated sludge	39
	River water, casein-enriched river water	HPLC[a]	River biofilm	40
Peptidase	L-leucine-β-naphthylamide	Fluorimetric	River biofilm, drinking water biofilm	41
	L-leucine-4-methyl-7-coumarinylamide	Fluorimetric	River biofilm	40
	(L-leucine-7-amido-4-methylcoumarin)		Activated sludge	42
			Marine aggregates	43–45
			Wastewater biofilm	46
	L-alanine-4-nitroanilide	Photometric	Sewer biofilm	47,48
			Activated sludge	47,48
	L-leucine-4-nitroanilide	Photometric	Activated sludge	48
	4-MUF[b]-*p*-guanidinobenzoate	Fluorimetric	River biofilms	40,49
Carbohydrate-Degrading Enzymes				
Endocellulase	Carboxymethyl cellulose	Viscometric	River biofilm	50
Chitinase	^{3}H-chitin, ^{14}C-chitin	Scintillation counting	River and estuarine sediments	51
Alginate lyase	Native alginate in biofilm	Electrophoretic	Pure-culture biofilm (*P. aeruginosa*)	52
α-Glucosidase	*p*-nitrophenyl-α-D-glucopyranoside	Photometric	Epilithic river biofilm	50
			Sewer biofilm	47

potential of polymer degradation and metabolism in their respective environments. Thus, β-glucosidase, α-glucosidase, β-xylosidase and β-N-acetylglucosaminidase represent ectoenzymes or extracellular enzymes associated with the degradation of cellulose, starch, xylan, and chitin, respectively.

Enzymes usually act on more than one substrate. This allows for the use of synthetic substrate analogs instead of natural substrates for detection of enzyme activities. Hydrolytic activities in biofilms were mostly determined using model substrates consisting of a chromogenic or fluorescent molecule bound to a substrate monomer via ester, glycoside, or peptide (amide) bonds. Upon hydrolysis of the colorless or nonfluorescent model substrate, the chromogenic or fluorogenic groups are released; this can be monitored by an increase in absorbance or fluorescence. Examples of chromogenic or fluorogenic moieties of artificial substrates are 4-nitrophenol, 4-nitroaniline, β-naphthylamine, 4-methylumbelliferone, or fluorescein. Esterase activity is frequently measured as hydrolysis of fluorescein diacetate (FDA). Because FDA is nonspecifically cleaved by many different hydrolases (e.g., lipases, proteases, carbohydrate-degrading enzymes), this enzyme assay has been used as an indicator for general heterotrophic activity (66). Glycosidase, peptidase, and phosphatase enzyme activities are usually determined by more specific chromogenic or fluorogenic substrates (Table 2). Oxidoreductase enzyme activities have been determined photometrically by monitoring an increase in absorbance following reduction of tetrazolium salts (63,67) or L-3,4-dihydroxyphenylalanine (50). Enzyme assays are usually performed at relatively high substrate concentrations at saturation level under laboratory conditions, so that the kinetics of the reaction approach zero

order and are not dependent on substrate concentration (66); in addition, it has to be considered that the artificial substrates are analogs for naturally occurring compounds of unknown composition and concentrations, which can be expected to be limiting in certain oligotrophic environments. Thus, potential rather than actual enzyme activities are measured with the assays described earlier.

Research on enzymes in microbial aggregates has been restricted to selected environments; thus, enzyme activities have been frequently studied in river biofilms, in activated sludge flocs, in sediment biofilms, and in pure-culture biofilms grown under laboratory conditions (Table 2). Enzyme activities were measured either directly on undisturbed biofilms and suspended flocs or, alternatively, in homogenized biofilm suspensions after detaching the biofilm from solid supports by scraping and sonication techniques. The formation of undisturbed biofilms was accomplished on artificial substrata such as clay tiles glued to stream boulders in the riverbed (56), glass beads on nylon strings, or polycarbonate membranes in support holders placed in opaque pipes that were attached to the riverbed (40,49) and PVC coupons in drinking water systems (41). Alternatively, biofilms were obtained from natural substrata such as stones collected from the bottom of rivers (41,50) or sediments from streams, lakes, and oceans (53,54,68). In some studies, the biofilms were allowed to develop for several weeks before the solid supports with their attached biofilms were collected from the aqueous environment. In general, enzyme activities were determined subsequently by submerging biofilms still adherent to their substratum in solutions containing enzyme substrates or by shaking sediment samples or flocs in the respective substrate solution. After this incubation, biofilms were removed by centrifugation, before the products released enzymatically from the substrates were analyzed. Controls usually consist of formaldehyde-killed biofilms to assess abiotic substrate degradation in the absence of living biofilm organisms.

In some studies, a fractionation of biofilms and flocs was performed by methods such as centrifugation, filtration, or extraction of the EPS using ion-exchange resins (42,46,50,63). These techniques were applied to separate inorganic particulate material, cellular aggregates, and single cells from the cell-free aqueous phase in order to distinguish between particle-sorbed/cell-bound enzymes and cell-free extracellular enzymes, which were obtained by 0.2-μm membrane filtration as the final step in the fractionation procedure. In studies of freshwater and marine aggregates, greater than 3.0-μm size fractions were considered to represent particle-attached microorganisms (43,69). The separation procedures of centrifugation and/or filtration employed in many studies of biofilms and flocs do not necessarily allow discrimination between enzymes localized within the periplasm, bound to integral components of the cell surface, and those cell-free enzymes immobilized within that fraction of the EPS matrix that may not be removable but still remains associated with cells. At present, for routine extraction of EPS from many biofilms and flocs with a high yield, particularly of proteins, the best choice seems to be the use of a cation-exchange resin (Dowex), combined with stirring under defined conditions (70). The method is based on the removal of calcium ions, destabilizing the EPS structure and facilitating the separation of EPS from the cells. Because the extraction efficiency for enzymes varies depending on the type and origin of the microbial aggregate under study and on the fractionation technique used, the distinction between cell-bound enzymes, ectoenzymes, and extracellular enzymes must be considered as strictly operational.

Enzyme activities in biofilms can also be studied by analyzing the enzymatic degradation products from naturally occurring substrates or model compounds. Thus, the proteolytic activity of river biofilms was determined by monitoring the release of amino acids from river water proteins in the presence or absence of added casein using high-performance liquid chromatography (40). The size-fractionated hydrolysis products resulting from the enzymatic degradation of bovine serum albumin by wastewater biofilms were quantified with a colorimetric protein assay (71). The proteolysis of various cytokines by laboratory biofilms of *Porphyromonas gingivalis* was demonstrated using denaturing polyacrylamide gel electrophoresis, Western blotting, and antibodies recognizing both intact cytokines and their breakdown products (72). The decrease in the length of the exopolysaccharide alginate in biofilms of *P. aeruginosa*, as a result of the action of an endogenous alginate lyase, was followed by nondenaturing gel electrophoresis (52); degradation products of alginate were visualized by staining the gel with toluidine blue O. Extracellular polysaccharide lyase in a *Pseudomonas fluorescens* biofilm was detected by incubation of sample solutions in wells cut into substrate agar plates that contained biofilm-derived exopolysaccharide as the test substrate; after flooding the plates with cetylpyridinium chloride and counterstaining with congo red, enzyme-positive solutions produced a clear zone against an opaque, orange background (73).

Another approach to enzyme analysis in biofilms is the direct microscopic visualization of enzyme activity in the biofilm by the application of in situ staining procedures with fluorogenic substrates. Using this nondestructive technique, phosphatase activity in laboratory biofilms and in activated sludge flocs was detected using the water-soluble substrate ELF 97-phosphate, which yields an insoluble fluorescent precipitate upon cleavage by the enzymes; this method allowed the study of the spatial distribution of phosphatase activity in whole flocs and in vertical cross sections of biofilms (27,28,62). Extracellular redox activity in activated sludge flocs was visualized by the reduction of the tetrazolium salt 5-cyano-2,3-di-4-tolyl tetrazolium chloride (CTC) to CTC-formazan crystals, which were viewed by confocal laser scanning microscopy (63).

An indirect approach to assessing the polymer-degrading potential of microbial aggregates is the detection of extracellular enzyme-producing bacteria using substrate-containing agar media. Using this method,

amylase-, protease-, and lipase-producing bacteria from wastewater environments were quantified on agar media containing starch, gelatin, and olive oil, respectively, as the substrates (47). High colony counts of 10^9 to 10^{10} colony-forming units per gram dry weight of polymer-degrading bacteria were measured in sewer biofilms and activated sludges, indicating that these biofilms and flocs were highly active biocenoses (47).

DISTRIBUTION OF ENZYME ACTIVITIES IN BIOFILMS

Localization of Enzymes

A different situation exists for single planktonic cells in the bulk-liquid phase as compared with cells immobilized in biofilms and flocs. After secretion from single, free-living cells, extracellular enzymes can dissolve, readily diffuse away from the producing cell and be diluted in the aqueous environment. In cell aggregates, the mobility of enzymes leaving the cell surface may be restricted by diffusion limitation within the viscous gel-like EPS matrix, by immobilization through interactions with structural polymers, for example, by forming enzyme-polysaccharide complexes (74) or by binding to inorganic and/or organic particulate material incorporated in the biofilm (75,76). Thus, release of extracellular enzymes from microbial aggregates into the surrounding environment may be delayed or even prevented, resulting in a local accumulation of enzymes within biofilms and flocs. This may enhance the probability of nutrient acquisition by the whole biofilm microbial community. In the case of ectoenzymes, coupling of substrate degradation and uptake processes may even be more efficient because of the closer association of enzymes with the producer cell (34).

When enzyme activities were compared between the bulk-water phase and microbial aggregates, specific extracellular enzyme activities were usually higher in attached bacteria. This has been described for river biofilms (56) and freshwater and marine aggregates of different compositions (43–45,69). In a study of decaying marine phytoplankton, cell-specific aminopeptidase activities of detritus particle-attached bacteria were several times higher than those of free-living bacteria, and also higher than glucosidase activities (45); this could be interpreted as the potential for faster solubilization of proteins relative to polysaccharides and might reflect specializations for the hydrolysis of different polymers by free-living and attached bacteria (45). In general, higher enyzme activities of attached bacteria compared with free-living cells may reflect differences in nutrient availability and composition in the different habitats (69). Particulate matter itself can be used as a substrate, but organic matter from the bulk-water phase can also adsorb to the particulate material. These conditions provide an accumulation of nutrients, whose utilization is coupled to the synthesis and secretion of appropriate enzymes by the colonizing microbial community.

Many enzyme activities in biofilms were often found to be associated with the cells and/or other particulate material. In epilithic biofilms, phenol oxidase, peroxidase, and phosphatase activities were largely particle-associated; in contrast, the largest pool of carbohydrate-degrading enzyme activities were in the aqueous phase (50). In wastewater biofilms, most of the leucine aminopeptidase and α-glucosidase activities occurred cell-bound, whereas only a minor fraction of these hydrolytic activities (no more than 3%) was found to be located in the cell-free (<0.2 μm) fraction (46). In activated sludge, the majority of enzyme activities seem to be associated with the suspended flocs (39,48,62). Thus, 75 to 99% of phosphatase, glycosidase, and aminopeptidase activities were found to be located in the flocs (48,62). Similarly, hydrolytic enzymes (starch-hydrolyzing enzymes, α-glucosidase, protease) of activated sludge cultivated in a sequencing batch reactor were also mainly associated with the flocs (39). Using the cation-exchange technique for the recovery of EPS, approximately 85% of the total esterase activity (FDA-hydrolyzing activity) were found in the EPS extracts from activated sludge, without observing any significant cell lysis (42). This clearly indicated that esterase enzymes were part of the EPS matrix in the flocs. Similarly, a study of natural and batch-cultured stream sediment biofilms indicated that extracellular esterases (FDA-hydrolyzing enzymes) were predominantly associated with the biofilm EPS (53). In addition to the determination of hydrolytic activities, cation-exchange extraction also allowed the detection of small amounts of oxidoreductase enzymes in EPS-containing extracts from activated sludge (63).

The relationship between extracellular enzyme activity and microbial abundance in biofilms has been shown to vary depending on the enzyme studied, on the type of biofilm, on the growth phase, and the environmental nutrient conditions. In river biofilms, phenol oxidase, peroxidase, and phosphatase activities that were largely particle-bound often correlated with microbial biomass, whereas carbohydrate-degrading enzymes with their main activities in the aqueous phase of the biofilms were not correlated with biomass (50). In activated sludges, only a poor correlation of esterase activity (FDA hydrolysis) and biomass has been observed (77). Good correlations have been shown between fixed bacterial biomass and proteolytic activity (41) or esterase activity (49,60) in river and drinking water biofilms. Because these enzyme activities were considered to be near-constant properties of biofilm bacteria, the determination of protease and esterase activities measured by the hydrolysis of L-leucyl-β-naphthylamide and fluorescein diacetate, respectively, were proposed as rapid and simple methods for measuring bacterial biomass and monitoring biofilm growth on surfaces (41,60). On the basis of this principle, the measurement of extracellular proteolytic activity has been used to quantify attached bacterial biomass in various French drinking water distribution systems (78).

Association of Enzymes with the EPS Matrix

On the basis of the observation of enzyme abundance in biofilms, it has been assumed that ectoenzymes and extracellular enzymes accumulate and become stabilized in biofilms by binding at the cell surface of biofilm bacteria or by interacting with structural EPS such as polysaccharides within the biofilm matrix (49,50,75,79).

Only few reports in the literature describe the interactions between enzymes and polysaccharides, and little work has been done to study such interactions in biofilm bacteria.

The exopolysaccharide matrix may not be homogeneous, but rather may display microenvironments called *microdomains* with different physical and chemical properties at the molecular scale (80). It was proposed that extracellular enzymes could be localized in hydrophilic, exopolymer-mediated microdomains as a useful strategy to retain enzymes in close vicinity to microbial cells (80). Microdomains would provide relatively stable ionic and pH environments for enzymes to function efficiently, to prolong their half-life, and to prevent their denaturation. Because polysaccharides comprise the major structural molecules in biofilms, it can be assumed that they play a major role in localizing extracellular enzymes in the biofilm matrix, so that interactions between enzymes and polysaccharides within the extracellular matrix can be expected.

Pure-Culture Studies

In general, it is assumed that the synthesis and release of enzyme proteins and polysaccharides occur independently from each other, so that interaction between them may occur after transport across the bacterial membranes. Mucoid strains of *P. aeruginosa* provide a suitable model to study interactions between EPS, because they are characterized by the simultaneous production of extracellular polysaccharides and different enzymes (Table 1). The extracellular polysaccharide alginate, which is overproduced in mucoid variants, is supposed to be a key factor in the formation and persistence of *P. aeruginosa* biofilms on human mucosal tissues [e.g., in chronic lung infections of cystic fibrosis (CF) patients] (81). In mucoid strains of *P. aeruginosa*, the simultaneous secretion of alginate and lipase has been demonstrated (74). Mucoid strains isolated from CF patients displayed up to ninefold extracellular lipase activities (74). Enhanced de novo synthesis and release of lipase and an accumulation of enzyme activity in the EPS matrix were supposed to be the reasons for higher extracellular lipase activities in mucoid *P. aeruginosa* strains. Confirmation of an association between extracellular lipase and alginate surrounding the cells came from the observation that dissolution of the bacterial slime by the addition of a purified alginate lyase resulted in an additional release of lipase activity without killing the cells (30). From in vitro experiments using lipase preparations from *P. aeruginosa* and other microorganisms, it was concluded that alginate was able to bind lipases with a concomitant change of enzyme properties (82). As an example, lipase activity proved to be more resistant to heat inactivation at 70 °C in the presence of alginate than in its absence (82). Similarly, the extracellular polysaccharide xanthan from *Xanthomonas campestris* was also able to protect extracellular lipase activity of *P. aeruginosa* from thermal denaturation (83). The in vitro binding studies demonstrated that the interactions between alginate and lipase seemed to be based on weak binding forces (82), which are typical of interactions between EPS in bacterial biofilms (84).

The ability of alginate to interact with enzymes other than lipases has also been reported. For example, an interaction of alginate from *P. aeruginosa* with the exogenous human leukocyte elastase has been demonstrated (85). It was proposed that each elastase molecule interacted with 19 uronic acid residues of alginate, predominantly through electrostatic forces. In addition, alginate reduced the association rate between elastase and α-1-proteinase inhibitor, but increased its association rate with secretory leukoprotease inhibitor (85). It was assumed that alginate in microcolonies of mucoid *P. aeruginosa* represented an important factor in determining the local concentration of the host leukocyte elastase and in influencing the protease-antiprotease balance in the infected lungs of CF patients.

The interaction between certain polysaccharides, including alginate and lipase, with concomitant change of enzyme properties and location may be a common phenomenon in pro- and eukaryotic cells. In *P. aeruginosa*, the interaction between lipase and alginate is expected to occur after secretion. Alginate-lipase complexes may temporarily remain associated with the cell surface, before being extruded into the intercellular space within the biofilm. Detachment of lipase from surface-binding sites by alginate from the same cell may trigger novel enzyme synthesis and secretion of the enzyme (74). Thus, in biofilms of mucoid bacteria, alginate production may result in an autostimulatory effect with respect to extracellular lipase formation. In the biofilm matrix, lipase may remain noncovalently associated with alginate, resulting in increased stability and accumulation of enzyme activity in the microenvironment of the slime-embedded cells. Similarly, stabilization of other extracellular enzymes due to their noncovalent interaction with extracellular polysaccharides produced by the same bacterium has been described for an agarase from a *Cytophaga* species (86), a β-lactamase from *Bacillus cereus* (87), and a protease activity within an extracellular protein-polysaccharide-lipid complex from slime-forming *Myxococcus virescens* (88). Thus, it may be a general property of extracellular polysaccharides to function as a matrix for enzymes in biofilms with concomitant changes of enzyme properties.

In certain instances, polysaccharides already interact with enzymes during secretion. In *Micrococcus sodonensis*, the appearance of extracellular enzyme activities of alkaline phosphatase, nuclease, and protease has been shown to be dependent on the cosecretion of at least one of several polysaccharides produced by this bacterium (89). On the basis of a more detailed study of alkaline phosphatase, it was hypothesized that the polysaccharide protected the polypeptide chains of the enzyme from proteolytic degradation during a vulnerable stage of enzyme secretion (89).

Occasional reports in the article indicate that growth in a biofilm markedly influences the expression, stabilization, and accumulation of extracellular enzyme activities in the EPS matrix of the immobilized cells. Extracellular protease activity of *Staphylococcus epidermidis* studied at varying specific growth rates was generally higher in biofilms than in planktonic populations (90). In biofilms of *P. aeruginosa*, the bacteria revealed lower levels

of β-lactamase induction by β-lactam antibiotics than planktonic populations (91). One reason for this effect was supposed to be the trapping and accumulation of β-lactamase enzyme within the biofilm to such levels that afforded protection of the sessile bacteria from β-lactam antibiotics by inactivating them.

Terrestrial and Aquatic Biofilms

In studies of natural biofilms, the presence of humic substances has to be considered. Extracellular enzymes can form stable complexes with humic compounds (75), which are abundant in aquatic and terrestrial ecosystems and may be important components in the EPS matrix of soil and water biofilms. In soil biofilms, humic-enzyme complexes and enzyme complexes with clay particles were supposed to contribute significantly to total enzyme activity, giving the soil environment a persistent extracellular catalytic activity independent of the existing microflora (75). Complexes between enzymes and humic matter from soil have been reported to be extremely resistant to thermal denaturation, dehydration, and proteolysis (75). The formation of polyphenolic-enzyme complexes can partially or entirely inactivate enzymes in a reversible manner (34). It was proposed that, in these associations, enzymes can be protected from the environment, can be stored in a suppressed but chemically active state, and can be reactivated at the same or displaced sites to full enzyme activity (34). Thus, it can be assumed that potential enzyme activities in humic acid-containing biofilms may be higher than what is normally observed.

In models of river biofilms composed of autotrophic (algae, cyanobacteria) and heterotrophic microorganisms, extracellular enzymes were included as essential components of the EPS matrix. In a structural-functional model for epilithon (biofilms adherent to stone surfaces in streams and rivers), it was suggested that the polysaccharide matrix was a site for attached enzymes analogous to enzyme-humus complexes in soil (79). The biofilm matrix should retain and possibly protect extracellular enzymes, but also retain any products of extracellular enzymatic hydrolysis (79). This concept, originally developed for epilithic biofilms, was supposed to apply, with some modifications, to all biofilms on wetted surfaces (92). Biofilms submerged near water surfaces (e.g., on the upper surfaces of stones) are composed of autotrophic microorganisms (algae, cyanobacteria) and heterotrophic microorganisms, whereas biofilms within the stream bed will be predominantly heterotrophic. Thus, depending on the type of biofilm, substrates for extracellular enzymes may be exudates/photosynthates released from algae or from colonized river macrophytes and mosses, dissolved organic matter, and particulate organic matter trapped from the surrounding water (93). In biofilms on wood, products from surface and subsurface fungal hydrolysis may act as an additional nutrient source. An advantage for microorganisms in aquatic biofilms would be the availability of low molecular weight reaction products in the immediate vicinity of the immobilized cells. The long-term existence of different enzymes from the same and previous generations in the biofilm may exclude the requirement of novel enzyme synthesis and the initiation of enzyme induction, because high levels of products are maintained by the activity of the immobilized enzymes (79). The stabilization of extracellular enzymes due to their interaction with matrix polysaccharides may result in persistence of enzyme capacity within the biofilm, which is independent of the usual forms of regulation and control of enzyme synthesis and secretion. Thus, enzyme activities may be decoupled from their producer cells. This may be one reason why the activities of certain enzymes were not to be found in correlation with parameters for cell or biomass densities in biofilms (49,50). The reservoir of extracellular degradative enzymes within the polysaccharide matrix was assumed to buffer the biofilm community to sudden changes in the composition and concentration of dissolved organic matter in the bulk-water phase (49). The accumulation and stabilization of polysaccharide-bound enzymes within the biofilm matrix seem to be essential processes that have to be considered in the understanding of structure and function of biofilms in different ecosystems.

INFLUENCE OF ENVIRONMENTAL FACTORS ON ENZYME ACTIVITY IN BIOFILMS

The expression of ectoenzymes and extracellular enzymes in biofilms is dependent on various physical, chemical, and biological factors. The patterns of enzymatic activities reflect the metabolic status of microbial populations as a phenotypic adaptation to the predominating environmental conditions. Enzyme activity can be directly affected by variables such as temperature, pH, or ionic environment, because the rate of enzyme-catalyzed reactions is largely determined by these factors; enzyme activities can also be impaired when inhibitory or inactivating substances are present. An indirect mechanism of controlling the activities of secreted enzymes is the regulation of their synthesis by induction and repression processes in response to substrate availability; in addition, the expression of many extracellular enzymes is positively regulated by signal molecules, which mediate cell-to-cell communication within bacterial population (illustrated later). Observations of natural biofilms and of single-species laboratory biofilms indicate relationships between certain environmental factors and enzyme activities in biofilms.

Extracellular enzyme activities in river biofilms and in sediments have been found to be subject to seasonal variations. These differences were related to climatic characteristics (especially temperature) and to the ratio of bacterial and algal biomass, but also to the availability and composition of assimilable organic matter.

In a comparative study of the environmental conditions, biofilm composition, and extracellular enzyme activities of three Mediterranean and six Atlantic streams and rivers, the biofilms from Mediterranean streams revealed higher extracellular enzyme activities than biofilms of comparable composition from Atlantic systems (93); an explanation for this observation could be climatic differences such as lower irradiance and lower temperatures in the Atlantic-dominated streams. Water temperature has also been described to influence the production of extracellular enzymes involved in the degradation of cellulose

(β-glucosidase) in biofilter biofilms used for wastewater treatment (57). During the cold period (influent water temperature 7.5 °C to 13.5 °C), the biomass contained less extracellular β-glucosidase activity than during the warmer period. This weak hydrolytic activity, coupled with an accumulation of polysaccharides in the biofilm, was supposed to promote the rapid clogging of the biofilter observed during the colder period (57).

Ionic content of stream water seems to be another factor that can account for the variability in heterotrophic biofilm activities. In a study of three Mediterranean streams, the high concentrations of calcium and magnesium at calcareous sites were supposed to be responsible for higher extracellular enzyme activities, because both ions are known to act as activating cations in enzyme reactions (94).

In general, algal biomass in biofilms is an important biological factor stimulating heterotrophic activities. In a comparative study of stream biofilms of different geographic regions, highly heterotrophic biofilms showed lower extracellular enzymatic activities (β-glucosidase, β-xylosidase, phosphatase) than more autotrophic biofilms; maximum enzyme activity was achieved when the algal biomass was two- to threefold higher than the bacterial biomass (93). The relevance of algal biomass on the activity of heterotrophic bacteria was supposed to be related to the physical proximity between these organisms in a common biofilm matrix, facilitating the supply of algal exudates and lysis products, which are known to be major nutrient sources for heterotrophic microorganisms. A high proportion of these compounds are polymeric and can only be used by enzyme-mediated hydrolysis, so that ectoenzymes and extracellular enzymes in biofilms form the link between the presence and productivity of algae and the growth and metabolic activity of heterotrophic organisms (93).

The availability and qualitative composition of exogenous organic matter as another nutrient source in the bulk-water phase can also determine enzymatic activities of heterotrophic biofilm organisms. As an example, the enzyme activity (as β-glucosidase) of epilithic biofilms in a Mediterranean river was enhanced during higher discharge periods, which were coupled with higher dissolved organic carbon content in the stream water (56). In biofilms from different fluvial systems and grown on different substrata, the ratio of β-xylosidase to β-glucosidase activity was always similar (approximately 0.5), indicating a higher microbial utilization of cellobiosic than xylobiosic substrate molecules (93). This may reflect a higher abundance of cellulose than hemicellulose in river environments and/or a preferential degradation of polysaccharides, whose end products are energetically more favorable for bacterial growth and metabolism (β-D-glucose from cellulose vs. β-D-xylose from xylan as a major component of hemicellulose).

In littoral lake sediments, a linear positive relationship between extracellular enzyme activities (β-glucosidase, exoglucanase, endopeptidase, esterase) and organic matter content was observed (54). The patterns of enzymatic activities were different for inside and outside a reed bed; inside, polysaccharide-degrading enzymes associated with the decomposition of cellulose (β-glucosidase, exoglucanase) and xylan (β-xylosidase) and mannosidase dominated, whereas protein-degrading enzyme activity (endopeptidase) was elevated outside the bed. This pattern of enzyme expression was related to the polymeric composition of the major sources of organic matter (macrophyte-derived polysaccharides inside the bed, algal and cyanobacterial proteins outside the bed). In another study, the specific α- and β-glucosidase activities of lake sediments were strongly induced by their natural substrates (starch and cellulose, respectively) and were not inhibited by glucose, whereas proteins inhibited these activities (55). These observations suggest that an adaptation of microbial biofilm communities to the available organic matter in their environment consists of producing extracellular enzymes that are related to the composition of the predominant nutrient sources. Therefore, it was proposed to use patterns of enzymatic activities to obtain information on organic matter sources that are utilized by microbial population in natural systems (54).

Enzyme activities in activated sludge flocs also seem to be influenced by the composition of the organic matter in the wastewater feed. In full-scale plants, it was observed that addition of hydrolyzed starch resulted in high specific α-glucosidase activities, suggesting the presence of starch-utilizing populations (61). Specific alanine aminopeptidase activities were elevated in activated sludge when a higher content of proteinaceous material was in the inlet of the plant (61). When activated sludge was cultivated in sequencing batch reactors, about four times higher extracellular redox activity was measured in reactors fed with lignin compared with reactors fed with amylose. On the basis of this observation, extracellular redox enzymes were supposed to facilitate the enzymatic attack on recalcitrant molecules such as lignin (63).

The influence of environmental factors on alkaline phosphatase has been studied in pure-culture biofilms. Alkaline phosphatase was expressed in biofilms under conditions of phosphate starvation. In biofilms of *P. aeruginosa*, alkaline phosphatase was formed only in a relatively thin layer at the biofilm-medium interface, whereas in biofilms of *Klebsiella pneumoniae* it started to appear at the biofilm surface, but subsequently spread throughout the biofilm (27). In addition, alkaline phosphatase expression in *P. aeruginosa* biofilms was limited to regions of oxygen availability (28). These observations indicated a marked spatial physiological heterogeneity mediated by environmental factors such as nutrient and oxygen availability.

REGULATION OF EXTRACELLULAR ENZYME ACTIVITY IN BIOFILMS

Induction Mechanisms

Very little is known about the regulation of ectoenzymes and extracellular enzymes in biofilms. Extracellular enzymes are commonly synthesized and secreted at a low basal level. If macromolecular substrates are

present, they are degraded to small products, which are transported into the cell to induce further synthesis of the enzyme (6). Thus, the microorganisms can monitor the level of product and regulate enzyme synthesis accordingly. Enzyme synthesis may again be slowed or repressed in the presence of an excess of low molecular weight products or other carbon sources, which are easily taken up and metabolized by the cell (6). This catabolite repression allows for the efficient control of the synthesis and secretion of enzymes. Many extracellular polymer-degrading enzymes of single species in laboratory cultures have been found to be regulated in this way. However, it is unknown if these mechanisms are also employed by biofilm populations. Some observations on biofilm and floc enzymes being expressed in the presence of their natural substrates indicate that induction mechanisms may be the cause for the production of enzymes in response to the prevailing nutrients. However, changes in microbial population composition may be an alternative explanation for the dynamic expression of enzymes, occurring as an adaptation to varying concentration and composition of nutrient sources. Induction mechanisms are short-term reactions of biofilm microorganisms at the physiological level, whereas population shifts represent long-term adaptation processes. As an example, enzyme activities in starved, activated sludge were induced by the addition of lactose; within two hours, glucosidases and galactosidases reached their maximal enzyme activity (48).

Major changes in the composition of an attached bacterial community were observed during the colonization of decaying phytoplankton particles, accompanied by a pronounced increase in the cell-specific enzymatic activities of aminopeptidase, β-glucosidase, and lipase during 11 to 15 days (45). The analysis of the bacterial community composition suggested that the extensive colonization was accomplished by highly hydrolytic "particle specialist" bacteria, which belonged to the *Cytophagales* and *α-Proteobacteria* groups (45).

Regulation of Extracellular Enzyme Gene Expression by Quorum Sensing

The development and maintenance of biofilms constitute a type of community behavior among bacteria and it is now clear that these biofilm communities represent more than the sum of their individuals (95). Bacteria can obviously coordinate their activities, that is, the expression of specific genes, by producing and sending out chemical signals that are perceived by other members of the same species or even members of different species. When, with increasing cell densities, these signaling molecules reach a certain threshold concentration within a population, they bind to specific intracellular receptors, the so-called R-proteins, which can in turn activate or repress a specific set of target genes. Because the signaling molecules provide a mechanism for the bacteria to monitor their own population density, this type of cell density–dependent regulatory mechanism has been termed *quorum sensing* (96). However, because cell-to-cell signaling does not occur only at high cell densities, quorum sensing now refers to any bacterial intercellular communication by means of small diffusible molecules (97).

A prominent example of quorum sensing regulation in gram-positive bacteria is the regulation of virulence factor production in *Staphylococcus aureus* (98), in which small posttranslationally processed peptides are used as signal molecules. They interact with a membrane-bound sensor kinase named AgrC; this kinase constitutes one part of a two-component regulatory system. The corresponding response regulator AgrA is phosphorylated and subsequently activates the expression of numerous virulence genes, including those encoding lipase, protease, α-toxin, β-hemolysin, and enterotoxin.

In gram-negative bacteria, various types of signaling molecules have been detected, including N-acylhomoserine lactones (AHLs), 3-hydroxy-palmitic acid methyl ester, 2-heptyl-3-hydroxy-4-quinolone, and diketopiperazines (cyclic dipeptides) (97). Among them, AHLs are the best studied class of signaling molecules (99). Originally discovered in marine *Vibrio* species (100), these molecules have now been detected in more than 20 different bacterial species, including human pathogenic *P. aeruginosa*, *Burkholderia cepacia*, *Serratia marcescens*, several *Vibrio* species, and a wide variety of plant-associated bacteria, including *A. tumefaciens*, *Pseudomonas aureofaciens*, *Pseudomonas syringae*, *P. fluorescens*, and *Rhizobium leguminosarum* (101). These findings clearly demonstrated that signaling by low-molecular-weight compounds has emerged as a major pathway in bacteria interspecies communication.

The best studied organism with respect to gene regulation by quorum sensing is the opportunistic pathogen *P. aeruginosa*. Extracellular enzymes of this species include the proteases LasA and LasB (elastase), an alkaline protease, the ADP-ribosylating toxins (exotoxin A and exoenzyme S), the lipolytic enzymes (phospholipase C, lipases A and C), and the outer membrane esterase (EstA) (7,102). A number of these enzymes are known to be virulence factors in human infections (7). *Pseudomonas aeruginosa* possesses two quorum-sensing regulatory systems whose functions are summarized in Figure 2 (103). The Las system consists of the LasI synthetase directing the synthesis of N-(3-oxododecanoyl) homoserine lactone (3-oxo-C_{12}-HSL), which binds to the regulator LasR. The LasR-3-oxo-C_{12}-HSL complex regulates the expression of the extracellular enzyme genes *lasA*, *lasB*, *aprA*, and *toxA* as well as *lasI* itself, thereby creating a feedback regulation loop. The second quorum-sensing system, Rhl, consists of the RhlI synthetase directing the synthesis of N-butanoyl-homoserine lactone (C_4-HSL), which binds to the regulator RhlR. The RhlR-C_4-HSL complex regulates the expression of the rhamnolipid biosynthesis genes *rhlA* and *rhlB*, *lasB*, *aprA*, the stationary-phase sigma factor *rpoS* and secondary metabolites pyocyanin and cyanide. It is interesting to note that the *xcp* genes, which build up the type II secretion machinery in *P. aeruginosa*, are also subject to regulation by both the Las and the Rhl system (104). The finding that LasR positively regulates *rhlR* expression demonstrated that quorum sensing in *P. aeruginosa* operates as a hierarchical regulatory cascade with the LasR/I system being the dominant regulator.

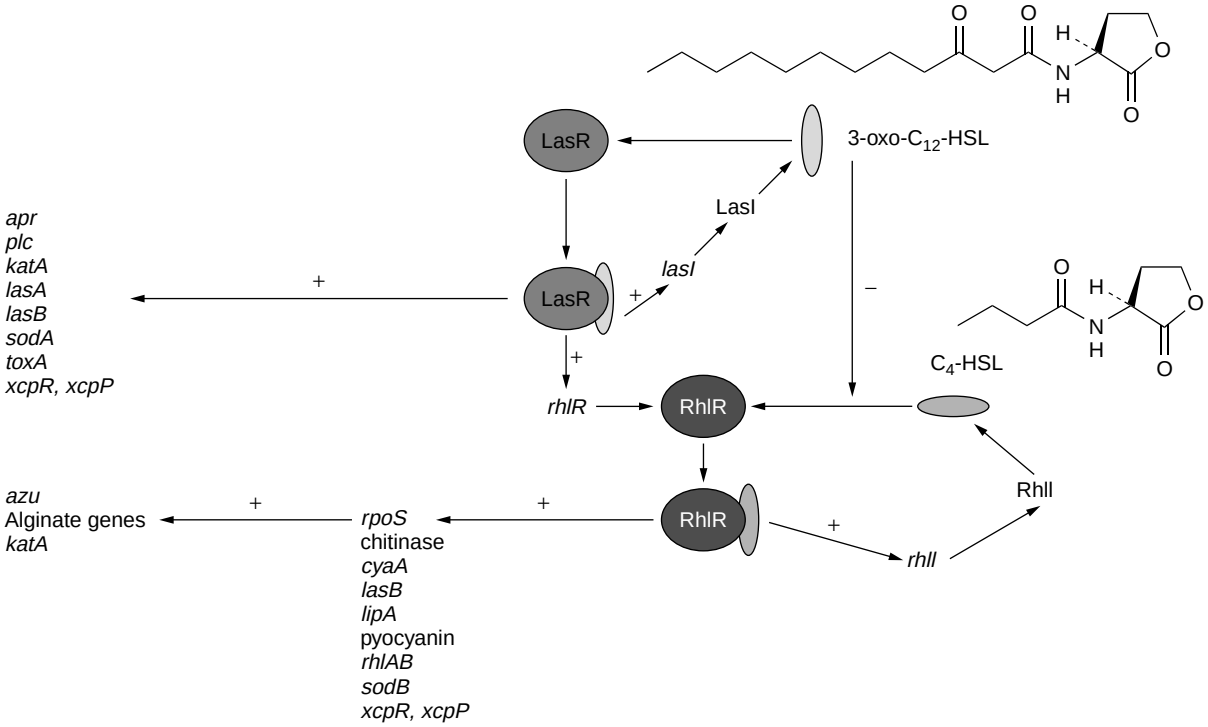

Figure 2. Quorum-sensing regulation of gene expression in *P. aeruginosa*. A plus (+) sign indicates positive regulation, a minus (−) sign indicates negative regulation. The genes encoding extracellular enzymes are printed in red. The main regulatory system consists of the regulator LasR and the autoinducer synthetase LasI, which directs the synthesis of 3-oxo-C_{12}-HSL. The LasR-3-oxo-C_{12}-HSL complex positively regulates the expression of genes *aprA* (encoding alkaline protease), *plcN* (phospholipase C), *katA* (catalase), *lasA* (staphylolytic elastase), *lasB* (elastase), *sodA* (superoxide dismutase), *toxA* (exotoxin A), *xcpR* and *xcpP* (proteins of the type II secretion system), and *rhlR* (the regulator RhlR). The RhlR-C_4-HSL complex positively regulates the expression of genes *rpoS* (stationary-phase sigma factor), a chitinase gene, *lasB* (elastase), *lipA* (lipase), *rhlAB* (rhamnosyltransferase), *sodB* (superoxide dismutase), and *xcpR* and *xcpP* (proteins of the type II secretion system). The sigma factor RpoS itself positively controls the expression of genes *azu* (azurin), *katA* (catalase), and the genes involved in the biosynthesis of alginate. See color insert.

How do the transcriptional regulators, LasR and RhlR, find their target genes? In the marine bacterium, *Vibrio fischeri*, a 20-nucleotide inverted repeat had been identified in the intergenic region between the *luxI* synthetase gene and the *luxR* regulator gene, which is required for the primary regulation of the *lux* gene expression. Such so-called *lux*-box like elements have since been identified upstream from a number of *P. aeruginosa* genes including *lasB*, *rhlI*, *rhlA*, *lasI*, *lasA*, *rhlR*, *lasR* (100), and also, more recently, *lecA* encoding the lectin PA-IL (105). *Lux*-box sequences therefore appear to be conserved regulatory elements and are likely to be targets for LasR and/or RhlR transcriptional regulators.

Biofilm formation by *P. aeruginosa* requires the coordinated expression of a specific set of genes (106). First, flagella enable the bacteria to approach a surface, attach, and form a monolayer. Subsequently, microcolonies are formed in a process that involves the so-called twitching motility mediated by type IV pili. Microcolonies then develop into a mature biofilm with its characteristic "tower and mushroom" structure (4). Finally, the biofilm cycle is closed by detachment of bacteria, which is either caused by unknown physiological events or results from mechanical forces. Recently, it was demonstrated that biofilm development by *P. aeruginosa* requires a functional Las system (107). A *lasI* mutant strain formed a thin and undifferentiated cell layer of densely packed cells. Importantly, the *lasI* mutant biofilms were susceptible to treatment with the anionic detergent SDS, whereas the wild-type biofilm was resistant. Addition of exogenous autoinducer 3-oxo-C_{12}-HSL restored the wild-type properties of the *lasI* mutant biofilm.

Pseudomonas aeruginosa plays an important role as an opportunistic pathogen, particularly in lung infections of CF patients. The bacteria are believed to exist in the form of biofilms that would render them refractile to phagocytosis, antibody and complement defense, and also to antibiotic treatment (108). Recently, it was demonstrated that sputum obtained from CF patients contained a characteristic distribution of quorum-sensing signaling molecules 3-oxo-C_{12}-HSL and C_4-HSL, with the latter compound dominating (109). The same relative abundance of acyl-HSLs was detected when *P. aeruginosa*

was grown in a laboratory biofilm model, indicating that lungs of CF patients are indeed colonized with *P. aeruginosa* biofilms.

Quorum sensing is an important regulatory circuit governing the expression of a set of genes including those that encode extracellular enzymes (Fig. 2). Also, we have described earlier that extracellular enzymes are present in biofilms. Therefore, it can be concluded that quorum-sensing regulation of extracellular enzyme gene expression will constitute a major regulatory principle when bacteria grow under biofilm conditions. However, experimental evidence for this is lacking so far. Recently, it was demonstrated that the quorum- sensing regulation under biofilm growth conditions can be fundamentally different from the one determined with planktonic bacteria (110). Future research on the role of extracellular enzymes will therefore concentrate on the identification of quorum sensing–regulated enzyme genes and the elucidation of their physiological function under biofilm growth conditions.

FUNCTIONS OF EXTRACELLULAR ENZYMES IN BIOFILMS

The primary function of extracellular enzymes is supposed to be the degradation of macromolecules to low molecular weight products, which are small enough to be transported into the cells to be available as carbon and energy sources for microbial metabolism. Thus, they are essential for providing nutrients for immobilized bacteria in biofilms by extracellular digestion of macromolecules; molecules larger than a few monomeric units cannot normally be transported across bacterial membranes. Because in many ecosystems organic material, either dissolved or particulate, is predominantly macromolecular, heterotrophic bacteria within biofilms are largely dependent on the presence of degradative extracellular enzymes in their microenvironment providing utilizable compounds for growth and maintenance of metabolic activity. In natural ecosystems, the degradation of biopolymers by microbial ectoenzymes and extracellular enzymes represents the rate-limiting step in the mineralization and cycling of particulate and dissolved organic matter. Since almost all microorganisms on earth live in microbial aggregates, polymer-degrading enzymes must predominantly originate from biofilm and floc organisms. It remains to be established what proportion of the degradation products is used by the enzyme-producing cells themselves or by other members of biofilm-mixed population, and what part of these products diffuse into the bulk-water phase to be available to planktonic organisms.

It seems that only a certain percentage of mixed microbial communities is able to produce extracellular polymer-degrading enzymes, whereas a greater number of physiological groups in a community can then metabolize the low molecular weight degradation products. The capacity of a microbial community to use dissolved and particulate organic matter is tightly coupled with the abundance and competitive success of certain species that secrete suitable polymer-degrading enzymes and provide nutrients for other members of the microbial community ("social function of extracellular hydrolysis"; 51). Thus, in a simple model of communities consisting of proteolytic and nonproteolytic *P. fluorescens* strains, the protein hydrolysates were found to be available to both strains (111). During the colonization of a chitin surface by *Pseudoalteromonas* bacteria, two physiologically different subpopulations developed: one that produced an extracellular chitinase and remained associated with the surface and another that was nonchitinase active and released daughter cells to the bulk-aqueous phase (58). It was hypothesized that the chitinase-active subpopulation supplied chitin-degradation products to the adjacent nonchitinase-active subpopulation for their cell replication and dissemination into the bulk-aqueous phase (58,112). Channels and pores in the EPS matrix near the surface were supposed to serve as conduits for transfer of soluble chitin-degradation products to nearby cells that were not producing chitinase (112). From these observations, it may be concluded that the processing of biopolymers in microbial aggregates can be mediated by cross-feeding interactions between bacteria with different enzymatic abilities.

Many extracellular enzymes of pathogenic bacteria have been shown to be virulence factors (7). The biofilm mode of growth is an important step in the establishment of human infections (4). Thus, a function of extracellular enzymes in biofilms may be the participation in the infection of eukaryotic organisms by causing tissue damage, promoting the invasion into the host organism or interfering with the defense mechanisms of the host.

The involvement in cell detachment and dispersal has been proposed as a novel function of ectoenzymes or extracellular enzymes in microbial aggregates. Certain enzymes produced by the biofilm bacteria are supposed to catalyze the partial depolymerization of structural polymers of the biofilm matrix with subsequent release of bacterial cells. Thus, enhanced expression of an endogenous alginate lyase in *P. aeruginosa* led to the degradation of the slime polysaccharide alginate and increased the detachment of cells from agar-grown biofilms, suggesting a role for this enzyme in the sloughing of immobilized bacteria from solid surfaces (52). Similarly, the action of an extracellular lyase enzyme in dense biofilms of *P. fluorescens* was specifically directed towards the biofilm exopolysaccharide (73). The enzymatic degradation of the exopolysaccharide was supposed to be responsible for the observed detachment of biofilm cells under starvation conditions during prolonged incubation (73). When exopolysaccharides isolated from biofilms of *P. fluorescens* were incubated with their corresponding spent culture media, the acetate content of the exopolysaccharide fell below detectable limits, probably because of the presence of esterase enzymes (113). These results indicate that not only depolymerization of polysaccharides, but also the enzymatic removal of noncarbohydrate substituents such as acetyl groups, may occur within the biofilm matrix. Because acetylation can provide protection against the action of polysaccharide-depolymerizing enzymes such as alginate lyases (114),

esterase enzymes may act synergistically with polysaccharide hydrolases or lyases in the destabilization of the biofilm matrix.

Methanosarcina mazei was shown to produce an extracellular disaggregatase that caused their cell aggregates to disperse into single cells (115). The enzyme appeared to be an endopolysaccharide hydrolase that degraded the capsular matrix polymer methanochondroitin to oligosaccharides, suggesting a function for this enzyme in the liberation of cells from cellular aggregates during certain stages in its growth cycle (115). Active detachment of *Streptococcus mutans* cells from biofilms on epon-hyroxylapatite surfaces coated with salivary proteins was observed (116,117); this process was mediated by the action of an endogenous surface protein–releasing enzyme.

All of these observations indicate that enzymes may cause the localized modification of the EPS matrix with concomitant changes in the physical and chemical properties of biofilms such as gelation behavior, ion binding, and mechanical stability. Enzymatic dissolution of the EPS matrix may promote the release of cells, allowing the spread of the biofilm bacteria and the colonization of new environments.

Extracellular enzymes can sometimes also function in biosynthetic processes. Extracellular polysaccharides such as dextrans or levans of *Leuconostoc mesenteroides* and *S. mutans* are polymerized from glucose and fructose, respectively, by extracellular glycosyltransferases (118). In *Azotobacter vinelandii*, extracellular calcium-dependent mannuronan C-5-epimerases catalyze the conversion of mannuronate residues to guluronate residues within homopolymeric mannuronan molecules after their polymerization and secretion to finally yield the extracellular polysaccharide alginate (119).

CONCLUSION

At present, we know that bacteria living in a biofilm mode of growth produce a number of different extracellular enzymes, which most probably also constitute a significant part of the biofilm EPS matrix. So far, our knowledge largely stems from the determination of various enzyme activities in biofilms. Future research will need more integrated experimental approaches that allow for a parallel study of (*1*) the regulation of enzyme gene expression, (*2*) mechanism(s) of enzyme secretion, (*3*) assay of enzyme activities, (*4*) identification of enzyme proteins, and (*5*) analysis of enzyme-polysaccharide interactions. Such approaches should include molecular biological techniques to construct gene fusions and defined enzyme-negative mutant strains to assess the role of extracellular enzymes for the formation, maintenance, and decay of a biofilm. Biochemical, immunological, and biophysical analysis methods, including nuclear magnetic resonance spectroscopy, analytical mass spectrometry, and atomic force microscopy, will help to identify and characterize both the extracellular enzymes themselves and their interaction with other EPS components, particularly polysaccharides. Finally, powerful in situ imaging techniques such as confocal laser scanning microscopy will allow us to understand how bacteria in a biofilm regulate the expression of extracellular enzyme genes, how the corresponding enzymes are secreted, and where they are finally localized in the intact biofilm.

EXTRACELLULAR POLYMERIC SUBSTANCES (EPS): STRUCTURAL, ECOLOGICAL AND TECHNICAL ASPECTS

H.-C. Flemming
J. Wingender
Gerhard-Mercator Universität
Duisburg
Duisburg, Germany

The vast majority of microorganisms on earth live in aggregates such as films, flocs ("planktonic biofilms"), and sludges. An everyday feature of such aggregates is addressed by the term *slime*, which refers to highly, hydrated, thick biofilms. They are slippery and can have different effects. An article on diffusion in biofilms owes its existence to that property and is explicitly acknowledged by the author: "This review was written because of a biofilm that caused me to lose my grip and be carried down a small waterfall. The result was adequate to immobilize me sufficiently and for a long enough period to organize the diverse body of material presented" (1). Microbial aggregates are kept together by means of biopolymers of microbial origin, which are generally called *extracellular polymeric substances* (EPS). The abbreviation "EPS" is used as a more general and comprehensive term for different classes of macromolecules such as polysaccharides, proteins, nucleic acids, (phospho)lipids, and other polymeric compounds that have been found to occur in the intercellular space of microbial aggregates (2). They are responsible for the cohesive forces that keep these aggregates together, namely, biofilms, flocs, and sludge (3). Although somehow inexactly used, the expression "biofilm" is commonly expanded to all these forms of microbial aggregates. The EPS fill and form the space between the cells; they are responsible for the architecture and morphology of the matrix in which the cells live. Thus, the EPS can be considered as the "house" of the microorganisms.

From a technical point of view, biofilms can have both detrimental and beneficial effects. In either case, their EPS play an important role because this is the material that keeps microbial aggregates such as films, flocs, and biological sludge together and attaches biofilms to surfaces. The EPS are the prerequisite for the existence of all microbial aggregates. Although polysaccharides and proteins are the main EPS constituents, in general, only the polysaccharide moiety has been investigated further, whereas the role of proteins still remains largely unclear. To a certain extent, they may be exoenzymes, but it is possible that some of the extracellular proteins have different functions. With regard to the technical aspects, however, the focus of this article is centered mainly on the polysaccharides, for which the largest body of knowledge exists.

COMPOSITION OF EPS

The production of EPS is a general property of microorganisms in natural environments and has been shown to occur both in prokaryotic (Bacteria, Archaea) and in eukaryotic (algae, fungi) microorganisms. Biofilms containing

mixed populations of these organisms are ubiquitously distributed in natural soil and aquatic environments, on tissues of plants, animals, and man as well as in technical systems such as filters and other porous materials, reservoirs, plumbing systems, pipelines, ship hulls, heat exchangers, separation membranes, etc. EPS are mainly responsible for the structural and functional integrity of biofilms and are considered to be the key components that determine the physicochemical and biological properties of biofilms. The EPS form a three-dimensional, gel-like, highly hydrated and often charged biofilm matrix in which the microorganisms are embedded. The EPS create a microenvironment for sessile cells, which is conditioned by the nature of the EPS matrix. In general, the proportion of EPS in biofilms can vary between approximately 50 and 90% of the total organic matter (4,5). The composition of EPS as analyzed largely depends on the method used for isolation. In general, no method has been developed that reliably yields complete extraction of EPS without contamination from intracellular components. Nielsen and coworkers (6) have compared many different methods and the resulting quantities of EPS and give the most effective methods of EPS recovery for different systems. The component of EPS that is best investigated is the polysaccharide moiety (7,8). However, the matrix is composed also of other components such as proteins and nucleic acids (9,10) and lipids (11). Table 1 gives an idea about data from various natural and engineered systems.

The EPS of *Pseudomonas aeruginosa* may serve as an individual example because this is a model organism with which many biofilm investigations have been carried out and the heteropolysaccharide alginate is known to be the main EPS component. The data are summarized in Table 2.

Interestingly, even in *P. aeruginosa* biofilms, more than 45% of the overall protein mass is found in the EPS in which they represent more than 30% of the EPS mass. Using the activity of glucose-6-phosphate dehydrogenase, a strictly intracellular enzyme, as a marker for contamination of intracellular components (13), it could be shown that the cells remained intact during the entire extraction procedure. Thus, the proteins found in the EPS matrix were not of intracellular origin. Preliminary investigations revealed that they are of relatively small molecular mass, that is, between 5,000 and 150,000 Da. Strong protease activity was found, which leads to a rapid breakdown of extracellular proteins (Broekman and coworkers, unpublished results).

Considering the matrix as a whole and in nonlaboratory systems, not only polymers of microbial origin are retained in the matrix, but because of their adhesive properties, particles also can be trapped and integrated, thus influencing the microenvironment and possibly providing nutrients (14,15). Common particulate components of the matrix are debris and humic particles, clay, silt, and calcium sulfate. Substances dissolved in water can also be sorbed into the EPS molecules.

Table 1. Composition of Extracted EPS and Concentration Range of Component

Component	Content in EPS
Polysaccharides	40–95%
Protein	<1–60%
Nucleic acids	<1–10%
Lipids	<1–40%

Table 2. Composition of EPS from Agar-Grown Biofilm of *P. aeruginosa*, Data Related Per Cell

Component	Biofilm (fg/cell)	EPS[a] (fg/cell)	Proportion found in EPS
Total carbohydrates	0.99	0.76	76.0%
Uronic acids (alginate)	0.47	0.40	85.0%
Proteins	0.59	0.27	45.5%

Source: After J. Wingender and coworkers, Biofilms II, in R Doyle, J. N Abelson, and M. I Simon, eds., *Methods in Enzymology*, vol. 336, pp. 302–314 (12).

[a]The EPS components were quantitated in cell-free solutions obtained after removal of biofilm bacteria by centrifugation and membrane filtration of the supernatants.

ECOLOGICAL FUNCTION OF EPS

Adhesion and Cohesion

A major ecological advantage of the biofilm form of life is that consortia of various organisms can establish and maintain their position over a long period of time, compared with the planktonic forms of life. This applies not only to biofilms but also to flocs (16,17) and allows for the development of synergistic relationships between microorganisms. A classical example is the nitrification that takes place in biofilms and allows the spatial closeness of ammonia oxidizers to nitrite oxidizers (17). The EPS molecules, which keep the organisms together and, if they form a biofilm, are responsible for adhesion to a given surface, provide this advantage. There is literally no surface material that cannot be colonized sooner or later, but there are strong differences in the colonization kinetics. Paul and Jeffrey (18) demonstrated that one organism can adhere to hydrophobic and hydrophilic surfaces by means of different EPS components. Busscher and van der Mei (19) have emphasized the role of the forces responsible for the adhesion to surfaces because the entire biofilm can detach if these forces are exceeded either by external shear forces or by a decay of the molecules performing the binding. In some cases, attachment was found to stimulate the synthesis of EPS (20). Both adhesion and cohesion are based on weak physicochemical interactions and not on covalent bonds. Three major kinds of forces can be distinguished, namely, electrostatic interactions, hydrogen bonds, and London dispersion forces (including so-called hydrophobic interactions and van der Waals interactions) (21–23). The individual binding force of any of these interactions is relatively small compared with a covalent C–C bond. However, the total binding energies of weak interactions between EPS molecules multiply with the large number of binding sites available in the macromolecules and add up to bond values exceeding those of covalent C–C bonds. As

mentioned earlier, hydrophilic and hydrophobic properties of EPS have been demonstrated; on the basis of these results, all three types of binding forces are expected to contribute to the overall stability of floc and biofilm matrices, probably to various extents. The result is the formation of a three-dimensional, gel-like network of EPS, whose composition, structure, and properties may vary dynamically because the microorganisms respond to changes in environmental conditions. Entanglements of the macromolecules also contribute to the overall stability but cannot be addressed as binding forces in a strict sense. Their contribution will decrease with the time of stress because the molecules will glide along each other and release the tension.

The matrix network is formed by fluctuating adhesion points and the resulting matrix can behave as a gel as long as a certain shear stress is not exceeded. In this phase, the adhesion points flip back to their original arrangement. Above that point ("yield point"), new adhesion points assemble and the matrix behaves as a highly viscous fluid; fluidized biofilms could be demonstrated by Stoodley and coworkers (23). The mechanical stability of a *P. aeruginosa* biofilm was investigated by a film rheometer in which the force for compression of a flat biofilm is measured. It allows for the determination of an apparent elasticity modulus that can be taken as a parameter for biofilm stability (24). A typical compression diagram for a *P. aeruginosa* biofilm is given in Figure 1.

It could be demonstrated that in this biofilm matrix that is dominated by polysaccharides with carboxyl groups, calcium acts as an important bridging ion that increases the stability of the network significantly. This is also the case for copper and iron but not for magnesium. In such cases, surfactants will not contribute to the dissolution of biofilms. However, if other biopolymers dominate, it is possible that surfactants have a more significant effect. Hydrogen bonds are also part of the overall binding force. They can be influenced by so-called chaotropic agents, which have a high affinity for water, thus interfering with the water shell around the biopolymers, a fact known since protein biochemistry. In some cases, this type of bond dominates the binding forces. The extent to which each bond contributes to the cumulative binding force depends strongly on the nature of the EPS molecules. Because different strains can produce different EPS, the variety is considerable, suggesting that not all biofilms can be dissolved by means of only one cleaning formulation. This coincides well with observations from practice. EPS are not totally insoluble in water. A certain amount of EPS is continuously lost to the water phase. In wastewater effluents, this contributes to important measures of process parameters such as chemical oxygen demand (COD) (25).

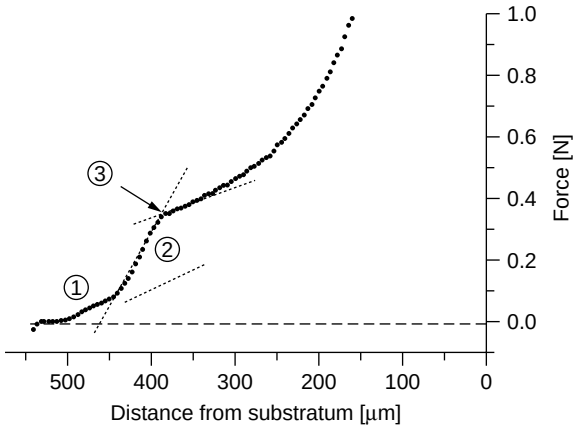

Figure 1. Compression diagram of a *P. aeruginosa* biofilm. 1: adjustment phase, 2: linear phase (apparent elasticity modulus calculated from slope), in which the matrix behaves as a gel, 3: yield point — from here on, the matrix behaves as a highly viscous fluid (after V. Körstgens, J. Wingender, H.-C. Flemming, and W. Borchard, *Water Sci. Technol.* **43**(Suppl. 6), 49–57.)

Matrix Architecture

The architecture of the EPS matrix influences the processes within biofilms profoundly. Costerton and coworkers (26) have shown that pores and channels occur in which convective transport is possible to a certain extent (27). Hoffman and Decho (28) postulated areas of different density of the matrix, which have been observed experimentally. These features result in an extremely heterogeneous structure. This structure is dynamic; Schmitt and coworkers (29) showed in a *Pseudomonas putida* biofilm, which was challenged with toluene, that a rising concentration of toluene caused the formation of more polysaccharide and, furthermore, these compounds contained more carboxyl groups. Heise and Gust (30) showed that the EPS that were formed in the exponential growth phase of a marine isolate were different from those that were formed during the plateau phase. Limitation in nitrogen and phosphorus availability is also of importance for the composition of EPS, but not investigated in depth yet.

An important question is whether the EPS matrix acts as a diffusion barrier. The major component of that matrix is water. It could be shown by NMR measurements that the self-diffusion coefficient of water within the biofilm is practically the same as in free water, and only a very small fraction, that is, less than 0.1%, displays a lower diffusion coefficient (31). There is evidence that noncharged molecules up to a molecular mass of around 10,000 Da experience practically no diffusion limitation. However, if they are consumed, as is the case with oxygen, gradients arise because oxygen consumption by aerobic organisms can occur faster than oxygen can follow the diffusion gradient. This is the manner in which anaerobic zones in biofilm arise and the reason anaerobic organisms can find suitable habitats directly below respiring-aerobic colonies. Charged molecules can interact with charged groups of the EPS, which may slow down their mobility to a certain extent. This makes perfect sense from an ecological point of view because the mobility of nutrients, exoenzymes, and other products is not restricted within the matrix, which is of great importance for cells located in the center of clusters.

Mass transport is influenced not only by the internal architecture of biofilms but also by their interface with the water phase. Some biofilms have a highly filamentous appearance, whereas others are smooth. It is obvious that

a large number of filaments will increase the surface area on which interactions with components of the water phase are possible.

Investigations on the molecular mass of *P. aeruginosa* alginate revealed a mass between 1 and 2 Mio Da [(32), Windhues and coworkers, unpublished results] that corresponds to a length of up to 5 μm of the threadlike molecule. According to a gross estimate, based on a water content of approximately 95% in the EPS matrix, a volume element of 1 μm^2 and 10-nm thickness contains around 10 molecules of alginate and 300 protein molecules with an average molecular mass of 30,000 Da. With these data, realistic size relations of alginate and proteins, such a volume element can be schematically depicted as in Figure 2.

The data given in Table 2 refer to *P. aeruginosa* as a model system. In other systems, other organisms produce other EPS molecules in other concentrations. Because biopolymers generally tend to form hydrogels, the ecological advantage of a matrix can be provided by a wide variety of different EPS. This provides a certain level of protection against enzymes specific for certain types of EPS because, subsequently, organisms producing other types of EPS can protect their matrix against such enzymes. Although alginate is a relatively stable EPS component, proteins obviously undergo a more rapid turnover. The metaphor of the EPS matrix as the "house" of biofilm organisms can be further expanded; polysaccharides may represent "walls, ceilings, and floors," whereas proteins represent the "furniture" of the "house." This system arranges the proteins in proximity to the cells and prevents washing out of exoenzymes that would be easily lost under conditions of convectional flow.

An interesting aspect of the matrix architecture is the general interaction between exoenzymes and exopolysaccharides. Wingender and coworkers (33) showed that the heat stability of an extracellular lipase of *P. aeruginosa* was significantly increased in the presence of bacterial alginate. The same was observed for pH stability. It is quite probable that there are many more interactions of this kind. Such phenomena support the view that the EPS matrix is an important component in the view of biofilms as a tissue, as suggested by Costerton and coworkers (34).

In photosynthetic systems such as microbial mats or stromatolites, the EPS play an important role in light-transmission. At the biofilm surface, the prevailing irradiance and spectral composition were found to be significantly different from the incident light. The EPS were suspected as photon traps. Multiple scattering leads to an intensity maximum for photic light (400 to 700 nm) of approximately 120% of incident quantum irradiation at the biofilm surface. At the bottom of the eutrophic zone in the biofilm, light was attenuated strongly to less than 5 to 10% of the incident surface irradiance (35).

Whether or not EPS are used as a carbon source is still an open discussion. Sutherland (36) has given an excellent overview about polysaccharide lyases, which are capable of cleaving a hexose-1-, 4-, or ß-uronic acid sequence by ß-elimination. This author assumes that EPS usually are not degraded by the organisms that have produced them (37). However, EPS must be biodegradable by other species sooner or later, or else it would persist forever, but it appears as if the polysaccharide matrix is relatively stable and not degraded in the short term, contrary to the EPS protein moiety. Again, this makes sense from an ecological point of view because many different organisms can use the "house" once the energy and carbon is spent to build it, even if this has been performed by a predecessor. Evolution has obviously not generated organisms that readily degrade EPS generally, or else such organisms would have one of the largest collective carbon sources imaginable. The generation of a strain capable of degrading any given EPS matrix in a short time would lead to an environmental disaster because it would destroy natural microconsortia, which perform a crucial role in the biogeochemical cycles of carbon, oxygen, nitrogen, sulfur, and others. It seems as if nature has prevented such a threat by the vast diversity of EPS molecules that all are capable of fulfilling the structural role required for the biofilm mode of life.

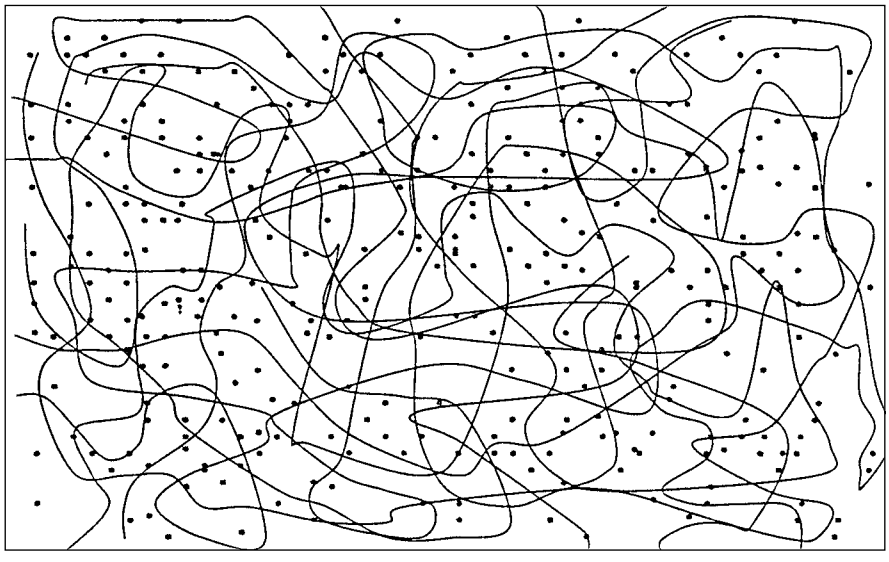

Figure 2. Size relationships of alginate and proteins in a volume element of an area of 1 μm^2 and a thickness of 1 nm, containing 10 molecules of alginate (2 Mio Da) and 300 protein molecules (30 kDa). 95% of the space is filled with water.

Enzyme preparations used for the dispersion of biofilms in biofouling cases (38) are ineffective for these reasons. This has been clearly demonstrated for papermaking processes (39).

EPS IN BIOFOULING, BIOWEATHERING, AND BIOCORROSION

EPS are involved in all kinds of biofouling (40) because they are the material that allows the existence of the microbial aggregates with biofouling properties. For example, the EPS keep biofilms on the surface of heat exchangers, ship bottoms, piping systems, medical devices such as implants, catheters, contact lenses, etc. and provide mechanical stability that is sufficient to withstand shear forces such as those occurring, for example, in pipes and on ship hulls. The damage done by biofouling is very difficult to assess, but even crude estimations lead to many millions of U.S. dollars every year in every industrialized country (41). Examples of problems caused by EPS will be mentioned here. At a first glance, some of them seem almost trivial, but they can result in severe consequences.

Mechanical Stability and Viscoelastic Properties

An important aspect of the EPS matrix is its mechanical stability (22), which has to be overcome by cleaners. Although mechanical cleaning is the most effective method, this is not always applicable, for example, when the biofouled surfaces are not accessible. Then, the cleaner has to interfere with the interactions that cause the cohesion. When biofilms develop on ship hulls or in piping systems, they will increase friction resistance because of the viscoelastic properties of the EPS matrix. This may lead to a substantial pressure drop and increase of energy consumption. Christensen and Characklis (4) assessed that a biofilm of 50-μm thickness, calculated as rigid roughness, can lead to a speed loss of 5 to 12% of a vessel. However, some EPS seem to reduce drag resistance, as is the case for organisms colonizing fast swimming fish (42). Unfortunately, this effect has not yet been transferred to engineered systems. An unexpected and significant increase of water viscosity in water as a result of the sudden increase of EPS production was attributed to phosphate limitation. This caused serious problems in a car production site where water was used for washing off excess spray paint. It could be reversed by external addition of a phosphate source (43).

Water Retention

Ophir and Gutnick (44) have investigated the role of EPS in the protection of biofilm organisms against desiccation. This is probably a very important ecological aspect of EPS because it maintains an environment in which microbial life is possible, but it also has technical relevance. When biological sludge has to be dewatered, for example, sewage or filter sludge, this water has to be removed. This is a significant economical aspect of water retention by EPS, considering the energy required for dewatering and the millions of tons of sewage sludge that have to be dewatered every year. Another more unexpected consequence of water retention is encountered when a biofilm develops on the cells of a battery, causing the battery to lose its charge (41).

Because the EPS are highly hydrated, they change the surface properties if biofilms develop on hydrophobic surfaces. When leaves fall into water, they will initially float because of their hydrophobic surface. After primary colonization, they are covered with a hydrophilic coating and sink. The hydrophobic surfaces (Teflon) of a calcium sulfate precipitation tank in the desulfurization unit of a power plant were colonized by a biofilm. This resulted in massive accumulation of calcium sulfate crystals at the wall, which had to be removed manually (unpubl. pers. obs.).

The water in the EPS dilutes the biopolymers and shields many of the potential binding sites that can bridge the macromolecules by electrostatic interactions, hydrogen bonds, and London dispersion forces (22). When a biofilm starts drying out, more of these binding sites will interact, because the water will not separate them from each other. This leads to a stronger cohesion that can be seen in many scanning electron micrographs in which the EPS appears as a filamentous structure, which is a result of the drying process required for SEM preparation and, thus, an artifact. Also, the adhesion forces to the substratum will greatly increase because they are based on the same mechanisms as in cohesion. This can be commonly observed with the naked eye on the walls of buildings when photosynthetic biofilms dry and curl up. Closer inspection reveals that, for example, on mortar, sand pebbles are removed from the mineral matrix. This is a process that increases weathering of mineral materials.

Heat Transfer

Another effect of the hydrated EPS matrix is that convectional transport of water is only possible to a very small extent when diffusive transport prevails. This is important for heat exchanger technology. Although the heat transfer coefficient for biofilms and water is practically the same (45), the performance of a heat exchanger can be significantly decreased by a biofilm because only diffusional heat transfer is possible. Convectional heat transfer as achieved by the tangential flow of water across the heat exchanger surface is hampered by the biofilm, which subsequently acts as an insulating layer for convection. This leads to significant losses in performance and increased energy demand in heat exchanger technology (41).

Biofouling and Calcium Scaling

In some cases, biofilms result not only in the unwanted accumulation of biological material on surfaces, but also promote the precipitation of minerals, especially calcium carbonate. This leads to mixed biological and nonbiological deposits (46) that are particularly difficult to remove. Calcium precipitation is an important aspect in scaling of surfaces, for example, on heat exchanger surfaces,

on separation membranes, on ship hulls, and oil rigs. This can occur preferentially in the EPS matrix, leading to deposits with remarkable mechanical stability. The same process happens in nature in a geologic scale and leads to the biogeochemical deposition of calcium carbonate (47).

Protection Against Biocides

It is well known that biofilm organisms can tolerate much higher concentrations of biocides and antibiotics than their planktonic counterparts (48,49). This can have extreme consequences. An example is given in Figure 3, which shows a SEM micrograph of a biofilm in a disinfection line constructed from copper. This biofilm developed in the presence of a quaternary ammonium compound. When isolated, the bacteria were sensitive to the biocide (50). It is a common observation that biofilm bacteria lose their biocide tolerance once they are isolated and cultivated in suspension (49).

The phenomenon is still not fully understood (51) and is associated with the EPS matrix but not with phenomena such as diffusion limitation, because diffusion of biocides is not significantly hindered by the matrix. Oxidizing biocides can be consumed by reaction with the EPS, as shown for chlorine by Wingender and coworkers (52) when comparing mucoid and nonmucoid strains of *P. aeruginosa*. However, when hydrogen peroxide was used, the mucoid strain was more susceptible than the nonmucoid strain.

Accumulation of Particles

EPS accumulate particles, which can lead to problems. An example of this is the production of paper, which is a large industry. Here, slime aggregates can develop in which cellulose fibers and organic and inorganic additives stick to surfaces and form slimy aggregates (Fig. 4). These aggregates eventually detach, leading to the formation of holes in the paper and ultimately in significant technical and economical losses (53).

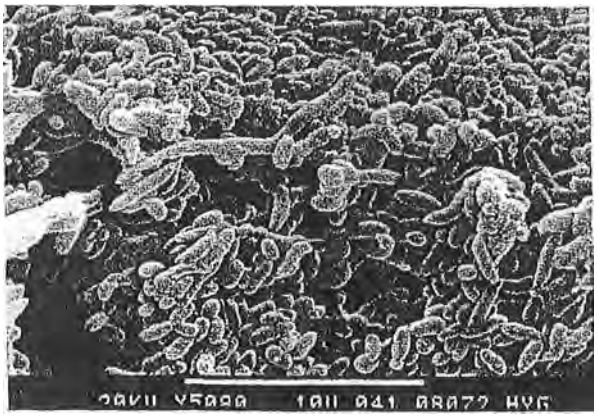

Figure 3. Scanning electron micrograph of a biofilm grown on the surface of a disinfection pipeline made of copper. The organisms have formed the biofilm in the presence of the disinfectant (quaternary ammonium compound) but were sensitive to it when isolated from the biofilm (courtesy of G. J. Tuschewitzki).

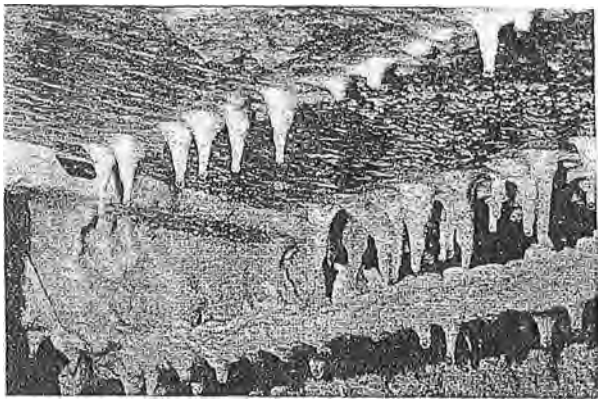

Figure 4. Aggregates of cellulose fibers caused by slime formation in a paper mill (courtesy of J. Klahre). Average length of slime aggregates: 5 to 10 cm.

EPS in Microbially Influenced Corrosion (MIC)

EPS are also involved in microbially influenced corrosion (MIC). In particular, their interaction with iron and other metals can increase the kinetics of metal corrosion as demonstrated by the EPS of sulfate-reducing bacteria (54). Little and coworkers (55) investigated the role of EPS in marine copper corrosion. They found a marine *Oceanospirillum* that produced copious amounts of copper-binding EPS when grown on copper surfaces; this may be a protective mechanism against copper toxicity. In principle, the contribution of EPS to the mechanisms of MIC is based on their binding of metal ions, either by chemical reaction, chelation, or by other ionic binding, and the subsequent dissolution of the metal. Also, EPS support the attachment of active bacteria to the biofilm. The mechanisms of MIC cases in which sulfate-reducing bacteria are not involved, however, the particular role of EPS in corrosion is sparsely investigated, although it must be suspected that they are involved in the corrosion mechanism. It is quite probable that extracellular redox enzymes may play a role in MIC.

SORPTION PROPERTIES

Dissolved substances also can be sorbed by biofilms and in particular by the EPS matrix (56). While some authors point out that the carboxylic groups of polysaccharides bind to heavy metals (57), such as copper (58), uranium (59), and cadmium (60), Wuertz and coworkers (61) could show that zinc and nickel accumulate on the cell surfaces in sewage sludge. In this case, the EPS tightly bound to the cell surface may be the major binding partners; however, this has not been investigated in detail. Decho (14) speculates that the sorption of heavy metals is part of a protection strategy against toxic effects. Not much is known about the sorption of anions but it can be expected that they are accumulated in the matrix, compared to the bulk-water phase. Although the matrix

is a hydrogel and as such hydrophilic, it must contain hydrophobic areas. This has been shown by sorption experiments with benzene, toluene, and xylene into sewage sludge. They were clearly accumulated in the EPS fraction (62). The exact sorption sites of such compounds in the EPS matrix is still unclear. Interestingly, biofilms can respond dynamically to sorption processes (63), as demonstrated earlier with the various responses of a *P. putida* biofilm to toluene (29).

Whether particle binding belongs to the aspects of sorption may be doubtful, but particles can be retained by biofilms because of the "sticky" properties of the EPS. Not only biodegradable particles, which would provide nutrients, but also sand grains can attach to biofilms because of adhesion of EPS molecules. This is an important feature in a geologic scale in diagenesis of sediments (64), mainly because of diatom EPS (65). The transport of sand in sediments is also influenced by EPS, as shown by Dade and coworkers (66) for the polysaccharides of the benthic marine bacterium, *Alteromonas atlantica*. This observation is important, for example, for modeling the transport of sediments in rivers. Also, the hydraulic conductivity of sand is influenced by EPS (67), an effect that is also known for other materials and can lead to clogging of filters (68).

EPS IN BIOTECHNOLOGY

Biotechnological applications of EPS have focused so far only on polysaccharides. Some EPS are used for increasing the viscosity of technical materials and food; they are also used as biosurfactants. Selected EPS hold a potential for medical purposes and for biologic glue. Sutherland (69) has compiled a comprehensive list of the uses of microbial exopolysaccharides, for example, in the food industry, as additives for oil-drilling emulsions and others. In most cases, EPS are incorporated to alter the rheological properties of the water present and, thus, change the texture of the product. Advantage is also taken of the ability of some mixtures of polysaccharides to exhibit synergistic gelling, which allows the application of smaller amounts of EPS. Associated with the readily measurable properties such as viscosity, others such as "mouth feel," which are more difficult to define, are of practical importance. Xanthan, a polysaccharide produced by *Xanthomonas campestris*, is used to maintain the consistency of some toothpastes. Other polysaccharides such as gellan or the synergistic mixture of xanthan-galactomannan were recommended for further use in the food industry. Polysaccharide lyases, that is, extracellular proteins, were suggested for biotechnological use, for example, to degrade the walls of marine algae in protoplast production (70). Sutherland (71) has listed established applications of microbial extracellular polysaccharides (Table 3).

EPS Used for Metal Removal

EPS were also used for use in metal removal from water. Because the EPS from *Bacillus megaterium* bind large amounts of copper, they were suggested for use in copper removal (72). A marine bacterial EPS exhibited a high affinity for cadmium (60) and holds potential for specific cadmium removal. Algal EPS are used for the same purpose in terms of natural attenuation of aqueous metal contamination by an algal mat (73). Guezennec and coworkers (74) isolated uronic-rich EPS with a potential for biotechnological usage for metal removal from deep-sea organisms. Potential and limits of this approach has been reviewed by Geesey and Jang (75).

EPS as Biosurfactants

The properties and uses of EPS as biosurfactants have been intensively investigated (76). Such organisms can be preferentially isolated from oil production

Table 3. Some Examples for Established Applications of Microbial Extracellular Polysaccharides

Properties	Use	Polymer
Biological	Antitumor agents	β-D-Glucans
	Eye and joint surgery	Hyaluronic acid
	Heparin analogs	*Escherichia coli* K 5 EPS
	Wound dressings	Bacterial cellulose
Chemical	Enzyme substrates	*E. coli* K 4 and K 5 EPS
	Oligosaccharide preparation	Curdlan, pullulan, scleroglucan
Physical		
Emulsion stabilization	Foods, thixotropic paints	Xanthan
Fiber strength	Acoustic membranes	Bacterial cellulose
Film formation	Food coatings	Pullulan
Flocculant	Water clarification, ore extraction	Various
Foam stabilization	Beer, fire-fighting fluids	Xanthan
Gelling agents	Cell and enzyme technology, foods	Gellan
Hydrating agent	Cosmetics, pharmaceuticals	Hyaluronic acid
Crystal-formation inhibitor	Frozen foods, pastilles, sugar syrups	Xanthan
Viscosity control	Oil-drilling 'muds', jet printing	Xanthan
Suspending agent	Food, paper coatings	Xanthan

sites or spills (77). Interestingly, some bacteria seem to use surface-active EPS to facilitate their transport through sandy soil (78). Some examples for surface-active EPS of technical relevance are given in Table 4 (79). These EPS may be used in tertiary oil production to mobilize residual oil from surfaces and capillaries.

OUTLOOK

It is justified to speculate that the functions of the EPS for the ecology of microbial aggregates is much more complex than it appears at a first glance. Possibly, the matrix is not just an arrangement of randomly associated biopolymers but is synthesized and degraded in a way that supports the life of the organisms in such aggregates. It is evident that the matrix is heterogeneous in composition and architecture and over time, represents a dynamic system. Possibly, an important parameter such as cell surface hydrophobicity may be regulated by surface-active EPS as suggested by Neu (76). Recent research indicates that alasan, a surface-active exocellular emulsifier produced by a strain of *Acinetobacter radioresistens* could be transferred horizontally to *A. calcoaceticus* when both strains were grown together, changing the surface properties of the latter (80). The EPS matrix and the properties that it determines represent important and complex aspects when considering biofilms as a first step to the evolution of multicellular organisms.

The use of EPS as food additives is promising but strongly restricted by legal regulations. Thus, it may be difficult to introduce new EPS because of the lengthy and costly registration procedure. However, as additives for paints and other technical materials, EPS still hold a potential that is not yet exploited. In addition, EPS may be useful as biologic glue. The role of EPS in biofouling and biocorrosion is also worth further investigating. In particular, the adhesive and cohesive forces play a fundamental role when biofilms have to be removed (22). The use of cleaners and biodispersants is still based on empirical experience and plausible considerations but few fundamental researches. Here, further progress may result in more effective approaches and concepts for prevention and removal of biofilms.

Table 4. Some Microbial Biosurfactants

Biosurfactant	Source Organism
Glycolipids	*Pseudomonas aeruginosa*
Lipopeptides	*Bacillus. licheniformis*
Fatty acids	*Candida lepus*
Emulsan	*Acinetobacter calcoaceticus*
Biodispersan	*Acinetobacter calcoaceticus*
Liposan	*Candida lipolytica*

EXTREMOPHILES: LIFE IN EXTREME ENVIRONMENTS

Costanzo Bertoldo
Ralf Grote
Garabed Antranikian
Technical University
Hamburg-Harburg
Hamburg, Germany

Extremophiles are organisms that can survive and grow optimally under extreme conditions. MacElroy first introduced the term *extremophile* in 1974 (1), and to define it accurately, it is necessary to define a nonextreme or normal environment. Although there are no strict definitions of a "normal" environment, there is a general view about most of the important physical and chemical factors available under these conditions. A normal environment has a temperature between 10 and 40 °C, a pH from 5.0 to 8.0, a pressure of 1 atm, and a salinity corresponding to the salinity of freshwater or of seawater (up to 30 g/l) (2). Environments in many parts of the world are considered extreme. These include geothermal environments, polar regions, acid and alkaline springs, and cold, pressurized depths of the oceans. It can be speculated that the species diversity decreases when environmental stress increases. As conditions become increasingly demanding, extreme environments become exclusively populated by microorganisms belonging to the bacterial and archaeal domains (prokaryotes). It is very likely that higher organisms are unable to survive under extreme conditions because of their cellular complexity. The realization that extreme environments harbor a different kind of prokaryotic lineage has resulted in a complete reassessment of our concept of microbial evolution and has given considerable impetus to research on extremophiles (3).

Enzymes and proteins that work under extreme conditions mediate metabolic processes and specific biological functions of these microorganisms. Consequently, constant increasing scientific interest has been aroused not only because these microorganisms grow in some of the harshest environments on Earth but also because they provide a valuable source of unique enzymes. Modern biotechnology, which provides a whole new repertoire of methods and products, still tries to mimic nature, thus demanding continuous efforts in the isolation and characterization of novel microorganisms. This article focuses on microorganisms that live under extreme conditions in terms of high and low temperature, extremes of pH, and high salinity. Such extremophiles can be found in terrestrial and marine environments, including the polar regions, solfataric fields, and soda lakes as well as in shallow and abyssal hydrothermal vent systems. Examples of microorganisms representative of each of these extreme habitats are given in the text that follows.

MICROORGANISMS LIVING AT LOW TEMPERATURE

Temperatures in many parts of the world seldom or never reach above 5 °C. This is mainly because almost 70% of the Earth is covered by deep oceans that can be considered as cold environments. Furthermore, the polar regions provide a permanently cold terrestrial habitat that is surrounded by an aquatic belt of melting ice. Numerous microorganisms, in particular bacteria, yeasts, unicellular algae, and fungi, have successfully colonized cold environments. These microorganisms, generally defined as "psychrophiles" are able to grow at temperatures close to 0 °C and have developed various adaptations in the form of finely tuned structural changes at various metabolic and cellular levels, for example, adaptations of their enzymes, enabling them to compensate for the deleterious effects of low temperature. Most of the cold-adapted microorganisms have been characterized from the Arctic and Antarctic seawaters; the latter not only are a cold habitat (around −1 °C) but also exert a high selective pressure on endemic microorganisms because the temperature of their environments is constant. Despite the harsh conditions, the density of bacterial cells in the Antarctic oceans is as high as the density reported for temperate waters (4). The microorganisms that are able to grow at or close to the freezing point of water can be divided into two main groups: psychrophiles and psychrotolerants. Pyschrophilic microorganisms are more strictly defined by an optimum temperature for growth of about 15 °C, a maximum growth temperature of about 20 °C, and a minimum temperature for growth at 0 °C or lower. In comparison, psychrotolerant organisms generally do not grow at 0 °C but do grow at 3 to 5 °C, and have optimum and maximum growth temperatures above 20 °C (4). In general, psychrophiles have significantly narrower growth temperature ranges and lower optimum/maximum growth temperatures compared with psychrotolerant microorganisms. Psychrophiles can be found in permanently cold environments such as the deep-sea, glaciers, and mountain regions, in soils, and in fresh or saline waters associated with cold-blooded animals such as fish or crustaceans. The first psychrophilic bacteria were isolated from preserved fish by Forster in 1887 (2).

Recently, a systematic investigation has been carried out to understand the rules governing the molecular adaptation of psychrophiles to low temperatures (5). These fundamental aspects are closely associated with a strong biotechnological interest aiming at the exploitation of these microorganisms and their cell components such as membranes, polysaccharides and enzymes. The specific activity of wild-type, cold-adapted enzymes and some of their recombinant forms produced by Antarctic and Arctic microorganisms have been determined for several enzymes, including alcohol dehydrogenase, α-amylase, aspartate transcarbamilase, metal-protease, citrate synthase, subtilisin, triose phosphate isomerase, and xylanase (5). In general, cold-adapted enzymes have higher specific activity at low and moderate temperatures than that of their mesophilic counterparts, and are inactivated easily by a moderate increase in temperature. These properties can be extremely useful in various applications. The possible applications include the use of enzymes (proteases, lipases, and cellulases) in detergents (cold washing), as flavor-modifying agents for food processing, such as cheese manufacture, meat tenderizing, and

lactose hydrolysis (5). Table 1 presents some representatives of psychrophilic microorganisms and their optimum growth conditions.

MICROORGANISMS LIVING AT HIGH TEMPERATURE

Microorganisms that are adapted to grow optimally at high temperatures (60 to 108 °C) have been isolated so far from high-temperature terrestrial and marine habitats (2,6). The most common biotopes are geothermally heated hydrothermal vent systems such as solfataric fields, neutral hot springs, and submarine hot vents. Submarine hydrothermal systems are situated in shallow or abyssal depths. They consist of hot fumaroles, springs, sediments, and deep-sea vents with temperatures up to 400 °C ("black smokers") (7). Shallow marine hydrothermal systems are located for instance at the beaches of Vulcano, Naples, and Ischia (Italy), Sao Miguel (Azores), and Djibouti (Africa). Examples of deep-sea hydrothermal systems are the Guaymas Basin (depth 1,500 m) (8), the East Pacific Rise (depth 2,500 m) (9), both off the coast of Mexico, the Mid-Atlantic Ridge (depth 3,700 m) (10), and the Okinawa Trough (depth 1,400 m) (11). Because of their ability to convert volcanic gases and sulfur compounds at high temperatures, hyperthermophilic communities living in such hydrothermal vents are expected to play an important role in marine ecological and geochemical processes (12). Shallow-sea and deep-sea hydrothermal systems harbor members of the genera *Igneococcales*, *Thermococcales*, *Methanococcales*, *Archaeoglobales*, and *Thermotogales*. To date, members of the genus *Methanopyrus* have been found only at greater depths, whereas *Aquifex* spp. have been isolated exclusively from shallow hydrothermal vents (7). Recently, biotopes of extreme and hyperthermophilic microorganisms were discovered in deep, geothermally heated oil reservoirs around 3,500 m below the bed of the North Sea and the permafrost soil of North Alaska (13,14).

Table 1. Microorganisms Living at Low or Elevated Temperatures

Microorganism	Optimum Growth Temperature (°C)
Psychrophilic Microorganisms	
Vibrio spp.	15–20
Micrococcus criophilus	15–20
Arthrobacter glacialis	15–20
Vibrio psychroerythreus	15–20
Aquaspirillum articum	15–20
Shivanella frigidimarina	15–20
Moderate Thermophiles (50–60 °C)	
Bacillus acidocaldarius	50
Bacillus stearothermophilus	55
Extreme Thermophiles (60–80 °C)	
Thermus aquaticus	70
Thermoanaerobacter ethanolicus	65
Clostridium thermusulfurogenes	60
Fervidobacterium pennivorans	75
Hyperthermophiles (80–110 °C)	
Thermotoga maritima	90
Aquifex pyrophilus	85
Archeoglobus fulgidus	83
Methanopyrus kandleri	88
Sulfolobus sulfataricus	88
Thermococcus aggregans	88
Pyrobaculum islandicum	100
Pyrococcus furiosus	100
Pyrodictium occultum	105
Pyrolobus fumarii	106

Microorganisms capable of growing optimally between 50 and 60 °C are designated as moderate thermophiles. Most of these microorganisms belong to many different taxonomic groups of eukaryotic and prokaryotic microorganisms such as protozoa, fungi, algae, streptomycetes, and cyanobacteria, which comprise mainly mesophilic species. It can be assumed that moderate thermophiles, which are phylogenetically closely related to mesophilic organisms, may be secondarily adapted to life in hot environments. Extreme thermophiles, which grow optimally between 60 and 80 °C, are widely distributed among the genera *Bacillus*, *Clostridium*, *Thermoanaerobacter*, *Thermus*, *Fervidobacterium*, *Thermotoga*, and *Aquifex* (Table 1). Conversely, most of the hyperthermophiles grow optimally between 80 and 108 °C (15). Interestingly, and as shown in Figure 1, the majority of the hyperthermophiles isolated to date belong to the archaeal domain of life and so far no eukaryotic organism has been found that can grow at the boiling point of water. A 16S rDNA-based universal phylogenetic tree (16,17) shows a tripartite division of the living world consisting of the domains Bacteria, Archaea, and Eukarya (Fig. 1). The archaeal domain consists of two major kingdoms: the Crenarchaeota (some genera are *Sulfolobus*, *Picrophilus*, *Pyrodictium*, *Pyrolobus*, *Pyrobaculum*, and *Thermoproteus*) and the Euryarchaeota, which include a number of hyperthermophiles (some genera are *Thermococcus* and *Pyrococcus*), methanogens (e.g., *Methanococcus*, *Methanobacterium* and *Methanosarcina*), sulfate-reducers (e.g., *Archaeoglobus*) and halophiles (including genera such as *Halobacterium* and *Halococcus*). Short phylogenetic branches indicate a rather slow evolution. Deep branching points are evidence for early separation of the two groups. The separation of the Bacteria from the Eukarya-Archaea lineage is the deepest and earliest branching point known so far (7). Hyperthermophiles are represented among all the deepest and shortest lineages, including the genera *Aquifex* and *Thermotoga* within the Bacteria, and *Pyrodictium*, *Pyrobaculum*, *Thermoproteus*, *Desulfurococcus*, *Sulfolobus*, *Methanopyrus*, *Pyrococcus*, *Thermococcus*, *Methanococcus* and *Archaeoglobus* within the Archaea (Fig. 1; Table 1).

The relative abundance of Archaea and Bacteria in high-temperature environments was, until recently, mainly studied by cultivation-based techniques. Because of the frequent isolation of Archaea from these habitats, it was assumed that Archaea dominate the high-temperature biotopes (18). Recently, the application of molecular-biological methods revealed a quite different picture. Slotbot hybridizations of rRNA-utilizing oligonucleotide probes targeting the 16S rRNA of Archaea and Bacteria revealed that Bacteria are the major component of the microbial community along a thermal gradient at a

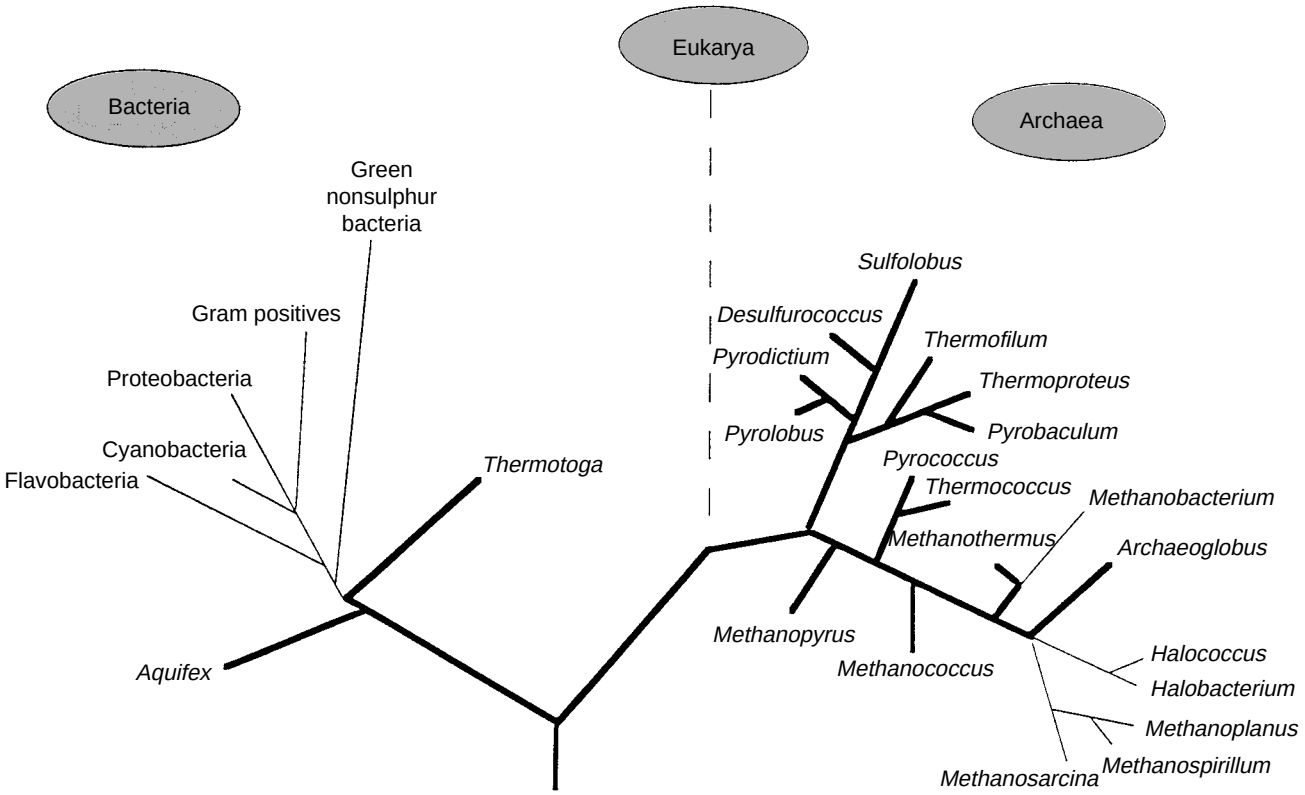

Figure 1. Phylogenetic tree of the three domains of life. Hyperthermophilic species are highlighted by bold branches. Branching order and branch lengths are based on 16S/18S rDNA sequence comparisons. The tree is a modified version of that from Blöchl and coworkers (18).

shallow submarine hydrothermal vent near Milos Island (Greece) (19). Bacteria made up at least 78% (mean 95%) of the prokaryotic rRNA. Along the steepest temperature gradient, the proportion of archaeal rRNA increased. Nevertheless, even in the hottest sediment layer, archaeal rRNA made up only around 12% of the prokaryotic rRNA. These results suggest that Archaea may generally be of lower abundance in hot environments than could be assumed from cultivation-based experiments. However, the factors that allow Bacteria to dominate in high-temperature habitats that were once believed to be the realm of Archaea remain unknown.

To date, most of the extreme thermophiles and hyperthermophiles isolated were investigated in the laboratory, and little information is available on the growth behavior in their ecosystems. In addition, a large number of hyperthermophiles remain undiscovered and continue to thrive in various ecosystems.

Although most of the hyperthermophiles appear as single cells, there have been some reports on the existence of multicellular forms during growth at elevated temperature. This has been observed in the case of *Thermococcus aggregans*, *Staphylothermus marinus*, *Pyrodictium occultum*, and *P. abysii*. The formation of large, grape-shaped cell aggregates ("giant cells") that can reach up to 1.5 mm in size, are frequently observed in *Staphylothermus marinus*. *Thermococcus aggregans*, recently isolated from a hydrothermal vent site at the Guaymas Basin was found to form aggregates consisting of up to 50 cells, particularly when cultures were grown on media containing yeast extract/peptone and elemental sulfur (7).

Of interest are the two archaeal strains *P. abysii* and *P. occultum* that grow optimally at 100 °C and build a network structure in which the cells are connected. *Pyrodictium occultum* is able to grow at temperatures up to 110 °C and can even survive one hour of autoclaving at 121 °C (18). A network of hollow tubules, therefore called cannulae, which measures about 30 nm in diameter, connects the coccoid-shaped cells of *P. occultum*. Attempts to grow *P. abyssii* in fermentors under agitation were not successful because of the instability of the network structure. It is still an open question whether these observations, that is, the network formation and aggregation, are due to specialized laboratory conditions or if they are a phenomenon that can be observed in nature (21).

Most of the microorganisms mentioned above can be found in low-salinity and submarine environments and are strict anaerobes. Terrestrial solfataric field as can be found in Italy or Iceland harbor members of the genera *Pyrobaculum*, *Thermoproteus*, *Thermofilum*, *Desulfurococcus*, and *Methanothermus*. *Pyrobaculum islandicum*, and *Thermoproteus tenax* are able to grow chemolithoautotrophically, gaining energy by anaerobic reduction of S^0 by H_2 (7,18). In contrast to these strictly anaerobic microorganisms, *Pyrobaculum aerophilum* and *Aeropyrum pernix* are able to use oxygen as final electron acceptor.

Methanothermus fervidus, is highly sensitive to oxygen and can only survive in low redox environments at temperatures between 65 and 97 °C. Some microorganisms from marine environments, such as members of the genera *Archaeoglobus*, *Methanococcus*, and *Methanopyrus* are able to grow chemolithoautotrophically, gaining energy by the reduction of SO_4^{2-} by H_2 (*Archaeoglobus lithotrophicus* and *A. fulgidus*) or by the reduction of CO_2 by H_2 (*Methanococcus jannaschii*, *Methanopyrus kandleri*). It is noteworthy that the microbial production of methane has a significant impact on the global budget of trace gases (e.g., H_2, CO_2) that are discussed to influence the world's climate. Other members of the hyperthermophilic genera *Staphylothermus*, *Pyrococcus*, *Thermococcus*, and *Pyrodictium* are adapted to marine environments. Most of them gain energy by fermentation of polysaccharides, peptides, amino acids, and sugars (22).

Among the bacterial domain of life, members of the genera *Aquifex* and *Thermotoga* represent the deepest phylogenetic branches. Cells of *Thermotoga* are rod-shaped and possess a characteristic sheath-like structure, the so-called toga, which surrounds the cells and forms terminal "balloons." Within this genus, *Thermotoga maritima* and *T. neapolitana* are the most thermophilic species, with maximal growth temperature of about 90 °C. Microscopic observations showed that depending on the nutritional conditions, few cells could grow in the same toga forming a filamentous structure (7). So far, *Aquifex pyrophilus* is the most thermophilic species among the Bacteria (T_{max} 95 °C). This strain grows strictly chemolithoautotrophically under microaerophilic conditions with hydrogen or sulfur as electron donors, forming H_2O and H_2SO_4, respectively (18).

MICROORGANISMS GROWING AT EXTREMES OF PH

Solfataric fields are the most important biotopes of microorganisms that prefer to live under both thermophilic and acidic conditions. Solfataric soils consist of two different layers that can be easily distinguished by their characteristic colors: the upper, aerobic layer has an ochre color because of the presence of ferric iron, and the layer below, which is anaerobic, appears rather blackish-blue as a result of the presence of ferrous iron. According to the chemical parameters of the two layers, different kinds of microorganisms can be isolated from these habitats. *Thermophilic acidophiles* belonging to the genera *Sulfolobus*, *Acidianus*, *Thermoplasma*, and *Picrophilus*, with growth optima between 60 and 90 °C and pH 1.0 to 5.0 are commonly found in the aerobic upper layer, whereas slightly acidophilic or neutrophilic anaerobes such as *Thermoproteus tenax* or *M. fervidus* can be isolated from the lower layer. Species of Thermoplasma (growth optima: pH 2 and 60 °C) have been found in hot springs, solfataras, and coal refuse piles (23). Their closest known phylogenetic relatives, also found in solfataras, are species of the genus *Picrophilus*, which are so far the most extreme acidophiles, with growth optima close to pH 0 (24). *Picrophilus oshimae* and *P. torridus* are both aerobic, heterotrophic Archaea that grow optimally at 60 °C and pH 0.7 and utilize various polymers such as starch and proteins as carbon source (Table 2a).

Table 2. Microorganisms Growing at Extreme pH Values

	Optimum Growth	
	(°C)	pH
a) Acidophilic microorganisms		
Sarcina ventriculi	37	4.0
Thiobacillus ferrooxidans	37	2.5
Alyciclobacillus acidocaldarius	55	2.0–6.0
Picrophilus oshimae	60	0.7
Picrophilus torridus	60	0.7
Thermoplasmaacidophilum	60	2.0
Sulfolobus acidocaldarius	75	2.5
Acidianus infernus	75	2.0
b) Alkaliphilic microorganisms		
Many cyanobacteria	20–37	6.0 to 8.0
Spirulina spp.	37	8.0 to 10.0
Chromatium spp.	37	8.5
Bacillus spp.	37	11.5
Anaerobranca gottschallki	55	9.0
Thermococcus alcaliphilus	85	9.0
Thermococcus acidoaminivorans	85	9.0

Members of the genus *Sulfolobus* are strict aerobes growing either as autotrophs, heterotrophs, or facultative heterotrophs (6,24). During autotrophic growth, S^0, S^{2-}, and H_2 are oxidized to sulfuric acid or water as end products. *Sulfolobus metallicus* and *S. brierley* are able to grow by the oxidation of sulfidic ores. A dense biofilm of these microorganisms is responsible for the microbial ore leaching process in which heavy metal ions such as Fe^{2+}, Zn^{2+}, and Cu^{2+} are solubilized. During heterotrophic growth, a range of sugars and proteinaceous substrates are utilized (25). A spore-forming sulfur-oxidizing thermoacidophile, designated *Thiobacillus caldus* (T_{max} 55 °C), was isolated by Hallberg and Lindström (26). It seems likely that *T. thiooxidans*, a sulfur-oxidizing mesophilic acidophile, would have been supplanted by the similar but more thermotolerant *T. caldus* in which the temperature exceeded 35 to 40 °C. Other hyperthermophilic acidophiles have been affiliated with the genera *Metallosphaera* (growth range: 50 to 80 °C, pH 1 to 4.5), *Acidianus* (growth range: 60 to 95 °C, pH 1.5 to 5), and *Stygioglobus* (growth range: 57 to 89 °C, pH 1 to 5.5) (3).

Alkaliphiles

Alkaliphilic microorganisms are widely distributed throughout the world. They have been found in carbonate-rich springs and alkaline soils, where the pH can be 10.0 or even higher, although the cytoplasmic pH is maintained around 8.0. In such places, several species of cyanobacteria are normally abundant and provide organic matter for diverse groups of heterotrophs, the best known of which are alkaliphilic *Bacillus* spp. Alkaliphiles require alkaline environments and sodium ions not only for growth but also for sporulation and germination. Sodium ion-dependent uptake of nutrients has been reported in alkaliphiles.

Many alkaliphiles require various nutrients for growth; few alkaliphilic *Bacillus* strains can grow in simple minimal media containing glycerol, glutamic acid, and citric acid. In general, cultivation temperature is in the range of 20 to 55 °C. Many haloalkaliphiles isolated from alkaline hypersaline lakes can grow in alkaline media containing 20% NaCl. The soda lakes in the Rift Valley of Kenya and similar lakes found in a few other places on earth are highly alkaline, with pH values between 11.0 and 12.0, and represent a typical habitat where alkaliphilic microorganisms can be isolated. Thermophilic anaerobic spore-forming alkaliphiles, such as thermoalkaliphilic *Clostridia*, have been isolated from sewage treatment plants (3). Very recently, two new, moderately thermoalkaliphic microorganisms, *Anaerobranca gottschalkii* and *Anaerobranca horikoshii*, have been isolated from Lake Bogoriae in Kenya and from Yellowstone National Park, respectively. The new isolates represent a new line within the Clostridium/Bacillus subphylum. The only archaeal thermoalkaliphiles identified to date are *Thermococcus alcaliphilus* and *Thermococcus acidoaminivorans*, both growing optimally at 85 °C and pH 9.0. (Table 2b). These alkaliphiles are unique microorganisms with great potential for biotechnological exploitation. The main industrial application of alkaliactive enzymes is in the detergent industry, where they account for approximately 30% of total worldwide enzyme production. Alkaline enzymes have also been used in the hide-dehairing process, where dehairing is carried out at pH values between 8.0 and 10.0 (27).

MICROBIAL LIFE AT ELEVATED SALT CONCENTRATIONS

The halophiles comprise Bacteria and Archaea that grow optimally in NaCl concentrations above those of seawater (>0.6 M NaCl). In general, halophilic microorganisms are classified as moderate halophiles if they can grow in salt concentrations between 0.85 and 1.7 M NaCl and as extreme halophiles if they require NaCl concentrations above 1.7 M for growth (28). Halophiles have been mainly isolated from saline lakes, such as the Great Salt Lake in Utah (salinity >2.6 M) and from evaporitic lagoons and coastal salterns with NaCl concentrations between 1 and 2.6 M (29). Saline soils have been less well explored. Bulk salinity measurements of 1.7 to 3.4 M NaCl have been reported for saltern soils (28). Saline soils constitute less stable biotopes than hypersaline waters since they are subjected to periodic and significant dilution during rainy periods. It can be assumed that microbial survival under these oscillating conditions would be even more demanding. There is no doubt that almost all hypersaline habitats harbor significant populations of specifically adapted microorganisms. However, it remains unclear what substrates for growth might be available in these biotopes. Hypersaline lakes often contain up to 1 g/L of dissolved organic carbon. In many of these lakes, primary producers such as cyanobacteria, anoxygenic phototrophic bacteria, and algae may be the main source of organic compounds (29,30). It has also been speculated that organic compatible solutes produced by many of the phototrophs as a means of counterbalancing the osmotic stress contribute significantly to the input of carbon sources. It is noteworthy that, despite the typically large surface-to-volume ratios, hypersaline environments are low in dissolved oxygen (<2 mg/L) and might be essentially anaerobic (for reviews, see 29,31).

In a study of aerobic heterotrophs in marine saltern, it has been shown that bacterial halophiles were dominant up to 2 M NaCl. Above this concentration, archaeal halophiles become predominant, almost to the exclusion of bacteria (32). Halophilic primary producers mainly belong to the cyanobacteria and anoxygenic phototrophic sulfur bacteria. The former often thrive in eutrophic salterns, in which they form large, floating mats. The latter group, on the other hand, grows either in anaerobic sediments or in the water column where they are responsible for the characteristic red color of highly saline habitats (33). The range of heterotrophic Bacteria comprises proteobacteria, actinomycetes, and gram-positive rods and cocci. Fermentative anaerobes as well as sulfur oxidisers, sulfate reducers, and nitrate reducers are also present and give rise to the assumption that all kinds of metabolic features may be found in high-salinity environments (Table 3). Halophilic bacteria do not belong to one homogeneous group, but rather fall into many taxa in which the ability to grow at high salt concentrations is a secondary adaptation.

The term "halobacteria" refers to the red-pigmented, extremely halophilic Archaea, that is, members of the family *Halobacteriaceae*, the only family in the order Halobacteriales (29,31). Most halobacteria require 1.5 M NaCl to grow and to retain the structural integrity of the cell. Halobacteria can be distinguished from halophilic bacteria by their archaeal characteristic, in particular the presence of ether-linked lipids (34). Most halobacteria are colored red or orange because of the presence of carotenoid pigments, but some species are colorless, and those with gas vesicles form opaque, white, or pink colonies. A purple hue may be seen in halobacteria that form the bacteriorhodopsin-containing purple membrane (29). Halobacteria are the most halophilic organisms known, and form the dominant microbial population when hypersaline waters approach saturation (33). Interestingly, the reddening caused by halobacterial blooms has an impact on the evaporation rates in the saltern. It is known that the carotenoid pigments of halobacteria absorb solar radiation,

Table 3. Salt Requirements of Halophilic Microorganisms

Halophilic Microorganism	Salinity (M NaCl) for Growth		
	Minimum	Optimum	Maximum
Dunaliella spp.	0.3	–	5.0
Clostridium halophilum	0.15	0.6	6.0
Haloanaerobium praevalens	0.8	2.2	4.3
Halobacterium spp.	–	2.0	5.5
Halobacterium denitrificans	1.5	2.5	4.5
Haloferax vulcanii	1.0	1.5	3.0
Methanohalobium evestigatum	–	–	4.3

thus increasing the ambient temperature and evaporation rates.

Halobacteria form a diverse group with at least nine major taxa that have all diverged from a common ancestor at about the same time (35,36). In general, soda lakes harbor a restricted range of alkaliphilic taxa characterized by a requirement for high pH and high salt levels, whereas neutral hypersaline environments harbor a wider range of neutrophilic taxa (29). It has been shown recently that neutral hypersaline waters all over the world at saturation point for NaCl harbor populations of virtually identical halobacteria belonging to the genera *Haloarcula*, *Halobacterium*, and *Halorubrum* (37). Conversely, salted foods invariably enrich for the proteolytic *Halobacterium salinarium*. Representative strains are presented in Table 3.

CONCLUSION

Extremophiles are unique microorganisms that can survive in ecological niches such as high and low temperature, extremes of pH, high salt concentration, and high pressure. These microorganisms, which belong to the archaeal and bacterial domains, produce stable biocatalysts and organic compounds that function under extreme conditions. To obtain detailed insight in the molecular properties of the enzymes and genes, further research is required. There is little doubt that extremophiles will supply novel products in the near future that will be exploited by the biotechnological industries.

FATE AND MICROBIAL DEGRADATION OF HALOGENATED AROMATICS

PETER ADRIAENS
The University of Michigan at Ann Arbor
Ann Arbor, Michigan

ANDREI L. BARKOVSKII
Georgia College and State University
Milledgeville, Georgia

During the last 30 years, significant strides have been made in cataloguing the environmental distribution and fate of halogenated aromatic compounds in soils, freshwater, estuarine, and marine environments, and the atmosphere. Whereas the main areas of emphasis have been in qualitative aspects of their formation, photolytic degradation, and microbial mineralization, transformation, and humification reactions, the quantitative aspects of microbial contributions to mitigate aryl halide fluxes in the various environmental compartments have had limited attention. Thus, most information on the microbial degradation of this class of compounds should be considered assessments of microbial potential, rather than expressed environmental activity. Nevertheless, a fundamental understanding of the relative contributions of intrinsic chemical reactivity versus those expressed in microbial systems provides paramount guidance to applied areas of pollution prevention or green chemistry, environmental forensics, and engineering methodologies aimed at stimulating microbial activity for end-of-pipe remedial approaches. This contribution will explore aspects of the global distribution of aryl halides in light of thermodynamic and molecular properties, microbial fate mechanisms, and adaptive genetic strategies affecting the reactivity of this class of compounds

BACKGROUND

Improvement by orders of magnitude in the sensitivity of analytical instrumentation, and innovative analytical methodologies, coupled to our increased knowledge on the pathways of degradation, have allowed a better understanding and interpretation of the fate and distribution of halogenated aromatic compounds in various environmental compartments. Yet, the assessment of what constitutes a recalcitrant versus a reactive compound is largely operational and depends on a combination of analytical, chemical, and microbial expertise and insights.

Phenomenological Observations in Soils and Sediments

Halogenated aromatic compounds are ubiquitous in the various environmental compartments because of direct industrial discharge and diffuse sources such as runoff, atmospheric deposition, and biogenic formation (predominantly in marine and estuarine environments) (1 and references cited therein). Because of the halogen substitution, which confers hydrophobic properties, often in combination with reactive functional groups (e.g., carboxyl, hydroxyl, methoxy, nitro, and amino) that lend themselves to various coupling mechanisms, aryl halides tend to partition into organic-containing matrices such as biota, and soil or sediment organic matter. Hence, their ambient distribution in water is on the order of microgram or nanogram per liter in groundwater aquifers and sediment pore waters. Considering that microbial reactions are largely accepted to take place in solution, the availability of these compounds to microbial reactions may be significantly impacted (see section on matrix considerations).

Despite these characteristics, aryl halides have been demonstrated to undergo what are collectively termed "natural attenuation" reactions, which include nondestructive (e.g., volatilization, advective, and convective transport, dispersion in aqueous matrices, and sorption) and destructive (e.g., abiotic hydrolysis and microbial transformation) processes (Table 1). The combined release and attenuation processes have resulted in two main observations. First, many volatile persistent organochlorine compounds such as hexachlorobenzene (HCB), the hexachlorocyclohexane isomers (α,β,γ,δ-HCH), and p,p'-dichloro-diphenyl-trichloroethane (p,p'-DDT) and its degradation products p,p'-dichloro-diphenyl-dichloroethane (p,p'-DDD) and p,p'-dichloro-diphenyl-dichloroethene (p,p'-DDE), as well as other pesticides and nonvolatiles such as polychlorinated dibenzo-p-dioxins (PCDD) and furans (PCDF), are globally distributed because of the distillation effect, which transports organic compounds from warm source regions to areas of higher latitude. During the last few years, several global maps have been generated, which document the distribution of these compounds based on the analysis of tree bark samples (2), rural soils and isolated water bodies (3), and butter samples (4) have been generated. The second outcome has been the emergence of the field of environmental forensics, whereby the distribution and chemical characteristics of aryl halides observed in the environment are used to apportion source contributions to the contamination and to derive indicators for natural reactions. Primary emphasis has been placed on compounds, which exhibit source-specific characteristics such as congener and isomer ratios (e.g., PCDD/F, polychlorinated biphenyls — PCBs, HCH, DDT, and pesticides), and enantiomer patterns of chiral pesticides [e.g., chlorofibric acid and mecoprop 5 or recognizable degradation patterns [e.g., the accumulation of lesser chlorinated congeners and chlorobenzoic acids from commercial Aroclor mixtures, DDD, DDE; (1)]. Due to the complexity of source and sink patterns (e.g., in the case of PCDD/PCDF or PCB contamination), environmental forensics rely heavily on the use of multivariate statistical analysis to apportion the contributions of source

Table 1. Natural Attenuation Processes Affecting the Fate and Transport of Aryl Halides

Process	Description	Dependencies	Effect
Advection	Movement of solute by bulk water movement	Aquifer, sediment properties (hydraulic conductivity, porosity, hydraulic gradient) Independent of contaminant properties	Contaminant movement in the subsurface
Dispersion	Fluid mixing due to water movement and subsurface heterogeneities	Aquifer or sediment properties and scale of observation Independent of contaminant properties	Longitudinal, transverse, and vertical spreading of contamination, reduction in concentration
Diffusion	Spreading and dilution due to molecular diffusion	Contaminant properties Concentration gradients	Contaminant diffusion from high to low concentration zones
Sorption	Reaction between solid matrix (organic carbon or clays) and solute	Aquifer or sediment matrix properties (foc, clay content, bulk density, sp. surface area, porosity...) Contaminant properties (solubility, K_{ow}, substituents...)	Reduces apparent solute transport velocity Removes solutes from solution
Recharge	Movement of water across the water table or sediments into saturated layers	Aquifer matrix properties, depth to groundwater, surface water interactions,...	Dilution Changes in groundwater or pore water geochemistry
Volatilization	Contaminant transfer into vapor phase	Contaminant properties (vapor pressure, Henry's constant)	Removes contaminants from aqueous phase
Ebullition	Contaminant mobilization and transport via biogenic gases	Sediment properties (effective porosity, density,...) Microbial respiratory activity Contaminant properties	Contaminant removal from sediments to the air-water interface
Biodegradation	Microbially mediated redox reactions	Groundwater or pore water geochemistry Microbial communities Contaminant properties	Biotransformation and biodegradation Mass reduction Detoxification
Abiotic degradation	Chemical transformation reactions	Contaminant properties Groundwater or pore water geochemistry Matrix surface properties	Transformation Polymerization

contamination patterns as well as nondestructive and destructive degradation patterns. For example, the application of these techniques to dioxin-contaminated Passaic River (New Jersey) sediments, with incorporation of both point and diffusive sources, has indicated that a multiple point sources may be responsible for the majority of the contamination (8,9). However, neither sediment transport, nor environmental transformation reactions were taken into account, resulting in an incomplete assessment of the site whereby 84% of the sample variance could be explained by source contributions. The remaining 16% might then be the result of biotic or abiotic environmental transformations. The best-illustrated case that includes the contribution of microbial transformation reactions (in this case dechlorination) to the interpretation of environmental sinks, is the case of PCB-contaminated sediments (10). When sink patterns were found to deviate from known PCB sources with distinct patterns, and the potential effect of abiotic reactions was considered, the disproportionate appearance of lesser chlorinated congeners not present in the source material was attributed to natural dechlorination reactions, which were later confirmed to be of a microbial nature (11). One potentially complicating factor that may interfere with this analysis is the natural occurrence of aryl halides as the result of diagenic or biogenic processes, as is the case with dioxins and a wide range of pesticide analogs (12,13).

Hence, careful observation of aryl halide occurrence and distribution in environmental samples, and consideration of known source contributions and abiotic (nondestructive) processes, may result in an inference of environmental reactivity. This interpretation should then be confirmed and validated using environmentally relevant laboratory assessments, using the so-called "field-to-flask paradigm" or "deductive approach." This approach is counter to the much more widely used "inductive approach" in which organics are screened for their degradability or microbial degradative potentials are assessed. Whether this potential is actually expressed or can be stimulated under relevant biogeochemical conditions remains an issue of considerable contention.

Recalcitrance Versus Analytical Limitations

Because of their molecular properties, which confer extreme hydrophobicity, most aryl halides are, despite the fact that degradation pathways have been demonstrated in the laboratory, considered recalcitrant. Even the ubiquitous PCBs, which after research on their reactivity during the last two decades, have been shown to be susceptible to (even naturally occurring) dechlorination reactions, are considered refractory because of the unacceptable kinetic rates of dechlorination (one chlorine removed every 7 to 12 years). Kinetics may be a valid argument from a policymaking perspective ("to

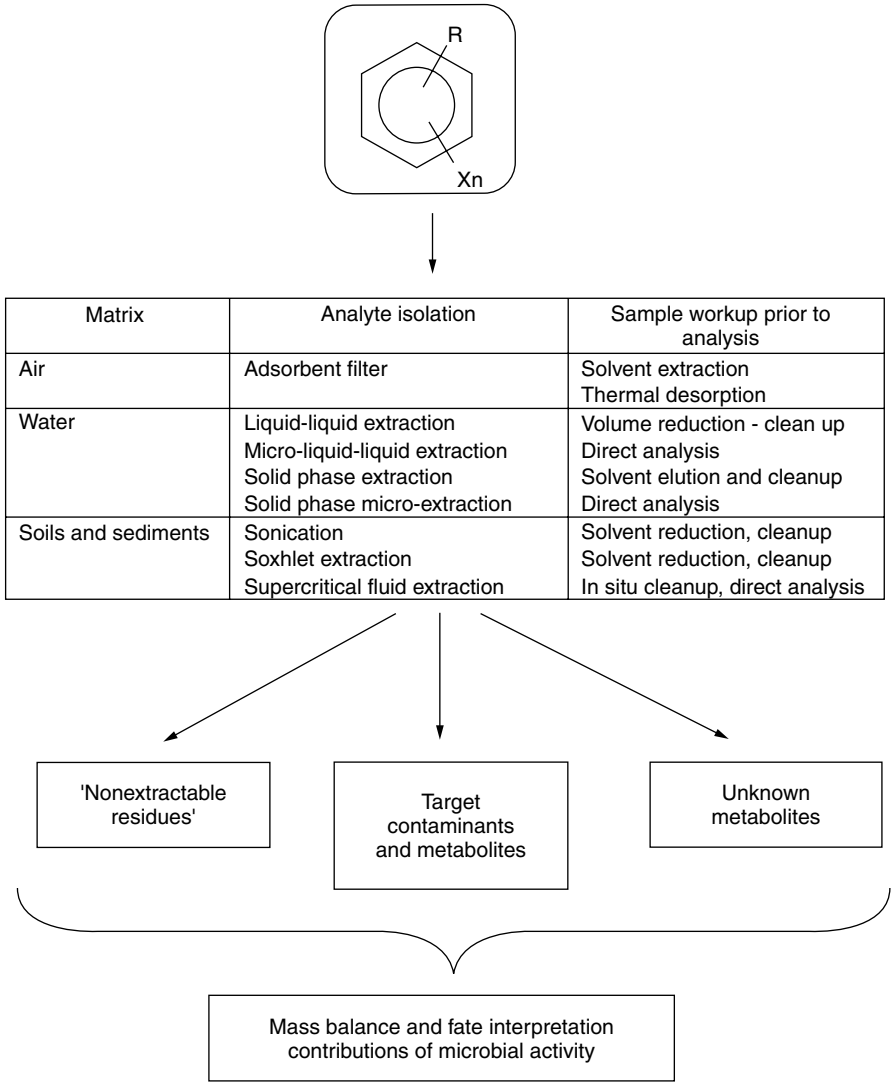

Figure 1. Operationally defined aryl halide fractions recoverable from environmental matrices.

dredge or not to dredge"), however, the operational term "recalcitrance" is often bestowed on compounds for which (*1*) no information is available on the degradation pathways, or (*2*) the availability of analytical methodology is too limiting to resolve and screen for structurally similar compounds (which may be degradation products) in the contaminated matrix (1,14). The latter is particularly the case when metabolites from aerobic degradation and hydrolysis products are considered.

Hence, the analytical limitations may be related to matrix-specific or analyte-specific considerations (1). The former refer to the implementation of proper extraction and sample work-up techniques to isolate and separate the nonpolar and often covalently bound parent compounds and metabolites from the solid-organic matrix. The latter represent challenges of analytical sensitivity and congener-, isomer-, or enantiomer-specific separation, which may impact the interpretation of fate mechanisms. These concepts are illustrated in Figure 1, which incorporates the analytical and sample work-up procedures required to assess the variety of processes affecting the fate of chlorinated aromatics in various environmental matrices. As noted on the bottom of Figure 1, environmental reactivity of this class of organics, and thus the interpretation of whether microbial processes may be responsible for these reactions are typically based on one-third of the analyte classes (target contaminant and metabolites), although most information may be hidden in the "nonextractables" (usually operationally defined) or "unknown metabolites" classes. For example, the U.S. EPA has promulgated analytical methods focused on the most toxic dioxins, that is, those with four or more chlorines and all with the lateral (2,3,7,8) positions occupied. Hence, the dechlorination of dioxins to congeners with less than four chlorines is missed, yet they may represent the dominant groups resulting from intrinsic (microbial) dechlorination (15). The story is even more poignant in the case of chlorinated pesticides (with an aromatic moiety), which often exhibit a fairly complex structure with many functional groups such as alkyl side chains (e.g, Alachlor, others). Slight modifications of the side chains would be missed in typical environmental analyses, and thus result in a conclusion that the parent compounds

are recalcitrant, although the total concentration of all potential metabolites exceeds that of the parent compound (e.g., Alachlor) by threefold (16). These and other examples indicate that there is a need for a comprehensive fundamental understanding of microbial degradation potential and intrinsic chemical reactivity to make a considered decision on whether a given halogenated aromatic compound is likely to undergo a microbially mediated transformation reaction under ambient biogeochemical conditions.

FUNDAMENTALS OF ARYL HALIDE DEGRADATION

Halogenated aromatic compounds have been distributed in the ambient environment in one form or another for millions of years. Even compounds such as dioxins appear to have been formed in million-year-old ball clays (13) by means of mechanisms that are yet known, and are by-products during natural incineration processes such as forest fires. In addition, plants, algae, and microorganisms produce and release these compounds for various physiological and ecological reasons, indicating that some latent activity for biosynthesis and thus biodegradation pathways may have been subject to substantial evolutionary processes as new aryl halides entered the various environmental compartments. Sources of halogenated aromatics have boosted fluxes immensely since the advent of the industrial revolution in the 1800s, and more significantly since heavy manufacturing was in the exponential phase in the early 1900s. Despite these relatively recent events, the microbial versatility to convert extremely stable environmental contaminants present at parts-per-trillion to parts-per-million concentrations keeps astounding us as we learn more about new enrichment techniques aimed at harnessing and exploring the microbial ecological potential (17,18). This section provides an overview of the thermodynamic, genetic, and physiological boundary conditions imposed on microbial transformations of aryl halides as we know them to date.

Thermodynamic Considerations

The propensity of organic compounds, including aryl halides, to undergo oxidation and/or reduction reactions is often expressed in terms of the energetic properties associated with their chemical structure (19–21). These properties include, but are not limited to, redox potential ($E^{o'}$, mV), Gibbs free energy of formation ($\Delta G^{o'}$, kJ/reaction), carbon-halogen bond strength, and ionization potential [often also expressed as the energy gap between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO); in eV]. The interpretation of the former two parameters is closely related to the potential of these compounds to be used as terminal electron acceptors by microorganisms, whereby more oxidized (highly halogenated) molecules exhibit more negative redox potentials (and according to Nernst Law) and greater potential (Gibbs free) energies than lesser chlorinated compounds. Hence, the higher chlorinated (halogenated) aromatics would then compete more effectively with the terminal electron acceptors for growth. The top plot of Figure 2 illustrates that the $E^{o'}$ of aryl halides (266–478 mV) corresponds to the range for iron- and nitrate-reduction. Hence, these compounds are likely to be susceptible to reduction (resulting in dechlorination or dehalogenation — see following sections) as they reside in a range in which the addition of electrons is energetically favorable. We can further conclude that the oxidation of these already much-oxidized compounds will probably be limited to the lesser halogenated isomers because it will be difficult to release electrons. This concept is illustrated in Figure 2(a), where relative rates of oxidation and reduction are plotted as a function of level of chlorination; in practice, the literature has revealed that there may be a (chemical-dependent) zone in which oxidation and reduction reactions are equally likely. The

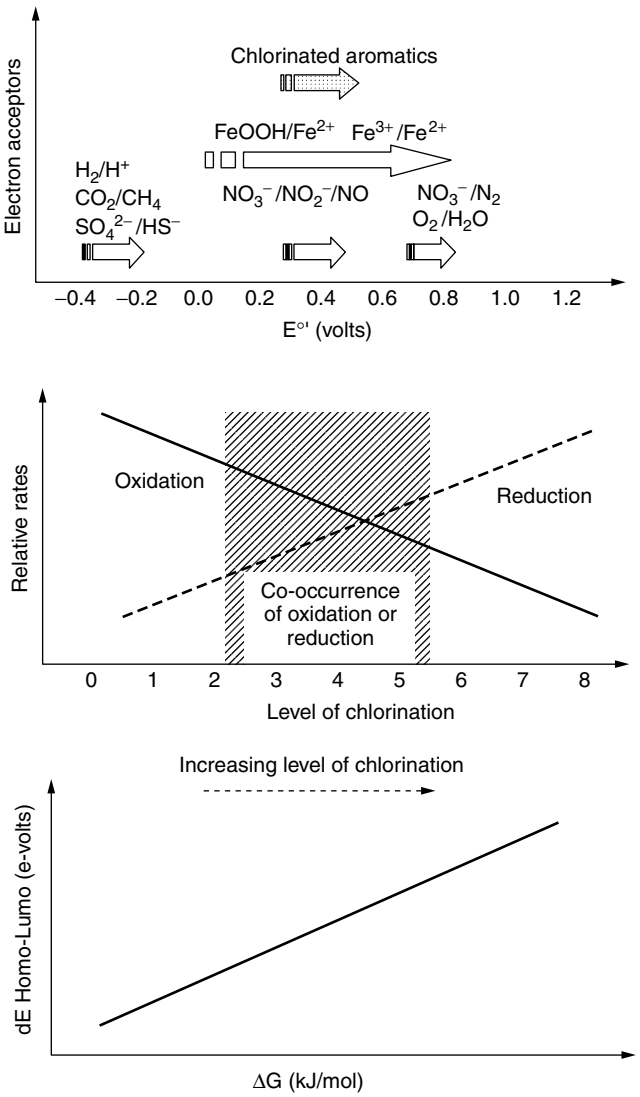

Figure 2. Thermodynamic and molecular attributed of aryl halides (**a**) comparison of redox potentials to terminal electron acceptors; (**b**) impact of chlorine level on relative occurrence of oxidation and reduction reactions; (**c**) correlation of Gibbs free energy and chlorine levels with electron potential gaps between HOMO and LUMO).

bottom plot of Figure 2 shows a trend between the Gibbs free energy and the HOMO-LUMO gap, both of which increase with increasing level of chlorination. It has been argued that the size of the gap is directly correlated to compound reactivity because it reflects the energy associated with electron release and acceptance (i.e., the ionization potential). Hence, higher chlorinated (halogenated) compounds would, according to this plot, be chemically more reactive than lesser halogenated isomers. It should be noted that there has been very limited biochemical validation of this concept, though correlations are apparent during reductive dechlorination. Other molecular descriptors describing the chemical reactivity of aryl halides, such as electronic, steric, and hydrophobic parameters, have been widely used. Their value will be assessed in the section on Structure-Reactivity Relationships.

Genetic Considerations

Considerable literature has been published on the evolutionary relationships of genetic sequences encoding, and operons facilitating the induction and expression of key metabolic enzymes required for the degradation of aryl halides (e.g., 22 to 27). The issues tend to center around the types and responsible processes for evolutionary changes, which have taken place to extend the core metabolic range of enzymes such that metabolism of halogenated aromatics can be accommodated, either through cometabolic or growth-based processes.

Under aerobic conditions, it has become widely accepted that the initial aerobic transformation steps of the aryl halides are carried out by different enzymes, but that the compounds are transformed to a limited number of intermediates such as dihydroxylated benzoic acids and substituted catechols. Further degradation of these central, dihydroxylated, metabolites proceeds then via either ortho- or meta-ring fission, which leads to intermediates of central metabolic pathways such as the tricarboxylic acid cycle. (See OXYGENASE ENZYMES: ROLE IN BIODEGRADATION, this Encyclopedia) The great diversity in the upper part of the pathway indicates that microorganisms have extended their range of biodegradative activities by evolving peripheral enzymes that "shunt" aryl halide metabolism toward central catabolic pathways. This theory is supported by amino acid analysis, and the genetic organization within operons of ring cleavage oxygenases and "upper pathway" oxygenases and dehalogenases (22,28). It was found that similarities exist in amino acid sequences of different aromatic pathway enzymes, whereas gene organization within the operon diverges strongly (22). These findings imply that microorganisms possess a range of genetic mechanisms to make evolutionary changes in existing catabolic pathways, which allows them to adapt to and grow on a wide range of aryl halides, provided sufficient selection pressure is imposed.

However, the evolution of catabolic genes does not mean they are actually expressed in environmental systems, as regulatory genes control the expression of haloaromatic catabolic pathways (Table 2). The great divergence in their evolutionary origins suggests that catabolic and regulatory genes have evolved relatively independently. Yet, despite this divergence, the general regulatory principle of activator-target DNA interaction, and transcription initiation is very similar for most known regulators (Fig. 3); regulatory specificity is then conferred by inducer molecules (e.g., pathway intermediates, target substrate). Evidence over the years has shown that catabolic promoters possess a remarkable level of nonspecificity (regulatory noise) with respect to the signals to which they respond, which allows them to evolve and to be recruited to control novel pathways. Indeed, more recently, a number of reports have been published describing the "directed evolution" of dioxygenases to accommodate chlorinated aromatic compounds through site-directed mutagenesis, in vitro DNA shuffling, and subunit or domain exchanges between dioxygenases of different bacterial origins (29). The "evolved" genes are then integrated into chromosomal operons for successful expression.

Our knowledge on the genetic evolution of anaerobic enzymes involved in microbial metabolism of aryl halides is still in its infancy, as only recently inroads have been

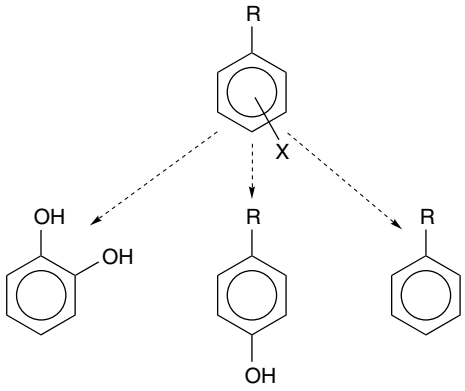
made in the functional analysis of key metabolic enzymes. Indirect evidence for the widespread, shared evolution of regulatory mechanisms has been gleaned from cross-acclimation studies. It has been proposed that derepression of enzyme induction plays a role in the acclimation period prior to dehalogenation of aryl halides, which can be triggered by amendment of the dehalogenating cultures or sediments with specific aryl halides, which may themselves serve as substrates (30,31). The possibility for cross-acclimation to induce dehalogenation, the specificity of dechlorination patterns observed (e.g., chlorobenzenes and polychlorinated biphenyls) in highly enriched cultures, and the suppression of electron transfer to the natural terminal electron acceptors during aryl dechlorination, appears to indicate that microorganisms have evolved to use aryl halides as a terminal electron acceptor (i.e., aryl halide respiration) (1,18,30–32).

Biochemical Considerations

The evolution of regulators and catabolic genes has resulted in an extraordinary metabolic versatility of microorganisms to transform or mineralize halogenated aromatic compounds, either via growth (energy-coupled) or nongrowth (cometabolic; nonenergetic) processes. The latter are often operationally defined based on specific laboratory conditions, whereas increasing evidence has come to the fore that many aryl halides are involved as fortuitous inducers controlling pathway-specific regulation (Fig. 3), although they do not serve as substrates for the catabolic enzymes (1,18). This gratuitous induction may then result in a partial transformation of the halogenated substrate, often resulting in enzyme inhibition (33). On the other hand, the cometabolic nature of dehalogenation has undergone a substantial revision during the last decade because the application of novel enrichment techniques has resulted in the discovery of a process called dehalorespiration. Dehalorespiration is an anaerobic dehalogenation processes generate energy through the promotion of a proton-motive force that allows the cells to recapture energy from the dechlorination step (18). Considering the redox potentials of aryl halides (Fig. 2a), these processes are energetically very favorable as they are at par with iron and nitrate reduction.

Adaptation of microorganisms to the presence of haloaromatics in the environment has resulted in a wide range of aerobic and anaerobic mechanisms that initiate haloaromatic degradation, including oxidative, hydrolytic, and reductive dehalogenation (Fig. 4). The former and latter processes occur predominantly under strictly aerobic and anaerobic conditions, respectively, whereas hydrolytic processes prevail in aerobic and microaerophilic conditions. It appears that complete or partial halogen removal is the predominant first step during microbial transformation of aryl halides, resulting in the accumulation of hydroxylated and/or lesser halogenated intermediates. Hydroxylated aromatics are considered "activated" as the functional group destabilizes the aromatic Π-electrons. The compounds are then rendered more susceptible to other chemical transformations, including those catalyzed by mono-or (ring fission) dioxygenases resulting in the production of catabolic intermediates that enter the tricarboxylic acid (TCA) or related ATP generating pathways. On the other hand, the extensive removal of halogens through reductive dehalogenation under anaerobic conditions allows either aerobic processes to commence or hydrogenase- and hydratase-type of anaerobic ring reduction and hydrolysis to productive catabolic intermediates.

A current list of known isolates capable of respiring chlorinated aromatics is presented in Table 3; it should be noted that the functional groups are limited to acids or hydroxyl substituents, and that ortho-dechlorination appears to be the dominant pattern. Unless experimentally proven, all other compound classes shown to undergo reductive dehalogenation should be considered cometabolic substrates. A group of compounds that may be a candidate for chlororespiration are the PCBs, as



Oxidative (dioxygenase)
R = COOH, H, NH_2
X (ortho) = F, Cl, Br, I

Hydrolytic (dehalogenase)
R = COOH, OH, NH_2
X (para) = F, Cl, Br, I

Reductive (reductase, dechlorinase)
R = COOH, H, OH, NH_2, phenyl
X = F, Cl, Br, I

Figure 4. Dechlorination mechanisms exhibited by aerobic and anaerobic bacteria.

Table 3. Anaerobic Bacteria Capable of Catabolic Reductive Dechlorination of Aryl Halides

Strain	Aryl Halide Substrate	Electron Donor	Dechlorination Pattern
Desulfomonile tiedjei	3-Chlorobenzoate; pentachlorophenol	Hydrogen, formate, pyruvate	*meta*
Isolate 2-CP1	2-Chlorophenol; 2,6-dichlorophenol	Acetate	*ortho*
Desulfitobacterium chlororespirans	2,4,6-Trichlorophenol; 3-Chloro-4-OH-phenylacetate	Hydrogen, formate, pyruvate	*ortho*
Desulfitobacterium hafniense	3-Chloro-4-OH-phenylacetetate; pentachlorophenol	Pyruvate, tryptophane	*ortho*/*meta*
Desulfitobacterium frappieri	2,4,6-Trichlorophenol; 3-Chloro-4-OH-phenylacetetate	Pyruvate	*ortho*/*meta*/*para*
Desulfitobacterium dehalogenans	2,4,6-Trichlorophenol; 3-Chloro-4-OH-phenylacetetate	Hydrogen, formate, pyruvate	*ortho*
Desulfitobacterium strain PCE1	2,4,6-Trichlorophenol; 3-Chloro-4-OH-phenylacetetate; 2-chlorophenol	Formate, pyruvate	*ortho*
Desulfitobacterium strain PCE-S	2,4,5-Trichlorophenol; pentachlorophenol	Pyruvate	*ortho*/*meta*

studies have shown that dechlorination patterns (ortho or meta+para) can be stimulated using selected PCB congeners exhibiting one pattern or another. Moreover, the recent reports that enrichment cultures have been established for ortho or meta+para dechlorination indicate that specific dechlorinases may have evolved in response to the presence of certain types of PCBs. The list of aerobic haloaromatic degraders is too extensive to be reviewed here, and the reader is referred to a number of critical reviews on the subject (e.g., 34–37).

The main observation here is that growth tends to be limited to mono- and dichlorinated compounds, with the exception of pentachlorophenol. Moreover, multiple strain–specific pathways exist for the same compound and the functional group substantially influences the reactive sites on the molecule. The effects of molecular descriptors on their reactivity is further explored in the section on quantitative structure activity relationships (QSARs). The catabolic substrate range of aerobic enzymes is evident from the number and range of cometabolic reactions that have been reported (1). As noted earlier, many aryl halides either act as gratuitous inducers for transcriptional regulators but are not actual substrates for the gene product, or serve as fortuitous substrates for the enzyme that is induced by the pathway substrate or one of its metabolites. In the latter case, the nonspecificity of the active site of the induced enzyme allows a number of "unintended" reactions to occur with either structurally similar (as in the case of biphenyl and PCBs) or dissimilar (as in the case of methane and PCBs) substrates (1,33,37). Perhaps one of the most versatile enzymes is the soluble form of the methane monooxygenase, which has the capacity to co-oxidize chlorobenzene and mono-or dichlorobiphenyls, in addition to many alkyl halides (38).

It should be noted that most of the biochemical information on microbial aryl halide degradation is based on axenic cultures isolated from a complex microbial community through selective enrichment techniques and is not necessarily representative of the original environmental system. Hence, it is imperative to place the fundamentals of aryl halide degradation within microbial ecology and ecosystem contexts to explore the impacts of system biogeochemistry and matrix effects.

ECOLOGY OF ARYL HALIDE DEGRADATION

During the last decade, substantial progress has been made to quantitatively explore the microbial community structure of contaminated environments such as groundwater, soils, and sediments. A major breakthrough has been the application of genetic tools to both phylogenetically and functionally characterize environmental samples with minimal enrichment bias, to assess the impact of chemical disturbances and matrix effects such as salinity and availability of electron acceptors. With respect to aryl halides, most of our understanding of microbial ecology and ecosystems is related to the degradation of PCBs and PCDD/F in sediments, and of chlorobenzenes and chlorophenols in groundwater environments.

Role of Microbial Communities

Considering the multitude of (bio)chemical reactions involved and the temporal and spatial variability of geochemical environments, it should not be a surprise that environmental transformation reactions in general and contaminant mineralization are the result of a complex network of microbial interactions. Hence, the selective enrichment approach aimed at stimulating and isolating target biodegradative activities are inherently artificial and biased toward a process that may actually not be relevant in the original system (39). The importance of community structure analysis and its relation to expressed microbial activities is illustrated by means of the following relevant examples.

Anaerobic Degradation of 3-Chlorobenzoate. Perhaps one of the first indications on the importance of community structure in the degradation of haloaromatics was derived from the analysis of the 3-chlorobenzoate degrading anaerobic mixed culture (reviewed in (30)). This food web consisted of a halorespirer, *D. tiedjei*, which derives energy from the dechlorination step, but requires a source of carbon and nutrients from other community members. The product of dechlorination, benzoate, is fermented to acetate and hydrogen by an acetogen strain BZ-1, which derives both carbon an energy from this process. Presumably, a feedback loop provides a fraction of the acetate to the halorespirer as a source of carbon. Both the acetate and the hydrogen are converted to methane and carbon dioxide by acetoclastic and hydrogenotrophic methanogens. Further cell leakage of amino acids and other inorganic nutrients closes the loop. The various interdependencies for sources of energy and carbon as well as the thermodynamic restrictions on the fermentative process necessitate a closely interwoven network of microbial activities to sustain 3-chlorobenzoate respiration. Similar networks presumably play a role in the physiological processes of model microorganisms listed in Table 3 and their relatives in naturally occurring microbial communities.

Anaerobic-Aerobic Degradation of PCBS. This class of compounds represents a complex mixture of congeners (biphenyls substituted with one up to ten chlorines) and isomers (different chlorine substitution patterns within each homolog group), and is often observed in parts per million (normalized per unit weight of sediment). Up to six different dechlorination patterns have been observed in sediment matrices, as a function of initial mixture and biogeochemical conditions, ultimately resulting in the accumulation of ortho- and ortho/para-substituted mono- and dichlorobiphenyls (40). As noted earlier, recent insights into the microbial ecology of PCB dechlorination have indicated that at least two types of dechlorination activity can be enriched, ortho- or meta/para- dechlorination (41,42). Furthermore, community analysis using genetic methods shows that the community structure associated with each dechlorination pattern differs markedly, indicating that at least two communities potentially exist within PCB-contaminated sediments. Sediment analysis has further indicated that chlorobenzoates and PCB ring fission products accumulate (43), suggesting that even in anaerobic and reduced sediments, some aerobic activity is prevalent, as these products require dioxygenase-mediated reactions (44).

As currently understood, PCBs do not serve as sources of carbon and energy under anaerobic or aerobic (except for some mono- and dichlorobiphenyls) conditions; thus, the cometabolizing populations need to be supplied with catabolic substrates. Some evidence exists that the PCBs or chlorinated aliphatic acid intermediates may serve as inducers for transcription of dioxygenase activity (1). Despite the fact that PCB-degradation is still operationally defined as being of a cometabolic nature, the possibility that the microorganisms reap some metabolic benefit from the reactions described earlier should be considered. For example, Kim and Rhee (45) demonstrated that the increase of PCB-dechlorinating populations can be assayed using the most probable number technique, and that different dechlorinating activities can be separated using a dilution fractionation method (46) all these reactions can be observed in single sediment core, because it follows that substantial cell-to-cell communication, chemical gradients, and sufficient labile organic carbon may be required to sustain in situ activity. Conversely, the absence of these conditions may play a role in sediments in which the PCBs have not undergone substantial alteration via dechlorination processes. For example, it has been observed that the increase in electron fluxes by amendments with simple organic substrates stimulates dechlorination (and methanogenic) activity (40). Perhaps more importantly, the amendment with brominated ortho-substituted aromatic substrates (biphenyls and benzoates) or other halogenated aromatics (benzenes, benzoates, and phenols) substantially increased dechlorination activity (40,47–50). These compounds presumably serve as an alternate electron acceptor to the dehalogenating populations (the substrate was debrominated during the process). Further, the addition of the nonchlorinated analog, biphenyl, stimulated the dechlorination activity, indicating that PCB-dechlorinators can be enriched on this substrate, whether it serves as an inducer for transcriptional activity or simply increases electron flow in anaerobic environments. Amendment strategies such as the addition of electron shuttles (e.g., vitamin B_{12}) depressed dechlorination activity for unknown reasons (51). The role

of sediment organic carbon as a potential electron acceptor or electron transfer mediator has not been explored or correlated to observed (microbial) dechlorination activity.

Anaerobic Dechlorination of Dioxins. Contrary to PCBs, dioxins represent a class of compounds, which were never produced intentionally (except for analytical standards), but result as by-products from combustion and chemical manufacturing processes, atmospheric condensation of phenols, and biogenic production (15). Their ether-linked benzene structures (Fig. 5a) and random chlorination patterns results in up to 75 congeners

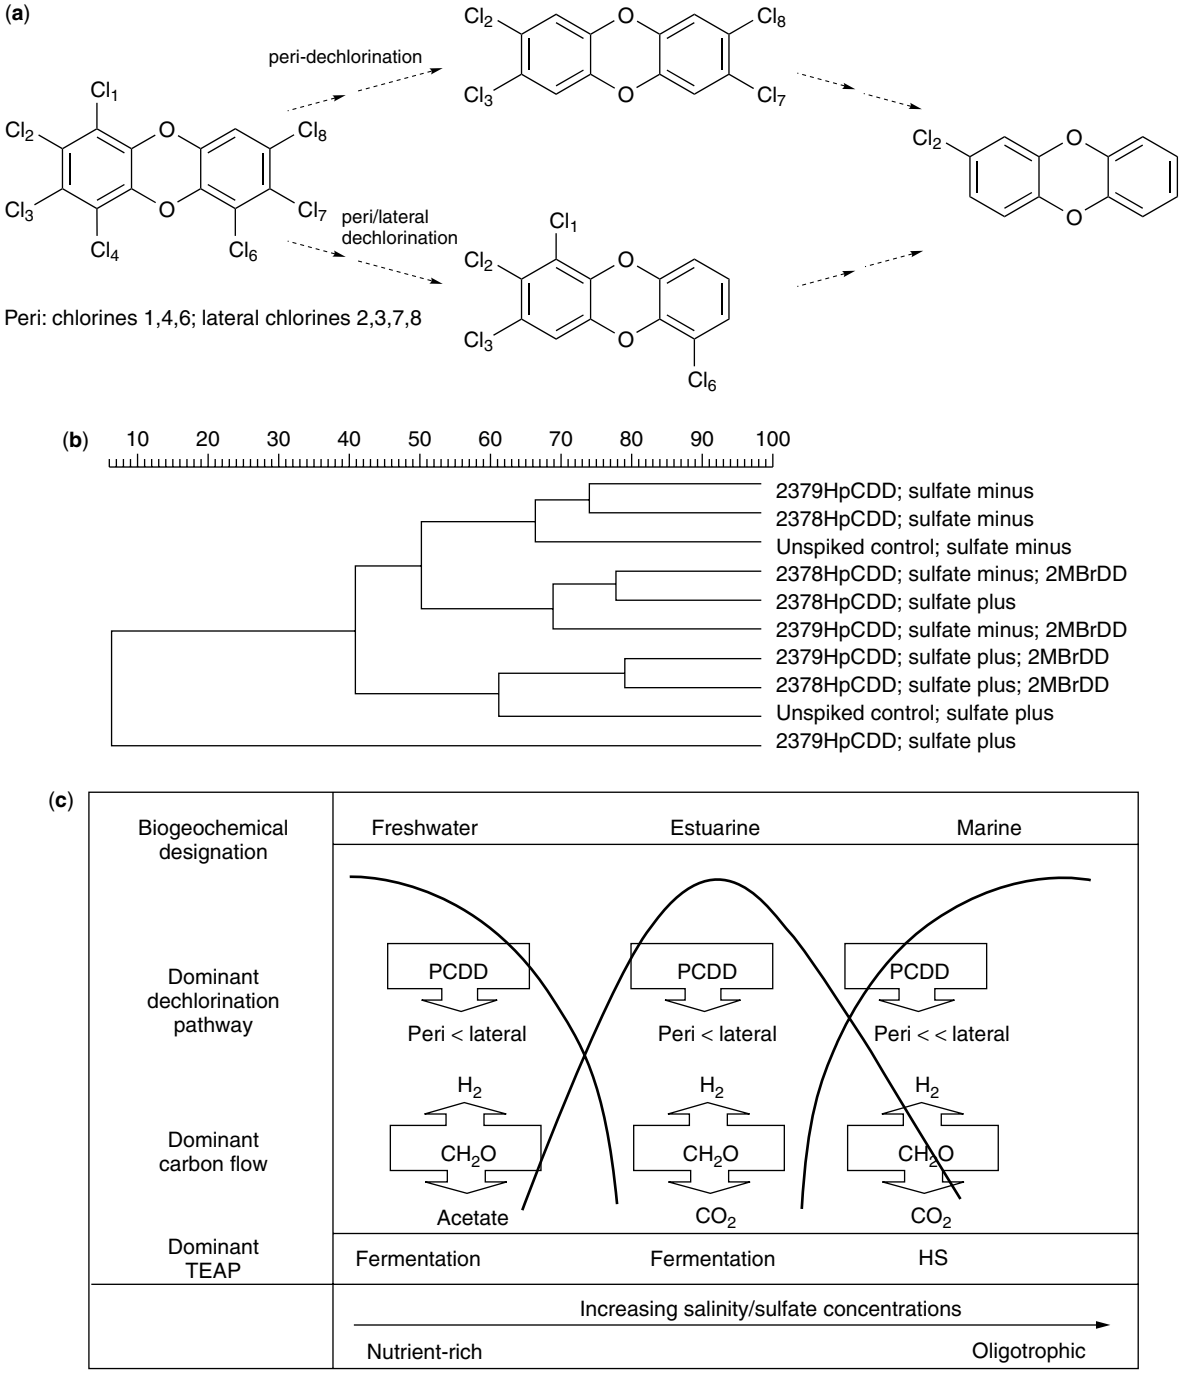


Figure 5. Effect of biogeochemical conditions on population distribution, carbon, and electron flow and PCDD dechlorination pathways (**a**) scheme of peri- and mixed peri/lateral dechlorination; (**b**) statistical analysis of community banding patterns after exposure to dioxins, methanogenic and sulfate-reducing conditions, and amendment with a priming compound; (**c**) conceptual integrative model [modified from Q. S. Fu, A. L. Barkovskii, and P. Adriaens, *Appl. Environ. Microbiol.* Submitted (2001a) and Q. S. Fu, A L. Barkovskii, and P. Adriaens, *Chemosphere* **43**, 643–648(2001b)].

with environmental patterns either dominated by the hepta- and octachlorinated congeners, or by the most toxic 2,3,7,8-tetrachlorodioxin. Ambient concentrations are on the order of parts-per-quadrillion to parts-per-billion, and thus presumably would not be able to serve as significant (extreme oligotrophs?) sources of carbon and energy. Yet, they have been shown to be subject to both microbial and abiotic (organic carbon mediated) dechlorination reactions, whereby either the peri (1,4,6,9) chlorines or a mix of the peri and lateral (2,3,7,8) chlorines are removed, ultimately resulting in the accumulation of mono- and dichlorodioxins (exemplified in Fig. 5a). Several studies have suggested that the composition of naturally occurring microbiol communities influences dechlorination processes: methanogenic and/or sulfate-reducing communities appear active on lesser chlorinated (2–4 chlorines), while fermentative activity is strongly correlated to highly substituted dioxins (4–8 chlorines). Moreover, similar to PCBs, the addition of a brominated analog, 2-monobromodibenzodioxin (2-MBrDD), substantially affected dechlorination activity by decreasing the relative ratio of peri to peri/lateral dechlorination.

This effect is likely to have been the result of a shift in the microbial community structure, as shown in Figure 5b, which uses a molecular tool for microbial community comparison (16S rRNA) to display how the community responds to external amendments. The data are presented as a similarity dendrogram comparing denaturing gradient gel electrophoresis (DGGE) banding pattern as a function of imposed geochemical conditions (high or low sulfate; plus or minus 2-MBrDD), and the resultant dechlorination pattern observed (53,55). The dominant role of the 2-MBrDD amendment on community structure is clear from Figure 5b, as the amended communities are similar regardless of other amendment. Although specific activities can be stimulated, the metabolic benefit of ppt-levels of dioxins is at best insignificant.

Effect of Biogeochemical Conditions

Our understanding of the effect of dominant electron acceptors and salinity gradients on the dehalogenation of aryl halides is predominantly derived from laboratory degradation studies of phenols, benzoates, PCBs, and dioxins under different redox conditions. The published work has emphasized the effects of alternate electron acceptors on reaction kinetics and substrate specificities, and of freshwater, estuarine, and marine conditions on dechlorination patterns and carbon flow.

Electron Acceptors. As discussed in the section on thermodynamic considerations, methanogenic and sulfate-reducing conditions effectively accommodate dehalogenation reactions because the redox potentials of these processes are well below those for halogenated aromatics. As shown in Figure 2, the range of dechlorination redox potentials coincides with those of iron and nitrate reduction. Therefore, in the case of halorespiration, competing electron acceptors (e.g., sulfate and nitrate) inhibit the dechlorination process (30,31). Indeed, most studies on (cometabolic) aryl halide dechlorination have shown strong correlations with methanogenesis and sulfate reduction, although the responsible populations have rarely been isolated. Exceptions include highly enriched sediment cultures on electron acceptors such as sulfate, iron(III), and nitrate that have been shown to support anaerobic degradation of halogenated phenols and benzoates (57 and references cited therein). In these cases, a stoichiometric correlation was observed between substrate mineralization and electron acceptor reduction, providing strong evidence for a coupled process. Moreover, inhibition of sulfate reduction and dechlorination with molybdate suggests that the sulfate-reducing bacteria were responsible for the process. The activity was found to be similar regardless of the geographic environment from which the cultures were derived, indicating that these represented ubiquitous metabolic processes.

Evidence for the direct involvement of sulfate reduction or methanogenesis during dechlorination of more complex halogenated organics such as PCBs and dioxins is more tenuous. Dechlorination of PCBs and dioxins has been observed under both methanogenic and sulfate-reducing conditions in freshwater and marine sediments, or enrichments derived thereof (15,40). Perhaps the most convincing evidence for coupled PCB dechlorination and sulfate-reducing bacteria is provided by Cutter and coworkers (42) who enriched methanogenic mixed sediment-derived marine cultures on PCB congeners selected to stimulate ortho-dechlorination activity. The inhibition of methanogenesis did not affect ortho-dechlorination activity, whereas the addition of sodium molybdate (an inhibitor of sulfate reduction) inhibited dechlorination (41). Extracted communities from estuarine sediments exposed to either sulfate or bicarbonate as the terminal electron acceptors exhibited dioxin dechlorination activity. However, insufficient evidence was available to determine whether sulfate reduction and methanogenesis, respectively, were coupled to the dechlorination activity. Electron mass balances demonstrated a strong correlation between transformation of highly chlorinated molecules and fermentative activity (54). The presence of millimolar concentrations of sulfate did not inhibit the extent of dioxin dechlorination.

Salinity Gradients. Microbial diversity in estuarine and marine environments is impacted by salinity gradients, high sulfate concentrations, and competition for electron donors. Salinity gradients between 5 and 20% reportedly exert a negative effect on aerobic heterotrophic, methanogenic, and anaerobic respiratory activities. In estuarine and marine environments, high sulfate content (20 to 30 mM) results in the dominance of sulfate reduction, but denitrification, methanogenesis, iron reduction, and fermentation have also been observed (58). Metabolic activities have been differentiated based on fatty acid turnover. Under freshwater conditions, fermentative processes were responsible for fatty acid consumption, whereas, a coupling between organic acid consumption and sulfate reduction occurred in sulfate-rich conditions (see Ref. 1 and references cited therein). The dechlorination of haloaromatics such as phenols, benzoates, catechols,

PCBs, and dioxins has been observed in estuarine sediments (1,10,59–61). On the basis of the available literature, it has been shown that sea salts affect dechlorination of PCBs in freshwater sediments, whereas a complex interrelationship exists between the effects of both sulfate and salt on dechlorination activity.

The effect of salinity on dioxin dechlorination was explored under a range of experimental conditions representative of freshwater, estuarine, and marine conditions to assess correlations between dominant terminal electron-accepting processes, carbon flow, and dechlorination patterns. As indicated in Figure 5 C, peri-dechlorination (i.e., removal of the 1,4,6,9-chlorines and concurrent transient accumulation of 2,3,7,8-tetraCDD) increased with increasing salinity of the medium (54). The shifts in dechlorination patterns are presumably due to a change in population distribution within the community. On the basis of hydrogen, the electron acceptor, and substrate analysis, the community shifted from methanogenic to sulfate-reducing via acetoclastic methanogenesis, whereas the importance of fermentation decreased with increasing salinity. No inhibitory effects of salinity on the dechlorination activity were observed.

MICROBIAL-ENVIRONMENTAL MATRIX INTERACTIONS

As noted earlier, recalcitrance of aryl halides is usually operationally defined or based on laboratory assessments in liquid culture. The former basis for recalcitrance tends to be influenced by issues of sampling heterogeneity or incomplete mass balances due to "nonextractable" fractions or unknown metabolites. For the latter, usually tight controls on the mass balance aid in the comparison of the extent and kinetics of degradation from one compound to another, yet results from these experimental systems are difficult to interpret because of sample homogeneity and selective enrichment.

Physical-Chemical and Biochemical Considerations

The physical-chemical properties of aryl halides, including generally low solubility (high distribution coefficients) and fugacity constants, and the characteristics of the dominant aryl halide sinks, generally high organic and silty sediments, affect the availability of these compounds to biochemical reactions (62,63). Additionally, because of the multitude of reactive phenolic and carboxylic functional groups in sediment organic matter and many aryl halides (or their metabolites), ample opportunity exists for cross-linking and other sequestration reactions (64).

The effect of condensation and addition reactions with humic materials on reaction stoichiometry has been clearly demonstrated for chlorinated anilines, phenoxyherbicides, and other pesticides. The fate of 3,4-dichloroaniline in an anaerobic rice paddy included the formation of operationally defined "polar material" and a condensation product of two dichloroaniline molecules (65). In the case of phenoxyherbicides, 20 to 35% of 2,4-D and 2,4,5-T were recovered from humic and fulvic acids and humin fractions, indicating the formation of polymeric humic substances (66). The fate of other aryl halide herbicides such as solan (3-chloro-2-methyl-p-valerotoluidide), propanil (N-3,4-dichlorophenyl-propionamide), and chlorodimeform (N′-4-chloro-2-methylphenyl-N,N-dimethylmethanimida mide) is similarly affected by incorporation of metabolites in soil organic matter or condensation reactions (67). Dioxin dechlorination reactions in the presence of dissolved organic matter (DOM) resulted in the production of polymeric materials and transchlorinated (transfer of the chlorine from dioxins to DOM) products (68).

In the case of aerobic degradation mechanisms, mass balances become even more complicated as the molecular structure of the contaminant changes and several oxidative coupling mechanisms have been identified. The latter result in the formation of dimers or polymers, as has been shown for chlorophenols and chloroanilines (69,70), or addition and condensation products with humic matter constituents (71), that are undetectable unless stringent extraction procedures are used. Particular problems surround the oxidative degradation of pentachlorophenol (PCP) by white rot fungi (e.g., *Phanerochaete chrysosporium*). The majority of the product was recovered as pentachloroanisole, with the remainder labeled as "unextractables" (72,73). Because peroxidases have been shown to catalyze the formation of polychlorinated dioxins and dibenzofurans from pentachlorophenol (74), this fraction should be further characterized.

Hence, it is apparent that a significant fraction of aryl halide molecules (and their microbial metabolites) will ultimately be bound to natural soil constituents. Considering the difficulty of liberating these soil-bound residues for analytical purposes, Alexander (62) and Hatzinger and Alexander (75) argue that the hazard and risk associated with toxic chemicals diminishes as they persist in soil. On the other hand, several cases have been reported in which bound residues were released and further transformed. Four possible scenarios have been recognized for soil-bound residues (64): (*1*) noncovalently bound residues are liberated via bond cleavage at the original site of attachment as has been shown for chlorophenols, and chloroanilines; (*2*) cleavage of soil constituents to monomers containing the aryl halide, as has been demonstrated for fungal oxidation of humic 3,4-dichloroaniline complexes; (*3*) bond cleavage at a site other than the original attachment, and (*4*) mineralization of the soil-bound residue. However, because the different possible binding mechanisms to high molecular weight humic material under oxic and anoxic conditions are poorly understood, predictions on the fate of these complexes are uncertain at best. A summary of possible matrix interactions is presented in Table 4.

Kinetic Considerations

Because of the factors affecting aryl halide availability mentioned earlier, it is likely that the presence of solids and organic matter (dissolved or solid) will affect not only the extent but also the rate of degradation. With respect to matrix interactions, the kinetic considerations consist of at least two components: (*1*) the differences in degradation rates between freshly spiked and historically present contaminants, and (*2*) the role of organic matter as a source of

Table 4. Biotic and Abiotic Reactions of Aryl Halides in Soil or Sediment Environments (Modified from Scheunert, 1993)

Types of Transformation	Reaction	Examples
Synthetic Processes	Conjugation	Dichlorophenols
	Reaction with natural humic substances	Chlorinated anilines, phenols chlorinated dioxins
	Interactions between aryl halides	Chlorinated anilines, phenols
	Di- and polymerization	Chlorinated anilines, phenols
	Transchlorination	Chlorinated anilines, phenols, dibenzo-*p*-dioxins
Redox reactions	Oxidative coupling	Chlorinated anilines, phenols
	Dechlorination	DDT, chlorinated dioxins, and furans hexachlorobenzene
Surface-catalyzed reactions	Dehydrochlorination	DDT, chlorinated dioxins, benzenes
	Polymerization	Chlorinated phenols, anilines

electrons during reduction reactions and as an alternative electron acceptor during oxidation reactions. The former is related to mass-transfer limitations, which because of molecular and matrix characteristics, have an impact on the extent to which sorption and sequestration take place. Hence, biodegradation in matrices in which these factors dominate are controlled by desorption and diffusion processes (76). Indeed, studies have shown that while in situ short-term aerobic degradation of PCBs was limited by the desorption kinetics from high organic sediments (77); long-term dechlorination processes may not be significantly impacted by mass-transfer limitations (51). Whereas natural in situ dechlorination reactions are estimated to result in the removal of one chlorine every seven to ten years (54), no natural aerobic field rates are available despite the occurrence of aerobic metabolism in sediments (43). In low organic environments such as groundwater systems, the first-order degradation rates of aryl halides (chlorobenzenes, chlorophenols, and chlorocresols) determined in the field (in situ microcosms) do not differ significantly from those observed in the laboratory, as based on disappearance relative to control experiments (78). Hence, attempts at increasing the availability of aryl halides from environmental matrices (e.g., via surfactant amendments) is likely to have mixed effects, depending on whether mass-transfer or biodegradation processes control the kinetics of transformation.

Organic matter (solid or dissolved can enhance degradation processes by playing a key role as electron shuttles for dechlorination, or potential electron acceptors for growth of anaerobic populations. Laboratory studies on the microbial dechlorination of dioxins by sediment-eluted mixed cultures demonstrated that dissolved organic matter was capable of enhancing the rates and extent of reaction, presumably due to electron shuttling by the phenolic functional groups (68,79). More importantly, historical dioxins in sediments dechlorinated along a pattern characteristic of abiotic rather than microbial activity (56). It is speculated that for trace levels of aryl halides, sediment organic matter may serve as the direct catalyst of dechlorination. Considering the substantial electron-accepting capacities associated with soil and sediment humic and fulvic acids (80), the contribution of quinonic moieties to the total sediment reactivity is likely to be very significant. Moreover, the potential role for fermentative microorganisms to either directly or indirectly (via hydrogen generation) mediate aryl halide dechlorination reactions (e.g., 54) would be significantly correlated to the availability of sediment organic matter.

SARs and QSARs for Aryl Halide Degradation

Structure-activity relationships (SARs) between chemical reactivity and molecular descriptors for aryl halides are valuable tools for exploring mechanistic determinants influencing biodegradation, and to predict rate constants within classes of compounds. An abundance of these statistically significant correlations based on appropriate predictor variables is available, yet very few of these yield useful quantitative expressions (QSARs). One of the limitations is the scarcity of relationships between readily available molecular descriptors and important microbial transformation reactions. Another relates to the lack of understanding of contaminant-matrix interactions, which govern the degradation process. Perhaps not surprisingly, the most robust SARs and QSARs have been generated for strictly abiotic transformation processes such as hydrolysis, direct photolysis, and oxidation. More recently, correlations have been generated describing fortuitous degradation processes (e.g., cometabolic reductive dechlorination) or for enzymes exhibiting broad substrate specificities (e.g., soluble methane monooxygenase) (20,81,82).

Most QSARs are based on the Hansch method where biological response is expressed as a linear function of hydrophobic, electronic, and steric properties (e.g., 81,83). More recently, first principle (ab initio) and semi-empirical molecular orbital calculations have been used to obtain molecular descriptors such as electron density distributions of the highest occupied π orbital (84), carbon-chlorine bond charges (82), heats of formation and ionization potentials (85), or HOMO-LUMO gaps (20,86). One or more of these parameters have been found to be strongly correlated

to the observed dechlorination pathways of dioxins and substituted benzenes (20,82), to the preferred methane monooxygenase oxidation pathways of ortho-substituted biphenyls (87), or dioxygenase-mediated oxidation of dioxins and furans (88).

A robust QSAR was developed to predict the reductive transformation constants of 45 halogenated monoaromatic hydrocarbons in anoxic sediments from four readily available molecular descriptors (83). These were the carbon-halogen bond strength, the summation of the Hammett sigma constants and inductive constants for the additional substituents, and the steric factors for these substituents. Although the electronic properties of the substituents exhibited a positive effect (increased the reaction rate), steric and bond strength factors decreased the predicted reaction rate. When the sediment organic matter content was included in the prediction, the correlations improved when the fraction of the compounds sorbed to the solid phase was considered. This indicates that, although molecular descriptors can provide a measure of reaction regiospecificity, the predicted reaction rate in more complex environmental samples is controlled by mass-transfer limitations.

CONCLUSION

As testified by the multitude of reviews over the years, the fate of halogenated aromatic compounds as affected by microbial activity is extremely difficult to summarize, both with respect to pathways of transformation and to reaction kinetics. The difficulty stems from complex interactions between diverse chemical (multiple and variable substituents) and microbial (acclimation mechanisms, enzyme specificities) processes. It is clear from this review that the transition of mechanistic observations to fate predictions in environmental matrices is complicated by the multiple attenuation processes affecting these compounds and the overall lack of mass balance due to either irreversible sequestration mechanisms or incomplete analysis for transformation products. Considering that these poorly understood issues continue to play a role in the (incomplete) decision-making framework for PCBs, (arguably the best studied group of chlorinated aromatics), research with respect to most aryl halides (except for perhaps pesticides) should still be considered in its infancy.

Despite these limitations, great strides have been made during the last decade with respect to the understanding the microbiology of aryl halide degradation. Consider, for example, the progress made in elucidating the genetic basis for microbial adaptation to structurally similar chemicals, and the requirements for transcriptional activation of key metabolic enzymes in aryl halide pathways. Dehalorespiration of chlorinated aromatic compounds, whether via direct demonstration of growth or hinted at via stimulation of specific dechlorination pathways using selected priming molecules, may be widespread in nature. This opens up a vast array of new possibilities to understand the complexity of microbial niche development. Recent advances in molecular ecological characterization methods have afforded substantial advances in this area, such as aryl halide-induced population behavior and shifts within complex communities as the result of these chemical stresses. Complementary to microbial research, the thermodynamic underpinnings of which transformations are likely to occur have aided in directing fate mechanism studies. Intrinsic chemical reactivity, as quantified using ab initio calculations have been shown to be particularly useful in radical-catalyzed oxidations and reductions. As a third line of progress, field observations have proven to be particularly useful to "calibrate" fundamental research approaches, and have in a limited number of cases demonstrated the validity of laboratory investigations for environmental fate predictions.

Ultimately, the application of each of these convergent disciplines is directed toward risk reduction from these chemicals. Key questions such as "Is the chemical transformed to a less toxic intermediate?," "Are the likely microbial reaction kinetics sufficient to prevent accumulation to levels impacting the food chain?" and "Does microbial humification result in irreversible binding to soil or sediment organic matter?" Given this state of knowledge, the regulatory community faces an enormous challenge as it is is unclear how new research information should be incorporated into risk-based decision models. Conversely, new research frontiers aimed at overcoming the limitations imposed on natural (intrinsic) microbial activity, such as mass transfer limitations, are abundant. Both regulatory and research paths will require more quantitative answers to the questions posed earlier, to allow further definition of the boundary conditions on reaction rates and pathways as a function of the relevant impacted geochemical system under consideration.

Acknowledgments

FATE OF VIRUSES AND PROTOZOAN PARASITES IN AQUATIC SEDIMENTS

MOHAMMAD R. KARIM
American Water Works Service Company
Belleville, Illinois

CHARLES P. GERBA
The University of Arizona
Tucson, Arizona

The discharge of large quantities of domestic wastewater into coastal waters is still the most common method of disposal. Pathogens present in these discharges may eventually find their way into the sediments of natural bodies of water. Here, they may accumulate and survive for prolonged periods, to be later resuspended, resulting in a degradation of water quality. Understanding the occurrence and fate of enteric pathogens in sediments is critical in assessing their impact on water quality.

Because of their colloidal nature, free suspended viruses do not settle by themselves from the water column. However, viruses associated with large particles soon leave a water column and settle into the bottom sediments (Fig. 1). Suspended solid-associated virus that settle out of the water column accumulate as a loose, fluffy layer over the compact bottom sediment, which may contains 10 to 10,000 more viruses per unit volume than the overlaying water (1). Disturbance of these sediments by rainfall, water turbulence, or any other unnatural event may result in the resuspension of these organisms. In artificial environments, such as reservoirs for drinking water, settling tanks of drinking water or sewage treatment facilities, resuspension of sediments may result in a breakthrough, through the treatment system. In the environment, resuspended microorganisms can be transported from polluted to nonpolluted recreational water, or shellfish growing area, increasing the risk of public exposure to microbial pathogens. Giardia cysts and Cryptosporidium oocysts are very large, relative to viruses, and settle out relatively quickly from the water column. Little is known about their eventual fate in sediments.

OCCURRENCE OF VIRUSES AND PARASITES IN AQUATIC SEDIMENTS

Enteric Viruses

Recent advances in recovery methods of solid-associated viruses have made possible the studies on the concentration and distribution of enteric viruses in sediments. Studies have shown that many times more viruses exist adsorbed to sediment, than in the overlaying water on a volume basis (2), and sediments may play a role in the persistence of viruses in the marine environment (3,4) (Table 1). A 10 to 10,000-fold greater virus concentration in sediments was found, than in the overlaying water in the coastal Texas and Florida waters polluted by sewage discharge (5). In another study along Galveston Bay, Rao and coworkers (2) found a higher concentration of enterovirus in sediments compared with the overlaying water. Enteric viruses were detected 47% of the time in fluffy sediments compared to only 14% of the water samples. A greater number of enteroviruses were recovered from fluffy sediments (39–398 plaque forming units-PFU) compared with overlaying water (3–12 PFU) on a volume basis.

Protozoan Parasites

Giardia cysts and *Cryptosporidium* oocysts are known to occur in high concentration in wastewater. Sykora and coworkers (7) studied the concentration of *Giardia* cysts in raw sewage. The concentration of *Giardia* cysts in raw sewage varied from 560 to 14,000 per liter. Several other studies reported the concentration of *Giardia* cysts in the influent of constructed wetlands, which received raw sewage or secondary unchlorinated sewage. The average concentration of Giardia cysts found in the influent of a pilot scale constructed wetland receiving domestic raw sewage in Arizona was 7,444 cysts/L (8).

Rose and coworkers (9) studied Cryptosporidium oocyst concentrations in raw sewage and found an average

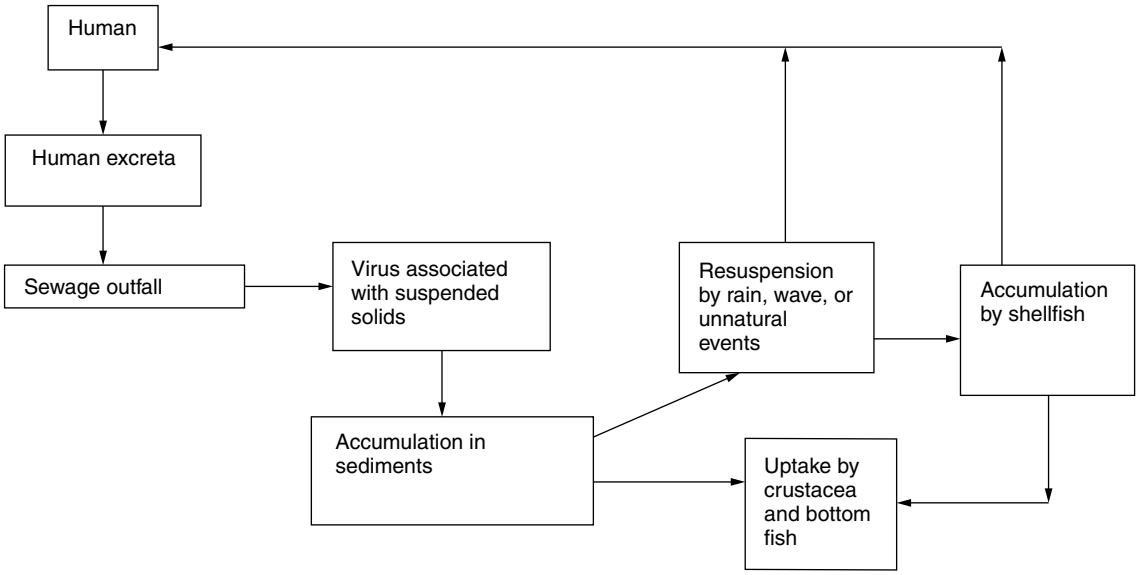

Figure 1. Transmission of viruses in coastal systems (modified from Melnick and Gerba, 1980).

Table 1. Concentration of Bacteriophage and Viruses in Sediments and Overlaying Water

Type of Sediment	Virus Type	Site Location	PFU in Overlaying Water	PFU in Sediment	Reference
Marine Sediment	Enterovirus	Hollywood	0.3[a]	3,160[a]	5
		Miami	0.5[a]	2,160[a]	
	Miami Beach	7.3[a]	9,830[a]		
Marine Sediment	Enterovirus	Galveston Bay	3–12[b]	39–398[b]	2
Wetland sediment	Coliphage	Constructed wetland (duckweed pond)	33,000[c]	14,000[c]	6
		Constructed wetland (waterhyacinth pond)	34,000[c]	8,500[c]	

[a] = Plaque Forming Unit (PFU) per 100 liters.
[b] = PFU of virus estimated for 379 liters of water.
[c] = PFU per 100 ml of water or 100 gm of wet sediment.

concentration of 5,291 oocysts per liter. The presence of *Cryptosporidium* in surface and groundwater has also been reported. *Cryptosporidium* was found to be present in 65 to 87 percent of surface water samples tested throughout the United States (10,11). One out of 18 groundwater samples tested was found to be contaminated with *Cryptosporidium* (10). The occurrence of *Cryptosporidium* in eight natural wetlands in Arizona has been studied. The concentration of *Cryptosporidium* ranged from below detection level to 0.3 oocysts/ L with an average value of 0.06 oocysts/ L (12).

Giardia and *Cryptosporidium* are larger than bacteria and viruses and would easily settle in the bottom sediment in aquatic environments. However, reports on *Giardia* and *Cryptosporidium* concentration in sediments have been very scarce. The only known study compared *Giardia* and *Cryptosporidium* concentration in overlaying water and sediment of two constructed wetlands built for the purpose of wastewater treatment. The wetlands received secondary unchlorinated wastewater. The concentration of *Giardia* in the sediment was two to three orders of magnitudes greater compared with the concentration in the overlaying water in both wetlands (Table 2). Similar to *Giardia*, larger numbers of *Cryptosporidium* were found in the sediment than in the overlaying water. Generally, from 1 to 2 $\log_{10}$ greater *Cryptosporidium* numbers were found in the sediment than in the water column. *Giardia* cysts concentration in one of the wetland (duckweed pond) waters was 130 cysts/L compared to 84,000 cysts/L in the sediment. *Cryptosporidium* oocysts concentration in water (duckweed pond) was 21.9 oocysts per liter compared with 2,300 oocysts in the sediment.

Detection of Enteric Viruses in Sediments

Detecting viruses in sediment involves a three-stage process. The first stage is the collection of samples. Sediment samples are usually collected with a grab sampler or an Ekman dredge sampler. The second stage consists of eluting the sediment-associated viruses using a beef-extract based eluant and subsequent reduction

Table 2. Concentration of *Giardia* Cysts and *Cryptosporidium* Oocysts in the Water Column and Sediment of Two Constructed Wetlands Built for the Purpose of Wastewater Treatment

Protozoan	Site	Concentration of (oo) cysts in water column/L	Concentration of (oo) cysts in sediments/L
Giardia	Duckweed pond	130	84,000
	Water hyacinth pond	95.2	14,000
Cryptosporidium	Duckweed pond	21.9	2,300
	Water hyacinth pond	47.6	3,400

Source: M. R. Karim, Survival of Indicator Microorganisms and Enteric Pathogens in Wetlands, Ph.D. Dissertation, The University of Arizona, Tucson, Ariz., 1999.

in volume by low pH organic flocculation. Viruses can be isolated from the sediments by using the following procedure (13). Briefly, viruses are eluted from sediments by suspending the sediments into three volumes of beef-extract glycine, mixed for five minutes and centrifuge at $2,510 \times g$ for 10 minutes. The pellet is discarded and the eluted virus is then concentrated using the low pH organic flocculation method. The pH of the supernatant is adjusted to 3.5, and centrifuged at $2,510 \times g$ for 5 minutes. The pellet is then resuspended into 10 ml of 0.05 glycine buffer, centrifuged at $2,510 \times g$ for 20 minutes and the supernatant passed through a 05s Zeta-plus filter to reduce toxicity. The whole process results in a known volume of concentrate containing viruses. The pellet from organic flocculation can also be processed by resuspending in 0.15 M Na_2HPO_4 (pH 9.0–9.5), as described in Information Collection Rule virus methodology (14). Several other methods for virus isolation from sediments are described in the literature (2,15)

The third stage is the assaying of viruses contained in the sample concentrate. In general, the infectivity of enteric viruses contained in the sample concentrate is examined by inoculating the sample concentrate into a mammalian cell culture. This is often done by using either a cytopathogenicity (CPE) assay or by a plaque formation assay technique. The Baffalo Green Monkey (BGM) kidney cell line is the most commonly used cell line for the detection of enteroviruses in the sediment. There is no single universal cell culture system that will detect all or even a majority of the enteric viruses present in sediments. The use of the other cell line is required to detect other groups of enteric viruses. Cytotoxicity is a problem often encountered in the assay of sample concentrate from sediments. The cell monolayer washing procedure described in the ICR virus assay method can be used for reducing cytotoxic effect. Molecular methods such as polymerase chain reaction can also be used to detect the presence of viruses in the sample concentrate. However, currently available molecular methodology cannot differentiate between infective and noninfective stages of the virus.

DETECTION OF PARASITES IN THE SEDIMENT

Sediment samples are usually collected using an Ekman dredge. Twenty milliliter of sediment is mixed with 30 ml of sterile deionized water, and after homogenization, the samples are passed through a series of two sieves of gradually finer mesh (opening two mm; 300 μm) to remove fibrous and other large materials. The sample is then centrifuged ($1,050 \times g$; 10 minutes) and the supernatant aspirated off without disrupting the pellet. The cyst and oocyst-containing pellet is washed twice with deionized water. The pellet volume is adjusted to 20 ml with an elution solution. The sample is then vortexed and clarified by using a Percoll-sucrose (sp. gr. 1.10) density gradient. The debris is pelleted to the bottom of the centrifuge tube by centrifugation ($1,050 \times g$; 10 minutes). The supernatant (20 ml) as well as 5 ml past the interface is collected with a pipette. The sample is then washed by centrifugation with the eluting solution and then aspirated down to 5 ml (plus pellet). Cysts and oocysts in the pellet are detected by immunofluorescence by filtering 0.5-ml aliquots of the final concentrate through 0.2-μm pore size cellulose acetate membrane filters. *Giardia* cysts and *Cryptosporidium* oocysts are identified on the basis of size, shape, and immunofluorescence. The results are reported as the total number of *Giardia* cysts and *Cryptosporidium* oocysts per liter of sediment or per kg of dry sediment. For those samples in which no cysts or oocysts are detected, the detection limit is calculated as follows (Eq. 1).

$$\frac{< X}{100} = \frac{[< 1(100)]}{FVR} \text{ where;} \quad (1)$$

F = volume of concentrate floated/total concentrate volume (ml)
V = volume of original sample (L)
R = volume of suspension filtered/interface volume (ml)

SURVIVAL OF VIRUSES IN SEDIMENTS

Enteric viruses are known to readily attach to particles in water and wastewater. Suspended solids-associated virus that settled out of the water column, accumulates in the bottom sediment. An assessment of the public health hazard associated with sedimented viruses depends on the survival of viruses in the sediment. During the past two decades, many reports have addressed the persistence of viruses in sediments. Virus survival was found to be prolonged in the presence of marine

sediments (4). Echovirus 1 had the longest survival time, greater than 18 days followed by coxsackievirus B3–18 days; poliovirus 1, 14 days; and coxsackievirus A9, four days. In comparison, samples containing seawater alone, coxsackievirus A9 was undetectable after two days, and coxsackievirus B3, echovirus 1, and poliovirus 1 persisted for 4, 6, and 10 days, respectively. In another study, (16) survival of poliovirus 1 and echovirus 1 in estuarine water and sediments was studied in the Galveston Bay, Texas, under field conditions. Viruses were suspended in estuarine water and sediments, and placed both in dialysis tubes and in chambers constructed with polycarbonate membrane walls. Virus adsorption to sediments greatly increased the survival time. The time required for inactivating 99% of poliovirus increased from 1.4 days in seawater alone to six days when adsorbed to sediments. Virus survival in the environment is influenced by temperature, pH, virus adsorption to soil particles, exchangeable aluminum, indigenous bacteria, and calcium hardness (17–20). However, little is known about the mechanism of how sediments prolong virus survival and infectivity. Liew and Gerba (21) studied the thermostabilization of enterovirus by estuarine sediments. Polioviruses type 1 survived longer in artificial seawater containing 12.5% (wt/vol) sediment than the water alone. In addition to prolonging virus survival time in the presence of sediments, the level of infectivity of virus in seawater containing sediments was at least one log higher than the seawater alone, suggesting that estuarine sediments protected enteroviruses against thermal inactivation. Other studies have shown that clay particles can exert some protective effect against heat inactivation of viruses (22). Particulate matter may exert a protective effect on the viruses. Gerba and Schaiberger studied the effect of particulates on virus survival in seawater (23). The presence of as little as 5mg/L clay particles greatly reduced the inactivation of virus in artificial seawater. Laboratory studies demonstrated that the sediment is also capable of protecting the poliovirus from the inactivating effects of other microorganisms as well as heat and salts, resulting in a longer survival (17). Thus, sediments could potentially serve as a reservoir of human viruses, which could be released into the water column by storms or unnatural events (i.e., dredging).

SURVIVAL OF PROTOZOAN PARASITES IN SEDIMENTS

Numerous waterborne outbreaks of giardiasis and cryptosporidiosis have been reported, yet little is known on the viability of *Giardia* and *Cryptosporidium* in different aquatic environment. DeRegnier and coworkers studied the survival of *Giardia* cysts in lakes, rivers, and tap water (24). Cysts suspended at 30 ft in lake water remained viable for up to 56 days; whereas, cysts stored at 15 ft were nonviable after 28 days. *Giardia* cysts suspended in either lake or river water were viable for 56 to 84 days compared with cysts suspended in tap water remaining viable for 14 days. Lower ($<10\,^{\circ}C$) temperature was found to be prolonging the survival of *Giardia* cysts. In a recent study, the survival of *Giardia* in the sediment and overlaying water in a constructed wetland (built for the purpose of wastewater treatment) was compared (6). *Giardia muris* cysts were placed in plastic bottles containing wastewater or wastewater plus sediment (20%). The survival of *Giardia* in water and sediment is presented in Figure 2. *Giardia* survival in the sediment was found to be opposite of what has been demonstrated for viruses. The die-off rate of *Giardia* in sediment was greater than the die-off rate in water. *Giardia* reductions in the water and sediment in five days were 0.03 $\log_{10}$ and 1.81 $\log_{10}$, respectively. The die-off rates in water and sediment were 0.02 $\log_{10}\,day^{-1}$ and 0.37 $\log_{10}\,day^{-1}$, respectively, suggesting that the wetland sediment environment is unfavorable for the survival of *Giardia*. A few survival studies suggest that temperature plays an important role in the survival of *Giardia* (24,25). Biological antagonism is thought to be a mechanism of *Cryptosporidium* oocyst die-off in natural waters (26). A plausible explanation of greater reduction of *Giardia* in the sediment could be due to biological antagonism or the presence of organic substances, which enhanced die-off of the protozoan parasites. No data exist in the literature on the survival of *Giardia* and *Cryptosporidium* in marine sediments. Future studies are necessary to study the effect of sediments on the survival of *Giardia* and *Cryptosporidium* in estuarine sediments.

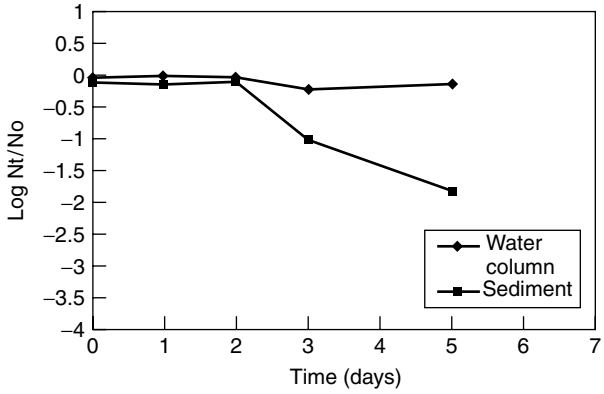

Figure 2. Survival of *Giardia muris* in sediment versus water column of a artificial wetland. M. R. Karim, *Survival of indicator microorganisms and enteric pathogens in wetlands*, Ph.D. Dissertation, The University of Arizona, Tucson, Ariz., 1999.

CONCLUSION

Sediments represent a potential reservoir of viruses contributing to the prolonged survival. In marine environments, resuspended sediment-associated viruses can be transported from polluted to nonpolluted recreational water, or shellfish growing areas, thus posing a potential public health risk. *Giardia* and *Cryptosporidium* are larger than bacteria and viruses and would easily settle in the bottom sediment in an aquatic environment. However, currently no data exist in literature on their occurrence and survival in marine and freshwater sediments. Consequently, the public health implications on sediment bound cysts and oocysts are not known.

Future research is needed to study the occurrence and survival of (oo) cysts in marine and freshwater sediments.

FECAL CONTAMINATION, SOURCES OF

SALINA PARVEEN
University of Florida
Gainesville, Florida
Delaware State University
Dover, Delaware

MARK L. TAMPLIN
Water Examination
Technologies Inc.
Gainesville, Florida

Fecal pollution impacts many aquatic environments and it can originate from a variety of sources, including human (HS) and nonhuman (NHS) animal species. The consequences of fecal contamination include affecting the safety of surface and ground waters, as well as the economic well-being of fisheries, especially shellfish industries, where harvesting areas are strictly defined by levels of fecal contamination. Consequently, techniques for differentiating HS and NHS pollution are required to determine the sources of the fecal contamination and the appropriate level of protection for water systems, including effective remediation techniques, epidemiological information, and regulatory actions. Although much effort has been given to define better indicators of fecal contamination, such research is still in its infancy.

MICROORGANISMS USED FOR DETECTING SOURCES OF FECAL CONTAMINATION

Fecal Streptococci

Fecal streptococci have been used to indicate fecal contamination because they inhabit the intestinal tract of humans and other warm-blooded animals. The four primary species of interest are *Streptococcus faecalis*, *S. bovis*, *S. equinus*, and *S. avium*. These species show prolonged persistence in water, and do not reproduce. *Streptococcus faecalis* and *S. faecium* (enterococci) have been shown to be useful for indicating the presence of viruses, particularly in biosolids and seawater. The ratio of fecal coliforms to fecal streptococci has been used as an indicator of fecal source, whereby a ratio of 4.0 or greater was considered to indicate HS contamination, whereas that of 0.7 or less indicated NHS (1). However, after further examination, this ratio has proven unreliable for chlorinated effluents, and some investigators have questioned its overall usefulness (2).

Bacteroides. It has been suggested that bacteria of the genus *Bacteroides* might be used to distinguished HS and NHS fecal contamination. *Bacteroides* dominate the human fecal flora, and outnumber the coliform bacteria (3,4). Recently, a polymerase chain reaction (PCR) assay was developed to discriminate human and ruminant feces on the basis of host differences in *Bacteroides-Prevotella* genes encoding 16S rRNA (5,6). However, for several reasons, *Bacteroides* spp. may not be suitable for discriminatory applications. First, being obligate

anaerobes, *Bacteroides* spp. do not survive in oxygenated waters (7,8). Second, the most abundant *Bacteroides* spp. in human feces have been detected only at low levels or not at all in feces from other animals (7,9). However, the need to maintain anaerobic conditions during growth, isolation, and biochemical identification of *Bacteroides* spp. has discouraged their use as indicators. Furthermore, the survival of *Bacteroides* spp. in water is less than that of *Escherichia coli* or *S. faecalis* and other enteric pathogens. Consequently, this genus is not practical for differentiating HS and NHS fecal contamination (3,8).

Bifidobacteria

Bifidobacteria are anaerobic, non-spore-forming, gram-positive bacteria that have been proposed as indicators of fecal contamination. They are the third most common genus found in the intestines of warm-blooded animals. At the present time, the genus *Bifidobacterium* includes 28 species (10 species of human origin, 13 species of other warm-blooded animal origin, 3 species from honey bees, and 2 species from sewage) and it has been suggested that these species may help distinguish between human and animal contamination. *Bacteriodes* spp. can be differentiated on the basis of carbohydrate acidification, serological characteristics, and DNA-DNA hybridization (10,11). However, acidification tests performed with carbohydrates are not sufficient to identify bifidobacterial species. The results of other techniques that are based on electrophoretic patterns of soluble proteins (12) or transaldolase and 6-phosphogluconate dehydrogenase activities (13) do not strongly correlate with phenotypic or genomic descriptions of the species.

Clostridium perfringens. *Clostridium perfringens* is an anaerobic, gram-positive, spore-forming, rod-shaped, sulfate-reducing bacterium found in the colon of warm-blooded animals. It has been suggested as a suitable indicator for viruses and protozoan cysts because it's spores are resistant to environmental stresses and to disinfection. However, it cannot differentiate HS and NHS fecal contamination (14).

Bacteriophages

Bacteriophages are similar to enteric viruses, but are found in higher numbers than enteric viruses in wastewaters and other environments. Simple and rapid methods are available for detecting bacteriophages from various environments (15–17). Therefore, these organisms have been proposed as water quality indicators in estuaries, seawater, recreational freshwater, and potable water (18). They may also serve as indicators for assessing the process efficiency of methods to remove pathogens from water and wastewater (16). Some coliphages, particularly RNA phage f2, are more resistant to chlorination than enteroviruses, such as poliovirus type 1. However, MS2, another RNA phage, is not suitable as a surrogate for enteric viruses when determining ozone disinfection efficiency (19). Therefore, it is doubtful that bacteriophages can be used as indicators for enteric viruses in all situations (16). In other studies, investigators observed that animal and human feces contain different serotypes of RNA coliphages (20,21), which may be useful for discriminatory applications.

F-specific bacteriophage (male-specific phage) are single-stranded RNA phage (FRNA) that possess structures and sizes very similar to enteric viruses. They infect only those bacterial hosts that produce F or sex pill and were proposed as indicators of HS contamination (22). Because F-specific phage are infrequently detected in human fecal matter and show no direct relationship with fecal contamination level, they cannot be considered as indicators of HS contamination.

The potential bacteriophage of *Bacteroides* spp. to serve as indicators of viral contamination has been explored (23). Phage active against *Bacteroides fragilis* HSP 40 were detected in 10% of human fecal samples, but not in animal feces, sewage, and other polluted aquatic environments, such as river water, seawater, groundwater, sediments; the phage were absent in nonpolluted sites (23,24). In addition, bacteriophage of *Bacteroides* spp. do not replicate in the environment, they have decay rates similar to those of human enteric viruses in environmental samples (25), and they are more resistant to chlorine than bacterial indicators (26,27) but are less resistant than coliphage f2 to UV irradiation (26). Thus, these organisms may be considered as suitable indicators of human fecal contamination and might be used to differentiate HS and NHS fecal contamination. However, the primary disadvantage of this indicator is that it occurs in relatively small numbers in human feces.

Fecal Sterols

Investigators have reported a correlation between the presence of fecal sterols and fecal contamination. Fecal sterols include coprostanol, coprosterol, cholesterol, and coprostanone. The main excretory products of body cholesterol, bile acids, such as hyocholic and hyodeoxycholic acids are produced in substantial amounts by pigs as compared to humans, whereas the later produce deoxycholic and lithocholic acids, which are virtually absent in pigs. Bile acids are more resistant to degradation than coprastanol and may help distinguish between HS and NHS (pig) fecal contamination (28).

Escherichia coli. The fecal coliform, *E. coli*, has been used as an indicator of human enteric pathogens for many years (29). However, it is well established that *E. coli* also inhabits the intestines of other warm-blooded animals. Human feces potentially carry many enteric pathogens, such as *Salmonella typhi*, *Salmonella paratyphi*, *Shigella* spp., pathogenic forms of *E. coli*, hepatitis A, and Norwalk-group viruses. In contrast, animals are rarely colonized by human enteric viruses (30–33). However, before *E. coli* can be used to indicate human health risks from contact with water, it is important to define bacterial characteristics that are associated with strains representing potential source(s) of fecal contamination.

NEW APPROACHES FOR DIFFERENTIATING BACTERIAL STRAINS

Bacterial pathogens have been typed and differentiated by biochemical tests (34,35), phage susceptibility (36), outer membrane protein profiles (37), antibody reactivity (38), fimbriation (39), bacteriocin production and susceptibility, and other methods (40). However, these typing systems suffer from several disadvantages, including (*1*) the unstable nature of some phenotypic properties, (*2*) low discriminatory power at the intraspecies level, and (*3*) limited specificity (41).

Recent techniques in DNA analysis have reduced dependence on phenotypic traits. These methods, such as plasmid profile analysis, comparison of DNA restriction endonuclease digestion fragment patterns, and the use of nucleic acid probes, have been used to discriminate bacterial strains within a single species (41). Analysis of chromosomal DNA avoids the potential pitfalls associated with variable expression of phenotypes and with the biologic instability of plasmids. It has been suggested that these techniques can be used to discriminate sources of *E. coli*.

Even though one can argue that bacterial genotypic traits are more stable than phenotypic properties, the latter have been shown to provide useful levels of discrimination in certain situations, including multiple antibiotic resistance (MAR), fatty acid methyl ester (FAME), and strain serotype (31,42–44).

MAR has been used to differentiate *E. coli* from different sources by employing antibiotics commonly associated with human and animal therapy, as well as in animal feeds (31,43,45,46).

Bacterial serotyping is based on the presence or absence of somatic (O), flagellar (H), capsular or envelope (K) antigenic determinants, and their reaction with specific antisera. Several investigators have used this method for discriminating *E. coli* from different sources (42,47).

Pulsed-field gel electrophoresis (PFGE) is a measurement of restriction fragment length polymorphism (RFLP) of the whole chromosome that can highly resolve bacterial strains. Numerous investigators have described the use of PFGE in differentiating bacteria from specific sources, especially in epidemiological studies (48–51). The PFGE technique involves digesting chromosomal DNA using low-frequency restriction endonucleases to produce high molecular weight fragments. DNA fragments are then separated on a polymeric gel by alternating pulsed-electric fields.

Ribotyping, another method of "DNA fingerprinting," has provided a very powerful tool to differentiate and cluster bacterial strains (30,36,38,52–54). Ribosomal RNA (rRNA) is ubiquitous, highly conserved, and multiple copies are present on the bacterial chromosome. These factors have allowed the use of a single probe to characterize phylogenetically distant bacteria following digestion of DNA with restriction endonucleases. Generally, members of *Enterobacteriaceae* yield more restriction fragments than other bacteria, owing to a greater number of rRNA operons (55).

The purpose of this article is to discuss phenotypic and genotypic methods, which have been used to differentiate HS and NHS bacterial strains in water environments, with a focus on the historic indicator organism, *E. coli*.

MULTIPLE ANTIBIOTIC RESISTANCE (MAR)

Owing to the increasingly widespread use of antibiotics in human and animals, antibiotic resistance among bacteria is common. Because of different applications of a wide variety of antibiotics, bacterial clones can be identified via antibiotic resistance patterns that can be helpful for source tracking applications. It is important to consider that many resistance characters are transmissible, and by nature, not stable (56). However, several researchers have described patterns of antibiotic resistance in *E. coli* that are useful in determining isolate source.

Kaspar and coworkers (43) isolated a total of 202 *E. coli* from rural and urban waters and tested them with 11 antibiotics commonly associated with animal feeds and/or clinical treatments. They found that 90 and 32% of urban and rural *E. coli* isolates, respectively, were resistant to one or more antibiotics. The average MAR index for urban areas was 0.090, 3.2 times greater than that for the combined rural areas (0.028). MAR indices varied considerably among samples and geographical area.

In another study, *E. coli* isolates, which were collected from environments that were considered to pose low and high enteric disease risk to humans, were screened against 12 antibiotics (31). The MAR index for isolates from raw human sewage was greater than the index for isolates obtained by direct anal swabbing (31). It was proposed that several factors may have contributed to this difference, such as a high concentration of nutrients and exchange of plasmids in the sewage system. It was also observed that the MAR index of *E. coli* isolates from wild animals was generally low, whereas that of human and poultry isolates was relatively high (31).

Parveen and coworkers (46) reported that MAR patterns of *E. coli* may be used to differentiate HS and NHS fecal contamination. In this study, a total of 765 HS and NHS *E. coli* were collected from the Apalachicola National Estuarine Research Reserve (ANERR) in Florida and their MAR profiles were determined using 10 antibiotics. Eighty-two percent of the isolates were resistant to one or more antibiotics. *Escherichia coli* from HS showed significantly greater resistance ($P < 0.05$) to antibiotics and higher MAR indices than NHS (Tables 1 and 2). Sixty-five different resistance patterns were observed among HS isolates, compared to 32 for NHS. Examples of contrasting resistance included chlortetracycline-sulfathiazole (33.7%) and chlortetracycline-penicillin G-sulfathiazole (14.5%) for HS isolates, versus 15.4 and 1.7%, respectively, for NHS. In all 15 and 38% of HS isolates had MAR indices of less than or equal to 0.1 and greater than or equal to 0.3, respectively. Conversely, 45 and 7.6% of NHS isolates had MAR indices less than or equal to 0.1 and greater than or equal to 0.3, respectively. In addition, the average MAR index for HS isolates was 0.25 compared to 0.13 for NHS isolates.

The relationship of antibiotic resistance pattern for HS versus NHS, based on coefficients of similarity measured

Table 1. Percentage of *E. coli* Human Source (HS) and Nonhuman Source (NHS) Isolates Resistant to Antibiotics

Antibiotics	Percent Resistant Strains[a]	
	HS ($n = 407$)	NHS ($n = 358$)
Ampicillin	12.5	4.5
Chlortetracycline	88.5	61.2
Kanamycin	6.9	0.6
Nalidixic acid	2.9	0
Neomycin	3.2	0.3
Oxytetracycline	10.3	3.4
Penicillin G	38.6	37.7
Streptomycin	10.8	2.8
Sulfathiazole	66.3	21.0
Tetracycline	10.3	1.7
Total	94.6	67.6

[a]The *P*-value for HS and NHS isolates was calculated by a two-sided binomial test to determine the significant differences between HS and NHS isolates. All *P*-value for HS and NHS isolates were significant ($P < 0.05$), except penicillin G ($P > 0.05$) (46).

Table 2. Predominant Antibiotic Resistance Patterns of *E. coli* Isolated from Human Source (HS), Nonhuman Source (NHS), and Human* and Animal Feces*

Antibiotics[a]	Percentage with Each Resistant Pattern			
	HS[b]	NHS[c]	Human[d*]	Animal[e*]
C-Su	33.7	15.4	40.0	ND[f]
C-P-Su	14.5	1.7	ND	ND
C	7.9	8.4	16.7	ND
C-P	7.4	28.2	ND	6.9
Su	2.2	1.4	6.7	ND
Other resistant patterns[g]	28.9	12.5	23.3	20.7
Sensitive to all antibiotics	5.4	32.4	13.3	72.4

[a]C, chlortetracycline; P, penicillin G; Su, sulfathiazole.
[b]$n = 407$.
[c]$n = 358$.
[d]$n = 30$.
[e]$n = 29$.
[f]ND: none detected.
[g]Each of the other 59 patterns for HS, 26 patterns for NHS, 6 patterns for human*, and 3 patterns for animal feces isolates contained insignificant number of isolates are not shown.
Note: Asterisk (*) indicates isolates obtained directly from human or animal feces.

by Euclidean distance, is shown in Figures 1 and 2. At an Euclidean distance of approximately 1.8, seven clusters were formed among HS isolates, designated as P_1 to P_7. In contrast, four clusters were observed for NHS isolates N_1 to N_4. A covariance matrix of principal components clearly showed more diversity among HS isolates. In contrast, NHS isolates formed six focal groups. Clusters N_2 and N_4 were found in groups A, B, D; N_1 only in C; and N_3 only in E and F (Fig. 3). These results indicated that the MAR profile of *E. coli* was associated with source.

Discriminant analysis (DA) is a statistical method that can classify entities into groups on the basis of several classification variables (57). DA of MAR profiles was able to correctly classify 82% of HS and 68% of NHS isolates, and the average rate of correct classification (ARCC) was 75%. The ARCC is the average of the percentage of correctly classified isolates. *Escherichia coli* isolates obtained directly from human and animal feces showed that 77% of human and 79% of animal fecal isolates were correctly classified, with an ARCC of 78%. The combination of drugs that had the highest ARCC was ampicillin, chlortetracycline, penicillin G, and sulfathiazole (58).

Parveen and coworkers (59) recently found that DA of MAR patterns of *E. coli* isolates correctly classified 58% of poultry, 55% of beef, and 54% of dairy isolates. Swine isolates were poorly classified, whereby 44 and 25% of swine isolates were misclassified as poultry and dairy isolates. When beef and dairy isolates were pooled as cattle isolates, 80% of the cattle isolates were correctly classified. However, correct classification rates for swine and poultry remained similar. It was observed that omission of any of the antibiotic resistance data resulted in poorer classification of isolates. In addition, significant variations in MAR patterns were noted over the geographical areas for both beef and dairy isolates. In contrast, no significant variation was observed in MAR patterns for swine and poultry isolates, possibly because of the use of common antibiotics over a wide geographical area.

In a separate study, Harwood and coworkers (60) determined the MAR patterns for fecal streptococci and fecal coliforms and found that DA of MAR profiles of *E. coli* isolates correctly classified 54% human, 57% chicken, 54% cow, 95% dog, 73% pig, and 51% wild isolates.

Wiggins and coworkers (61) further demonstrated the utility of antibiotic resistance patterns for differentiating HS and NHS fecal contamination in water, focusing on its application for fecal streptococci. They found that 92% of HS isolates were correctly classified, with an average rate of correct classification (ARCC) of 84%. Wiggins and coworkers (62) also reported that DA of MAR profiles of fecal streptococci may be used for identifying specific animal sources of fecal contamination. They found that when isolates were classified individually, the ARCC ranged from 64 to 78%.

In similar studies, Hagedorn and coworkers (63) analyzed the MAR patterns of 7,058 fecal streptococci isolated from Montgomery County, Virginia, by DA. They found that 86% beef cow, 85% chicken, 87% dairy cow, 84% deer, and 93% human isolates were correctly classified, and the ARCC was 87%.

O-SEROGROUPING

Somatic (O)-serogrouping of bacteria is based on the presence or absence of O-antigenic determinants and their reaction with specific antisera. The O-antigen is a thermostable surface structure found in morphologically smooth strains of Enterobacteriaceae. It constitutes the O-polysaccharide of the bacterial cell wall lipopolysaccharide and is determined by chromosomal genes (64). Several investigators have used this method for discriminating *E. coli* from different sources (42,47). The distribution of various *E. coli* serotypes appears to be different for

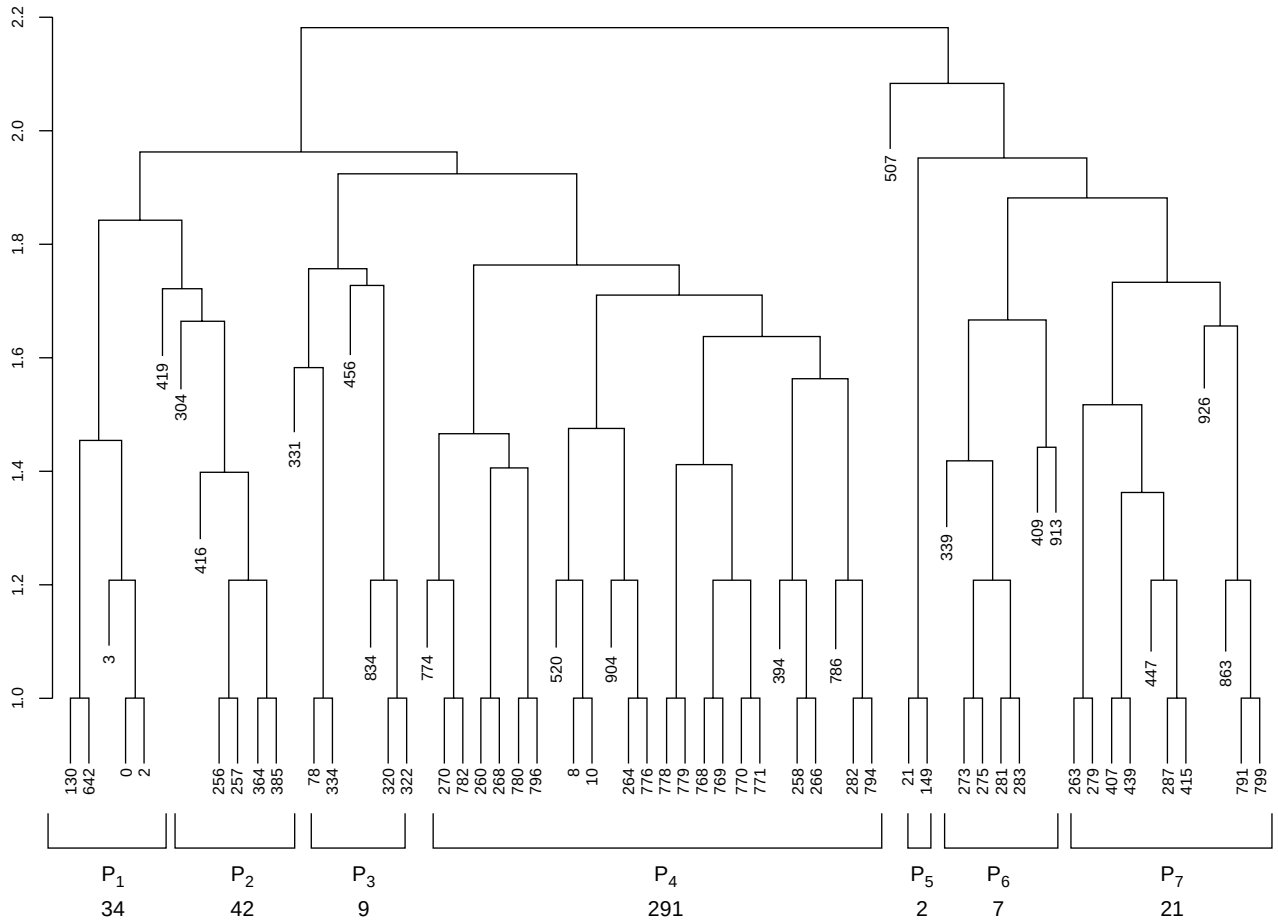

Figure 1. Dendrogram of antibiotic resistance profiles for HS *E. coli* isolates determined by Euclidean metric, average linkage analysis. Clusters were defined at a distance of 1.8. Numbers on dendrogram represent antibiotic resistant pattern, not strain numbers. Numbers at bottom indicate the number of isolates in each cluster; the Euclidean distance is indicated on the left axis (46).

humans and animal isolates (33,65,66), although many human serotypes can also be associated with other organisms (33). Parveen and coworkers (67) serogrouped a total of 100 HS and NHS isolates and found that 77% were typeable. The predominant O-serogroups are shown in Table 3. Human source isolates exhibited 19 serogroups, with 48% belonging to seven serogroups (O2, O20, O28, O79, O148, O153, O159) and the remaining isolates to 12 additional serogroups. In contrast, NHS isolates displayed 26 serogroups, with 36% in seven serogroups (O8, O11, O × 13, O19, O150, O152, O15/143), and the remaining isolates in 19 additional serogroups. Only 2 of 50 NHS isolates shared the seven most frequently detected serogroups for HS isolates ($P < 0.01$). This indicated that there was an association between O-serogroups and the isolate source. From this study, it was determined that the O-serogroups of HS isolates were rarely found in NHS isolates, similar to previously published studies (33). The majority of O-serogroups that we observed for NHS isolates were previously reported for cattle, chicken, and swine (33). These results also agree with studies by Hartley and coworkers (66) who compared the prevalent O-serogroups of diseased animals and humans, and found that most strains associated with diarrhea in pigs and humans were different, whereas those from infantile and piglet diarrhea have many common traits.

In conclusion, serogrouping may be a useful tool for differentiating HS and NHS *E. coli*. Drawbacks include the need for a large panel of antisera, many of which are not commercially available, and also that some isolates cannot be typed.

PULSED-FIELD GEL ELECTROPHORESIS (PFGE)

PFGE is a genotypic method that detects variations in nucleotide sequences of chromosomal DNA. From the literature, it is apparent that PFGE has been mainly used in epidemiological studies, especially for *E. coli* O157:H7 (68,69). Herbein and coworkers (70) reported PFGE profiles for three raccoons, one otter, one goose, three humans, and one muskrat. Within this limited sample size, they found that PFGE profiles of raccoons differed significantly from those of the otter and goose. There was no significant difference between PFGE profiles of raccoons, humans, and a muskrat. Parveen and

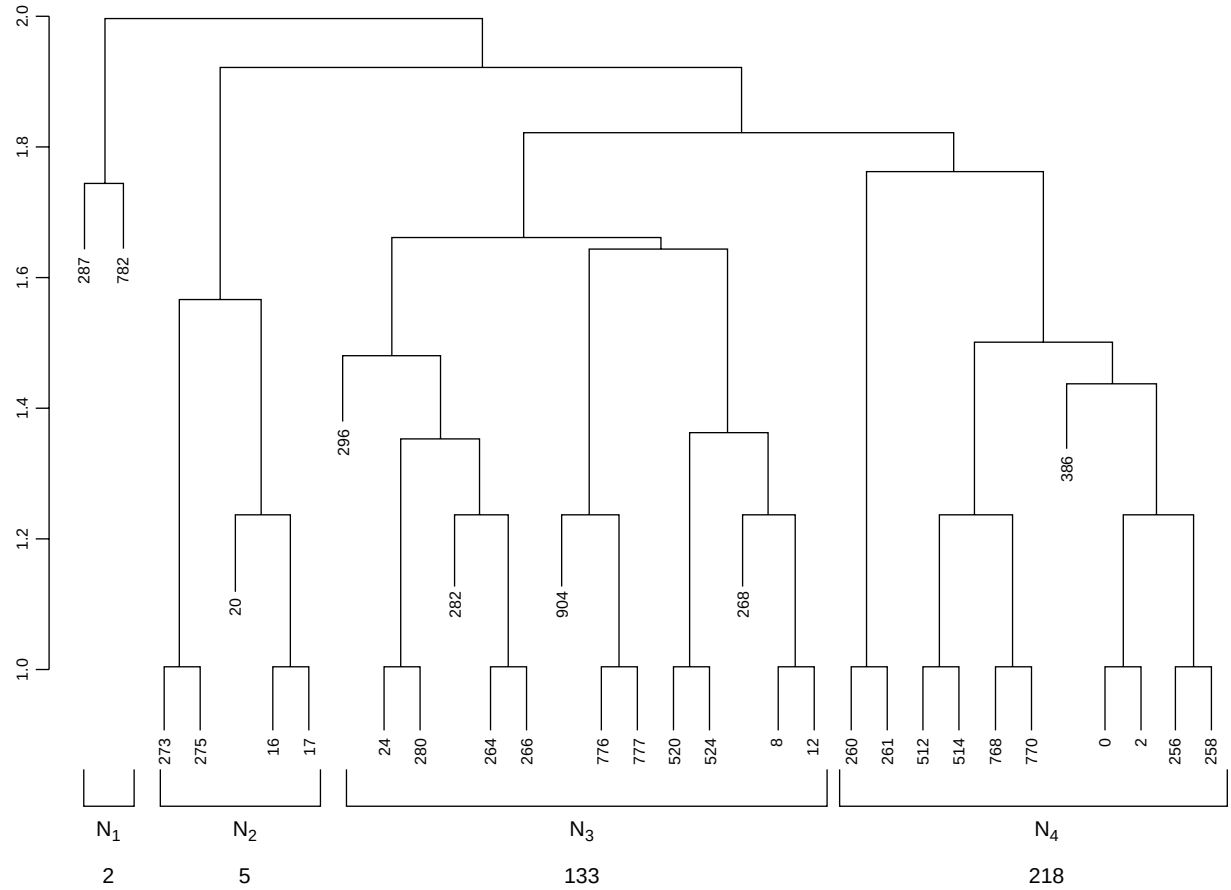

Figure 2. Dendrogram of antibiotic resistance profiles for NHS *E. coli* isolates determined by Euclidean metric, average linkage analysis. Clusters were defined at a distance of 1.8. Numbers on dendrogram represent antibiotic resistant pattern, not strain numbers. Numbers at bottom indicate the number of isolates in each cluster; the Euclidean distance is indicated on the left axis (46).

coworkers (67) analyzed a total of 32 *E. coli* isolates for PFGE profile, and found that HS and NHS isolates formed 9 and 18 PFGE profiles, respectively. There was no association between PFGE profile and isolate source. PFGE profiles of *E. coli* were not able to differentiate HS and NHS isolates. This was not surprising as PFGE detects small sequence differences that may not associate with a specific bacterial characteristic, such as host source.

RIBOTYPING

Ribotyping, a relatively recent development in DNA analysis, is the study of the distribution of the restriction sites throughout rRNA genes. It has been successfully used to characterize microorganisms belonging to different genera (55,71,72) and research has been done to differentiate *E. coli* source by ribotype (RT). Samadpour and Chechowitz (73) were able to identify 71% of HS and NHS *E. coli* isolates using ribotyping. Simmons and Herbein (74) used ribotyping for differentiating HS and NHS *E. coli* for a limited number of isolates. Hartel and coworkers (75) used an automated instrument to ribotype *E. coli* isolates from two small streams in Georgia. They were able to discriminate among ribotypes of *E. coli* from a pasture stream, a wooden stream, and cow manure, but the discrimination was insufficient within a specific site.

Parveen and coworkers (76) isolated a total of 238 *E. coli* from HS and NHS in the ANERR, and directly from human and animal feces, and tested the isolates for RT. HS and NHS isolates showed 41 and 61 RT profiles, respectively. At approximately a 50% similarity index, HS and NHS isolates demonstrated four clusters, with the majority of HS and NHS isolates located in two clusters; isolates obtained directly from human and animal feces also grouped within these clusters. DA of RT profiles showed that 97 and 67% of NHS and HS isolates, respectively, were correctly classified. The ARCC for HS and NHS isolates was 82%. DA of *E. coli* isolates obtained directly from human and animal feces showed that 67 and 100% of human and animal fecal isolates were correctly classified, respectively, and the ARCC was 84%.

In another study, a total of 287 *E. coli* strains isolated from humans, cattle, pigs, horses, chickens, turkeys, migratory geese, and dogs were analyzed by RT. It was

found that DA of RT were correctly classified for 95% HS and 99% NHS strains. The ARCC of *E. coli* RT from human, cattle, pig, horse, dog, chicken, turkey, and goose were 93, 74, 66, 49, 55, 96, 81, and 76%, respectively. It was also observed that the classification accuracy was best when analysis was limited to three host sources (77). It can be concluded that DA of RT profiles is a useful method to identify HS and NHS fecal contamination, and potentially facilitates management practices.

Recently, Dombek and coworkers (78) reported that rep-PCR fingerprint technique can be used to differentiate human and animal sources of fecal pollution. In rep-PCR DNA fingerprinting, PCR amplification of the DNA between adjacent repetitive extragenic elements is used to obtain strain specific DNA fingerprints, which can be easily analyzed with pattern recognition computer software. The animal isolates included in this study were two types of waterfowl (geese and ducks) and common farm animals (cows, pigs, sheep, and chickens). They used two primers (BOX and REP) to generate DNA fingerprints from *E. coli* strains isolated from human and animal sources. The DNA fingerprints obtained with one primer (BOX) were more effective for grouping *E. coli* strains than the DNA fingerprints obtained with another primer (REP). A statistical analysis (Jackknife) of DNA fingerprints obtained with one primer (BOX) correctly

classified 83% human, 81% of goose, 78% of duck, 90% of sheep, 81% of pig, 100% of chicken, and 100% of the cow strains.

CONCLUSION

We have reviewed the traditional and modern methods used to detect and differentiate sources of fecal contamination in aquatic and other environments. Each method has advantages and disadvantages. For example, phenotypic methods are influenced by environmental factors, and they may vary in different geographical areas, and over time. In contrast, genotypic methods are more stable and are less influenced by environmental factors. However, the latter methods can be expensive, time-consuming, and laborious. In addition, there is the possibility of low level transfer of fecally derived organisms among different animal species.

There is probably no ideal method that is suitable for all environments. Research is in progress in many laboratories throughout the world to develop an ideal method for differentiating sources of fecal contamination. Hopefully, biotechnological advances will result in rapid, simple and reliable methods to detect sources of fecal pollution in aquatic as well as other environments.

FECAL STREPTOCOCCI/ENTEROCOCCI IN AQUATIC ENVIRONMENTS

Reus, Spain

INTRODUCTION: DEFINITION AND TAXONOMIC POSITION

The term *fecal streptococci* has been used to describe a group of taxonomically diverse streptococci associated with the gastrointestinal tract of humans and animals (1). Thiercelin (2) described the most common organisms isolated from human stool in 1899 as "enterococcus" to emphasize their intestinal origin. A few years, later Andrewes and Horder (3) described the species *Streptococcus faecalis* from various infections and, in 1919, Ora-Jansen (4) reported the species *S. faecium* isolated from human and animal feces. Sherman (5) indicated that the term enterococcus had been used to refer to different microorganisms ranging from the broad definition of any fecal streptococcus to a narrow definition of organisms that appeared to be identical to *S. faecalis*. Sherman proposed a classification scheme that separated streptococci into four divisions, namely, pyogenic, viridans, lactic, and enterococcus. The latter term was used for organisms that grew at both 10 °C and 45 °C, in 6.5% NaCl, at pH 9.6, reduced 0.1% methylene blue in milk, survived at 60 °C for at least 30 minutes, and were able to use esculin. Sherman's classification also correlated with the serological scheme proposed by Lancelfield (6) for the identification of streptococci. In that scheme, the enterococci reacted with group D antisera, whereas the pyogenic streptococci reacted with groups A, B, C, E, F, or G, and the viridans streptococci were ungroupable. However, streptococci classified by Sherman scheme as viridans streptococci, such as *S. bovis* and *S. equinus*, have shown to react with group D antiserum. On the other hand, some strains of enterococci were found to react not only with Lancefield's group D antiserum but often also with group Q, such as *S. avium* (7). The terms fecal streptococci, enterococci, and group D streptococci have been used indistinctively in the literature (1). Taking into account Sherman's criteria and Lancefield antigens, Clausen and coworkers (8) proposed to consider the following species as fecal streptococci: *Streptococcus faecalis*, *S. faecium*, *S. durans*, *S. avium*, *S. bovis*, *S. equinus*, *S. mitis*, and *S. salivarius*. The latter two were described as inhabitants of the nasopharyngeal tract and usually grouped with the "oral streptococci" (9). Bridge and Sneath (10) described a new group D streptococcus from chickens and it was designated *S. gallinarum*.

Kalina (11), on the basis of physiological characters, suggested that a new genus named *Enterococcus* should be proposed to include the enterococcal streptococci

including *S. faecalis* and *S. faecium* and the subspecies of these two taxons. In fact, the genus *Enterococcus*, which included *Enterococcus faecalis* and *E. faecium*, was separated from *Streptococcus* on the basis of DNA hybridization data by Schleifer and Klipper-Bäz (12). These changes were, however, not taken into account in the 1986 edition of *Bergey's Manual* (13), but they did appear in the 9th edition of *Bergey's Manual of Determinative Bacteriology* (14). The use of nucleic acid relatedness has clarified and expanded the classification scheme for enterococci. As reflected in Table 1, it has been proposed that 19 species should be included in the genus *Enterococcus* (1,15–17). In the 9th edition of *Bergey's Manual of Determinative Bacteriology* (14), only 16 species within the genus *Enterococcus* are recognized, excluding *E. columbae*, *E. flavescens*, and *E. sulfureus*.

The taxonomy of *Enterococcus* or *Streptococcus* genera has not yet been fully resolved. The terms *fecal streptococci*, *enterococci*, or *intestinal enterococci* embraces species of the genera *Enterococcus* and *Streptococcus*, although there is no complete agreement about which species should be included under these terms (Table 2; 1,8,18–22). In practice, detection and enumeration will be the conventional approach when studying these organisms in aquatic environments and therefore this disagreement may not be very important. In water samples influenced by human fecal pollution, the predominant species identified are *E. faecium*, *E. faecalis*, and *E. durans* (23–26). Therefore, the terms fecal streptococci, enterococci, intestinal enterococci, and Enterococcus group when used in the literature to refer to indicators of fecal pollution can be considered in practice synonymous. Phenotypic characterization carried out in the past may not match new taxonomic descriptions (1), and, therefore, this should be taken into account when reading the comparisons made throughout this chapter.

IDENTIFICATION

The genus *Enterococcus* consists of gram-positive (G + C content of 37 to 45 mol %), facultatively anaerobic organisms, which are ovoid in shape and may appear on smear in short chains, in pairs, or as single cells. Like streptococci, these organisms do not have cytochrome enzymes and are thus catalase negative, although some strains do produce pseudocatalase. Hydrolysis of L-pyrrolidonyl-ß-naphthylamide (PYR) and production of leucine-aminopeptides (LAP) are characteristic features coincident with group A streptococci but not with other streptococci (27). Most strains in the genus *Enterococcus* possess the characteristics of Sherman's scheme, but there are several different characteristics among enterococcal species (Table 3). All enterococci are able to hydrolyze esculin in the presence of bile salts, and so this test has been used for the rapid discrimination between *Enterococcus* and *Streptococcus* (28). However, several other gram-positive organisms can also yield a positive reaction in some of these tests, and for this reason Facklam and coworkers (29) designed a battery of tests for the complete discrimination of enterococci, including gas from glucose and vancomycin susceptibility testing (Table 4).

For routine monitoring of water samples, it will not be necessary to identify enterococci to the species level, although this may be necessary in other instances, for example, in many clinical cases, for epidemiological surveillance, or for establishing the predominance of the species in a given water environment. A number of

Table 1. Proposed Species of the Genus *Enterococcus* and Their Habitat (1,16)

Species	Previous Name in *Streptococcus*	Habitat
E. avium	*S. avium*	Avian, canine, and human GIT
E. casseliflavus	*S. casseliflavus*	Plants, soil, and chicken feces
E. cecorum	*S. cecorum*	GIT of chicken
*E. columbae**	ND	GIT of pigeon
E. dispar	ND	Human specimens and feces
E. durans	*S. durans*	Milk, dairy products
E. faecalis	*S. faecalis*	GIT of humans and animals
E. faecium	*S. faecium*	GIT of humans and animals
*E. flavescens**	ND	Human clinical specimens
E. gallinarum	*S. gallinarum*	Chicken feces
Enterococcus hirae	ND	Chicken crops and feces, GIT of cattle, pigs, canines, horses, sheep, goats, and rabbits
E. malodoratus	*S. faecalis subsp. malodoratus*	Cheese and unpasteurized milk
E. mundtii	ND	Plants, soil, and GIT of pigs, cattle, horses
E. pseudoavium	ND	Bovine mastitis
E. raffinosus	ND	Human infection
E. saccharolyticus	*S. saccharolyticus*	Cows
E. seriolicida	ND	Yellow-tail fish, subclinical mastitis
E. solitarius	ND	Rumen and clinical human samples
*E. sulfureus**	ND	Plants

*Species excluded in the *Bergey's Manual of Determinative Bacteriology* (14);
Note: New description (ND); gastrointestinal tract (GIT).

Table 2. Proposed Species to Be Included in the Group Fecal Streptococci/Enterococci

Species	Clausen (8) Sinton (19)	Devriese (18) Leclerc (1)	Dionisio and Borrego (21) Borrego and Figueras, (22)	Anon. (20)

Table 3. Test Differentiating Between Enterococcal Species (14,15)

Test	Typical Results	Exceptions
Lancefield group D	+	*E. cecorum*, *E. seriolicida*, *E. dispar*, *E. saccharolyticus*, *E. sulfureus*, *E. columbae*, and many strains of *E. avium*
Growth at 45 °C	+	*E. dispar*, *E. malodoratus*, *E. sulfureus*
Growth at 10 °C	+	*E. cecorum*, *E. columbae*
Growth at 6.5% NaCl	+	*E. cecorum*, *E. columbae*, *E. pseudoavium*
PYR	+	*E. cecorum*, *E. columbae*, *E. saccharolyticus*
Motility	−	*E. casseliflavus*
Voges-Proskauer test	+	*E. saccharolyticus*, *E. malodoratus*, *E. avium*, and many strains of *E. solitarius*
ß-glucuronidase	−	*E. cecorum*
Alkaline phosphatase	−	*E. cecorum*, *E. columbae*
Arginine dihydrolase	+	*E. cecorum*, *E. pseudoavium*, *E. avium*, *E. saccharolyticus*, *E. sulfureus*, *E. columbae*, *E. malodoratus*, *E. raffinosus*
Hippurate test	−	*E. gallinarum*
Pyruvate test	−	*E. avium*, *E. solitarius*
Pigment production	−	*E. casseliflavus*, *E. mundtii*
Acid production from:		
Sucrose	+	*E. pseudoavium*, *E. seriolicida*, *E. durans*, and certain strains of *E. faecium*
Adonitol	−	*E. avium*, *E. pseudoavium*, *E. malodoratus*, *E. raffinosus*
Glycogen	−	*E. gallinarum*, *E. cecorum*, *E. columbae*
Lactose	+	*E. seriolicida*, *E. solitarius*, and asaccharolytic variants of *E. faecalis*
L-Rhamnose	−	*E. avium*, *E. casseliflavus*, *E. malodoratus*, *E. mundtii*, and certain strains of *E. faecalis*
D-Xylose	−	*E. gallinarum*, *E. casseliflavus*, *E. mundtii*, and certain strains of *E. malodoratus*
D-Arabitol	−	*E. avium*, *E, pseudoavium*, *E. malodoratus*, *E. raffinosus*, *E. saccharolyticus*
Inulin	−	*E. gallinarum*, *E. casseliflavus*, *E. saccharolyticus*, *E. cecorum*, *E. columbae*
Mannitol	+	*E. cecorum*, *E. columbae*, *E. dispar*, *E. durans*, *E. hirae*
L-Sorbose	−	*E. avium*, *E. pseudoavium*, *E. malodoratus*, *E. raffinosus*
Raffinose	−	*E cecorum*, *E. casseliflavus*, *E. malodoratus*, *E. mundtii*, *E. gallinarum*, *E. hirae*, *E. raffinosus*
Sorbitol	−	*E. avium*, *E. pseudoavium*, . *E. raffinosus E. mundtii*
L-Arabinose	−	*E. avium*, *E. casseliflavus*, *E. faecium*, *E. raffinosus*, *E. gallinarum*, *E. solitarius*

biochemical traits facilitate differentiation of enterococcal species, such as the ability to grow in the presence of tellurite, reduction of tetrazolium salts, acid production of several compounds (D-tagatose, sorbitol, glycerol, melibiose, and L-arabinose), motility, pigment production, hydrolysis of arginine and PYR (15,30,31). Panosian and Edberg (32) have recommended the detection of ß-D-glucosidase activity in the presence of 2.5% sodium deoxycholate, α-D-galactoside, and PYR for the rapid identification of *S. bovis*, *S. equinus*, *S. pneumoniae*,

Table 4. Tests Used to Differentiate Selected Gram-Positive Organisms (29)

Tests	% Positive					
	Enterococcus	*Lactococcus*	*Aerococcus*	*Pediococcus*	*Leuconostoc*	*Lactobacillus*
Gas from glucose	<1	0	0	0	100	50

Growth at 10 °C	85	100	0	4	75	100

[a] PYR: Pyrrolidonyl-ß-naphthylamide.

Enterococcus spp., and the viridans streptococci. More recently, Devriese and coworkers (33) described the usefulness of a test based on acid production from methyl-α-D-glucopyranoside for differentiating *E. gallinarum* and *E. casseliflavus* from *E. faecalis* and *E. faecium* as the former species are unable to produce acid from this substrate. Manero and Blanch (34) provided a six-step biochemical key for species identification within the genus *Enterococcus*, which is easier to perform than previously proposed keys (15,35), and it allows the identification of all known species (Table 1).

Clinical laboratories generally use commercially miniaturized systems, such as the API 20 S (bioMérieux), the Vitek System GP1 card (bioMérieux), the Rapid Strep System (API), or the RapID STR System (Innovative Diagnostic Systems). Most of these test systems provide an identification in about four hours. Although Vitek and API 20S have proven useful for the identification of clinical enterococci to the species level (36), they can produce erroneous identification for environmental enterococcal strains, and the results of conventional tests and miniaturized tests do not always agree (37,38).

Commercially available chromogenic tests based on the pyrrolidonyl carboxylic acid or pyroglutamic acid conjugates of ß-naphthylamine have been evaluated comparatively (39). The chromogenic PYR tests are included in API 20 STREP kit, RapID STR system, MicroScan Conventional Gram-Positive Panels (Dade Intl.), Pasco Gram-Positive ID Panel (Difco Lab.), BBL Crystal Rapid Gram-Positive ID Panel (Becton Dickinson & Co.), and Vitek II System (bioMerieux-Vitek, Inc.).

A rapid nonradioactive DNA probe (AccuProbe Enterococcus DNA culture confirmation probe, Gen-Probe, Inc.) has been used for positive identification of enterococci because most species react positively with the probe with the exceptions of the strains of *E. cecorum*, *E. columbae*, *E. seriolicida*, *E. solitarius*, and *E. saccharolyticus* (31). However, other nonenterococcal species, such as *Vagococcus fluvialis*, have been shown to react positively with this AccuProbe genetic probe (40).

HABITAT AND CLINICAL SIGNIFICANCE

Enterococci are ubiquitous and can be found as free-living in soil, on plants, in dairy products, and as part of the normal microbiota of the gastrointestinal tract of humans, other mammals, and birds. They have been implicated in outbreaks of food-borne illnesses, and they can possess both a beneficial and detrimental role in foods (41). Enterococci are also used as probiotics to improve the microbial balance of the intestine, or as a treatment for gastroenteritis in humans and animals (41). In humans, enterococci are found in the feces of most healthy adults (more than 95%) at concentrations ranging from 10^5 to 10^7 colony forming units (CFU) per gram of feces (42,43), *E. faecalis* being more common and found in higher numbers than *E. faecium* (42).

Enterococci are less commonly found in other human sites such as vaginal tract (44) and oral cavity (45), and results are sometimes quite variable. Campbell and coworkers (46) found higher rates of enterococcal carriage among long-term hemodialysis patients and cardiac patients, *E. faecium* being outnumbered by *E. faecalis* isolates.

Several authors have thoroughly reviewed the variety of human infections in which enterococci are involved (30,47,48). These organisms most commonly infect the urinary tract, bloodstream, endocardium, biliary tract, burn wounds, indwelling devices, abdomen, and can produce enterococcal bacteremia. In addition, several infections have occasionally been reported in other organs and tissues, such as the central nervous system, lung, soft tissues, paranasal sinuses, ear, eye, and periodontal tissues.

Between 80 and 90% of clinical enterococcal isolates have been classified as *E. faecalis*, whereas 5 to 10% will correspond to *E. faecium* (31,49). Other enterococcal species, including *E. avium*, *E. casseliflavus*, *E. durans*, *E. gallinarum*, *E. hirae*, *E. malodoratus*, *E. mundtii*, *E. raffinosus*, and *E. solitarius*, are infrequent causes of human infections (50). Enterococci have become major nosocomial pathogens because they are the fourth leading cause of hospital-acquired infections and the third leading cause of bacteremia in the United States (51,52). Increases

in enterococcal infections, especially in hospitals, are associated with virulence factors (Table 5), which according to Jett and coworkers (49) are related to: (*1*) adherence to host tissues, (*2*) invasion and abscess formation, (*3*) factors potentially relevant to modulation of host inflammatory responses, and (*4*) potentially toxic secreted products.

Recent attention has focused on enterococci because of their remarkable and increasing resistance to antimicrobial agents. Antimicrobial resistance can be divided into two general types, namely, inherent and acquired. The genes for intrinsic or inherent resistance appear to reside in the chromosome, whereas acquired resistance results either from a mutation in the existing DNA or acquisition of new DNA from plasmids or transposons (30). The various intrinsic traits expressed by enterococci include resistance to semisynthetic ß-lactams, cephaloporins, low levels of aminoglycosides, and low levels of clindamycin. Examples of acquired resistance include resistance to chloramphenicol, erythromycin, tetracycline, vancomycin, and high levels of clindamycin and aminoglycosides. Resistance to high levels of penicillin and resistance to fluoroquinolones are not known to be plasmid or transposon-mediated and are presumably due to mutations, as in other microorganisms such as *Salmonella* (30,53).

Recent data from the Centers for Disease Control and Prevention indicate that up to 50% of *E. faecium* clinical strains are resistant to vancomycin (54). Vancomycin-resistant strains have disseminated throughout the United States and Europe in recent years, many of these organisms being also highly resistant to ß-lactams and aminoglycosides (55). Mortality rates for patients with vancomycin-resistant enterococcal bacteremia are extremely high (55). Vancomycin-resistant enterococci (VRE) have been isolated in stools of asymptomatic individuals who have neither been hospitalized nor received antibiotics (56,57). If asymptomatic fecal carriers of VRE are admitted to hospital, they may act as the source of hospital outbreaks (56). VRE have also been found in sewage, stool of healthy farm animals, animal products, and foodstuffs (56,57). VRE may also enter the food chain by the use of glycopeptide antibiotics in animal feed (56–58). Although enterococci have been traditionally regarded as low-grade pathogens, they now have to be seen as important opportunistic pathogens, especially when VRE are involved.

Table 5. Virulence Factors for Enterococci (49)

Factor	Observed Activities
Cytolysin	— Lytic toward gram-positive bacteria and eukaryotic cells
	— Decreased LD_{50}
	— Increase mortality in animal models
Aggregation substance	— Binding of donor and recipient cells in pheromone mating response
	— Increase the adherence to eukaryotic cells
	— Increase animal mortality in conjunction with cytolysin
Pheromones	— Chemoattractant for neutrophils
Lipoteichoic acid	— Stimulation of cytokine production
	— Binding ligand for aggregation substance in pheromone mating response
Protease (gelatinase)	— Zinc-endopeptidase
Hyaluronidase	— Mucopolysaccharidase
AS-48	— Bacteriocin with activity against gram-positive and gram-negative bacteria

FECAL POLLUTION OF NATURAL WATER ENVIRONMENTS

Concept of Indicator Organisms

Natural waters are subject to important changes in their microbial quality because of occasional discharges of wastewater as a result of human activity or stormwater runoff. Sewage effluents contain a wide range of pathogenic microorganisms that may pose a health hazard to the human population if contaminated water is used for drinking, shellfish growing, and/or recreation. The density and variety of these pathogens are related to the size of the population, the seasonal incidence of the illness, and the dissemination routes of pathogens (22,59).

The presence of enteric pathogens in drinking and recreational water is of great concern (59–61). Therefore, it is extremely important to determine the microbiological safety of these waters by analyzing them for the presence of specific pathogens of concern. However, a wide variety of microorganisms have been shown to be involved in waterborne disease outbreaks, and their presence in polluted waters is intermittent and/or in low concentrations; thus, it would be impractical to look for every pathogen potentially present in water samples (62). In addition, the methods for the detection and enumeration of pathogens are frequently complex and expensive, involving concentration processes and subsequent selective enrichment or amplification by molecular techniques. Additionally, the recovery efficiency of the procedures is low and these techniques are limited to specialized research laboratories (63). Alternative organisms that are consistently present in fecal material survive reasonably well in water compared with pathogens, and are easier to detect, and have therefore been widely used as fecal pollution "indicators."

Indicator organisms must fulfill the following requirements (64):

1. Indicators should also be present in feces, sewage, and sewage-polluted water whenever the pathogens are present, and should be absent in water without fecal pollution.
2. The levels of indicators should have some direct relationship to the density of pathogens in aquatic environments, and should be proportional to the extent of pollution.
3. The survival rate of indicators in water must be at least similar to that of pathogens. In addition, the resistance of indicators to environmental inactivation factors and disinfectants should be at least similar to that of the pathogens.

4. Indicators must be detectable by a simple, inexpensive, accurate, and rapid laboratory methodology.
5. Indicators should be nonpathogenic and applicable to all types of water samples that require a monitoring program.
6. Their characteristics must be constant.
7. Indicators must not grow and multiply in water.

Mossel (65) defined the term *model organism*, which refers to two different functions, index and indicator. "Index organisms" are related, directly or indirectly, either to the health hazards or to the pathogen presence, and they must fulfill three types of criteria, namely, similar ecology, similar resistance and persistence, and simple methodology. On the other hand, "indicator organisms" are related only to the effects of treatment processes or control of water quality. The requirements for "indicator organisms" are less restrictive than those for an index organism; their resistance to the environment must be only similar to that of pathogens and they require more simple laboratory methodologies.

The use of "index" or "indicator" organisms to assess the microbiological and sanitary quality of water is well established and has been practiced for almost a century. The most widely used indicator organisms are total coliforms, fecal coliforms (and *Escherichia coli*), and fecal streptococci (or enterococci) (66). However, it is widely acknowledged that no single indicator group or species can be expected to provide a satisfactory indication of disease risk in all situations (67), and most of them are more susceptible to adverse environmental conditions than pathogenic microorganisms are, including viruses (68).

Accordingly, there is an increasing number of investigations on alternative indicators of water quality. These include sulfite-reducing clostridia (*Clostridium perfringens*) (69,70), *Staphylococcus aureus* (71,72), *Pseudomonas aeruginosa* (73,74), bifidobacteria (75), several groups of bacteriophages (76–80), and fecal sterol biomarkers (81). The advantages and disadvantages of classical and alternative indicators have been broadly discussed in the recent literature (66,82).

Fecal Streptococci/Enterococci as Indicator Organisms

At the beginning of the twentieth century Houston (83) noted the abundance of streptococci in sewage and proposed that they might be useful for detecting contamination of water by human feces. Since then, fecal streptococci have received widespread acceptance as useful indicators of fecal pollution in natural aquatic ecosystems, on the basis of the following characteristics: (*1*) they show a high and close relationship with health hazards associated with bathing in marine and freshwater environments, mainly for gastrointestinal symptoms; (*2*) they are not as ubiquitous as coliforms are; (*3*) they are always present in feces of warm-blooded animals; (*4*) they are unable to multiply in sewage-contaminated waters; and (*5*) they die more slowly than coliforms in seawater, and their persistence patterns are similar to those of potential waterborne pathogenic bacteria or viruses (19,84–88).

To determine the usefulness of fecal streptococci as indicators of fecal pollution, it is important to ascertain whether they exist in nature only in association with feces, or whether they can persist and multiply in the environment independently of any input of fecal pollution. In animal feces, fecal streptococci generally outnumber fecal coliforms, although the overall incidence and concentration appears to differ markedly among animal species (1). In contrast, streptococcal concentrations in human feces (about 3×10^6/g) are generally lower than those for fecal coliforms, which are typically around 1.3×10^7/g (89). It appears that enterococci that dominate fecal streptococci in human effluents are present in municipal sewage in concentrations 10,100 times lower than *E. coli* (90). Although fecal streptococci are present in raw (1×10^4/mL) and treated (2×10^2/mL) wastewater at lower levels than *E. coli*, the numbers of fecal streptococci consistently exceed those of both bacteria and viral pathogens (88). The resistance of fecal streptococci to disinfection processes is about twice that exhibited by *E. coli* (88).

Numerous old studies have reported the occurrence of fecal streptococci, including enterococci, on plants and insects. Geldreich and Kenner (91) found that 46.1% of plant fecal streptococci were enterococci, 9% were *S. bovis* or *S. equinus*, and 43.9% were atypical strains. The occurrence of fecal streptococci on plants may be due to three possible causes (8): (*1*) as a result of direct contamination from warm-blooded animals and /or insects; (*2*) streptococci are temporary residents on plants, where they are capable of limited reproduction; and (*3*) they exist on plants in a truly epiphytic relationship, they spread by seeds, and are able to reproduce on the growing plant. Many of the enterococci isolated from plants have been reported to differ from strains characteristics of warm-blooded animals; thus, Geldreich and coworkers (92) detected starch hydrolysis in 37.7% of enterococci isolates from plants, whereas this characteristic was uncommon in strains recovered from humans (93).

Fecal streptococci have been recovered from a variety of insects, including *E. faecalis* and *E. faecium*, but not *S. bovis* and *S. equinus* (92,94). These authors suggested that fecal streptococci are not common residents of insects but are present as a result of chance contacts with streptococci in the environment. Clausen and coworkers (8), on the basis of similarities between plant and insect strains, suggested the existence of frequent exchange of organisms between both sources, whereas according to Leclerc and coworkers (1), the enterococci populations are most likely carried to the plants by insects. These authors indicated, however, that the studies on which these conclusions are based were performed before the genus *Enterococcus* was redefined and rearranged and that similar studies using modern taxonomic concepts are needed to validate the conclusions.

Stormwater runoff can influence the microbiological quality of surface water and, in fact, streptococcal numbers in natural water can be strongly related to their incidence in soil. Medreck and Litsky (95) found enterococci in only 2.2% of unpolluted soil samples, but Geldreich and Kenner (91), in a study of fecal streptococci species from agricultural soils, found that 35% were *S. faecalis* sub sp. *liquefaciens*, 63% were other *S. faecalis* strains, and 2%

were *S. bovis* and *S. equinus*. There are no clear data in the recent literature about the influence that these naturally occurring enterococci may have on the final concentration of fecal streptococci found in water samples.

Applications of Fecal Streptococci to Distinguish Between Human and Animal Sources

In studies of contaminated aquatic systems, it is often desirable to differentiate between humans and animals as the probable source of fecal pollution because this would assist in the overall management of microbial water quality (96). Although both fecal coliforms (FC) and fecal streptococci (FS) are present in high numbers in the feces of humans and animals, the ratio of FC to FS has been proposed as an indicator of the origin of the contamination by Geldreich and Kenner (91). These authors indicated that a ratio greater than 4 is characteristic of human fecal contamination, whereas a ratio less than 0.7 suggests animal wastes. These authors recommended that the FC to FS ratio should be considered indicative of a particular source only if the sample is collected within 24 hours of the fecal material entering the watercourse. However, this would not take into account the time between defecation and discharge, and in practice it is usually impossible to determine the age of fecal pollution in water (97). Poucher and coworkers (98) have shown that even in the first few hours after collection, the FC to FS ratio is not constant, even for samples of the same origin. Some reports have indicated that the FC to FS ratio possesses a limited value as a means of differentiating human from animal fecal pollution (66,98–100), on the basis of the differential die-off kinetics either of the two bacterial groups or of individual species within the fecal streptococcal group (101). Thus, die-off rates of fecal coliforms and fecal streptococci in natural water is *S. bovis-equinus* group greater than FC and FC greater than *E. faecium-faecalis* group (102). Feachem (103) argued that the differential rates of die-off of fecal streptococcal species, in fact, enhanced the value of the FC to FS ratio in distinguishing among pollution sources, because a predominantly human source (dominated by enterococci) should exhibit an initially high FC to FS ratio (>4), which falls during storage, whereas nonhuman sources (dominated by *S. bovis* and *S. equinus*) should exhibit an initially low FC to FS ratio (<0.7) with subsequent rises.

Wheater and coworkers (104) observed that not all animals maintain a FC to FS ratio of less than one. They determined that although FC to FS ratios in sewage effluents (human source) were invariably more than one, they did not always exceed four, and that ratios varied depending on the enumeration methodology used. Borrego and coworkers (99) concluded that FC to FS ratio does not give an absolutely trustworthy indication of the type of fecal pollution or its origin. It is more related to the pollution degree of the water sample and to the distance from the pollution source, because the index ≥ 4 can be found at the points near the pollution source, and ≤ 0.7 at more distant points.

Although many researchers who have examined fecal streptococcal population in human and animal fecal stools have commented on the implications of their findings with respect to pollution source identification, there have been relatively few studies designed to test this approach in aquatic environments. One of the difficulties associated with such field studies is the broad spectrum of streptococcal and enterococcal biotypes likely to be encountered. Thus, biochemical classification of fecal streptococci from the Nile River showed that about 78% of the isolates were distributed among atypical or unclassifiable categories (105). Bayne and coworkers (106) detected in a sewer outfall predominantly *E. casseliflavus* (formerly *S. faecium* var. *casseliflavus*), a species that is associated with plants rather than animals; and Wheater and coworkers (104) found that *S. bovis* was the predominant organism in samples from above a sewer outfall but the species was not recorded in sewage samples.

Rutkowski and Sjogren (107) characterized various pollution sources using the medium M2. In human sources (sewage treatment plants), the enterococci dominated at 61.5%, the group D viridans enterococci followed at 29.4%, and the oral streptococci ranged from 2 to 7.6%. In nonhuman sources, the group D nonenterococci constituted 93.3% of the total streptococcal population, with the remainder being enterococci. No oral streptococci (*S. mitis*, *S. salivarius*, and *S. sanguis*) were found in samples from animal sources.

The occurrence of enterococci in cattle dung water from the basins of animal farms was determined by Laukova and coworkers (108). The enterococcal predominant species were *E. faecium*, *E. faecalis*, and *E. durans* (average 36.5%) compared with *E. casseliflavus* (19.2%) and *E. avium* (1.9%). The predominance of human species should be explained by the fact that *E. faecium* and *E. faecalis* produced heat-stable bacteriocins, which exert a strong inhibitory effect on other enterococci (109,110).

Wiggins (111) used discriminant analysis of antimicrobial resistance patterns in fecal streptococci to differentiate between human and animal sources of fecal pollution in natural water. Bahirathan and coworkers (112) employed antibiotic susceptibility tests and restriction enzyme analysis (REA) of genomic DNA to characterize the relationship between sources of isolates of yellow-pigmented enterococci. More recently, patterns of antibiotic resistance in enterococci have been used to identify sources of fecal pollution in rural watershed (113) and in surface water and groundwater (114). The results obtained in these studies suggested that there are measurable and consistent differences in the antibiotic resistance patterns of enterococci isolated from various sources of fecal pollution, and, therefore, the antibiotic resistance analysis can be used to determine reliably the sources of fecal pollution (see also FECAL CONTAMINATION, SOURCES OF, this Encyclopedia).

EPIDEMIOLOGICAL STUDIES

A significant amount of epidemiological evidence has accumulated on the relationship between bathing in polluted water and illness. The majority of epidemiological studies have been conducted on marine beaches in England (87,115), France (116), Spain (117,118), Israel (119), other Mediterranean countries (120–122), Hong Kong (123,124), and the U.S. (125). Similar studies have been

carried out in fresh waters in Canada (126,127), the United States (128), France (129), England (130), and the Netherlands (131). Extensive revisions of the epidemiological studies carried out in bathing waters had been recently published (132,133). All these studies have demonstrated an excess rate of minor disease incidence among bathers when compared with nonbather control groups. The diseases observed in these epidemiological studies have been generally associated with infections of the gastrointestinal tract, ear, nose throat, and skin.

Prospective epidemiological studies of swimmers and nonswimmers at several paired (nonpolluted and barely acceptable) U.S. beaches were conducted since the 1970s (134). Two types of symptoms were defined, namely, gastroenteritis (GI) and highly credible gastroenteritis (HCGI). The principal finding was that a significant "swimming-associated gastroenteritis rate" was always observed at the more polluted beaches but not at the less polluted beaches, giving rise to a significant risk of acute gastroenteritis associated with swimming in polluted water (85,101,132,135). Skin, ear, eye, and respiratory symptoms were attributed to cross-contamination among bathers in conditions of heavy use and poor water exchange. In fact, an increasing risk of acquiring otitis externa after swimming in freshwater lakes in the Netherlands containing *Pseudomonas aeruginosa* have been demonstrated by van Asperen and coworkers (131). For marine beaches, enterococci showed the strongest relationship to gastroenteritis, and at freshwater beaches, illness was best correlated with *E. coli* densities, but the correlation with enterococci was still almost as high as that at marine beaches. On the basis of these findings, USEPA (134) established new bacteriological criteria, in which the geometric mean of the indicator bacteria densities should not exceed 126 *E. coli* per 100 mL or 33 enterococci per 100 mL for fresh water, and 35 enterococci per 100 mL for marine water. Similar conclusions have been reported by Ferley and coworkers (129) and Fleisher and coworkers (136), who indicated that enterococci were the only indicator organisms able to predict the occurrence of gastroenteritis among bathers of fresh and marine water respectively, contaminated with domestic sewage.

Although several investigations have indicated the close relationship between enterococci and the disease risks (132,137,138), other microorganisms have been reported as alternatives. Thus, staphylococci were found to be the best overall health risk indicator in several epidemiological studies, both in marine and freshwater ecosystems (119,123,126,127,139,140).

Mariño and coworkers (141) carried out an epidemiological-microbiological study on selected beaches on the Mediterranean coast of Spain to establish an association between use of the beaches and enteric and nonenteric diseases of the bathers. The results indicated that a significant correlation was established only between nonenteric symptoms of the bathers (skin infections) and the titers of *P. aeruginosa*, *Candida albicans*, and *Aeromonas hydrophila* in seawater samples. These authors also studied the applicability of World Health Organization/United Nations Environmental Program (WHO/UNEP) criteria and the European Union bathing water directive as microbial water quality guidelines (142). The conclusions of this study revealed that in coastal water with low fecal pollution level, the best indicators were fecal coliforms, *E. coli* and coliphages, whereas at high fecal pollution levels, the best indicators were enterococci and coliphages.

A preliminary epidemiological-microbiological study was conducted in Cape Town (South Africa) by von Schrinding and coworkers (143). An excess in gastrointestinal, respiratory, and skin symptoms was found among swimmers compared with nonswimmers at the polluted beach. Although not statistically significant, the results suggest a relationship between swimming-associated illness and water quality determined by analysis of enterococci, fecal coliforms, staphylococci, coliphages, and F-male specific bacteriophages.

Fleisher and coworkers (144) have identified possible dose-response relationships among bathers exposed to marine water contaminated with domestic sewage and subsequent risk of nonenteric illness in the United Kingdom. The results obtained indicated that exposure to fecal streptococci was predictive of acute febrile respiratory illness, whereas exposure to fecal coliforms was predictive of ear ailments. Estimated thresholds of effect occurred at bather exposures more than 60 fecal streptococci and 100 fecal coliforms per 100 mL of water, respectively.

The health effects of swimming in ocean water contaminated by storm-drain runoff in Santa Monica, California, was investigated using an epidemiological cohort study by Haile and coworkers (145). The higher risks for swimmers were related to the proximity to storm drains, a high level of single bacterial indicators (total and fecal coliforms, *E. coli*, and enterococci), a low ratio of total coliforms/fecal coliforms, and the presence of enteric viruses.

SURVIVAL OF FECAL STREPTOCOCCI/ENTEROCOCCI IN AQUATIC ENVIRONMENTS

Survival in Sewage, Ground water, and Fresh water

Few studies, compared with other indicators, have been performed on the survival of fecal streptococci or enterococci in aquatic environments. Some studies have shown that fecal streptococci outnumber coliforms. Thus, Cohen and Shuval (146) reported that removal of fecal streptococci (most of which were probably enterococci) from a primary settling and a biological filtration system was considerably lower than that of coliforms, and more closely resembled virus survival. In an open sewage channel receiving effluent, viruses showed the lowest die-off, followed by fecal streptococci.

However, the phenomenon of a higher survival of fecal streptococci has not been supported by other studies. For example, Hanes and coworkers (147) reported that overall die-off rates of enterococci stored in diluted sewage were similar to or greater than that of coliforms. Burman and coworkers (97) also observed die-off rates, which were similar to or greater than that of fecal coliforms in stored samples of settled sewage, diluted sewage, and river water. Granai and Sjogren (148) determined the "in situ" survival of *E. coli* and *E. faecalis* in clean and polluted lake water.

In clean water, the survival of *E. faecalis* was superior to that of *E. coli* (96 hours vs. 48 hours), whereas in polluted lake water, survival times of both microorganisms were similar (10 hours vs. 12 hours).

There are several possible explanations for the conflicting results in the literature. First, the survival rate of fecal streptococci will depend on species composition because the survival rates of different fecal streptococci species appear to differ significantly; several enterococcal species persisted significantly longer than fecal coliforms, and *S. bovis* and *S. equinus* died off rapidly in stormwater samples (91). Second, it appears that the comparative survival of coliforms and fecal streptococci in the same water sample will differ according to the available nutrients because higher organic matter concentrations are required for the growth of fecal streptococci compared with those of coliforms (86). Third, streptococcal survival is considerably influenced by water temperature, and they die off faster than *E. coli* at both high (20 to 30 °C) and low (5 to 8 °C) temperatures (97).

Data on the survival of fecal streptococci or enterococci in soil and groundwater are scarce. McFeters and coworkers (102), using survival chambers immersed in a tank through which groundwater was continually pumped, found that *E. faecium*, *E. faecalis*, and *E. durans* exhibited superior survival characteristics to coliforms, but that coliform survival exceeded that of *S. bovis* and *S. equinus*. Using a similar experimental setup, Keswick and coworkers (149) found that an unidentified streptococcus from sewage exhibited superior survival to *E. coli* and coliphage f2. Bitton and coworkers (150), using groundwater stored in a glass flask, found that *E. faecalis* survived better than *Salmonella typhimurium* and *E. coli*, and had survival characteristics similar to those of coliphage f2. Recently, Hassen and coworkers (151) concluded that fecal streptococci introduced by wastewater had a higher survival in soil and water than fecal coliforms; Ramos-Cormenzana and coworkers (152) obtained a similar persistence of fecal streptococci and fecal coliforms in groundwater.

There is very little information on the comparative die-off rates of enterococci in freshwater ecosystems, and the results are sometimes contradictory (101). McFeters and Stuart (153) obtained a T_{90} (time required for 90% of the population to die off in days) of 2.7 for *E. coli* and 4.2 for enterococci using well water. On the contrary, Hanes and Fragala (154) reported T_{90} of 4.6 for *E. coli* and 3 for enterococci in freshwater. Dutka and Kwan (155) showed that the die-off of enterococci was lower than that of fecal coliforms in a stream. In a similar study, de Vicente and coworkers (156) obtained a higher survival capability of enterococci in river water compared with total and fecal coliforms and *P. aeruginosa*.

Survival in Seawater

Slanetz and Bartley (157) compared the survival of coliforms and fecal streptococci in dialysis bags containing untreated sewage effluent and suspended in seawater. Coliform numbers in bags increased 310 times over the first two days and remained at these levels for about seven days before the onset of die-off. There was no increase in the numbers of fecal streptococci in the bags and a rapid decrease occurred within four to six days. The authors concluded that fecal streptococci would make the most accurate indicators in seawater containing organic material because they do not multiply in such water and they show appreciable die-off rates within a two- to three-day period.

Vasconcelos and Schwartz (158) investigated bacterial survival in seawater and found that *E. faecalis* survived longer than either *E. coli* or *Enterobacter aerogenes* but that all the three species survived over a period of seven days. Evison and Tosti (159), studying the survival of fecal streptococci in the Bay of Naples, found that the natural attenuation of fecal streptococci was lower than *E. coli*. In laboratory studies with seawater, these authors found that survival of both *E. coli* and fecal streptococci was inversely related to temperature, but fecal streptococci consistently survived longer than *E. coli* at all temperatures and in the dark. Lessard and Sieburth (160) reported that the decay rates for enterococci in an estuary and a salt marsh were significantly correlated with temperature. Enterococci survived longer than *E. coli* in estuary water, but showed lower survival rates in the more eutrophic salt marsh.

Borrego and coworkers (84) determined the survival capability of pathogenic and indicator microorganisms by comparing the concentrations of each at increasing distances from a marine-sewage outfall. The results obtained indicated that coliphages and fecal streptococci (predominantly enterococci) showed the lowest degree of reduction in polluted seawater (84 and 174 minutes, respectively). The other microbial parameters tested showed similar inactivation rates among them (26.4 minutes for total coliforms, 35.4 minutes for fecal coliforms, and 33 minutes for *Salmonella*). Using a similar methodology, Fattal and coworkers (161) investigated the relative dying away of bacteria and enteric viruses. They found that total and fecal coliforms disappeared more rapidly than viruses, whereas the reduction of fecal streptococcal concentrations was similar to the dying away of virus. Studies using "in situ" membrane diffusion chambers showed that the die-off of fecal coliforms and fecal streptococci to 10% of their initial numbers occurred in marine sediments near a sewage outfall within 85 days (162).

Why fecal streptococci exhibit superior survival characteristics in seawater is not completely clear. Some authors have indicated that the higher salt tolerance (163,164) or the lower susceptibility to sunlight (165,166) compared with fecal coliforms, may be some of the explanations to these findings. For this reason, controlled studies under laboratory conditions have been conducted to demonstrate the influence of several biotic and abiotic factors on fecal streptococci. de Vicente and coworkers (167) and Cornax and coworkers (68) investigated the survival of several indicator organisms and the pathogens *P. aeruginosa* and *Salmonella* spp. in the marine environment and in the laboratory under controlled conditions. The "in situ" studies showed that the die-off of enterococci in seawater was very similar to that of those pathogens, and slower than total and fecal coliforms (T_{90} of about 40 minutes for enterococci vs. 20 minutes for coliforms). The laboratory survival

experiments showed that the visible light and the nonfiltrable biotic factors produced most important inactivating effects on the microorganisms.

Similar to other allochthonous bacteria of the aquatic environments, the phenomenon of nonculturability (i.e., the inability to grow sublethally injured bacteria in culture media) has been demonstrated in *E. faecalis* in fresh and marine systems under illumination (168), in drinking water (169), and in filtered lake water (170).

ENUMERATION TECHNIQUES

The acceptance of fecal streptococci or enterococci as valid and useful fecal indicators was closely linked to the development of isolation and enumeration methods. Early attempts to quantify fecal streptococci relied on enrichment-tube procedures associated with the use of the most probable number (MPN) method, Rothe Azide Dextrose broth, followed by a confirmation in Ethyl Violet Azide (Litsky) broth being the procedure most widely accepted (171). A new modification of MPN technique to enumerate enterococci directly from Rothe broth has been presented by Donnison (172), who uses a confirmation on m-E agar and subsequent transfer to Esculin Iron (EIA) agar.

The membrane-filtration technique using the m-Enterococcus (or SB) medium was the first reported method for the enumeration of fecal streptococci or enterococci in fresh and marine water since the 1950s (173). Since then, more than 70 selective media have been proposed, such as Kenner Fecal Streptococcus (KF) agar, Pfize Selective Enterococcus (PSE) agar, and Tallous Acetate (Barnes) agar. In addition, several media have been also developed for the specific isolation and enumeration of enterococci by membrane filtration. The first and most used is m-Enterococcus medium (100). For recovery of enterococci, Standard Methods (100,174) recommends the use of m-E agar (175), followed by transfer to EIA agar, but several other media can be employed, such as Kanamycin Esculin Azide (KEA) agar (176), mSD agar (175), and mAC agar (177). The standard procedures (APHA and ISO) for the detection of fecal streptococci have recently been described by Figueras and coworkers (82).

Other media formulations and incubation procedures for fecal streptococci have been proposed for specific situations (178), increasing the membrane incubation period from 48 to 72 hours to recover stressed fecal streptococci from chlorinated effluents. Rutkowski and Sjongren (107) developed a medium that designated M2 to help in distinguishing between human and animal pollution sources. M2 supported the growth of a wider selection of streptococci than is normally associated with the fecal streptococci, but the authors reported that more than 90% of their isolates on this medium belonged to Lancefield's group D. Hernandez and coworkers (179) designed a miniaturized fluorogenic assay for enumeration of enterococci in marine water incorporating 4-methylumbelliferyl-ß-D-glucoside (MUD) into a selective medium contained in a sterile 96-well microtiter plate. This technique yields slightly lower recoveries compared with the membrane filtration technique using two selective media. This method has now become an ISO standard for the detection of intestinal enterococci from bathing water (82,180). Niemi and Ahtiainen (181), in a comparative study, reported that both the microtiter and membrane filtration methods allowed the growth of nonfecal *Enterococcus* and *Staphylococcus* species.

Several studies have been conducted to compare the selective methods used for the enumeration of fecal streptococci and/or enterococci from natural water (175,182–189); however, the results obtained were widely different and sometimes contradictory. More recently, Dionisio and Borrego (21) compared eight currently used methods to recover and enumerate fecal streptococci from natural water samples, on the basis of a few media characteristics, namely, accuracy, specificity, selectivity, precision, and recovery efficiency. The authors concluded that none of the compared methods would be considered as optimum for enumeration of fecal streptococci from water samples; however, m-Enterococcus agar using the membrane filtration technique showed the best performance characteristics of the enumeration media tested because this medium possessed the best recovery efficiency, precision, and accuracy (Table 6). Other studies have demonstrated the low selectivity and specificity of m-Enterococcus medium (26,190,191), and, for this reason, modifications of m-Enterococcus have been performed to increase its selectivity. Mates and coworkers (192) proposed the supplementation of the m-Enterococcus agar with antibiotics, whereas Figueras and coworkers (190) proposed transferring the membrane filters from m-Enterococcus to bile-esculine medium as a confirmation technique to eliminate the false positives. A variant of this last method has been adopted as an ISO method (193) for the isolation of enterococci from drinking water samples.

The most widely used media for fecal streptococci or enterococci determination by the membrane-filtration technique required a long incubation period (48 to 72 hours), and the need of a confirmatory step extend the time of the analysis to three or more days, which is a big disadvantage for their use in water analysis. The KEA agar proposed by Mossel and coworkers (176) presents two promising advantages: (*1*) the results are available in 24 hours, and (*2*) esculin hydrolysis can be observed directly on the filter. However, KEA agar presents a low capability of discrimination between typical and nontypical fecal streptococcal colonies (23), and very low specificity, allowing the growth of *Staphylococcus*, *Pseudomonas*, and *Vibrio* strains, whose colonies resemble those of fecal streptococci (21,194).

To avoid these shortcomings, Audicana and coworkers (25) modified the KEA formulation by replacement of kanamycin sulfate by oxolinic acid and increasing the sodium azide concentration to achieve the inhibition of the nonenterococcal background microbiota. This modification of KEA agar, named *oxolinic acid-azide* (OAA) agar, has been comparatively evaluated with other selective enterococcal media (25,26). The OAA agar showed the highest specificity, selectivity, and relative recovery efficiency; in

Table 6. Performance Characteristics of Several Selective Media for Enterococci Applying the Concordance Coefficient of Kendall (21)

Characteristics	m-Enterococcus	KF	PSE	KEA	Barnes	BE	MS	Rothe-Litsky
Qualitative growth								
Enterococci	3	3	3	6	3	NT	7	3

Note: Not tested (NT).

addition, no confirmation of typical colonies was needed while using this medium.

Rhodes and Kator (195) modified the medium m-E by adding the chromogenic substrate indoxyl-ß-D-glucoside and reducing the concentration of TTC to recover enterococci in 24 hours. This new medium, named *mEI*, has been compared to m-E medium and showed similar results at shorter time (196).

Enterolert (IDEXX Laboratories, Inc.), a semiautomatic MPN method, has been used for enumeration of enterococci in comparison to the standard membrane filter method used for recreational natural water analysis. No statistically significant differences between the two techniques have been obtained, but Enterolert required less time for set-up (24 hours) (197–199).

Recently, a molecular biological procedure for the detection of enterococci in water samples has been designed (200). The method consists of a short enrichment of the water sample, followed by an amplification step and a hybridization reaction using 23S rDNA-targeted oligonucleotide probes. The detection limits of this molecular method is about 1 CFU per mL and the results are available within 26 hours.

CONCLUSION

The taxonomy of *Enterococcus* and *Streptococcus* general has not yet been fully resolved. The terms *fecal streptococci*, *enterococci*, or *intestinal enterococci* embrace species of the genera *Enterococcus* and *Streptococcus*, although there is no complete agreement about the species that should be included under these terms. In practice, fecal streptococci, enterococci, intestinal enterococci, and *Enterococcus* group when used in the literature to refer to indicators of fecal pollution can be considered synonymous.

Fecal streptococci and enterococci are ubiquitous and can be found free-living in soil, on plants, in dairy products, and as a part of the normal microbiota of the gastrointestinal tract of humans, other mammals, and birds. However, they have been implicated in outbreaks of food-borne illnesses, and they can possess both a beneficial and detrimental role in food. These microorganisms may be involved in a variety of human infections, named *enterococcal bacteremia*, including infections of the urinary tract, bloodstream, endocardium, biliary tract, burn wounds, and indwelling devices, *E. faecalis* being the species most frequently isolated from clinical samples.

Fecal streptococci/enterococci have received widespread acceptance as useful indicators of fecal pollution in natural aquatic environments on the basis of their close relationship with health hazards associated with bathing in aquatic environments, their constant presence in feces of warm-blooded animals, their inability to multiply in sewage-contaminated water, and their long persistence in natural water.

The survival of fecal streptococci/enterococci in aquatic environments, including sewage, groundwater, fresh water, and seawater, has also been reviewed. Several studies have demonstrated that the survival capability of these microorganisms is higher than that of coliforms, and similar to virus survival. However, the survival rate of fecal streptococci will depend on species composition because the survival rates of different fecal streptococcal species appear to differ significantly. In addition, the comparative survival of coliforms and fecal streptococci in the same water samples will differ according to the available nutrients, because higher organic matter

concentrations are required for the growth of fecal streptococci compared with those of coliforms. In addition, streptococcal survival is considerably influenced by water temperature, and they die off faster than *E. coli* at both high (20 to 30 °C) and low (5 to 8 °C) temperatures.

The acceptance of fecal streptococci/enterococci as valid and useful fecal indicators is closely linked to the development of reliable isolation and enumeration methods. For this reason, the last part of this article is dedicated to the revision of the current detection and enumeration methods for these microorganisms. Several media have been developed for the specific isolation and enumeration of enterococci/fecal streptococci by the membrane-filtration technique. However, this technique required a long incubation period and the need of a confirmatory step. To avoid these shortcomings, new media formulations, the addition of chromogenic substrates, and the application of a molecular biological procedures have recently been proposed.

FIELD RELEASE OF GENETICALLY ENGINEERED MICROORGANISMS (GEM)

Steven Ripp
Gary S. Sayler
University of Tennessee
Knoxville, Tennessee

A field release can be defined quite simply as the deliberate introduction of a bacterial strain into a natural environment. The bacterial strain being released has typically undergone some type of genetic manipulation in the laboratory to enhance its ability to perform a specific task. In bioremediation practices, for example, genetically engineered microorganisms (GEMs) are used for the cleanup of environmental pollutants in terrestrial and aquatic environments, biomining industries are attempting to use GEMs for the extraction of various natural resources, and in agriculture, GEMs can be released into crop ecosystems as biofertilizers or biocontrol agents (biopesticides, biofungicides, or bioinsecticides). In this article, the basis for why field release studies are necessary, the problems associated with introducing engineered bacterial strains into the environment, and viable methods for alleviating some of the obstacles to bacterial field releases will be explored.

THE NECESSITY FOR FIELD RELEASE TRIALS

All genetic engineering strategies begin in the laboratory, where operating conditions can be controlled and manipulated at will to thoroughly understand and predict metabolic and physiological functions of the bacterium under development. However, extrapolating laboratory-based results or scaling up laboratory-based studies to real-world environmental applications becomes all but impossible and must be approached with a great deal of caution and pessimism. While considering the vast number of biotic (i.e., competition, predation, starvation, and antagonism) and abiotic (i.e., temperature, moisture, adsorption, and pH) factors a bacterium must react to and interact within any typical environmental ecosystem, it readily becomes apparent that the environment is too complex to reproduce within laboratory confines or, for that matter, even within high-level computer modeling schemes. Therefore, true comprehension of an engineered bacterium's capabilities in bioremediation, biomining, or agricultural biotechnology requires unbiased, comprehensive exposure to the environment before adequate assessments, predictive ability, and possible benefits or hazards can be identified. However, although an abundance of GEMs have been developed for various biotechnological purposes, many of which have exhibited great potential in the laboratory, few examples of GEM field release trials actually exist (Table 1) (Fig. 1).

BARRIERS TO FIELD RELEASE STUDIES

Public Perception

The application of genetic engineering technologies has perhaps been shaped more by public fear and emotion than by an accurate understanding of the science involved and its potential risks and benefits. For example, a bacterium capable of increased metabolic degradation of crude oil constituents was met with public resistance because of the fear that these GEMs would eventually find their way into Texas oil fields and rapidly deplete U.S. oil supplies (1). Similarly, the planned release of a GEM for the prevention of frost damage in plants was met with public outcry because the "escape" of the gene involved would produce "super weeds" that would also survive frost damage (2). This "Jurassic Park" view of biotechnology has succeeded in delaying numerous field release trials and has led to what some deem an overregulated industry, in the United States as well as worldwide (3–5). Consequently, many researchers are intimidated or often outright impeded in their attempts to institute field release studies through public misperception and protest as well as through time-consuming governmental regulations and review.

Federal Regulation of Field Release Trials

Because the actual outcome of a field release cannot be reliably predicted, it becomes mandatory that oversights exist to ensure environmental and public health safety (6,7). However, the federal regulations and administrative processes required to initiate field releases of engineered microorganisms can be lengthy, complicated, and costly, and can frequently prevent GEMs from ever leaving the laboratory. Furthermore, for those GEMs that do receive field release approval, it is often the case that they are no longer state of the art, having undergone significant refinement and genetic restructuring during the regulatory waiting process. Consequently, research industries tend to avoid GEMs altogether, rather favoring methods in which environmental conditions are manipulated,

Table 1. Representative Field Release Studies Involving Genetically Engineered Microorganisms

Bacteria	Trait	Year of Release	Application	Country	Reference
Agrobacterium radiobacter K1026	Biological control agent for crown gall disease	1987	Almond seedlings	Australia	112
Pseudomonas aureofaciens 373RNL11	*lacZY*-marked	1987	Wheat plot	U.S.A.	79
Pseudomonas syringae	Ice$^-$ (biocontrol of frost)	1987	Strawberry	U.S.A.	113
Pseudomonas syringae	Ice$^-$ (biocontrol of frost)	1987	Potato	U.S.A.	114
Rhizobium leguminosarum RSM2004	Marked with plasmid-based Tn5 for determination of gene-transfer frequencies	1987	Peas, chick peas, wheat, barley	U.K.	29
Clavibacter xyli	Btk toxin (bioinsecticide)	1988	Corn	U.S.A.	115
Pseudomonas corrugata 2140	Biological control agent for take-all disease in wheat (*lacZY* marked)	1990	Wheat plot	Australia	116
Xanthomonas campestris JS414	*lux*-based marker	1990	Cabbage	U.S.A.	117
Clavibacter xyli MDR1.586 and MDR1.1413	Bioinsecticide against European corn borer	1990 1991	Corn	U.S.A.	118
Rhizobium meliloti	Biofertilizer (*nifA* and *dctABD* insertions)	1992	Alfalfa	U.S.A.	119
Xanthomonas campestris FD91L	*lux*-based marker	1992	Cabbage	U.S.A.	120, 121
Pseudomonas fluorescens SBW25EeZY-6KX	*lacZY*-marked	1993	Wheat plot	U.K.	42
Pseudomonas syringae	Tn5 insertion	1993	Bean plants	U.S.A.	122
Bacillus thuringiensis	Bioinsecticide (*cry* gene insertion)	1994	Crop plants	U.S.A.	123
Bacillus thuringiensis BtN14	Bioinsecticide	1994	Swampland soil	Sweden	124
Rhizobium leguminosarum CT0370	Marked with *Escherichia coli GUS* gene	1994	Peas	U.K.	125
Rhizobium leguminosarum Azospirillum brasilense	*lacZ*-marked	1994	Pea, broad bean, sorghum	Italy	34
Pseudomonas fluorescens R2f	*lacZ-nptII*-marked	1995	Wheat plot	Netherlands	126
Pseudomonas putida CMC4	*gef* killing gene linked to *xylS* for biological containment	1995	Soil	Spain	127, 128
Sinorhizobium meliloti RMBPC-2*	Nitrogen fixation	1995	Recombinant alfalfa	U.S.A.	71
Pseudomonas fluorescens HK44	Bioremediation of polyaromatic hydrocarbons	1996	Soil	U.S.A.	33

Note: A comprehensive list of U.S. and international field tests can be found in the Information Systems for Biotechnology database maintained by the Virginia Polytechnic Institute (*http://www.nbiap.vt.edu*).

**Sinorhizobium meliloti* RMBPC-2 was approved by the U.S. Environmental Protection Agency in 1997 for limited commercial application (500,000 pounds/year) as a microbial seed inoculant to coat alfalfa seeds before planting.

and not the microorganisms themselves, in attempts to increase indigenous microbial subpopulations to perform specific metabolic tasks. Following the Exxon Valdez oil spill in 1989, for example, fertilizers were applied to some shoreline sites to stimulate oil degradation by indigenous microbial populations (8). The exception occurs in agriculture in which GEMs are commercially available as biocontrol agents. For instance, *B. thuringiensis* strains can be genetically enhanced to produce toxins against certain crop pests. However, these engineered microbes are mass-produced in the laboratory and then killed before market release (9). Thus, only their synthesized toxins are actually environmentally applied, and not the GEMs themselves, thereby avoiding many of the regulatory overviews.

In the United States, GEMs, depending on their ultimate use, are regulated by the Environmental Protection Agency (EPA), Food and Drug Administration (FDA),

and/or the U.S. Department of Agriculture (USDA) (10). For example, GEMs destined for bioremediation, biofertilization, or biomining purposes are regulated by the EPA's Office of Pollution Prevention and Toxics (OPPT) under the Toxic Substances Control Act (TSCA) (11,12). The application process used by OPPT involves eight reviews, and several other technical documents, that detail the microorganism's genetic structure, identifies potential human and ecological risks associated with releasing the microorganism, and provides a technical plan describing the release site, the method of release, exposure risks to personnel during release, and methods to limit and monitor dissemination of the microorganism during release. Other Organization for Economic Cooperation and Development (OECD) countries require similar consents before deliberate GEM releases are allowed, and the United Nations possesses preliminary regulations in the form of a Code of Conduct and a Biosafety Protocol governing biotechnology industries worldwide.

Gene Transfer

Much of the public concern and governmental regulation concerning the release of GEMs is due to the fact that engineered genetic material can potentially be transferred from the GEM to indigenous members of the microbial consortia (13). This process occurs naturally in bacteria through conjugation (the transfer of genetic material by cell-to-cell contact), transformation (the uptake of naked DNA), and transduction (the transfer of DNA via bacteriophages). Transposition, the random "jumping" of specialized genes called *transposons*, may occur within the GEM or a recipient of a gene-transfer event (14–16). Each of these gene-transfer mechanisms occurs naturally in the environment and therefore each constitutes an inherent but poorly quantified risk factor in all field release experiments. Predicting the degree of risk is difficult because the frequency of gene transfer is dependent on the type of genetic material being transferred, the mechanism or combination of mechanisms mediating the transfer, the environmental conditions present at the time of transfer, and the perceived hazard of the gene. Studies have shown, for example, that genetic elements inserted within a plasmid can potentially be transferred at fairly high rates via conjugation (14,16). Even genes present on plasmids deficient in the transfer and mobilization elements (tra^-, mob^-) seemingly required for conjugation can still undergo gene transfer (17). It is therefore recommended that engineered genes in GEMs be chromosomally inserted. However, chromosomal DNA can still be transferred by any of the mechanisms already described, albeit at lower frequencies (14,16).

The environment into which the GEM is placed and the environmental factors impinging on the GEM will also affect gene-transfer efficiencies. Elevated transduction rates have been shown in freshwater ecosystems when particulate matter was present, probably as a result of the formation of bacteriophage–host cell microenvironments sorbed to clay particles (18). As an infected cell releases bacteriophage particles, a closely neighboring cell becomes readily infectible. Apparently for the same reason, bacteria growing in biofilms exhibit increased gene-transfer frequencies, as do microbial populations living within plant root rhizosphere systems (19,20). In soils and less so in aquatic environments, "naked" DNA released from living and dead microorganisms adsorbs to sand and clay particles in which it can exist in a transformable state for several months (21). Therefore, even after a GEM has been eradicated from its release site, the engineered DNA can still remain and be taken up by the indigenous microbial consortia. Also, because most environmental ecosystems are oligotrophic in nature, the addition of nutrients has been shown to increase gene-transfer rates simply because of corresponding increased rates of bacterial growth (22). Bacterial gene transfer has additionally been shown to occur in the digestive tract of cutworms, digestive vacuoles of protozoa, the guts of silkworms and microarthropods, and on plant leaf surfaces (23–27).

Considering the near-endless potential for gene transfer, it would seem reasonable from a critic's point of view, to ban field release studies altogether. However, much of the information available concerning gene transfer is obtained from laboratory microcosm data in which conditions were optimized to specifically enhance transfer events, thus creating a rather unrealistic "worst case scenario" portrayal of genetic exchange potentials. Considering the nonoptimized nature of the environment, it is presumed that gene transfer will occur at frequencies with lower orders of magnitude than that reported in laboratory microcosms. In fact, no direct evidence of recombinant gene transfer to indigenous microbial populations has been identified during several field release trials (28–34). This in no way signifies that gene transfer was not occurring; only that it was occurring at frequencies too low to be detected. Therefore, the risk is still present but it may be so negligible as to not constitute a significant environmental hazard. Additionally, although gene transfer is occurring in the environment continuously, the presence of identical gene sequences within distantly related bacterial species is rare. This is due to the fact that most genes obtained by a bacterium through gene transfer will be of no selective advantage and will subsequently disappear.

Persistence in the Environment

Ideally, on release into the environment, a GEM should only survive long enough to perform its specified task and then die off to ensure no further ecological risk. It is usually assumed that GEMs will gradually become extinct after release because they are unable to effectively compete with the indigenous microbial consortia. This reduced level of fitness is thought to be due to the extra energy demands mandated by the presence of the introduced genes and by the fact that GEMs are usually nurtured under optimal laboratory conditions for several years, thus making them physiologically weak and less prone to survive within harsh environmental ecosystems. Additionally, GEMs designed to survive under certain selective pressures should die off as those selective pressures are removed from their environment. For example, during bioremediation processes, GEMs maintain a selective growth advantage over the indigenous microbial

population because they are specifically designed to survive within the chemically contaminated environments into which they are placed. However, once the selective pressure of the contaminant is removed, all growth advantages cease, indigenous microbes soon flourish, and the GEMs are gradually displaced.

Numerous studies have shown GEMs to exhibit reduced fitness when direct comparisons are established against the parental strains from which they were originally derived (35–39). However, a decreased fitness level and corresponding reduction in growth rate simply implies that at some point in the future the GEM will eventually become extinct. A computer model estimated that GEMs are capable of surviving in introduced environments for approximately three years (40). In actual field release studies, a *lacZY*-marked *P. corrugata* strain was recoverable from soil four years after its introduction (41), a genetically modified *Rhizobium* strain was detectable in soil six years after its release (29), and a *P. fluorescens* strain capable of degrading polyaromatic hydrocarbons (PAHs) continues to persist in a soil ecosystem three years after its release, although the selective pressure of the PAHs has been significantly reduced (33). In contrast, a recombinant *P. fluorescens* strain was undetectable one year after its release into wheat plots (42), an engineered *P. aureofaciens* strain released by the Monsanto Corporation did not survive for more than two years (28,43), and a genetically modified *Azospirillum brasilense* strain fell to below-detection limits within one year of its field release (34). However, in other studies, GEMs that had been considered undetectable, later reappeared under suitable growth conditions (30,44). Therefore, labeling a GEM as "no longer detectable" in no way signifies that it is no longer present, only that it cannot be identified using the enumeration methods available. Enumeration techniques that rely on the isolation of visible GEM colonies are especially ineffective because microorganisms exposed to starvation conditions, as would be the norm in the environment, can enter a viable but nonculturable state, meaning that although they are still alive, they cannot be resuscitated on laboratory media (45). Molecular-based methods in which the genetic construct is identified as opposed to the microbe itself are much better indicators of GEM presence, but as will be seen later in this article, still cannot guarantee a GEM's absence. Furthermore, even if a GEM were to be completely eliminated from its environment, its engineered genetic material may still persist and contribute to gene-transfer events. Thus, it is probably correct to state that the persistence of GEMs and their genetic constructs will be impossible to predict following environmental introduction; subsequent risks must therefore be identified and minimized accordingly.

Environmental Transport

GEMs released into the environment should ideally remain within their confined application area to limit potential ecological hazards. However, preventing the dispersion and transport of GEMs in a complex environmental system is difficult. Bacteria can be transported via aerial dispersion, water flow, or plant and animal vectors. Additionally, in agricultural applications, soil tillage may affect dispersion rates. Aerial dispersion is perhaps more of a concern during the application process itself when GEMs are often applied in an aerosolized form. A model to predict aerial transport of bacteria within terrestrial environments has been developed, which suggests that few bacteria will disperse beyond a 1-m radius of the field release site (46). Actual aerial dispersion rates during soil-release experiments vary considerably, but most dispersion does indeed occur within a 1-m radius, less than 100 colony-forming units typically being detected per gram of soil (47,48). However, broad generalizations cannot be made when considering the numerous factors that can affect aerial dispersion rates (wind speed, wind direction, turbulence, humidity, and temperature), and caution during application methods is still highly warranted.

Water is perhaps the most efficient transport mechanism available to bacteria. Most water-induced transport mechanisms concerning GEMs have been studied in soil ecosystems (49) and models to predict dispersion rates have been developed (40,50,51). Water enters a field site through rainfall or agricultural irrigation where it percolates through the soil bed until it enters groundwater systems. Bacteria transferred with this water flow can potentially travel great distances. However, on distribution within groundwater flow systems, their numbers may be too low to constitute a significant environmental hazard. Also, bacteria can tightly adsorb to soil particles, making their dislodgment by percolating water difficult. The degree of bacterial adsorption to soil particles increases with time, so transport risks remain greatest directly after GEM application. In such cases a heavy rainfall could transport significant numbers of bacteria to depths approaching 2.5 m (52). In experiments in which water was not applied to the soil, introduced bacteria were detected only at depths above 40 cm (53). Adsorption is also dependent on cell surface properties, which can potentially undergo unknown alterations during the genetic engineering process making the GEM less prone to soil adhesion (54,55). Soil type and texture will also affect dispersion rates, and sandy soils exhibit higher transport frequencies than more densely textured soils. This is probably mainly due to preferential flow, the irregular flow of water through soil fissures and large pores, which has been shown to occur more readily in silty and sandy soils (56). Preferential flow effects can also be exacerbated by plant root growth or burrowing worms and insects (57). In bioremediation processes it has been demonstrated that chemically contaminated soils impede GEM transfer, probably because of an increase in soil bulk density that can limit preferential flow effects (58).

In aquatic systems, bacteria can be transported across great distances by normal water flow dynamics, but are usually so highly distributed that their low numbers in any given area pose little ecological threat. In freshwater streams, bacterial dispersion is limited by current flow and dispersion rates and is largely dependent on cycles of bacterial attachment and detachment from biofilms (59).

Bacterial transport via animal vectors during field release studies has primarily been demonstrated using

the earthworm as a model organism. Transport has been shown to occur in soil through bacterial attachment to the earthworm's surface and through ingestion and subsequent fecal deposition (60). GEMs applied to plant surfaces can undergo plant-to-plant transfer by similar ingestion and fecal deposition, as has been shown with the cutworm (61) and caterpillar (62). Similar data has been presented using grasshoppers as transport vectors (63). However, in these studies the GEMs were originally applied to the plant seeds, whereupon they subsequently colonized the roots and eventually became dispersed within aerial foliage. Grasshoppers feeding on the leaves became infested with the GEMs and transported them to previously uninoculated plants. GEM movement in this respect could substantially affect transport rates and needs to be studied in more detail before assessing the risks involved.

Transport of GEMs can also occur through bacterial taxis in which self-propulsion can be achieved through the action of a flagellum. Bacterial taxis through soil is too slow to be of any great concern but may be slightly more important in aqueous or heavily saturated environments in which flow rates are minimal (64). However, compared to the transport mechanisms already discussed, bacterial taxis should be considered an exceedingly minor form of natural dispersion.

Ecosystem Alterations

The introduction of GEMs can potentially affect the structure and balance of an ecosystem. This may occur by the displacement of an indigenous species in which the GEM outcompetes a resident microbial population. Enhanced nitrogen-fixing GEMs, for example, could overtake indigenous nitrogen-fixing bacteria in the root rhizosphere and significantly decrease or eliminate their populations. Species elimination has been shown to affect ecosystem function, but, conversely, redundancy within ecosystems may allow GEMs to simply replace an indigenous population with no adverse effects (65). Predicting what outcome will occur is extremely difficult but has been studied on a limited basis in laboratory microcosms, with conflicting results. A recombinant *P. putida* strain engineered to degrade the herbicide 2,4-dicholorophenoxyacetate (2,4-D) was found to significantly decrease the number of fungal propagules in a soil microcosm (66). Because fungi play important roles in plant growth and decomposition, thus being major contributors to soil fertility, their absence could considerably compromise a soil ecosystem. Similarly, in a study in which a recombinant *Klebsiella planticola* strain was introduced into a soil microcosm containing wheat plants, an increase in nematode populations was seen that coincided with plant death (67). However, several other microcosm studies have indicated that GEM introduction has limited influence on microbial community diversity in soil, rhizosphere, and aquatic ecosystems (68–71). The study by Doyle and coworkers (66) also demonstrated that the introduction of the GEM reduced carbon dioxide evolution, signifying that introduced GEM populations can affect ecosystem processes related to primary production and nutrient cycling, which in turn can have profound influences on global ecosystem fluxes (72). In other soil microcosm experiments, however, the introduction of recombinant microbes resulted in either no or only short-term process level changes in ecosystem fluxes (73–75).

Another ecosystem alteration more important to bioremediation field releases is the incomplete degradation of toxic chemicals by introduced GEMs. For example, microbes engineered to degrade the environmental pollutant trichloroethylene (TCE) produce as a byproduct, vinyl chloride that happens to be more toxic than the TCE itself (76). However, the degradation pathways of most bioremediative GEMs have been thoroughly studied in the laboratory before release, and risks owing to toxic intermediate production remain relatively low.

Monitoring

The ability to accurately monitor GEMs is critical to understanding their potential effects on any given environment. Considering that a bacterium is only microscopic

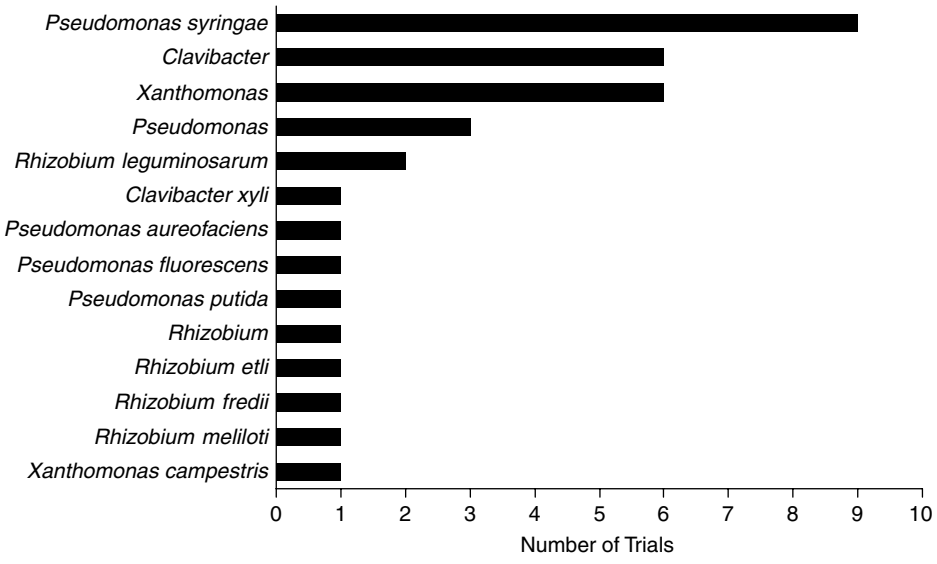

Figure 1. Number of approved field trials in the United States categorized by type of genetically engineered microorganism released.

in size, may spatially disperse within its environment, and may enter viable but nonculturable states, it readily becomes apparent that successfully tracking a particular bacterial population after introduction into a complex ecosystem will be difficult. To alleviate monitoring problems, GEMs can simply be selectively marked with an antibiotic resistance gene. In theory, plating onto media containing the antibiotic allows only the resistant GEMs to grow. However, with heterogeneous environmental samples, a background population of microbes also resistant to the antibiotic is usually present, thus making exclusive isolation of GEMs impossible. To overcome differentiation problems, antibiotic-resistant colonies can be further subjected to colony-hybridization techniques in which an additional selective marker can be identified with labeled gene probes (77). By targeting two selective markers, the GEM can first be identified phenotypically by its growth in the presence of an antibiotic and then genotypically by certifying that a specific target gene is present. However, an indigenous microbe resistant to the antibiotic that has also taken up the targeted gene sequence through a gene-transfer event will still remain indistinguishable from the GEM unless its colony morphology significantly differs from that of the GEM. Also, maintaining antibiotic resistance exerts an extra energy demand on the GEM that may affect its overall survival rate. Furthermore, because the antibiotic is not typically innate to the GEM's environment, no selective pressure persists to maintain the gene and it can subsequently be lost. Thus, although the GEM still exists in a form in which the antibiotic gene is absent, yet other engineered constructs are present, the GEM remains undetectable. The genetic transfer of antibiotic resistance genes to indigenous microbial populations is also a valid threat as has been demonstrated in medical practices in which the overprescription of antibiotics has led to numerous multidrug-resistant microbes (78). Therefore, antibiotic resistance as a genetic marker is discouraged in GEMs destined for field release.

A variety of selectable genetic markers that are less problematic than antibiotic resistance are available for integration into GEMs. The *lacZY* system, which allows GEM colonies to be distinguished by a characteristic blue color they produce on laboratory media containing the substrate X-gal, has been used in several field release studies (79). Similar in function is the *gusA* gene that cleaves the substrate X-glcA to produce blue colonies (80). Other genes include *xylE* (yellow product), *nahA* (blue product), TFD monooxygenase (red product), and *moc* (specific growth substrate requirement) (81–84). Also available are the *lux* and *luc* genes (bioluminescence) and the *gfp* gene (fluorescence) for generating "glowing colonies" as identifying markers (85,86). However, all of these marker systems rely on the growth of the tagged microorganisms; a colony existing in a viable but nonculturable state will never be initially detected on laboratory media. Additionally, increased energy demands as a result of the additional genetic load will still be prevalent and, in soil ecosystems, markers such as *lacZY*, *gusA*, and *nahA* still remain indigenous and will appear in background populations (87,88).

REDUCING RISKS DURING FIELD RELEASE TRIALS

A field release will never be risk-free. However, methods to reduce risks are available and are continually being incorporated into field release trials. These methods consist of structural and biological containment strategies that limit GEM access to the environment as well as the incorporation of better monitoring techniques following GEM release. Additionally, some risks related to the gene transfer of recombinant DNA to indigenous microbial populations can be reduced.

Physical Containment

The simplest manner in which to reduce environmental hazards associated with field introductions is to physically restrict the released microbe from freely entering the environment. This is usually accomplished by structurally enclosing the release site. For example, Figure 2 illustrates a series of subsurface soil lysimeters that served as containment structures during a bioremediation field release experiment (89). Because the GEMs never actually freely entered the open soil ecosystem, environmental hazards were significantly reduced. In agricultural field applications, containment is often achieved by confining the plants and associated GEMs to pots that are then placed outdoors. GEMs can also be applied to small plots of in-ground crop plants that are surrounded by alternating guard rows of fallow soil and plant species that are not infected (Fig. 3). In all cases, fences border release sites to prevent access by animals. With such degrees of containment, field release studies can be disputed to be nothing more than large-scale, controlled laboratory experiments performed in an artificial outdoor environment. Nonetheless, such studies represent a balance between risk assessment and environmental realism. Although always being only close approximations of natural environmental conditions, these studies will be inherently more

Figure 2. Physical containment of GEMs within a lysimeter structure. Lysimeters were 4 m deep by 2.5 m in diameter and filled with polyaromatic hydrocarbon–contaminated soil to study bioremediation-monitoring capabilities of an introduced GEM (33).

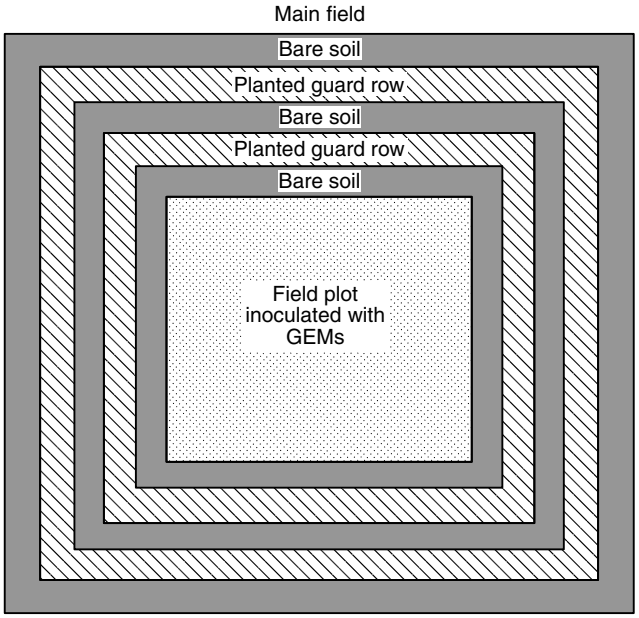

Figure 3. Typical containment design for GEMs released into agricultural crop plots.

indicative of actual field performance and ecological consequence than that achievable in conventional laboratory microcosms.

Biological Containment

One means of bypassing structural containment of GEMs is to design GEMs that are susceptible to biological containment. These GEMs are equipped with "suicide genes" that can be induced when necessary for eradication control. Induction of suicide genes such as *hok*, *gef*, and *relF* cause cell wall perturbations and subsequent death. The simplest biological containment strategies use suicide genes linked to genetic elements that are inducible in the presence of certain chemicals or substrates or by environmental factors such as temperature or nutritive status. For example, the *lac* gene is turned on in the presence of the chemical isopropyl-β-D-thiogalactoside (IPTG). Linking the *lac* gene promoter element to a suicide gene produces a genetic control mechanism in which the addition of IPTG turns on the suicide gene, thereby initiating cell death (90). In theory, IPTG can be added to the field test area and GEMs containing the *lac*–suicide gene construct will be eradicated. However, flooding a site with a control chemical is usually not environmentally or economically feasible and, because of high mutation rates, many of the cells develop suicide resistance making the degree of killing insufficient for adequate risk acceptance (91). The system can also work in reverse, where cell death by suicide genes is induced in the absence of a chemical rather than its presence (92). In bioremediation field releases such a suicide system would be advantageous because the GEMs could be designed to survive only as long as the environmental contaminant was present, after which the suicide genes would be induced to initiate self-eradication. But again, killing efficiency is unsatisfactory because of high mutation rates. Additionally, because many of the suicide vectors are plasmid-based, gene transfer risks increase. This problem has been alleviated in some systems by inserting the vector into the chromosome (93,94). Gene-transfer risks are also increased due to the large amounts of free recombinant DNA present following mass cell lysis. Attempts to overcome this obstacle have led to methods in which DNA-destroying nuclease genes are incorporated into GEMs in a fashion similar to suicide genes (95). Using this suicide scheme, GEMs are not only conditionally killed but their recombinant DNA is destroyed as well. In all of these suicide systems, however, complete eradication remains unattainable owing to the evolution of resistant mutant populations. Therefore, biological containment must be recognized as a viable method for minimizing, but never eliminating, GEM populations released into the environment, with risk factors being evaluated correspondingly.

Improved Monitoring Methods

Conventional methods for the detection and monitoring of GEMs after environmental release relied on growth and cultivation on nutrient media. Because of viable but nonculturable states of introduced populations, the need for selective markers such as antibiotic resistance, and bacterial numbers that fell below mediocre detection limits, culture methods have largely been replaced or supplemented with molecular methods. Primary among these is the polymerase chain reaction (PCR) technique that sensitively detects specific gene sequences rather than the microorganism itself (96). Thus both culturable and nonculturable microorganisms can be identified. DNA is extracted from the environmental matrix and a marker gene sequence specific to the GEM is amplified in the PCR reaction to increase detection capacity. Marker genes can consist of any unique DNA sequence that would be universally absent from the environmental introduction site. Often, markers consist of the engineered DNA sequence itself. Markers can also use gene sequences indigenously specific to the microbe, for example, 16S or 23S ribosomal RNA gene segments or the intergenic regions between these segments (97). Once amplified, PCR products are typically identified as being of GEM origin by applying DNA-hybridization techniques or, alternatively, a greater degree of sensitivity can be achieved by applying nested PCR, whereby another PCR reaction is performed to detect a specific sequence internal to the original PCR sequence (77,96). PCR was used in a soil field release experiment to detect fewer than 20 culturable Rhizobia cells per gram of soil (98) and in a soil microcosm to demonstrate that PCR was capable of detecting nonculturable microbial populations (99). New PCR techniques using fluorescently labeled probes (TaqMan, molecular probes) promise to increase detection limits even further, providing highly sensitive methods for GEM monitoring (100).

PCR can also be used to assess the effects of introduced GEMs on indigenous microbial populations. The most commonly used technique is discontinuous gradient gel electrophoresis (DGGE), which maps a microbial community

by each of its member's unique 16S ribosomal DNA fingerprint (101). The resulting pattern can be followed throughout a field release study to monitor alterations in community structure possibly attributable to GEM introduction. Various other similarly functioning PCR-based methods are also available for estimating microbial community diversity [amplified ribosomal DNA restriction analyses (ARDRA), terminal-restriction fragment length polymorphism (T-RFLP), ribosomal intergenic spacer analysis (RISA), length heterogeneity PCR (LH-PCR), repetitive extragenic palindromic PCR (REP-PCR), random amplified polymorphic DNA PCR (RAPD-PCR), arbitrarily primed PCR (AP-PCR), enterobacterial repetitive intergenic consensus PCR (ERIC-PCR)] (96,102–104). Methods that characterize bacterial populations based on energy metabolism (BIOLOG) (105) and phospholipid fatty acid composition (PLFA) are also accessible (106).

Although PCR has become the backbone of environmental monitoring methods, there still remain significant limitations to its use in field release studies. Primary among these is the presence of PCR inhibitors in most environmental samples, the commonest of which are humic acids that interfere with the Taq polymerase enzyme used in the PCR reaction (107). These contaminants can be partially removed through a series of purification steps but their complete elimination is impossible. Also problematic is the inability to completely extract and isolate total nucleic acid present within an environmental sample. Therefore, detection will always represent an underestimate of actual microbial numbers.

An alternative to PCR is to make use of immunological antibody–antigen reactions for detecting field released GEM populations (108). Monoclonal and polyclonal antibodies can be synthesized against GEM-specific antigenic determinants and used in enzyme-linked immunosorbent assays (ELISA). This technique has successfully been used to detect a recombinant *P. putida* strain in a mixed freshwater microbiota (109).

Methods for detecting and monitoring GEMs without removal from their introduced environment are also available. These methods typically use GEMs that have been engineered to bioluminescence, using either the *lux* or *luc* gene inserts. The presence of a light signal can be correlated with cell viability. Insertion of light detectors such as photon-counting modules within the field release site allows direct online visual monitoring of GEM populations (33).

Reducing Gene Transfer Risks

Early GEM constructs contained engineered gene sequences localized on plasmids, which are easily translocated through horizontal gene transfer events. Consequently, genetic techniques were developed for integrating engineered DNA sequences into the more stable host cell chromosome resulting in lowered gene transfer frequencies. Using disabled or truncated transposon vectors for inserting genetically altered DNA into the chromosome while preventing its exit further reduced gene transfer risks, as did the subsequent development of the DNA-degrading suicide genes (95,110). Further advances have been achieved using a system in which two genes, *colE3* and *immE3*, are used in concert to control gene transfer (93,111). The *colE3* gene encodes for colicin, an enzyme that inhibits protein synthesis and causes cell death. The *immE3* (immunity) gene product neutralizes colicin activity; thus in its presence, the colE3 gene product is rendered inactive and cell death does not occur. Therefore, only if both genes are present will the cell survive. In the genetic engineering strategy, the *colE3* gene is linked to the recombinant genes, whereas the *immE3* gene is placed far from the recombinant genes. If the recombinant genes undergo a gene transfer event, the *colE3* gene will follow, but the likelihood of the distant *immE3* gene being similarly transferred is remote. Thus, the recipient cell receives the recombinant genes, the *colE3* gene but not the *immE3* gene, and dies as a consequence. In test systems, gene transfer frequencies were reduced by four to five orders of magnitude. Thus, such a strategy could significantly decrease, but again not eliminate, gene transfer rates between released GEMs and indigenous microbial populations.

CONCLUSION

The future potential for GEMs in environmental applications will rely on a balanced assessment of possible adverse effects versus proposed benefits. On the basis of field release studies already performed, hazards seem remote, but owing to inherent difficulties in properly assessing GEM presence and in monitoring their diverse environmental interactions, a comprehensive and infallible evaluation of potential risks cannot, as of yet, be achieved. It is therefore necessary to exhaustively study GEMs within controlled habitats before any sort of uncontrolled or semicontrolled release to provide not a guaranteed assurance of no risk but rather a carefully derived prediction of GEM behavior on release, based on data gathered using the most sensitive techniques available. Once the ecological consequences of GEM introduction have been established, then proper regulation and management can be correspondingly applied in a manner in which some degree of uncertainty is necessarily accepted, yet overly precautionary restraint is avoided. GEMs show great promise in their abilities to bioremediate environmental pollutants and enhance and protect agricultural crops, and only through field release trials will their ultimate application be realized.

FILAMENTOUS BACTERIA IN ACTIVATED SLUDGE: CURRENT TAXONOMIC STATUS AND ECOLOGY

PETER KÄMPFER
Justus-Liebig-Universität Giessen
Giessen, Germany

MICHAEL WAGNER
Technische Universität München
Freising, Germany

Different applications of the activated-sludge treatment process are employed worldwide for the biological treatment of wastewater. However, from the beginning of its development, sedimentation problems, in particular sludge bulking and foaming, have been observed (1). The ability of the sludge to settle is assessed by measuring the

sludge volume index (SVI), which is the volume occupied by 1 g of sludge. An SVI higher than 150 mL/g^{-} is often found in connection with one of the main problems, filamentous bulking, which is caused by the overgrowth of filamentous bacteria in the aeration basin. As a result, sludge settling and compaction are hindered by the filamentous cell structures of the organisms, ultimately leading to a decreased effluent quality (2–4; see FILAMENTOUS BULKING IN ACTIVATED SLUDGE, CONTROL OF).

Various factors such as low food to microorganism (F/M) ratios, low dissolved oxygen concentration, low nutrient conditions, or the presence of high sulfide levels may promote the growth of different types of filamentous bacteria physiologically adapted to the respective conditions. The main cause of bulking in wastewater treatment plants, however, seems to be low F/M ratios (4,5). In Table 1, a summary of factors favoring the occurrence of filamentous bacteria in activated sludge (4) is given.

It is generally accepted that basic physiological differences between filamentous and floc-forming bacteria are responsible for the mass occurrence of filamentous bacteria under certain environmental conditions that cause sludge bulking. In most cases, filamentous bacteria are able to survive better under low oxygen concentrations and relatively low nutrient conditions. In addition to sludge bulking, the occurrence of foaming in activated-sludge plants has been documented in wastewater treatment plants around the world (6; see ACTIVATED SLUDGE — FOAMING). Foaming is also caused by the overgrowth of filamentous bacteria (mainly actinomycetes) in the aeration basin often at high mean cell residence times, resulting in a brown viscous scum. Some of the most common bacteria encountered in foam are *Candidatus* "*Microthrix parvicella*," *Gordonia amarae*, *Skermania piniformis*, and sometimes *Rhodococcus* spp. or *Streptomyces* spp. The ability to produce biosurfactants and to grow on hydrophobic substrates such as hydrocarbons, their higher resistance to desiccation and ultraviolet radiation, and their ability to store polyphosphates and poly-β-hydroxybutyric acid may represent selective advantages of actinomycetes in comparison with the floc-forming microorganisms. However, more detailed physiological studies of the bacteria causing bulking and foaming have been hampered by the fact that the majority of the microscopically observable filamentous bacteria are very difficult to culture (or even not yet culturable) under laboratory conditions. Since the pioneering work of Eikelboom and coworkers (2,3), who on the basis of morphological characteristics and simple staining techniques, described seven groups containing in total 26 morphological types of filamentous organisms, several attempts have been made to develop new methods for isolation, cultivation, and also identification of these unique bacteria. However, it is now clear that morphological criteria, which are still widely used, are not reliable enough to allow exact identification of a filamentous bacterium. For example, several phylogenetically unrelated filamentous bacteria cannot be distinguished from each other morphologically (e.g., bacteria erroneously lumped together as "*Nostocoida limicola*" or Type 1863, illustrated later). On the other hand, some species, such as *Sphaerotilus natans* and *Thiothrix* sp., occur either as single cells or as filaments depending the environmental conditions (7). To overcome the limitations of the existing identification schemes, several new approaches including fluorescently labeled 16S rRNA-targeted probes (7–9) and polyclonal and monoclonal antibodies (10,11) have been developed for the in situ detection and identification of these filamentous bacteria in activated sludge. Their precise identification is an important step in finding the reasons for a particular bulking or foaming event in a wastewater treatment plant. As an example, the occurrence of "*M. parvicella*" is often associated with low F/M ratios, whereas *S. natans* can indicate low dissolved oxygen in the aeration basin (3,4). As a result of a lack of knowledge of the identity and in situ physiology of the different filamentous microorganisms, excessive overgrowth of these bacteria in wastewater treatment plants is often combated by nonspecific measures like the use of oxidants (e.g., chlorine, hydrogen peroxide) or flocculants (e.g, iron, synthetic organic polymers, lime).

The aim of this article is to give an overview of the taxonomic status of the different filamentous bacteria and their ecology, with special emphasis on comparing classical approaches with modern molecular biological methods, including their in situ detection and identification.

Table 1. Factors of the Activated Sludge Process Favoring the Occurrence of Filamentous Bacteria (4)

1. Sludge age (mean cell residence time, MCRT; or food to microorganism ratio (F/M)):
   - — Low dissolved oxygen (DO)
   - — Low F/M ratio in completely mixed and continuously fed systems
2. Aeration basin configuration (wastewater feeding regime)
   - — Nature of organic substrate (soluble versus particulate; readily biodegradable versus slowly biodegradable)
3. Presence of initially unaerated zone (anoxic or anaerobic)
   - — Septic wastewater, nutrient deficiency, low pH (<6.5), seeding from surfaces, surface trapping, and foam recycle.

METHODS FOR THE DETECTION OF FILAMENTOUS BACTERIA INVOLVED IN SLUDGE BULKING OR FOAMING

Microscopy

The classical approach to the identification of filamentous bacteria was introduced by Eikelboom (2), who investigated thousands of activated-sludge samples using the phase contrast microscope. Differentiation of the different filaments was based on cell morphological characters, such as the presence or absence of a sheath or a slime layer, true or false branching, the length and shape of the filaments, and the diameter, length, and shape of the cells. Furthermore, the presence of cell inclusions (poly-β-hydroxybutyrate, polyphosphate, or sulfur), the capability for gliding motility, and the reaction to simple staining procedures were used as diagnostic criteria to classify the organisms into 26 types of filamentous organisms grouped into 7 assemblages (2,3) (Table 2). On the

basis of these findings, simple identification keys (2–4,12) were constructed.

These, however, do not represent a phylogenetic-based taxonomy of these filamentous organisms, but the identification keys are still useful for an initial characterization of these organisms, because the microscopic methods are relatively easy to use and no special laboratory equipment is required. For an exact identification, these methods cannot be recommended, because morphology and staining reactions are insufficient criteria to differentiate between phylogenetically unrelated bacteria. For example, *Thiothrix* filaments without sulfur granules cannot be morphologically distinguished from *Leucothrix* (15). Furthermore, nonfilamentous growth forms are documented for *H. hydrossis*, *S. natans*, *Thiothrix* sp., *Leucothrix mucor*, "*M. parvicella*," and Eikelboom Type 1863 (16–18). In addition, it has been suggested that the sheath forming capacity of *L. mucor* is plasmid encoded and thus can easily be lost (15). Another problem limiting the applicability of the traditional identification schemes is that certain filamentous organisms such as "*M. parvicella*," Eikelboom Type 1863, and others display variable gram stain reactions.

Table 2. Filamentous Organisms in Activated Sludge Grouped and Listed According to Eikelboom (2)

Group I:	Sheath Forming, Gram-negative Bacteria
	1. *Sphaerotilus natans*
	2. Type 1701
	3. Type 1702
	4. *Haliscomenobacter hydrossis*
	5. Type 0321
Group II :	Sheath Forming, Gram-positive Bacteria
	6. Type 0041
	7. Type 0675
	8. Type 1851
Group III:	Sheathless, Curled, Multicellular Bacteria Resembling Blue-Green Algae
	9. Type 021N
	10. *Nostocoida limicola*
	11. Cyanophyceae
Group IV:	Slender, Coiled Bacteria
	12. *Microthrix parvicella*
	13. Type 0581
	14. Type 0192
Group V:	Straight, Multicellular, Gram-negative Bacteria
	15. Type 0803
	16. Type 1091
	17. Type 0092
	18. Type 0961
Group VI:	Filamentous Bacteria Motile by Gliding
	19. Type 0914
	20. *Beggiatoa* spp.
	21. Type 1111
	22. Type 1501
Group VII:	Additional Types
	23. Type 1863
	24. Type 0411
	25. Fungi
	26. *Nocardia* sp.

Note: For details about morphological characters see (2–4). Additional types of filamentous organisms are documented in the comprehensive manuals of Lemmer and Lind (13) and Eikelboom and Geurkink (14).

Immunological Techniques

The application of specific antibodies allows a direct detection of certain filamentous bacterial species. Immunological techniques using fluorescent antibodies were used to identify actinomycetes (19–21), *S. natans* (10), *G. amarae* (17), and *Thiothrix* spp. (11) in activated sludge. Because of their high sensitivity and speed, these methods are attractive approaches to overcome the limitations of the traditional microscopic techniques (11). However, the applicability of the immunofluorescence approach for the analysis of microbial activated-sludge communities is limited by several factors. First of all, for the development and testing of new antibodies, culturable reference organisms are necessary. Thus, this approach is currently not suitable for the majority of the described filament types. In addition, unspecific binding of the antibodies to organic particles and fungal spores can lead to high levels of background fluorescence. Furthermore, penetration problems of the relatively large antibodies through the extracellular polymeric substances of activated-sludge flocs can result in detection problem for cells within these aggregates.

Detection and Identification of Filamentous Organisms by Using Ribosomal RNA (rRNA) Targeted Oligonucleotide Probes

16S rRNA gene sequence information can easily be obtained for cultured filamentous bacteria using standard techniques (8), but can also be retrieved for not yet culturable filamentous species either after their enrichment by micromanipulation (22) or directly from activated sludge (23,24; see ACTIVATED SLUDGE — THE MICROBIAL COMMUNITY). Using these techniques, the 16S rRNA gene sequences of many filamentous bacteria have been determined (Figs. 1, 2, and 3). On the basis of this data set, for some of the filamentous species, specific 16S rRNA-targeted oligonucleotide probes were developed for their cultivation-independent detection and quantification, using either membrane hybridization (21) or fluorescence in situ hybridization (FISH) (7,8). Table 3 lists currently available probes for the detection of bacteria involved in bulking and foaming. Because very rigorous methods can be applied for total RNA extraction, membrane hybridization is well-suited also for the detection of gram-positive bacteria with rigid cell walls such as the mycolic acid-containing filamentous actinomycetes (mycolata). In contrast to membrane hybridization, FISH allows us to specifically stain and visualize the filaments within the activated-sludge biomass (Fig. 4). If combined with confocal laser scanning microscopy (24), the specifically stained filaments can be quantified using recently developed image-analysis tools (25,26). Although standard FISH protocols can be applied for the detection of all gram-negative and many gram-positive filamentous bacteria (7,27), there is a need for the development of

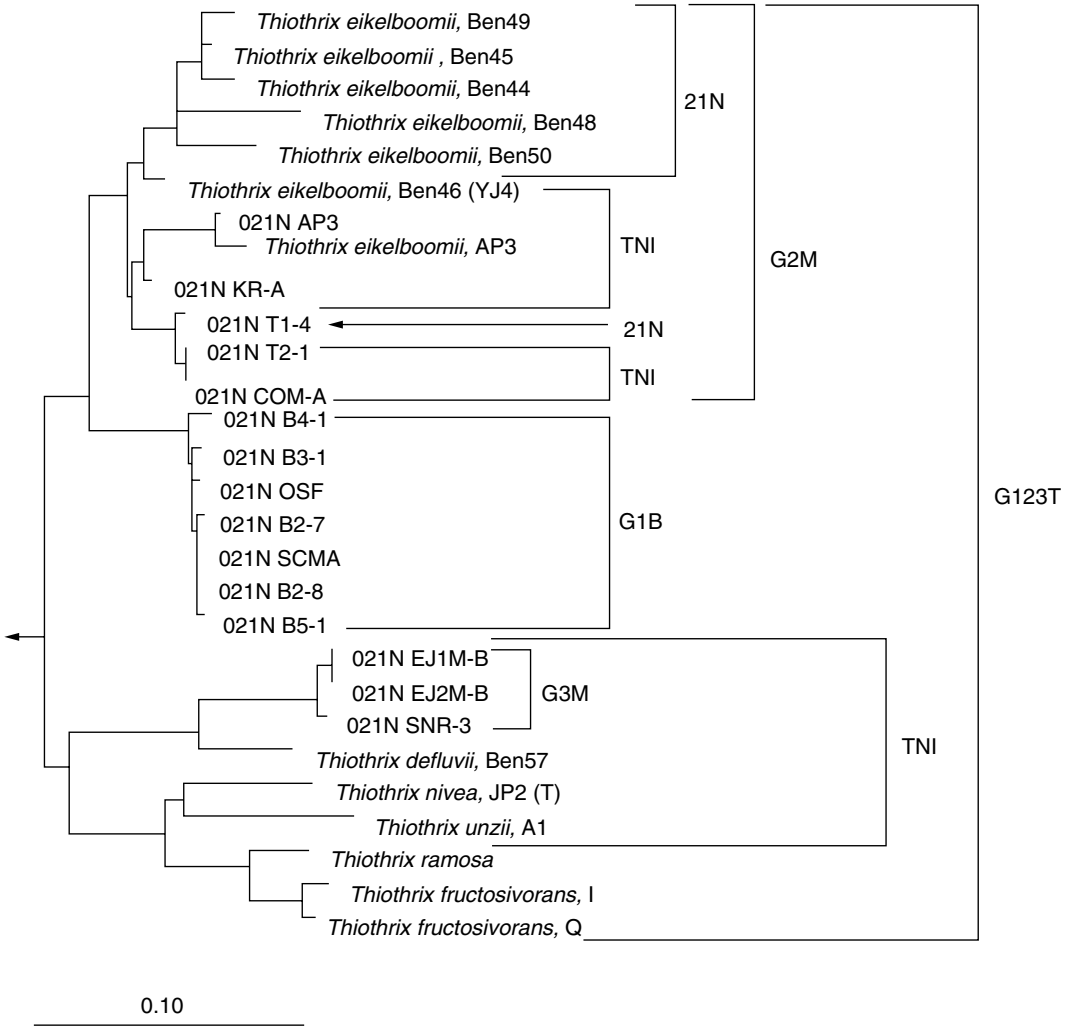

Figure 3. Phylogenetic 16S rRNA–based tree of the *Thiothrix*-Eikelboom Type 021N cluster. The specificity of the published oligonucleotide probes for these bacteria (7,8) is indicated by brackets and arrows. For probe sequences please refer to Table 3.

specific permeabilization protocols for some gram-positive organisms causing bulking and foaming (21,28,29).

ISOLATION AND CULTIVATION OF FILAMENTOUS BACTERIA INVOLVED IN SLUDGE BULKING OR FOAMING

Isolation Methods

The isolation of the majority of filamentous organisms, which is a prerequisite for the study of their nutritional requirements, is still a difficult task. Only a few exceptions to this rule that are relatively easy to isolate can be listed here: representatives of the *Sphaerotilus-Leptothrix* group, *Thiothrix* species, *G.* (formerly *Nocardia*) *amarae*, *S. piniformis* (formerly *Nocardia pinensis*), and some other nocardioform bacteria (16,35–38).

In case of successful isolation, often single isolates of various filamentous bacteria were physiologically characterized and described in detail (2,37,38). Direct dilution plating of activated sludge on different media is often unsuccessful (37–39) because the generally slow-growing filamentous organisms are overgrown by nonfilamentous rapidly growing bacteria. To overcome this problem, van Veen (40) developed a method for isolation of filaments on the basis of specific dilution procedures. An additional method was suggested by Williams and Unz (37) who used additional pretreatment procedures before plating samples on solid media. These methods were adapted and modified by Ziegler and coworkers (38). The pretreatments used in this study included washing the sludge several times after centrifugation, sonication, and subsequent dilution, gathering of filaments by using a very thin sterile pipette under a binocular and subsequent washing steps, and ultra turrax pretreatment or several minutes of whirl mixing in the presence or absence of a few small glass beads in a tube.

Another method for selective isolation of filamentous bacteria is micromanipulation with special microtools under a microscope. This technique was used, for example, for the isolation of *Gordonia* (*Skermania*) (39) and "*M. parvicella*" (41) and a modified method was applied

Table 3. Probe Sequences and Target Sites for Different Filamentous Bacteria

by Hornby and Horan (42) for isolation of other filaments. Details of the methods can be obtained from the original publications. The recommended methods for isolation of the most frequently seen filamentous organisms have been summarized by Kämpfer (43).

Cultivation of Filamentous Bacteria

Selected gram-positive filamentous bacteria, such as the nocardioform organisms, *G. amarae* and *S. piniformis*, and also *Rhodococcus rhodochrous*, can be cultivated on nutrient-rich media, such as yeast glucose agar and Tryptone-yeast extract agar (35,39,44,45). *Sphaerotilus natans* can also be grown on nutrient-rich media, such as Casitone-glycerol-yeast-autolysate (CGYA) (46) and media with moderate nutrient content like R2A agar (47).

Most of the gram-negative filamentous organisms, however, prefer media with low ($<0.5\ g\,L^{-1}$ of specific and/or complex carbon sources) or moderate nutrient concentrations (0.5 to $5\ g\,L^{-1}$ of specific and/or complex carbon sources) (37,38). Recommended media include I-medium, SCY-medium (sucrose-Casitone-yeast extract, 40), GC (glucose plus sulfide), AcS (sodium acetate plus sulfide), and SS-medium (sucrose plus sulfide, 48), LT (lactate), CGY (Casitone-glycerol-yeast-autolysate), and GS medium (glucose plus sulfide, 37), GMBN (glucose mineral base medium, 49), medium of Slijkhuis (50), and R2A medium (51). Aerobic incubation at 20 °C or 25 °C

(sometimes up to 30 °C) is preferred (up to six weeks). Resulting growth of filamentous colonies can be followed under a binocular (40x) or a microscope (160x). A table summarizing the isolation media and conditions is given by Kämpfer (43).

TAXONOMY OF FILAMENTOUS BACTERIA CAUSING FOAMING AND BULKING PROBLEMS IN THE ACTIVATED SLUDGE PROCESS

On the basis of comparative 16S rRNA sequence analysis, the phylogeny of many filamentous microorganisms has been elucidated. Figures 1 to 3 provide an overview of the phylogenetic affiliation of the most important filamentous bacteria, which are discussed in detail in the following text.

Actinomycetales

"Microthrix parvicella." "*Microthrix parvicella*" is a gram-positive, straight filamentous bacterium, which is very difficult to cultivate and to maintain (3,52). On the basis of 16S rDNA sequencing, "*M. parvicella*" was found to be a novel deep-branching member of the actinomycetes within the gram-positive phylum of the domain bacteria (41,52) (Fig. 1).

Morphologically it can be characterized by its thin filaments (0.3 to 0.7 μm diameter), which can be hundreds of micrometers long with a characteristic winding appearance (Fig. 5; 2–4,41,50,52). Individual cells in the filaments are difficult to detect by light microscopy. On the basis of electron microscopical studies (52), filaments are clearly gram-positive, although some of the cells (presumptively empty, autolyzed cells) stain gram-negative. Cells show intracellular inclusions of polyphosphate detectable by Neisser staining. Micromanipulation is recommended for their isolation (41). In the comprehensive studies of Blackall and coworkers (41,52), a few "*M. parvicella*" isolates grew best on fresh R2A or non-Tween medium (NTM), although even on these "optimum" media very poor growth was observed. Although some phenotypic features of "*M. parvicella*" have been reported by Slijkhuss and coworkers (53), no reference strains were deposited in culture collections. Because of the lack of information of phenotypic features, the name "*Candidatus Microthrix parvicella*" was proposed (52) on the basis of the suggestion of Murray and Stackebrandt (54) that the provisional status Candidatus be used for incompletely described prokaryotes. At present, no reference strains are available from culture collections.

"*Microthrix parvicella*" is found in activated sludge plants around the world, where it is responsible for solids-separation problems both in bulking and foaming (6,52). This organism is one of the most frequently identified causative agents for solids-separation problems in wastewater treatment plants (41,52,55) and can be found in both mixed liquors and foams. According to Wanner and Grau (12), "*M. parvicella*" can occur in anaerobic and aerobic zones of activated-sludge plants and is able to accumulate storage material, which allows successful competition with floc-forming bacteria. This may explain why selectors do not always control SVI to very low levels, in cases in which "*M. parvicella*" is the causative bulking agent (4). In systems with anaerobic zones, serious bulking problems caused by "*M. parvicella*" were reported (56). "*Microthrix parvicella*" is often associated with low F/M ratios. So far, "*M. parvicella*" has never been detected outside activated-sludge plants. However, the organism seems to be also present in activated sludge plants without bulking or foaming problems (6,55). There are also a number of reports implicating "*M. parvicella*" as the main causative organisms of foaming in South Africa, Australia, and Europe (6, and references therein). By using microautoradiography on activated sludge samples (57), it was shown that from six different substrates investigated (acetate, glucose, ethanol, glycine, leucine, and oleic acid), "*M. parvicella*" consistently took up only oleic acid. The uptake was observed under aerobic and anaerobic conditions, although it is still uncertain whether "*M. parvicella*" can grow anaerobically (57). "*Microthrix parvicella*" seems to be a specialized lipid consumer, able to take up long-chain fatty acids under anaerobic conditions and subsequently use the storage material for growth when nitrate or oxygen is available as electron acceptor (58). Some information on the physiology of "*M. parvicella*" was obtained from the studies of Slijkhuis and coworkers (53). First isolated by Van Veen (40) on a mineral salts medium containing a low glucose concentration (0.15 $g\,L^{-1}$) and small amount of thiamine and biotin, in the studies of Slijkhuis and coworkers (53), the organism was found to be more readily culturable on activated sludge medium (2). Carbon sources such as glucose, fructose, lactic acid, succinic acid, and citric acid were not used, but instead "*M. parvicella*" uses oleic acid and its polyoxyethylenesorbitan ester (Tween 80) as the sole source of carbon and energy (at low concentrations <0.15 g/L) (53). Shorter-chain fatty acids were also used, but only in the presence of Tween 20. As a result, the lipid composition of "*M. parvicella*" was very high (sometimes approaching 35% of the dry weight of the organism (50)), because the organism rapidly used (five days) the oleic acid and palmitic acid moieties of Tween 80 and Tween 60 and stored these as long-chain fatty acid esters (53). Because these esters were presumed to constitute the main components of large intracellular lipid globules detected microscopically (53), the authors suggested that the ability of "*M. parvicella*" to store long-chain fatty acids in the early growth stages would favor it in competition for substrates in activated-sludge plants containing such long-chain fatty acids. Thus, extensive growth of "*M. parvicella*" in wastewater treatment plants could be controlled by decreasing the amount of fats in the influent by physical means. Also, nitrogen and sulfur requirements for this organism were demonstrated. Nitrogen is required in a reduced form, for example, as ammonium sulfate. Consequently, potassium nitrate could not be used as a nitrogen source for growth (50). Although growth was observed at 8 °C, "*M. parvicella*" grows optimally at 25 °C, but very weak or no growth is found at 35 °C (50). "*Microthrix parvicella*" was found to grow in media with initial pH 7.5, 7.7, and 8.0, but no growth was detectable when the initial pH of the medium was 7.1 or lower.

Growth of "*M. parvicella*" is suppressed under continuous oxygen supply but not with intermittent aeration (59). Two possible explanations have been suggested. "*Microthrix parvicella*" might possess a high affinity for oxygen at low concentrations and can therefore successfully compete for this electron acceptor under conditions of reduced oxygen supply (50). Alternatively, "*M. parvicella*"

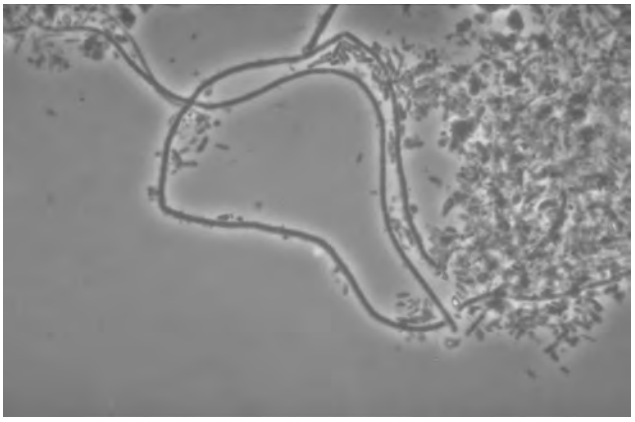

Figure 5. Filaments of "*Microthrix parvicella*" (×1250). Photo by D. Eikelboom, TNO-MEP, Apeldoorn.

might require reduced nitrogen and sulfur compounds for growth and the concentration of these in a fully aerated mixed liquor may be too low (59). It must be stressed that Blackall and coworkers (41,52), in spite of numerous attempts, could not grow "*M. parvicella*" cells according to the instructions of Slijkhuis and coworkers (53), a failure that might indicate that different organisms might have been investigated by the two research groups. In a new approach for kinetic and physiological characterization (60), two strains were studied in detail, and it could be shown that both strains were K_S-strategists with a high substrate affinity, are able to store PHA under aerobic/anoxic/anaerobic conditions, and have a resistance to long periods of anoxic/anaerobic conditions. For further understanding of the metabolism of "*M. parvicella*" and its ecological role, more pure-culture studies are urgently needed.

Other Actinomycetes

Actinomycetes have been frequently reported in connection with the formation and stabilization of biological foams in the activated-sludge process (Figure 6; 6,35,39,45,61). Although several species belonging to different genera have been detected in treatment plants all over the world, such as *Actinomadura* spp., *Micromonospora* spp., *Nocardia asteroides*, *Nocardia caviae*, *R. rhodochrous*, *Rhodococcus ruber*, *Streptomyces* spp., and some others, the most frequently found organisms are *Gordonia amarae* (former *Nocardia amarae*) and *Skermania piniformis* (former *N. pinensis*, 62). In contrast to "*M. parvicella*," most of these can be relatively easily isolated with standard spread-plate techniques, although micromanipulation can facilitate their isolation (39). The majority of them grow best at 25 to 30 °C even on relatively nutrient-rich media ($>5\ g\,L^{-1}$ of specific and/or complex carbon sources), such as yeast glucose agar and tryptone-yeast glucose agar, and can be maintained by lyophilization.

Several phylogenetic studies based on 16S rRNA sequences have been published (62–64). Further studies have clearly demonstrated the extent of actinomycete diversity in activated sludge foaming (9,65,66) and many probably still await identification (67).

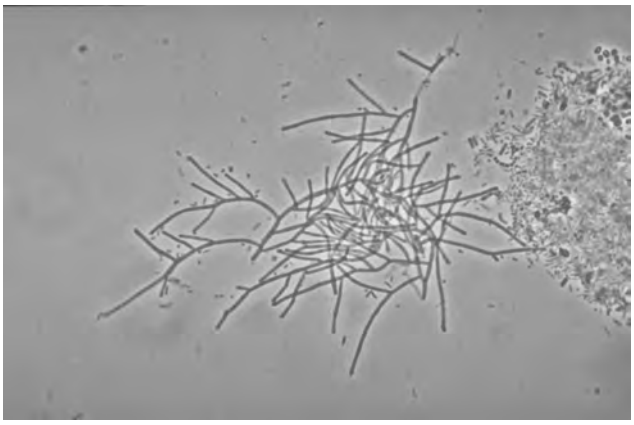

Figure 6. Filaments of actinomycetes (x 1250). Photo by D. Eikelboom, TNO-MEP, Apeldoorn.

For the identification at the genus or even species level, chemotaxonomic characterization (analyses of isoprenoide quinones, polar lipids, cell wall diamino acids, and fatty acids) is essential (62,63), in addition to morphological and physiological characterization. Cell wall types and further chemotaxonomic features differentiating actinomycetes at the genus level are shown in Table 4. Reference strains have been deposited in culture collections and should be included for control purposes in identification procedures of unknown isolates.

Gordonia amarae. *Gordonia amarae* is an aerobic gram-positive organism, producing a substrate mycelium with moderately branching vegetative hyphae that does not fragment in undisturbed cultures. Originally described as *Nocardia amarae* by Lechevalier and Lechevalier (44), it became evident from chemotaxonomic and other taxonomic studies that this species revealed note differences from the authentic *Nocardia* species with respect to the presence of MK-9(H_2) (63) as its major menaquinone, serological cross reactions, and sensitivity to nocardiophages. On the basis of 16S rRNA sequence analyses, the genus name *Gordonia* was revived, and it was subsequently shown that organisms classified as *N. amarae* belong clearly to the genus *Gordonia* (63).

Secondary branching of *G. amarae* is rare. The filaments are partially acid-fast. The substrates esculin, Tween 20, Tween 40, Tween 60, and urea are hydrolyzed, but not casein, elastin, gelatin, hypoxanthine, adenine, tyrosine, or xanthine. The organism can reduce nitrate to nitrite. A wide variety of carbon sources (sugars, alcohols, and organic acids) is used (63).

Gordonia amarae possess cell wall chemotype IV, with mesodiaminopimelic acid as the only diamino acid, and arabinose and galactose as major cell wall sugars. The predominant isoprenolog is MK-9(H_2), and polar lipids include phosphatidyl ethanolamine, diplphosphatidyl glycerol, phosphatidyl glycerol, phosphatidyl inositol, and phosphatidyl inositol mannosides. The species contains major amounts of straight-chain, saturated and unsaturated fatty acids, and tuberculostearic acid. Mycolic acids with 46 to 54 carbons and up to three double bonds are present. On pyrolysis gas chromatography of mycolates 16 : 0, 18 : 0, 16 : 1, and 18 : 1 fatty acid esters are released (Table 4). The G + C content of the DNA is 60 to 66 mol%.

Gordonia amarae was found to be the actinomycete from the most often isolated from foams from the treatment plants in the United States. In addition, *G. amarae* has been isolated several times as the predominant foam actinomycete in Australia, and also Europe (6,35,55, and references therein).

Some studies have been published on specific foam strains and it was found that, although pure cultures of *G. amarae* did not grow in sterile raw sewage without the addition of a carbon source (fructose), they did grow in sterile activated sludge. After removal of the solid components from the activated sludge, no growth was observed, suggesting that the solids supply some essential nutrients. High levels of emulsifiable fatty material (oil and grease) have also been associated with *Gordonia* and *Nocardia* growth and foaming, but until

now little experimental evidence has been presented to support a clear connection. Because of the hydrophobic cell walls of actinomycetes, hydrophobic substrates are selectively available to them, and this may lead to their successful competition for substrates in activated sludge. It should be noted that many authors have proposed that the hydrophobicity of the mycolic acid content of the actinomycete cell wall plays an important role in foaming.

Deficiencies of nitrogen and phosphorus, and also trace elements, cannot account for the excessive occurrence of nocardiae and/or gordoniae (35).

Examinations of the foaming environment have been conducted by Marshall (68), who showed that nutrients can accumulate at interfaces, leading to a relatively nutrient rich condition in an otherwise low-nutrient environment. On addition of surfactants, the growth of actinomycetes in a pilot plant increased, which suggests a role of surface-active agents, which might explain a greater substrate availability and an increased growth of *G. amarae* on the addition of hydrophobic substrates such as hexadecane, and industrial wastewater containing nonpolar hydrocarbons (35). *Gordonia amarae* grows between 23 to 37 °C, but not at 10° or 40 °C, although for some strains, growth as low as 10 °C has been reported (44).

A correlation between foaming and plant-operating temperature was suggested by Pipes (69) who observed that foaming occurred only at temperatures above 18 °C. However, Sakai and coworkers (70) detected and isolated *G. amarae* from plants operating between 14 °C and 26 °C, although in addition to temperature, growth rates also depend on the environmental pH. Optimum growth of *G. amarae* occurs at a pH of about 7 to 8, whereas only very slight growth was observed at pH 5 to 6. Oxygen supply is another important parameter, because *G. amarae* is a strict aerobic species. Blackall and coworkers (71) showed that *G. amarae* neither grows on, nor takes up, acetate under anaerobic (no nitrate, no oxygen) or anoxic (nitrate, no oxygen) conditions.

Actinomycetes found in foam and scum are generally considered as slow growers, with generation times of 4 to 13 hours under optimum conditions; however, large variations in this parameter (4 to 7 d) were described for *G. amarae* (6).

In modeling microbial growth, especially in continuous culture, the K_S value largely determines the steady state concentration of unused growth rate-limiting substrate, and thus is an important parameter showing the efficiency of conversion of substrate to biomass. Lemmer (72) proposed a model about growth strategies based on K_S values. She argued that foam-forming actinomycetes, including *G. amarae*, can switch between two strategies. The first strategy is characterized by high-substrate uptake efficiency at low substrate concentrations, low K_S values, and relatively low cell yield (K-strategy). At high-substrate concentrations, the second so-called μ_{max}- or r-strategy is used by the actinomycetes. This strategy is characterized by high biomass production and both growth rates exceeding those of K-strategists. Some other models have been proposed, and details and critical remarks on these models have been published by Soddell and Seviour (6) in their comprehensive review on activated-sludge foaming.

The bases for *G. amarae* growth and foaming in activated sludge are not well understood. In the literature, much contradictory information can be found, and many of the suggested countermeasures are based on anecdotal evidence (4). Different surveys have implicated that foam and scum problems occur in treatment plants with marked differences in sewage compositions and plant-operating systems. Ecological factors implicated with foam formation include the oxygen content of the aeration tank, the sludge age, and a high solid content of the mixed liquor, temperature, and the grease and oil content of the sewage. Details regarding these factors have been summarized by Soddell and Seviour (6). In the study of Stainsby and coworkers (67), it was shown that there is a higher diversity of mycolic acid-containing actinomycetes, including new *Gordonia* species associated with activated-sludge foam. Their role need to be elucidated in the future.

Skermania piniformis. *Skermania piniformis* was first described as *N. pinensis* by Blackall and coworkers (71) for actinomycetes responsible for extensive foaming or scumming in activated sludge sewage treatment plants in Australia. By using a combination of morphological, chemical, and physiological properties, these organisms were first assigned to the genus *Nocardia*. However, it was obvious that the organisms showed atypical features for *Nocardia*, including a relatively slow growth rate, mycolic acids, which were monounsaturated at position 2, and a different antimicrobial sensitivity pattern. The actinomycetes showing mycolic acids as distinctive chemotaxonomic features share many phenotypic properties (Table 4). On the basis of 16S rRNA sequence analyses, they form a distinct phyletic line, and are currently classified in the genera *Corynebacterium, Dietzia, Gordonia, Mycobacterium, Nocardia, Rhodococcus, Tsukamurella*, and *Williamsia*, primarily on the basis of chemical, molecular, and morphological markers. The 16S rDNA sequence of *N. pinensis* is substantially different from the corresponding sequences of the representative mycolic acid-containing actinomycetes. Almost equal levels of relatedness to the sequences of *Gordonia* strains (levels of similarity, 94.9 to 95.9%), *Nocardia* strains (94.5 to 95.9%), and *Rhodococcus* strains (94.5 to 95.9%) were observed (62). Lower levels of homology were observed with the sequences of *Mycobacterium* strains (94.0 to 94.7%), *Tsukamurella* strains (93.7 and 93.8%), a *Dietzia* strain (93.5%), and *Corynebacterium* strains (91.4 to 92.6%) (62).

Additional chemotaxonomic data confirmed a separate position for *N. pinensis*. High amounts of hexahydrogenated menaquinones with eight isoprene units, the last two of which were cyclized, were detected. In addition, the glycan moiety was rich in N-glycolated muramic acid. The organism also contains major amounts of diphosphatidyl glycerol, phosphatidyl ethanolamine, phosphatidyl inositol, and phosphatidyl inositol mannosides (41).

On the basis of phylogenetic, chemotaxonomic, and conventional phenotypic data it was evident that *N. pinensis* should be considered a member of a separate genus within

the mycolic acid-containing actinomycetes and the name *S. piniformis* was proposed by Chun and coworkers (62).

Skermania piniformis is a gram-positive, nonacid-fast, nonmotile actinomycete forming a mycelium, which does not fragment in undisturbed cultures. Secondary branching is rarely observed and aerial hyphae cannot be seen without the help of a microscope. The organism grows on tryptone yeast extract glucose (TYG) agar (71). During the early growth stages (24 hours), the light microscopic appearance of the organism resembles a pine tree. Strains isolated from activated-sludge plants often contain intracellular sudanophilic and polyphosphate inclusions.

Colonies on nutrient-rich media (TYG) are orange, opaque, macroscopically dry and friable, and microscopically moist and shiny, have a pasty texture, are difficult to emulsify or subculture, and are circular with entire edges. The minimum and maximum growth temperatures are 15 °C and 31 °C, respectively. The organisms are aerobic and catalase, oxidase, and urease positive. Growth cannot be enhanced in an atmosphere containing 5% carbon dioxide, nor does growth occur anaerobically, microacrophilically, or in a candle jar. Hydrolysis of esculin, casein, gelatin, hypoxanthine, Tween 20, Tween 40, Tween 60, and Tween 80 are negative. Nitrate is not reduced to nitrite. A large number of fluorogenic substrates are hydrolyzed (41,62,71). Because *S. piniformis* does not grow on many media, that support the growth of other actinomycetes, the exact nutritional requirements and utilized carbon sources are unknown. However, the organism grows well on media that contain glycerol as a carbon source and asparagine as a nitrogen source. The cell wall contains major amounts of mesodiaminopimelie acid, arabinose, galactose, glucose, ribose, and N-glycolated muramic acid. The peptidoglycan is of the A1-γ type. As polar lipids, diphosphatidyl glycerol, phosphatidyl ethanolamine, phosphatidyl inositol, and phosphatidyl inositol mannosides are predominant. Major fatty acids are straightchain saturated, unsaturated, and tuberculostearic fatty acids, mycolic acids with 58 to 64 carbons and monounsaturated side chains, and hexahydrogenated menaquinones with eight isoprenic units in which the last two units are cyclized. The organism has DNA that is rich in guanine and cytosine (67.5 mol%). In a numerical taxonomic study, 59 isolates showed the microscopic morphology and/or similar morphological features of *S. piniformis* clustered as two separate groups, probably representing new species (73).

Skermania piniformis was first isolated by filament micromanipulation (71). It has a relatively slow growth rate (10 to 21 d) (6) and constitutes the second most prevalent foaming organism in Australia (71) after *G. amarae*. As reported by Soddell and Seviour (6), microphotographs from activated-sludge samples outside Australia presented in earlier studies show organisms with the characteristic pine tree branching morphology (4) indicating that *S. piniformis* is not unique to Australia. Detailed knowledge on the global distribution and ecology of the organism, however, is still scarce.

Nocardia. Organisms belonging to the genus *Nocardia* are aerobic, chemoorganotrophic actinomycetes forming a rudimentary to extensively branched substrate hyphae. These hyphae often fragment in situ, or on mechanical disruption, into rod-shaped to coccoid, nonmotile elements. Aerial hyphae, most often visible only microscopically, are almost always present. *Nocardiae* have an oxidative type of metabolism. The chemotaxonomic features are listed in Table 4. Those *Nocardiae* playing a predominant role in foaming, for example, "*N. amarae*" and "*N. pinensis*," have been reclassified as *G. amarae* and "*S. piniformis*," respectively. There are only few reports on the occurrence of authentic *nocardiae* in bulking and/or foaming, although *Nocardia asteroides, Nocardia farcinica*, and *Nocardia caviae* have been isolated from foams of United States treatment plants (6,74).

Rhodococcus. The genus *Rhodococcus* contains aerobic, gram-positive, partially acid-fast, nonmotile actinomycetes-forming rods to extensively branched substrate mycelia. The growth cycle is quite complex. It starts with the coccus or short-rod stage. Different organisms then show a complex series of morphological stages: cocci may germinate only into short rods, or form filaments with side projections, or show elementary branching, or in the most differentiated forms, produce branched hyphae. Members of the genus *Rhodococcus* can grow well on most of the standard laboratory media at 30 °C although some strains require thiamine. Colonies may be rough, smooth, or mucoid, and they often show a buff, cream, yellow, orange, or red pigmentation, though colorless variants also occur. Rhodococci have an oxidative metabolism. They are catalase positive, sensitive to lysozyme, arylsulfatase negative, and produce acid from glucose oxidatively. Some important chemotaxonomic features are listed in Table 4.

Rhodococcus rhodochrous have been reported to be the main actinomycetes in foam in European treatment plants (35). However, *Rhodococcus equi, R. ruber*, *R. coprophilus*, and *R. erythropolis* have also been detected in plants from different parts of the world (6,35). They can use a wide range of different carbon sources and most of them grow between 10 and 40 °C. Although it has been speculated that rhodococci have a lower temperature optimum than *G. amarae*, and this explains the predominance of rhodococci in Europe and of *G. amarae* in the United States, some studies in Japan do not support this assumption (70). Kurane and coworkers (75) reported that *Rhodococcus* species, particularly *R. erythropolis*, which occurs in activated sludge, were able to produce chemicals that flocculate both organic and inorganic compounds, including cells of *E. coli, Saccharomyces sp.*, and *Macrocystis aeruginosa*. Therefore, it was suggested that these compounds flocculate bacteria or prevent their deflocculation in an activated sludge environment (73). In the study of Stainsby and coworkers (67), it was shown that there is a higher diversity of mycolic acid-containing actinomycetes, including new *Rhodococcus* species.

"Nostocoida limicola." Filaments of "*N. limicola*" were first characterized and isolated by van Veen (40), who characterized them as chains (0.6 to 0.9 mm long) of

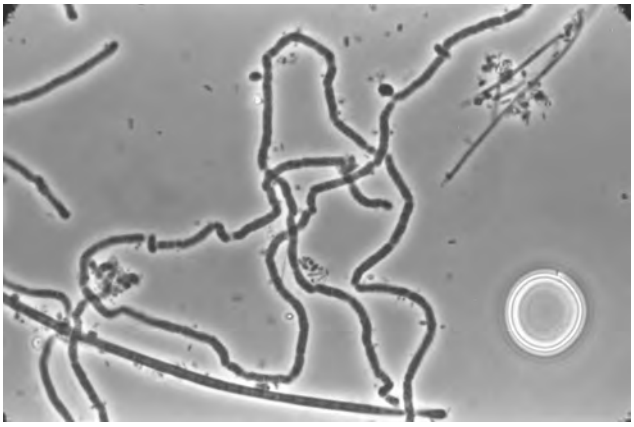

Figure 7. Filaments of "*Nostocoida limicola*." Phylogenetic group not determined (×1250). Photo by D. Eikelboom, TNO-MEP, Apeldoorn.

coccoid, gram-positive cells with spherical to ovoid appearance, 0.3 to 0.6 μm long with a diameter of 0.7 to 1.5 μm. A similar description was given by Eikelboom (2) and both authors described "*N. limicola*" as facultatively anaerobic to microaerophilic organisms. In the study of Eikelboom and Van Buijsen (3), three morphotypes were recognized and termed *N. limicola I, II*, and *III*. The incidence of "*N. limicola*" has been described for both bulking and foaming events, particularly in plants treating wastewater from industrial sources (Fig. 7). Recently, the phylogeny of all three morphotypes has been clarified (Figs. 1 and 2). "*Nostocoida limicola*" I contains at least two different low G + C gram-positive bacteria, which are very closely related to *Lactosphaera pasteurii* and *Streptococcus suis*, respectively (22). "*Nostocoida limicola*" II is affiliated with the actinomycetes (high G + C gram-positives). Representatives of the genera *Terrabacter* and *Janibacter* were shown to be the closest phylogenetic relatives of this morphotype (76). '*Nostocoida limicola*' III lumps together members of the *Planctomycetales*, which are most closely related to *Isosphaera pallida* (22). The actual diversity hidden behind the '*N. limicola*' morphotype might still be higher. Schade and coworkers (32) isolated '*N. limicola*'-like organisms, which on the basis of comparative 16S rRNA analysis were shown to belong to the green nonsulfur lineage. These results demonstrate that organisms from four different bacterial divisions possess the morphology of '*N. limicola*'. This example most drastically shows that morphological similarities between bacterial species are not indicative of a common evolutionary history. Five '*N. limicola*' filaments of the morphotype II could be isolated on R2A agar using a micromanipulator from two different activated-sludge sewage treatment plants in Italy and Australia (76). For all strains, the gram stain was extremely variable, and both gram-positive and gram-negative cells could be detected in the filaments. Neisser stain also gave positive results. The isolates were able to grow on several carbon sources, including organic acids and carbohydrates. Ammonium, nitrate, and urea were used as nitrogen source and the organisms grew in a temperature range between 15 °C and 30 °C, but not at 40 °C (76). In contrast to the description of van Veen (40) and that of Nowak and Brown (77), none of the strains could grow anaerobically or with nitrate as the terminal electron acceptor. Snaidr and coworkers (33) studied the diversity of '*N. limicola*'-like filaments from industrial wastewater treatment plants and found an additional type affiliated to the α-subclass of *Proteobacteria*. For these organism the genus name "*Alisphaera*" is proposed (33).

FILAMENTS AFFILIATED WITH THE β-SUBCLASS OF THE PROTEOBACTERIA

On the basis of 16S rRNA sequencing studies, some of the "classical" filamentous bacteria in activated sludge, such as *S. natans, Leptothrix* species, and Eikelbooms Type 0803, have been assigned to the *Rubrivivax* subdivision of the beta subclass of the *Proteobacteria* (Fig. 2). The class *Proteobacteria* has been proposed (78) as a suitable collective name for the phylogenetic relatives to the purple photosynthetic bacteria.

Sphaerotilus

Historically, organisms belonging to *S. natans* (at present the only species of the genus) have been regarded as the principal agents of filamentous bulking (37), but it is now clear that a wide variety of filamentous bacteria contribute to this problem. On the basis of 16S rRNA sequencing studies, the genus *Sphaerotilus* and the closely related genus *Leptothrix* belong to the *Rubrivivax* subdivision of the β-subclass of the *Proteobacteria* (46,79,80).

Sphaerotilus natans is a gram-negative straight rod, usually arranged in single chains with sheaths of uniform width. These sheaths may be attached by means of holdfasts to surfaces, and are not encrusted by ferric or manganese oxides. *Sphaerotilus natans* has an aerobic, chemoorganotrophic metabolism. It can grow at low concentrations of dissolved oxygen (below 1 mg/L^{-}) and has a temperature range from 10 to 37 °C (optimum between 20 and 30 °C). *Sphaerotilus natans* can be grown on a wide variety of media (43,49), with a preference for media with moderate nutrient concentrations (16,36). Reference strains are available from culture collections. Isolation can be successful by using the spread plate techniques (16), centrifugation pretreatment (37), or whirl-mix pretreatment of activated sludge (38).

Sphaerotilus natans contains ubiquinones of the type Q-8 as a major component (>90%), which is a common trait within genera belonging to the *Rubrivivax* group (81). Fatty acid analyses of all strains revealed characteristic profiles for *Sphaerotilus* with four major fatty acids, *cis*-9 hexadecanoic acid (16 : 1), hexadecanoic acid (16 : 0), *cis*-9,11 octadecanoic acid (18 : 1), and hexadecanoic acid (12 : 0). All strains contained the hydroxylated fatty acid 3-OH 10 : 0 (81). Similar to its quinone composition, the fatty acid profile closely resemble that of the genus *Leptothrix* (80). A clear differentiation at the genus level with these chemotaxonomic features is not possible. Strains of *Sphaerotilus* can grow on a wide variety of carbon sources including sugars, organic acids, and

alcohols. On the basis of carbon source utilization patterns, a differentiation between the genera *Sphaerotilus* and *Leptothrix* is possible (80,81). Because isolation and cultivation of these organisms is sometimes difficult and time consuming, the use of specific 16S rRNA-targeted oligonucleotide probes (7,46) can be very useful for in situ detection and identification of *Sphaerotilus* (43, Table 3). The mol % G + C of the DNA is approximately 70 mol%.

The original habitat of *S. natans* was slowly running fresh water heavily contaminated with sewage or wastewater from paper, potato, dairy, or other agricultural industries. Often long, slimy tassels attached to stones or plants are observed. *Sphaerotilus natans* is often present in activated sludge, but only under certain conditions does *S. natans* cause sludge bulking (2). *Sphaerotilus natans* primarily occurs in plants characterized by a low concentration of available nutrients (typically found in systems continuously fed with wastewater) and low oxygen tensions in activated sludge. The ability of *S. natans* to grow at very low pO values is an additional factor favoring the competition with floc-forming bacteria (16). However, Williams and Unz (37) isolated *S. natans* and also the morphologically very similar Type 1701 from aeration basins operated at both high- and low-bulk water dissolved oxygen conditions. They stated that certain operation parameters, such as organic loading or dissolved oxygen, should not be considered as sole reasons for bulking problems. Moreover, the interaction of coexisting factors, which are still unknown, seems to be important (37).

Although *S. natans* prefers a growth medium containing adequate amounts of easily assimilable organic nutrients, the occurrence of this organism has been reported for unpolluted water of brooklets, ditches, and ponds where unknown compounds are the substrates.

In the former habitat, the sheaths are thin and colorless; in the latter, particularly in the presence of soluble iron compounds, they may turn yellow-brown and sometimes become encrusted with ferric oxide. This characteristic can be clearly observed in a laboratory apparatus in which *S. natans* is grown in slowly running soil extract enriched with Fe (II). Under these conditions, the sheaths of *S. natans* are very similar to those of *Leptothrix ochracea*. For this reason, it has been suggested that both organisms are identical. However, in a polyphasic approach on the taxonomy of the genus *Leptothrix*, the separate standing of both genera has been clearly shown (80).

Leptothrix

Organisms belonging to the genera *Sphaerotilus* and *Leptothrix* are characterized by their ability to form sheaths. The formation of the sheaths is affected by the composition of the culture medium (16,36). *Leptothrix* is also placed within the *Rubrivivax* subdivision of the β-subclass of the *Proteobacteria* (Fig. 2). The genus includes six species, from which *L. discophora, L. cholodnii*, and *L. mobilis* (80) are available from culture collections. Strains of the remaining species, namely, *L. ochracea, L. pseudo-ochracea*, and *L. lopholea*, have never been grown in axenic culture (46). Representatives of the culturable species can be grown on nutrient-poor media, such as PTYP medium (46) and the medium described by Rouf and Stokes (82), incubated at 20 to 30 °C (optimum temperature) (16). *Leptothrix* and *Sphaerotilus* share a number of features, namely, motile cells, formation of poly-β-hydroxybutyrate (PHB), a requirement for vitamin B_{12}, but they can be clearly differentiated by the ability of *Leptothrix* to oxidize Mn^{2+} to Mn^{4+}, in addition to several other features listed by Mulder and Deinema (16), and Spring and coworkers (80). In the past, identification of both genera and the species within the genus *Leptothrix* was based largely on morphological and cytological criteria (2,16). However, for culturable representatives, several phenotypic characters have been described as well (16,37,46,55). Sheathed bacteria of the genus *Leptothrix* are often found in freshwater habitats, such as lakes, ponds, swamps, or springs. However, they have also been associated with bulking in activated sludge (2,7,36).

Eikelboom Types 1701, 1702, and 0803

Bacteria of the Type 1701 described by Eikelboom (2) share many morphological features with the *Sphaerotilus-Leptothrix* group, especially with *S. natans* (2,37,38). Eikelboom (2) stated that when grown on I-medium, colonies of Type 1701 closely resemble those of *S. natans*, but cells of Type 1701 are smaller compared with *S. natans* (3). However, detailed taxonomic studies are required to clarify the relationship of Type 1701 to *S. natans*. Phylogenetically Eikelboom Type 1701 is closely related to *S. natans* (unpublished results, Fig. 2). Type 1702 was also reported to produce long, unbranched, and slightly benched filaments. Compared with Type 1701, septa are not so clearly visible. The original description is given by Eikelboom (2). This type has never been obtained in pure culture. Type 1701 has been reported often in connection with mixed liquor suspended solids (MLSS) held under low dissolved oxygen concentrations (83,84).

On the basis of 16S rRNA sequence data, organisms of Eikelboom Type 0803 were recently shown to belong to the *Rubrivivax* subdivision of the β-subgroup of the *Proteobacteria* (85) (Fig. 2). Two strains under study showed highest sequence similarity with *Variovorax paradoxus* (94.8%), *Rhodoferax fermentans* (94.8%), and *Comamonas testosteroni* (94%) (85). Eikelboom Type 0803 bacteria form 50 to 150 μm straight, smoothly curved filaments with cells 0.6 to 0.8 × 0.9 to 3.0 μm in dimension. They are able to store volutin granules and are often found to be attached to inorganic material. The isolate studied by Bradford and coworkers (85) was able to grow on freshly prepared R2A agar, producing yellow, shiny, slightly elevated colonies. An earlier isolated strain (37) had similar properties. Morphologically, this filament may be confused with "*M. parvicella*" (37). Nutritional requirements are largely unknown, although the filament can be cultivated on fresh R2A medium (85) or SUC medium (37).

FILAMENTS AFFILIATED WITH THE γ-SUBCLASS OF PROTEOBACTERIA

The gram-negative organisms of the genera *Leucothrix, Thiothrix*, and *Beggiatoa* have all been shown to belong phylogenetically to the γ-subclass of the *Proteobacteria* (Fig. 2), and are filamentous sulfur bacteria. *Thiothrix* and Eikelboom Type 021N are frequently found in bulking sludge and their occurrences have been described in connection with specific plant operational factors (3,4,86).

Thiothrix, Leucothrix, Eikelboom Type 021N

Members of the genus *Thiothrix* produce colorless filaments, and are able to oxidize reduced sulfur compounds (87). They have striking morphological features such as their ability to produce gliding gonidia to form rosettes and to deposit intracellular sulfur granules (Fig. 8; 37,87–89).

In the past, the characterization of members of the genus *Thiothrix* was mainly based on morphological criteria, and it has been suggested that the aforementioned listed morphological features are sufficient for defining features of the genus (90). However, since the publication of Eikelboom (2) it is clear that some other filamentous bacteria like Eikelboom Type 021N (Fig. 9; 2), and also *L. mucor*, form rosettelike structures very similar to those produced by *Thiothrix* species. The production of gonidia has also been observed (37,91). As a consequence, there has been a controversial discussion regarding the value of morphological criteria for classification of these organisms, and also the relationship between Eikelboom Type 021N, *L. mucor*, and the genus *Thiothrix* (2,91,92).

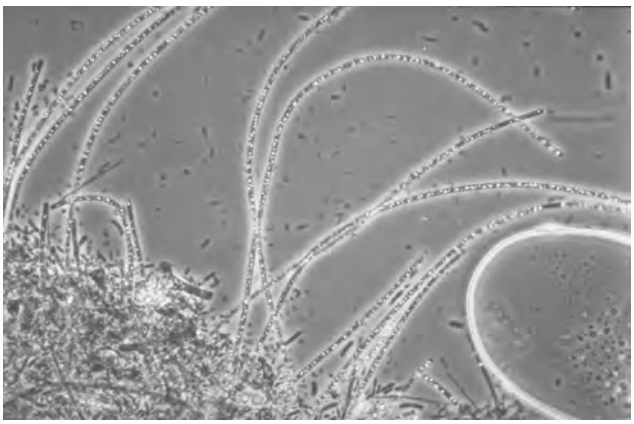

Figure 8. Filaments of *Thiothrix* sp. (×1250). Photo by D. Eikelboom, TNO-MEP, Apeldoorn.

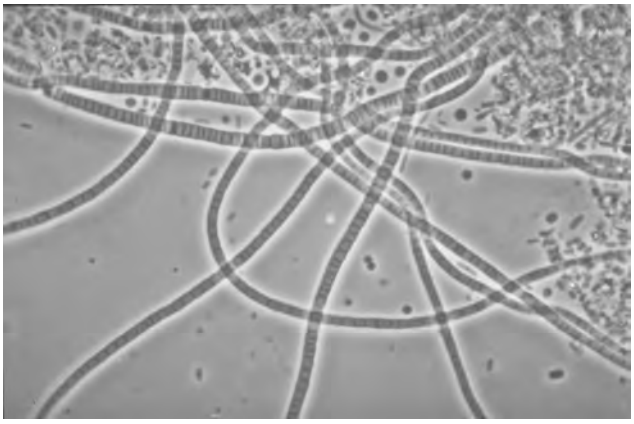

Figure 9. Filaments of Type 021N (×1250). Photo by D. Eikelboom, TNO-MEP, Apeldoorn.

Three named *Thiothrix* species, *T. nivea, 'T. ramosa'*, and *'T. arctophilia'* (excluding species incertae sedis), mainly isolated from freshwater habitats, have been studied extensively. These have been isolated in pure culture and subjected to phenotypic and genotypic characterization (90,92–95).

To clarify the phylogeny of *Thiothrix* sp. from different habitats, molecular biological approaches based on 16S rRNA sequence analysis have been conducted (90,95,96). All of the *Thiothrix* isolates and all but one of the Eikelboom Type 021N bacteria investigated by Howarth and coworkers (96) were members of the γ-subdivision of the *Proteobacteria.* This finding was similar to those of Polz and coworkers (90) and Teske and coworkers (95), who showed that *Thiothrix* formed a deeply branching lineage of the γ-*Proteobacteria* most closely related to sulfide-oxidizing symbionts of marine invertebrates and *Thiomicrospira* species. The 12 strains studied by Haworth and coworkers (96) were assigned to four new *Thiothrix* species, namely *T. unzii, T. defluvii, T. fructosivorans*, and *T. eikelboomii*, the latter species harboring the Type 021N strains. The authors who stated that the phenotypic characters frequently used to differentiate Eikelboom Type 021N bacteria from *Thiothrix* species are not totally reliable. An important result was that the Eikelboom Type 021N strains isolated independently from three different continents were phylogenetically homogeneous. However, Kanagawa and coworkers (8) recently demonstrated that additional diversity is found within this morphotype on the basis of fifteen isolates of the Eikelboom Type 021N from Japan. According to their 16S rRNA sequence, the isolates were subdivided into three distinct groups (Fig. 3). Group I is clearly separated from all currently recognized *Thiothrix* species and exclusively consists of seven isolates from Japan. Group II contains four isolates from Japan and clusters together with *T. eikelboomii*, whereas group III forms a monophyletic lineage together with *T. defluvii*. On the basis of the current perception of the diversity within the *Thiothrix*/Eikelboom Type 021N line of descent, the previously published oligonucleotide set for these microorganisms (7) was supplemented and now covers the entire group (8) (Table 2; Fig. 3).

Thiothrix unzii produces rod-shaped cell and forms multicellular filaments. Gliding gonidia have been observed. A sheath is not present, but rosettes and a holdfast are formed. Cell inclusions, such as volutin granules, sudanophilic granules, and PHB, are present within the cells. Growth is observed in the temperature range from 4 to 33 °C and pH ranges from 6.5 to 8.5, but no growth at 37 °C occurs. The organism is oxidase-positive and catalase-negative. A requirement for reduced inorganic sulfur for growth was

detected. Sulfur globules are deposited within invaginations of the cytoplasmic membrane. Hydrolysis of gelatin and casein is positive, whereas hydrolysis of starch, Tween 80, and urea does not occur. A small number of carbon sources (pyruvate, succinate, acetate, lactate, and propionate) are used if sodium thiosulfate is present. A large number of carbon sources are not used (96).

Thiothrix fructosivorans also produces rod-shaped cells and forms multicellular filaments. Similar to *T. unzii*, gliding gonidia are produced from the end of the filaments, but in contrast, a sheath is present. Rosettes and a holdfast can be detected, and volutin inclusions, sudanophilic granules, and PHB inclusions are observed within the cells. Its temperature and pH range is similar to that of *T. unzii*, but no requirements of reduced inorganic sulfur for growth are apparent. Sulfur globules are also deposited within invaginations of the cytoplasmic membrane after growth in the presence of reduced inorganic sulfur compounds. Gelatin can be hydrolyzed, but starch, casein, Tween 80, and urea are not hydrolyzed. In contrast to *T. unzii*, fructose, sucrose, and melezitose, and some organic acids are hydrolyzed.

Thiothrix eikelboomii (including some filaments morphologically similar to Eikelbooms Type 021N) also shows rod-shaped cells and forms multicellular filaments. A high degree of variablility in cell morphology is observed, including cuboidal, barrel-shaped, cylindrical, discoid, and beadlike cells (96). In addition, knots may be observed in filaments. The cells stain gram-negative or gram-variable. A sheath is not produced. Rosettes and a holdfast are not formed by all strains. As reported for *T. unzii* and *T. fructosivorans*, volutin inclusions, sudanophilic granules, and PHB inclusion within the cells are observed. The temperature range is also similar to these two species. Like *T. fructosivorans*, no requirement for reduced inorganic sulfur was detected, and sulfur globules are deposited within invaginations of the cytoplasmic membrane when cells are grown in the presence of reduced inorganic sulfur compounds. As reported for *T. fructosivorans*, gelatin is hydrolyzed and starch, casein, Tween 80, and urea are not hydrolyzed. Glucose, fructose, maltose, sucrose, trehalose, melezitose, mannitol, pyruvate, succinate, malate, acetate, lactate, and propionate can serve as sole sources of carbon.

Thiothrix defluvii shows a similar cell morphology to those reported for *T. unzii*, *T. fructosivorans*, and *T. eikelboomii*, but cell shape can be irregular. Elongated swollen cells are often present. A sheath is not produced. Rosettes, a holdfast, and gliding gonidia and knots in filaments may be formed but not by all strains. Cells can store intracellular elemental sulfur when grown in the presence of reduced inorganic sulfur compounds. In contrast to all other *Thiothrix* species, no volutin granules are present and PHB granules are not found. Because this species grows extremely slowly, its exact nutritional and biochemical properties are unknown.

Thiothrix species can be isolated from very different natural habitats, such as sulfide-containing natural water and irrigation systems, but also from activated-sludge plants (96, and references therein).

On the basis of morphology, the genera *Thiothrix* and *Leucothrix* have been grouped together in the family *Leucotrichaceae*. *Leucothrix* species can also form rosettes and gonidia, although no sheaths are produced. The capability of sulfide oxidation and accumulation of elemental sulfur are characters shared with *Thiothrix* species, and many Eikelboom Type 021N bacteria are isolated from activated sludge (37). On the basis of rRNA sequence analysis, *L. mucor* DSM 2157^T is placed as a deeply branching lineage at the base of the *Thiothrix* clade, and this may indicate that *Thiothrix* and *Leucothrix* share a common ancestry (7,96).

Eikelboom Type 1863

Filaments of Eikelboom Type 1863 are characterized by their short, *Streptococcus*-like chains of cells. They stain gram-negative and are 0.5 to 1.0 μm long and 0.8 μm wide. No sheath and slime layer is present (2). On the basis of this distinctive morphological description, Seviour and coworkers (18) isolated five filaments from activated sludge on R2A agar and identified the pure cultures using the 16S rRNA sequencing approach in connection with phenotypic features. From the results of this study, it is obvious that Eikelboom Type 1863 is not a single genetic entity. Consistent with a previous study (97), two isolates were identified as *Acinetobacter* spp., whereas another one was found to represent a *Moraxella* species (Fig. 2). Both genera belong to γ-subclass of the *Proteobacteria*. The other strains were identified as *Chyseobacterium*-like organisms belonging to the *Cytophaga* group of the *Flexibacter Cytophaga Bacteroides* phylum (18) (Fig. 2). Consequently, as discussed earlier for *N. limicola*, morphological characterization cannot be recommended for species allocation.

FLEXIBACTER CYTOPHAGA BACTEROIDES CLUSTER

The *Flexibacter Cytophaga Bacteroides* group has been described to constitute a separate phylum within the division bacteria, which contains at least three types of filaments that occur in activated sludge.

Haliscomenobacter Hydrossis, Type 0092, Type 0411

Filaments of the species *H. hydrossis* (at present the only species of the genus) are characterized by their straight, thin, needle-shaped cells (0.4 to 0.5 × 3 to 5 μm), usually in chains and enclosed by a hardly visible sheath. This organism is gram-negative and can be identified by its unique cell morphology. On the basis of 16S rRNA sequences, it was shown that the organism phylogenetically belongs to the *Saprospira* subgroup of the *Flexibacter Cytophaga Bacteroides* phylum (98; Fig. 2). Isolation can be facilitated by using a centrifugation or whirl-mix pretreatment (38). The organisms grow on I-medium (40) and GMBN medium (49,99) at 25 °C. They produce pinkish, smooth, or slightly filamentous colonies about 1 to 3 mm diameter on SCY agar. Mulder (100) described a requirement for thiamine and vitamin B_{12}. Growth occurs in a temperature range between 8 and 30 °C (optimum ~26 °C). The pH optimum is above that of

S. natans (100). The nine isolates of filamentous bacteria, obtained from activated sludge and morphologically assigned to the genus *Haliscomenobacter* in addition to the type strain of *H. hydrossis* DSM 1100^T studied by Kämpfer (99), had the MK-7-menaquinone as the major quinone, and the MK-6-menaquinone as minor component. The main components of cellular fatty acids in all strains were the 13-methyltetradecanoic acid (i15 : 0), followed by straight-chain unsaturated acids of 16 : 1 and saturated acids of 16 : 0 and 18 : 0. Hydroxylated fatty acids of 3-OH i15 : 0 and 2-OH i15 : 0 were found in higher amount in the type strain of *H. hydrossis*, whereas the isolates from activated sludge produced these acids in minor amounts or traces. Analysis of physiological properties showed phenotypic homogeneity among the tested organisms. From 240 tested organic compounds, only a few sugars (D-glucose, D-fructose, and a few others) could be used as sole carbon source (99). Instead of PHB inclusions (typically found within *Sphaerotilus* and *Leptothrix*), polysaccharide globules are detected (12). The G + C content of the DNA is 49 mol%.

If present in bulking sludge, *Haliscomenobacter* can occur in large numbers and often makes the sludge flocs voluminous. *Haliscomenobacter hydrossis* has been detected in activated-sludge plants in different continents. No clear indications concerning the causes of the predominance of *Haliscomenobacter* are available at present, however, Krul (101) found that *H. hydrossis* has a poor competition ability in heavily loaded activated-sludge plants because of the low growth rate related to the low substrate uptake rate. *Halismenobacter hydrossis* has also been detected in foams, but they are of less importance in comparison with "*M. parvicella*" and *Gordonia amarae* (55).

Eikelboom Types 0092 and 0411

The Types 0092 and 0411 also belong to the *Flexibacter Cytophaga Bacteroides* phylum (84). Type 0092 belongs to the *Cytophaga* subgroup and Type 0411 to the *Flexibacter* subgroup. Filaments of both types were isolated by micromanipulation and were grown on R2A agar (84). For Type 0092, only one earlier isolation has been described by Horan and coworkers (102).

Type 0411 has also been grown on I-medium and on SCY medium (2). In the earlier studies of Eikelboom (2) and van Veen (40), it was suggested that this type belongs to the genus *Flavobacterium* and/or *Flexibacter*. Detailed growth requirements are not known.

Eikelboom Type 1863

As mentioned earlier, Seviour and coworkers (18) isolated five filaments from activated sludge, two of which were identified as *Chyseobacterium*-like organisms belonging to the *Cytophaga*-group of the *Flexibacter Cytophaga Bacteroides* phylum.

CHLOROFLEXUS SUBDIVISION

Herpetosiphon

The occurrence of bacteria belonging to the genus *Herpetosiphon* in bulking sludge was reported first by Trick and Lingens (103) and Senghas and Lingens (104). In their study, they characterized their strains morphologically and physiologically. The organisms can be characterized by unbranched, flexible rods or filaments (0.5 to 1.5 × 5 to 150 μm) consisting of individual cells with a length of 2 to 3 μm. They stain gram-negative and are obligate aerobic organisms. Some polymeric substances can be degraded. The isolation can be performed by spread-plate techniques (104), and also by micromanipulation (85). *Herpetosiphon* belongs phylogenetically to the *Chloroflexus* subdivision of the green nonsulfur lineage (85). *Herpetosiphon* is not considered to be a prominent bulking organism.

OTHER FILAMENTOUS ORGANISMS

For several other filamentous bacteria (Types 1702, 0321, 0675, 1851, 0192, 1091, 0961, 0914, 1111, and 1501), only little information can be obtained from literature. The morphologies of Type 0041 and Type 0961 are shown in Figures 10 and 11, respectively.

The morphology of Type 0041 has been very deeply explored using electron microscopy because of specific

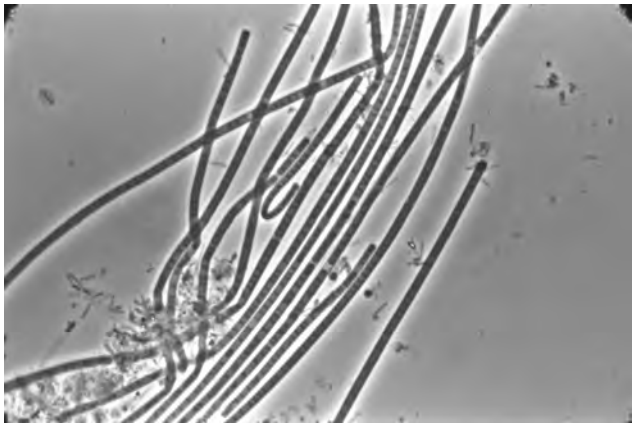

Figure 10. Filaments of Type 0041 (×1250). Photo by D. Eikelboom, TNO-MEP, Apeldoorn.

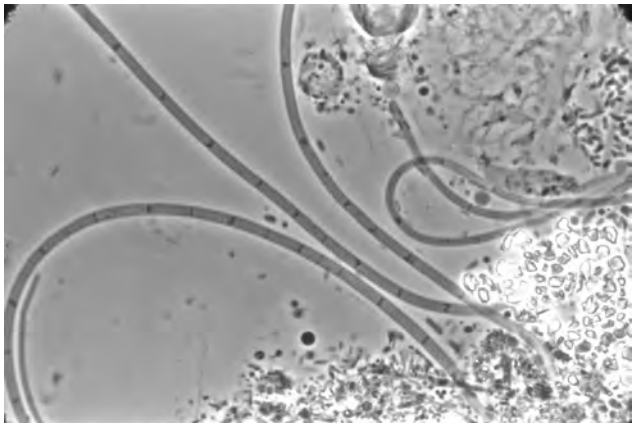

Figure 11. Filaments of Type 0961. Phylogenetic group not determined (×1250). Photo by D. Eikelboom, TNO-MEP, Apeldoorn.

interesting properties such as the presence of attached growth along the filaments of this sheathed organism (105). This organism was fortuitously studied recently when Hugenholtz and coworkers (106) designed FISH probes from environmental sequences from organisms in the recently described TM7 division. In this study, organisms morphologically described as Type 0411 bound a probe for the TM7 division and a probe for one of the TM7 subdivisions. Therefore, at least some Type 0041 filaments are phylogentically in the TM7 division.

For the other filamentous types, only their cell morphology has been studied and documented (2–4), and for some types, for example, Type 0581, successful cultivation on I- and SCY-medium has been described (2).

CONCLUSION

For the effectiveness and success of wastewater treatment (organic matter reduction, nitrogen and phosphorus removal), the complex structures and functions of the microbial communities are directly responsible. Community structure and function have also a direct effect on the ability of the activated sludge to settle and to be properly separated from the final effluent in the secondary clarifier. Filamentous bacteria have a key influence on sludge settling and consequently there is an urgent need to understand the phylogeny and ecology of these unique microorganisms. Traditionally, filamentous bacteria were classified according to morphology-based identification keys. Recent comparative 16S rRNA studies of filamentous bacteria, however, revealed that the established classification system is inconsistent with the phylogeny of these microorganisms. On the basis of morphological criteria, phylogenetically unrelated filaments were erroneously grouped together (e.g., "*N. limicola*," Type 1863), whereas closely related microorganisms were sometimes assigned to different taxonomic units (e.g., *Acinetobacter* and some filaments of the Eikelboom Type 1863). Today the 16S rDNA sequences of a large number of filaments have been determined and researchers began to develop an oligonucleotide probe set for fast, reliable, and cultivation-independent in situ detection of these bacteria directly within the activated-sludge samples. The 16S rDNA database has to be completed for the remaining filament types to establish a phylogenetically sound taxonomic system for all filamentous bacteria thriving in wastewater treatment plants. Such a system will also provide an excellent base for the design of oligonucleotide probes for all known filaments. FISH with these probes should then be used to quantify the different filament species in various wastewater treatment plants to identify process parameters, which influence their abundance. Furthermore, we need to directly investigate the physiology of the different filamentous bacteria. Keeping in mind that many filaments have not been successfully cultured or maintained in the laboratory yet, and that the metabolic activities of a bacterial species in its habitat cannot be directly inferred from pure culture experiments, methods for investigating the in situ physiology of filaments are required. Recently, a combination of FISH and microautoradiography has been developed, which allows to simultaneously identify microorganisms within their environment and to study their in situ physiology (107). This method has already been successfully used to investigate the in situ physiology of *Thiothrix* and Eikelboom Type 021N (108,109) and should in the future be applied to other filaments as well. These analyses will help to better understand the metabolic behavior and the ecology of filamentous bacteria in wastewater treatment plants with the ultimate goal of identification of causative factors for prevention of excessive filamentous growth causing bulking and foaming.

Acknowledgments

Alexander Loy is acknowledged for help with the phylogenetic analyses. We are very grateful to Dr. Dick Eikelboom, TNO-MEP-Apeldoorn, for supplying Figures 5 to 11.

FILAMENTOUS BULKING IN ACTIVATED SLUDGE, CONTROL OF

JIRI WANNER
Prague Institute of Chemical Technology
Prague, Czech Republic

The activated sludge process (see ACTIVATED SLUDGE — THE PROCESS, this Encyclopedia) is the most widespread biological wastewater treatment technique. The process is applied to both municipal and industrial wastewater treatment plants. It is used from the smallest units such as individual houses and farms to country hotels, reststops, and small settlements in rural areas, in large towns, and in metropolises or large industrial complexes. In all cases, biologically treated wastewater should be separated from the biomass of activated sludge to achieve high-quality final effluent. Although new separation processes such as membrane filtration have been tested in pilot- and full-scale units, conventional separation based on gravity sedimentation is still the only economically feasible option for most municipalities and industrial enterprises in the world. This fact stresses the importance of good settling properties of activated sludge. Activated sludge bulking caused by filamentous microorganisms is the most common operational problem associated with poor activated sludge separation. For this reason, the phenomenon of activated sludge filamentous bulking has been studied intensively since the 1960s. This article summarizes the current level of understanding of this separation problem and highlights the most common methods for control of activated sludge bulking.

WELL-SETTLING ACTIVATED SLUDGE

Requirements

One of the most characteristic features of wastewater treatment using activated sludge is that the biomass must be able to (*1*) flocculate (see ACTIVATED SLUDGE — THE FLOC, this Encyclopedia) and (*2*) settle and thicken by gravity sedimentation. With a few exceptions of small municipal plants or wastewater treatment installations in the industry, the treated wastewater is separated from the mixed culture of activated sludge in the so-called secondary clarifiers (or secondary settling tanks) in which the main driving force for separation is gravitation. Even the most sophisticated nutrient- removal activated sludge systems cannot work properly without good settling, thickening, and dewatering properties of the biomass. Poor separation and thickening of activated sludge in secondary clarifiers can lead to the following operational problems:

- The biomass of activated sludge escaping from the secondary clarifier deteriorates the quality of final effluent, not only in terms of suspended solids but also in BOD_5 (respiration of biomass), COD (organic nature of the biomass), and in N_{TOTAL} and P_{TOTAL} (the biomass contains a significant fraction of N and P compounds).
- A diluted return sludge stream does not allow the maintenance of the required biomass concentration in the aeration basin(s) and proper control over the sludge age.
- A diluted waste sludge stream results in hydraulic overloading of the sludge handling facilities.

From the point of view of the above operational problems, well settling activated sludge should exhibit the following features (1):

- It settles fast, with zone settling velocities of 3 m/h or more.
- It does not occupy an excessive volume after settling and thickening in a secondary clarifier.
- After sedimentation, it leaves a clear supernatant ($X = 15$ mg/L or less).
- It does not rise within at least a two- to three-hour period after sedimentation.

Measurement of Settling and Thickening Properties

The conditions during settling, in secondary settling tanks, can be best simulated by the measurement of zone

settling velocity. The measurement should be performed in transparent cylinders, so that the speed of movement of the sludge–supernatant interface can be noted. The higher and wider the cylinder, the more realistic the figures we obtain. A graph plotting sludge layer height versus time is called a settling curve that usually has three distinct settling phases: (*1*) reflocculation, (*2*) zone settling, and (*3*) transition and compaction.

The zone settling velocity is calculated from the slope of the curve in the phase of zone settling (II).

However, in wastewater treatment practice, the measurement of so-called sludge volume index SVI is the most common way to characterize activated sludge settleability. The standard sludge volume index is defined as follows:

$$\mathrm{SVI} = \frac{V_{30}}{X}$$

where

SVI = sludge volume index [mL/g]
V_{30} = volume of settled sludge after 30 minutes sedimentation in a 1-L cylinder
X = concentration of activated sludge (mixed liquor suspended solids) [g/L]

The numerical value of SVI is affected by many factors, especially by sludge concentration or the volume of sludge after 30 minutes sedimentation and by so-called wall effects in the cylinder. Therefore, in some countries the conditions of the settling test are standardized. Common standardization methods include:

- Stirred sludge volume index SSVI; the measuring cylinder is equipped with a slowly rotating stirring device.
- SVI at a standard concentration; the test is performed with a defined sludge concentration (for instance, 3.5 g/L $SVI_{3.5}$).
- Diluted sludge volume index DSVI; the volume of settled sludge after 30 minutes sedimentation should not exceed 200 mL/L, and if so, the test is repeated with a diluted sludge.

Activated sludge can be classified according to the zone settling velocity (ZSV) and the sludge volume index shown in Table 1.

When filamentous microorganisms cause sludge separation problems, it is useful to quantify the amount of these microorganisms in activated sludge. For that purpose, Sezgin and coworkers developed the measurement of total extended filament length (TEFL) (2), in which the total length of the filaments protruding from flocs or freely floating in the bulk liquid is measured. The TEFL values of 10^7 μm/mL or 10^4 m/g are considered to represent the boundary between nonbulking and bulking activated sludge (3).

Table 1. Types of Activated Sludge According to Its Settleability

Type of Sludge	SVI, mL/g	ZSV, m/h
Well-settling	<100	>3
"Light"	100–200	2–3
Bulking	>200	<1.2

The measurement of TEFL is rather laborious and time consuming, and so, Jenkins and coworkers developed routine examination of activated sludge, a rapid and simple method of subjective scoring of filament abundance (3). The abundance of filaments is classified according to scale from none to excessive and is given in Table 2.

In the case of increased abundance of foam-forming nocardioform actinomycetes, which are often irregular in shape and frequently branched, Pitt and Jenkins (4) recommend a modified method based on counting the number of intersections of these filaments with a hairline in the eyepiece.

Microscopic Features of Well-Settling Activated Sludge

A simple microscopic examination can be very useful for the identification of both well-settling sludge and activated sludge separation problems. Good settling sludge is composed of compact and firm flocs of quite a regular round shape. The average size of these is usually 100 μm or greater. When looking at the flocs (see ACTIVATED SLUDGE — THE FLOC, this Encyclopedia) under a microscope with higher magnification (1000×) and preferably using phase contrast, a "filamentous backbone" of the flocs can often be observed. The "filamentous backbone" can be seen better in samples stained with Gram or Neisser stain (3). This suggests that large compact flocs may be formed by bacterial growth on filaments observed inside the floc. Filaments protruding from the flocs into the bulk liquid

Table 2. Subjective Scoring of Filament Abundance According to Jenkins and Coworkers (3)

Numerical Value	Abundance	Description of Microscopic Picture
0	none	
1	few	Filaments present, but only observed in an occasional floc
2	some	Filaments commonly observed, but not present in all flocs
3	common	Filaments observed in all flocs, but at low density (e.g., 1–5 filaments per floc)
4	very common	Filaments observed in all flocs at medium density (e.g., 5–10 filaments per floc)
5	abundant	Filaments observed in all flocs at high density (e.g., >20 filaments per floc)
6	excessive	Filaments present in all flocs — appears more filaments than flocs and/or filaments growing in high abundance in bulk solution

could be one of the signs of bulking sludge (mentioned later). Then, we discuss poor floc macrostructure. In some activated sludge samples, the compact core of flocs created by bacterial biomass is missing and the flocs exhibit a loose open structure. The compact cores of activated sludge flocs may also be too small (usually 20–80 μm). Consequently, the reason for bad settling properties are seen in poor floc microstructure. These microstructure problems can be related to either insufficient production or overproduction of the glycocalyx, which is the biopolymer material binding together the cells in cores of activated sludge flocs.

ACTIVATED SLUDGE SEPARATION PROBLEMS

In wastewater treatment practice, six major problems related to microbial biomass quality can be distinguished as a consequence of three different causes (1,3).

Poor Floc Microstructure

Dispersed Growth. The activated sludge microorganisms are dispersed freely in the bulk liquid as individual cells or small clumps with a diameter of 10 to 20 μm. The sedimentation rate of these individual cells or bacterial clumps is too low for gravity sedimentation, and no zone-settling occurs in secondary settling tanks. This has two impacts on the activated sludge process:

1. The separation efficiency of the secondary settling tank is very low, and the final effluent is turbid.
2. Because of poor separation efficiency, a significant amount of biomass escapes from the system. Therefore, only low values of sludge age (Θ_X) can be maintained in the system. A system with dispersed growth resembles a chemostat more than a continuous cultivation system with biomass recycle.
3. This poor bioflocculation is caused by low production of extracellular biopolymers (the glycocalyx) creating a matrix of firm activated sludge flocs. One typical reason for the dispersed growth is a very high organic loading of biomass (high "foot to microorganisms" ratio, F/M), when bacteria do not need to produce the glycocalyx. Thus, the dispersed growth is a common problem in a start-up period of activated sludge systems. Another reason may be the toxicity of treated wastewater.

Unsettleable Microflocs. The outer symptom of this separation problem looks, superficially, very similar to the dispersed growth. The final effluent from a secondary clarifier is not clear and contains many microparticles of escaping biomass. However, the nature of the problem is different, as can be seen under the microscope. The unsettleable particles are of larger dimension (about 50–100 μm) than in the case of dispersed growth; and are approximately spherical and compact. These microflocs result from the disintegration flocs that were initially firm and sound.

During the settling test, the activated sludge rapidly separates into two parts. The larger flocs settle quickly, and when the sludge volume index is calculated on the basis of the volume of these larger flocs, its value is quite low (around 50 mL/g). However, the supernatant in the cylinder is turbid and a substantial fraction of total biomass remains in these unsettleable particles.

The reasons for this floc disintegration are:

- Insufficient production of glycocalyx or its consumption by bacteria inside the flocs due to a low organic loading of biomass (typical of high sludge age systems, extended aeration),
- Total absence of filamentous microorganisms that form the "backbone" of larger flocs (3), and
- Disintegration of flocs by shearing effects, for instance, by inappropriate mechanical aerators.

Viscous Bulking. The rather broad term, viscous bulking, describes the symptoms, but not the causes. Activated sludge contains an excessive amount of extracellular biopolymers, which impart a slimy jellylike consistency to the sludge. Because the biopolymers are hydrophilic colloids, the activated sludge becomes highly water retentive. Such a "hydrous" activated sludge exhibits low settling and compaction velocities. These biopolymers are also natural surface-active agents. When the viscous activated sludge is intensively aerated, strong foam may appear (1).

The production of biopolymers is characteristic of most floc-forming microorganisms, but under normal conditions (no toxic compounds and nutrient balanced growth) the amount of generated biopolymers is just enough for formation of firm flocs. On the other hand, zoogloeal bacteria always produce large amounts of biopolymers because the individual cells of *Zoogloea* are fixed in slimeous colonies. Thus, some authors use the term "zoogloeal bulking" for describing the settling problems caused by an excessive presence of highly hydrated zoogloeal colonies in activated sludge.

Poor Floc Macrostructure

Filamentous Bulking. Filamentous bulking is a typical problem of poor activated sludge compaction (phase III of the settling curve — mentioned earlier), which results in (1):

- Low return and wasted activated sludge solids
- Difficulties in maintaining the required activated sludge concentration in reaction basins
- Poor sludge dewaterability
- Hydraulic overloading of sludge handling facilities

Filamentous microorganisms interfere with the sedimentation and compaction of activated sludge flocs in two ways (3):

1. Some filamentous microorganisms prefer to grow inside flocs and produce flocs with a very diffuse open structure. These open flocs provide space for water retention inside them, so that although filaments protruding from the flocs do not mechanically hinder aggregation of individual flocs, excessive water remains "captured" in the settled sludge.

2. The second way that filaments can detrimentally affect the sedimentation and compaction of activated sludge flocs is much more common. Most of the filamentous microorganisms observed in activated sludges protrude from rather compact and firm flocs into the bulk liquid. The filaments, which in low numbers form a backbone of firm flocs, in large numbers, are able to prevent, mechanically, the compaction of individual flocs. This type of interference problems is called "bridging."

Foaming Caused by Filamentous Microorganisms. Biological foaming by "foam-forming" filamentous microorganisms (see ACTIVATED SLUDGE — FOAMING, this Encyclopedia) is a complex of physicochemical and biochemical interactions leading to the stabilization of a three-phase system of air-water-microbial cells. Stabilization of these biological foams results from the following features of foam-forming filaments:

- Production of extracellular materials such as lipids, lipopeptides, proteins, and carbohydrates, which have the properties of surface-active agents (biosurfactants)
- The cell walls of foam-forming microorganisms are strongly hydrophobic, contrary to other filaments and floc-formers.

The formation of stable foams in the aeration basins of activated sludge plants can create a wide range of operation problems:

1. Aesthetic problems, slippery path along the aeration basins covered by escaping foam.
2. Floating biomass in secondary clarifier deteriorating the final effluent quality.
3. Accumulation of significant amount of biomass into the foam, which is not available for treatment processes; loss of possibility of controlling activated sludge age.

Other Reasons

Rising Sludge. When this is the problem, the water surface in the secondary clarifier is covered by patches (or in worse cases at continuous cover) of floating activated sludge. If the phenomenon is observed in a glass cylinder, two phases can be distinguished:

- The activated sludge settles rapidly and a rather compact bottom layer of settled sludge and a clear supernatant are formed.
- After a certain period (at elevated temperatures even less than 30 minutes, which may raise difficulties in the SVI test), a part or a whole volume of the settled and thickened sludge starts to float and move up to the water surface.

The floating material is full of gas bubbles caused by an endogenous denitrification, which takes place in the settled and thickened layer of activated sludge. Because of a high biomass concentration, the dissolved oxygen from the previous aeration is quickly depleted and anoxic conditions are thus established, provided nitrification occurs in the system. The bubbles of nitrogen liberated during this endogenous denitrification act as sludge "carriers." Thus, the primary reason for this kind of separation problems does not lie in the activated sludge itself but in:

- Insufficient denitrification in the activated sludge system
- Poor performance of settled sludge removing equipment in secondary clarifiers, when the sludge remains too long in the bottom layer.

BASIC SELECTION MECHANISMS FOR FILAMENTOUS BULKING CONTROL

The actual microbial composition of activated sludge (see ACTIVATED SLUDGE — THE MICROBIAL COMMUNITY, this Encyclopedia) is a result of strong competition for energy and carbon sources, nutrients, and also for electrons. The competition is influenced by numerous factors, both intrinsic to the activated sludge process such as biomass retention time, actual substrate, oxygen, and nutrient concentrations in reactor or cultivation conditions (oxic, anoxic, and anaerobic) and external factors including wastewater composition, temperature, and pH. These are difficult to control, but their effect must be considered in wastewater treatment plant control strategies. The following basic mechanisms are thought to be decisive in selecting microbial species in activated sludge (1):

Kinetic Selection

This selective pressure results from differences in growth and substrate utilization rates. In the case of balanced growth (in which readily biodegradable substrate uptake and cell growth occur simultaneously), two types of competition strategy are possible, in terms of saturation kinetics.

Activated sludge floc-forming microorganisms are generally μ_{max}-strategists, whereas most of activated sludge filamentous microorganisms belong to theK_S-strategists. As shown in Figure 1, a substrate concentration gradient is necessary to support the growth of these μ_{max}-strategists. However, so-called unbalanced growth, when the phases of substrate (both soluble and particulate) or nutrient uptake and utilization are partially or fully separated, occurs in activated sludge processes with substrate concentration gradients. During competition under conditions of unbalanced growth, the microorganisms that can sequester substrate more rapidly from the bulk liquid will be favored, provided there is time enough for the regeneration of accumulation/storage capacity in these cells. In activated sludge, the accumulation or storage and regeneration selection mechanism is typical of most floc-forming microorganisms. The process of substrate accumulation or storage takes place in the contact zone of activated sludge systems (Fig. 2), which can be not only oxic but also anoxic or anaerobic. Meanwhile, endogenous metabolism (regeneration) occurs in the main aeration basin or in a

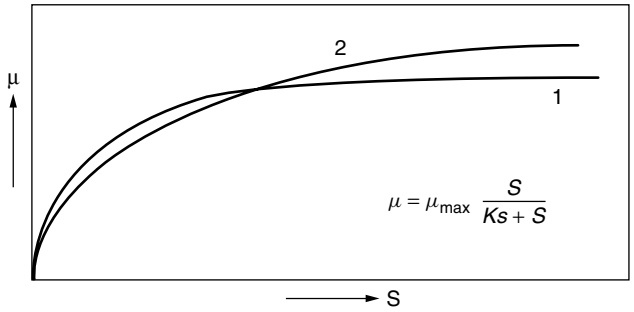

Figure 1. Schematic description of K_S-strategy (2) and μ_{max}-strategy (3) in terms of Monod kinetics. μ_{max}-strategy: maximum specific growth and substrate utilization rates at high substrate concentrations. K_S-strategy: high substrate affinity at low substrate concentrations.

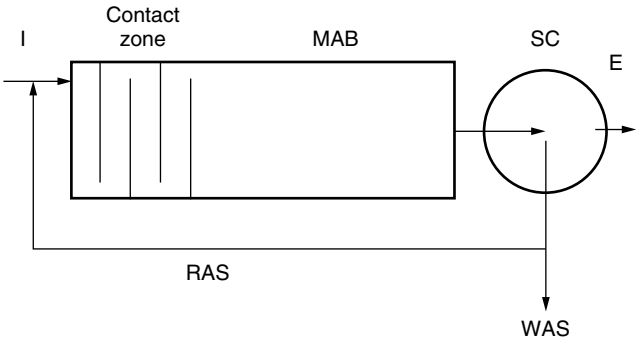

Figure 2. Activated sludge system with compartmentalized contact zone. I — influent, E — effluent, WAS — waste activated sludge, RAS — return activated sludge. Contact zone: Compartmentalized zone with substrate concentration gradient (accumulation and storage of organic substrate), MAB — main aeration basin: a part of the activated sludge system in which organic carbon removal is finished and in which the endogenous metabolism of accumulated/stored substrate takes place (regeneration). SC — secondary clarifier.

separate regeneration zone placed in the return sludge stream (Fig. 3) (1,5).

A compartmentalized contact zone of an activated sludge system is sometimes called a selector. However, for the selection of floc-forming organisms, the combination of a compartmentalized contact zone and regeneration is always necessary.

The results of competition between floc-forming and filamentous microorganisms based on kinetic selection are influenced by the following factors:

Wastewater Composition. Wastewater is a complex mixture of substrates, nutrients, and micronutrients, which support the community of activated sludge. In addition, wastewater continuously inoculates this consortium with the bacteria growing into sewers.

Readily Biodegradable Substrates. Bacterial cells can probably directly utilize low molecular weight organic compounds, that is, compounds with simple molecules. These compounds (e.g., monosaccharides, alcohols, volatile fatty acids, and amino acids) represent approximately 10

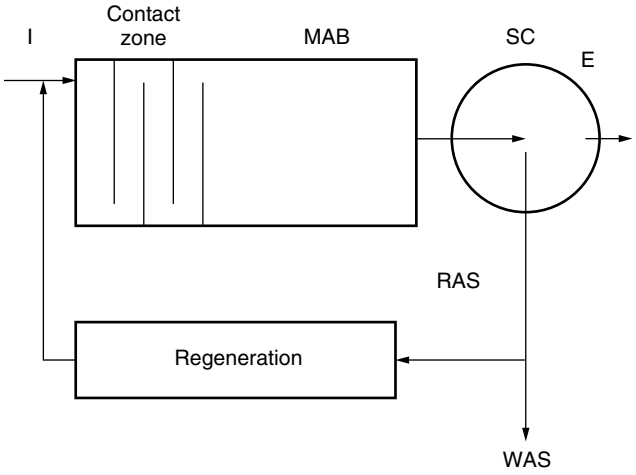

Figure 3. Activated sludge system with compartmentalized contact zone. I — influent, E — effluent, WAS — waste activated sludge, RAS — return activated sludge. Contact zone: Compartmentalized zone with substrate concentration gradient (accumulation and storage of organic substrate), MAB — main aeration basin: a part of activated sludge system in which organic carbon removal is finished, REGENERATION: a part of the activated sludge system in which the endogenous metabolism of accumulated or stored substrate takes place (regeneration), SC — secondary clarifier.

to 20% of COD of common municipal wastewaters. These substrates are thought to favor the growth of certain filamentous microorganisms, for example, Types 021N, *Sphaerotilus natans* /1,701, 0,041 and *Haliscomenobacter hydrossis*. Special attention has to be paid to the design of activated sludge systems for wastewaters containing an increased fraction of industrial wastewaters (food industry). Reduced sulfur compounds can also be readily metabolized, thus supporting the growth of sulfur-metabolizing filaments such as Type 021N/*Thiothrix* or *Beggiatoa*.

Particulate, Slowly Biodegradable Substrates. Most of the organic compounds in municipal wastewaters are present as so-called particulate substrates. These are formed by large-molecule organic compounds, which are present in the wastewater, either as colloids or as true suspended solids. In both cases, they have to be digested by extracellular enzymes before they become available for cells. The mechanism for particulate substrate disintegration is generally termed as hydrolysis, and the products of this process are very similar from a chemical point of view to the readily biodegradable substrates, originally present in wastewaters. However, the hydrolysis is a surface phenomenon and is connected with flocs. Therefore, if the main aeration basins where the hydrolysis occurs are not operated as completely mixed tanks, the readily biodegradable substrates released by hydrolysis will be more available to the floc-formers than the filamentous microorganisms.

Some specific particulate substrates can support the growth of certain filamentous microorganisms. As is seen with fats and grease, which are selectively concentrated in foams and thus, support the growth of nocardioform

actinomycetes. Long-chain fatty acids are reported as being specific substrates supporting the growth of *Microthrix parvicella* (6,7).

Inoculation of Activated Sludge Systems from Wastewaters. Sewerage network and wastewater treatment plants form one system, and processes in sewers may significantly affect the composition of the activated sludge community. Especially in extended sewer systems, readily biodegradable substrates can be taken up by bacteria growing in inner slimes. These wall growths are continuously sloughed off and they inoculate the treatment plant. In some cases, filaments such as *S. natans* can be found in that inoculum (1).

Biomass Retention Time. Biomass retention time Θ_X ("sludge age") has an impact on the distribution of individual microbial species in the consortium of activated sludge, according to their growth and decay rates. Low biomass retention time Θ_X may result in wash-out of slower-growing species whose net growth rate is slower than the dilution rate $D = 1/\Theta_X$. On the other hand, high Θ_X values favor the slow-growers. Unfortunately, the "safe" values of Θ_X, when all filamentous microorganisms are assured to be washed-out, are too low to be applied as a common bulking control measure.

Actual Substrate Concentration in Reactor. Activated sludge cultured in reactors with substrate concentration gradients acquires certain features that have been described as "selector" effect (8). They are:

1. High rates of substrate consumption,
2. High oxygen (or generally, electron acceptor) uptake rate, and
3. Enhanced growth of zoogloeal bacteria.

   The substrate concentration gradient produces a combined effect of both kinetic and metabolic selection (mentioned later). Because of floc stratification, a fourth feature can be added, that is,
4. Increased metabolic diversity of activated sludge.

Dissolved Oxygen, Nutrients, pH, and Temperature in Aeration Basins

Dissolved Oxygen (DO). Some filamentous microorganisms (e.g., *S. natans*/Type 1,701, *H. hydrossis*) exhibit a high affinity for dissolved oxygen at low concentrations because of low values of their half-saturation constant K_O (3). The boundary between "bulking" and "nonbulking" DO concentrations is not fixed because this value depends on the actual value of activated sludge loading (B_X) in the reactor. Nevertheless, DO concentrations less than 0.5 mg/L are dangerous for low DO bulking, especially when soluble substrate still remains in activated sludge mixed liquor (1,3,5).

Nutrients. As with DO, some filaments exhibit higher affinity to certain nutrients (i.e., nitrogen, phosphorus, and micronutrients). This is again the result of a K_S-strategy in certain filaments under conditions of balanced growth. Therefore, the addition of nutrients for controlling filamentous bulking is sometimes necessary. As guidelines for dosing with nutrients, the following empirical concentrations in final effluent might be used — ammonia nitrogen at least one mg/L and soluble orthophosphate phosphorus more than 0.2 mg/L.

pH. As far as is known, none of the most common filamentous microorganisms exhibits a special preference for extreme pH values. Some fungi prefer low pH values, although such a decrease in the pH in municipal wastewater treatment plants (e.g., by nitrification) leading to excessive fungal growth is improbable. Lime dosing equipment should be considered when an acid stream might be discharged into the plant.

Temperature. Temperature affects significantly the rates of all biochemical processes, and the solubility of oxygen in the mixed liquor. Thus, elevated temperatures will support the growth of filamentous microorganisms associated with low DO concentrations. The oxygenation capacity of the aeration systems should be calculated for the highest mixed liquor temperatures expected during the year in order to guarantee the recommended DO concentration is achieved in warm weather.

There are reports of significant seasonal shifts in the dominance of individual filamentous types. Typically, *M. parvicella*, which dominates the filamentous population in winters, is replaced by nocardioform actinomycetes, Type 0,041, or *Nostocoida limicola* in warm seasons. This shift is almost certainly associated with temperature changes, but an exact explanation of this phenomenon is still not available. According to practical experience, more severe *M. parvicella* foaming problems are to be expected in winter than in summers (9,10).

Metabolic Selection

In nutrient removal activated sludge systems, the decisive fraction of readily biodegradable substrates from wastewater is utilized not under oxic but under anaerobic and/or anoxic conditions. Thus, the microorganisms that are able to metabolize substrates under these conditions will be selected. This is the principle of metabolic selection.

Alternation of anaerobic and oxic cultivation conditions is a prerequisite for the enhanced biological phosphorus removal (EBPR) mechanism in nutrient removal. As the filamentous microorganisms from Groups S and C (shown later) are unable to utilize substrates under alternating anaerobic or oxic cultivation conditions at a rate comparable to that of floc-forming microbes, their suppression in nutrient removal activated sludge systems is based on metabolic principles. Although Group S and C filamentous microorganisms are quite common in conventional activated sludge plants, surveys of filaments in nutrient removal systems conducted in Europe, South Africa, U.S.A., Australia, and the Czech Republic (11) indicate that these filaments are not important in systems with anaerobic and/or anoxic zones. Elimination of Group S and C filaments in systems with anoxic zones is based on different denitrification rates between filaments and floc-formers (1,12).

Classification of Filamentous Microorganisms. The growth response of filamentous microorganisms to pressures caused by either kinetic or metabolic selection (or by the combined effect) can be used to classify the filamentous microorganisms found in activated sludge. Thus results from microscopic identification of filaments can be directly used in wastewater treatment practice in reaching proper remedial measures.

Wanner and Grau (12) summarized their own and literature data and proposed the classification of filamentous microorganisms into four groups. The groups were established on the basis of:

- Morphological similarity (sheath, trichome, and cells)
- Similar staining reactions, intracellular deposits
- Metabolic similarity, that is, the ability to utilize substrates and gain energy under the same cultivation conditions
- Occurrence in the same operational arrangements and conditions
- Similarity in problems that the filamentous microorganisms cause.

Group S: Sphaerotilus-like Oxic Zone Growers. They include sheathed filamentous microorganisms, which are able to utilize organic substrates only under oxic conditions. The presence of polyphosphates and PHB granules in cells may be observed, but the rate of their formation and exploitation is not technologically important. Their occurrence in activated sludges is connected with saccharidic and other readily biodegradable wastewaters, higher Θ_X, and low DO. Characteristic representatives are *S. natans* and Type 1701 and Types 0041 and 0675.

Group C: Cyanophycae-like Oxic Zone Growers. Group C includes filamentous microorganisms morphologically resembling colorless blue-green bacteria: Type 021N and *Thiothrix*. Type 021N is a very common filamentous microorganism in bulking activated sludges found in conventional activated sludge plants treating domestic or other wastewaters containing readily biodegradable substrates (1,3).

As opposed to oxic zone growers S, the microorganisms from group C are able to metabolize sulfur. *Thiothrix*, in particular, can take advantage of its mixotrophic way of life in systems with anaerobic zones (1,10).

Group A: All Zones Growers. The term "all zones growers" means that these microorganisms are equipped with such a diverse enzymatic apparatus that they can utilize substrates under all the conditions encountered in activated sludge plants. In addition, all zones growers accumulate low molecular substrates under both oxic and anoxic conditions, and synthesize storage products with rates comparable to those of the floc-formers. *Microthrix parvicella* and Type 0092 undoubtedly exhibit the characteristic features of the all zones growers, and *N. limicola* I and II are commonly found in full-scale plants with anaerobic zones (11). Foot (10) also added to this group Type 0803.

Group F: Foam-Forming Microorganisms. The foam-formers are microorganisms, which can produce biosurfactants enabling them to froth and create scum. The floating effect is supported by hydrophobic surfaces of cells. These hydrophobic cells stabilize the air bubbles or oil droplets entrapped in the foam. The formation of biological foams is associated with the Actinobacteria, especially the so-called norcardioform actinomycetes (*Gordona*, *Rhodococcus*) or bacteria-like *M. parvicella*. These microorganisms can be considered as primary foam-formers together with Types 0092, 0041, and *N. limicola* II. Other filamentous microorganisms commonly found in biological foams are probably not foam causers, but become associated with already established scums.

The differences among individual groups S, C, A, and F can be illustrated by the response of filamentous microorganisms to systems combining kinetic selection with metabolic selection under different cultivation conditions (Table 3).

APPLICATION OF BULKING CONTROL PRINCIPLES TO THE DESIGN AND OPERATION OF ACTIVATED SLUDGE PLANTS

Plant Configuration

The design of an activated sludge system has to combine all the factors that favor preferentially the growth of the floc-formers, that is:

- A substrate concentration gradient in the system (or at least in its head-end)
- A rapid accumulation ("biosorption") of substrate with subsequent regeneration of accumulation/storage capacity
- In the case of nutrient removal systems, utilization of most of the substrate under anaerobic and/or anoxic conditions.

There are principally four process configurations effectively supporting the growth of floc-formers. In these

Table 3. Response of Filamentous Microorganisms to Systems Combining Kinetic Selection (High Concentration Gradients) with Metabolic Selection Under Different Cultivation Conditions (13)

Group of Filamentous Microorganisms	Cultivation Conditions

configurations, the basic principles of kinetic selection are employed either alone or in combination with metabolic selection:

1. Sequencing batch reactor with short filling period ("dump-fill") or with an inlet mixing zone.
2. Continuous plug-flow reactors; as even the long corridor-type reactors exhibit a high degree of longitudinal mixing, the reactor should be compartmentalized to approach the plug-flow hydraulic regime.
3. Completely mixed or compartmentalized continuous-flow reactors with a contact zone placed ahead of the main reactor, where the contact zone should, preferably, be divided into two to four compartments.
4. Activated sludge system with return sludge regeneration, in which the main reactor should be arranged in configurations two or three.

In all these configurations, the return activated sludge can be mixed with the treated wastewater either under oxic or anaerobic or anoxic conditions. An example of an activated sludge configuration combining most of the factors favoring the growth of floc-formers is given in Figure 4.

Adding the anaerobic zone in front of the denitrification zone can modify the arrangement shown in Figure 4. In this so-called R-AN-D-N process, not only can enhanced biological phosphorus removal (EBPR) be achieved, but because of much stronger metabolic selection pressures these arrangements prove to be more resistant to bulking and foaming problems (15).

Design Parameters

Oxic Contact Zone Design. The design criteria for the oxic contact zone (1,5,16) can also be applied to the design of the inlet part of compartmentalized plug-flow systems or to the design of SBRs. However, the oxic contact zone (originally patented, as the so-called selector in Czechoslovakia) can only be used in conventional activated sludge systems, and not in biological nutrient removal (BNR) plants because the readily biodegradable substrate necessary for the EBPR and denitrification is "inefficiently" consumed under oxic conditions. The following parameters should be considered in the design of oxic contact zones.

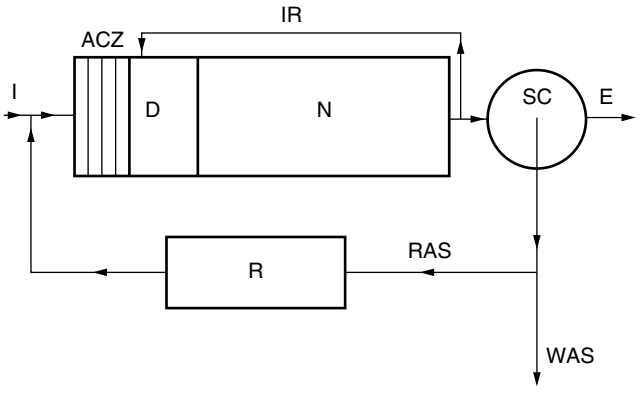

Figure 4. Schematic of the so-called R-D-N Process. ACZ — compartmentalized anoxic contact zone; D — denitrification zone; N — nitrification zone; SC — secondary clarifier; R — regeneration zone; I — influent; E — effluent; RAS — return activated sludge; WAS — waste activated sludge; IR — internal recirculation (14).

Contact Time. The contact time is based on the flow rates of mixed liquor and not only on wastewater flow rates. It is directly correlated with the size of the contact zone. When the contact time is insufficient, soluble substrate is not consumed in the contact zone, and enters the main reactor where it can support growth of filaments. On the other hand, when the contact time is too long, growth of filaments occurs right in the contact zone, especially when this is not compartmentalized. The recommended values for contact time have been summarized by Wanner (1), and lie in a range of 10 to 20 minutes.

For conventional activated sludge systems, this contact time results in the volume ratio V_{CZ}/V_{TOTAL} of about 1 : 10. This ratio is also sufficient for a full restoration of accumulation/storage capacity in the main reactor. The recirculation ratio of return activated sludge entering the contact zone should be less than one.

Activated Sludge Loading in the Contact Zone. Activated sludge loading (B_X) was selected as a design criterion instead of "floc loading." Although this parameter describes more precisely the relationship between actual substrate and biomass mass fluxes, for continuous-flow systems the activated sludge loading is more convenient for calculations. To achieve conditions for well settling sludge, the activated sludge loading B_X in the whole contact zone should be higher than three kg/kg.d (based on BOD_5 and X) (16). If the contact zone is compartmentalized, the recommended activated sludge loading B_X should be, for instance, at least 12 kg/kg.d in the first compartment of a four-compartment contact zone.

Conditions in the Main Reactor. The selection of floc-formers does not occur only in the contact zone, and the conditions in the main reactor following the contact zone are part and parcel of the selection process (in this sense the term "selector" should cover the whole configuration and not only the contact zone). The activated sludge retention time in the main aeration basin is sufficient for a complete restoration of accumulation or storage capacity, when the activated sludge loading in the whole system does not exceed 0.3 to 0.5 kg/kg.d (BOD_5, X) (5,16,17). If the main reactor is a tank with a high dispersion number, the soluble COD in the effluent from the contact zone should not exceed the final effluent soluble COD by more than 20 to 30 mg/L (1).

Design of Anaerobic and Anoxic Contact Zones of BNR Systems. The primary task of the anaerobic and anoxic contact zones in BNR (biological nutrient removal) activated sludge systems is to create conditions for nitrogen and phosphorus removal. Thus, the design of these zones has to follow principally the guidelines for BNR systems design. However, the designer should always

try to implement bulking control strategies in the design, although the conditions for bulking control can sometimes be contradictory to the requirements for BNR processes.

Anaerobic Zone. The anaerobic contact time sufficient for bulking control is about 0.5 to 1.0 hour, which is usually exceeded because of EBPR. The recommended B_X value of one kg/kg.d (BOD_5, X) in the anaerobic zone for efficient bulking control is also mostly met because of the general requirements of an EBPR design.

Anoxic Zone. A certain analogy with the design of oxic contact zones can be used because the floc-formers supported by anoxic contact zones are mostly the same microbes, which are favored by oxic contact zones. Thus, recommendations with regard to the construction and design of oxic contact zone can be applied to a certain extent, also for the design of anoxic contact zones in BNR plants.

Plant designers and operators should always be aware of the main principles of bulking control:

- In conventional plants, the majority of organic substrate available in treated wastewater should be removed in the head part of the activated sludge system, and the aeration basin should always be operated as a plug-flow reactor.
- In nutrient removal systems, the majority of the available organic substrate should be consumed in the anaerobic and/or anoxic zone.

NONSPECIFIC BULKING CONTROL METHODS

All the methods described earlier are selectively targeted at the control of excessive growth of filamentous microorganisms. However, in wastewater treatment practice, other methods of bulking control are commonly used. These methods are not aimed at the control of the growth of filaments, but at the suppression of problems resulting from the presence of filaments or at the entire elimination of the filamentous population.

Elimination of the Filamentous Population

This method is applicable when the problem of "floc bridging" is the case. The method exploits the fact that relatively thin filamentous microorganisms are exposed, directly and immediately, to concentrations of chemicals found in the bulk liquid; whereas most of the floc-forming microorganisms are exposed to lower concentrations because of diffusional resistance in the outer layer of activated sludge flocs. Therefore, the filamentous microorganisms protruding from the flocs can be selectively killed by adding toxic compounds to the return activated sludge stream, whereas most of the floc-forming organisms will survive inside the flocs. For the full-scale control of filamentous bulking, chlorine is used most often (3). However, chlorination of activated sludge is just a remedial method and should not be used as a permanent solution to bulking problems (1).

Increase of Sedimentation Velocities

As described earlier, excessive presence of filamentous bacterial populations reduces the sludge settling velocities by both mechanisms (floc bridging and "open" floc structure). One of method to compensate for this is to increase the specific weight of the activated sludge flocs. The following procedures can be used by process operators as remedial methods:

- Addition of mineral suspensions to the mixed liquor (e.g., soil suspension, primary effluent particles by reducing the capacity of primary settling tanks).
- Addition of digested sludge to the mixed liquor (this must be done very carefully to avoid any DO deficit in the aeration basins).
- Formation of heavy "cores" in the flocs by precipitation of mineral salts, the most common method of bulking control with this approach now is the addition of ferric salts to the mixed liquor (1,5,15)

Compensation of Slow-Settling Velocities

One possible solution is to construct new secondary clarifiers, which are less susceptible to poor settling properties of the activated sludge than the older constructions. The secondary clarifiers, which are more resistant to bulking activated sludge, should exhibit the following features (18):

- A specially designed zone for efficient flocculation of activated sludge.
- Deeper settling tanks providing enough "buffering" capacity.
- Reduction of any hydraulic or mechanical disturbances in the layer of settled sludge to avoid sludge resuspension.

CONCLUSION

Activated sludge process is the most common technology of biological wastewater treatment used today. Until other separation methods such as membrane filtration become economically feasible, activated sludge separation from treated wastewater by gravity sedimentation is the only real option. For this reason, good settling properties of activated sludge are still of primary importance for achieving the required quality of final effluent. Of the six different separation problems described in this article, activated sludge bulking caused by the excessive presence of filamentous microorganisms is the most serious operational problem. These filamentous microorganisms adversely affect activated settling properties by two different mechanisms, that is,

- By "bridging" firm and compact flocs
- By providing "open" and "diffuse" structure to the activated sludge flocs

The methods for activated sludge filamentous bulking control can be divided into two major groups:

1. Methods, which specifically control the growth of filamentous microorganisms on one hand and support the growth of floc-forming microorganisms on the other hand.

   The methods in this group exploit the principles of activated sludge population dynamics and support the floc-forming microorganisms in their competition with filamentous microorganisms. The selection of microbial community composition can be based either on kinetic or on metabolic principles. Kinetic selection of floc-forming microorganisms can be achieved in activated sludge systems by establishing substrate concentration gradients. For metabolic selection, the consumption of the most readily available substrates under anaerobic and/or anoxic cultivation conditions is decisive.

2. Methods eliminating the filamentous population by chemical action or compensating the negative effect of the excessive presence of filamentous microorganisms.

   From this group of methods, which do not prevent the excessive growth of filamentous microorganisms but solve the problems caused by their presence, the following are most commonly used:

   - Selective killing of filaments by chemical compounds such as chlorine.
   - Increase of floc settling velocity by addition of mineral particles or precipitants (e.g., addition of ferric salts).
   - Measures in the construction of secondary clarifiers compensating the low settling velocities of bulking activated sludge

Acknowledgments

The support of research on activated sludge bulking from the research project of the Ministry of Education of the Czech Republic, No. J19/98:223200003 is highly appreciated.

NOTATION

X — concentration of biomass expressed in terms of SS (suspended solids), mg/L or g/L B_X — activated sludge loading

$$B_X = \frac{S_1 \cdot Q}{V \cdot X}$$

where S_1 substrate concentration in the influent to the reactor
Q wastewater influent flow
V reactor (aeration basin) volume
X biomass concentration (MLSS) in the reactor

Θ_X — sludge age

$$\Theta X = \frac{V \cdot X + M_{SC}}{(Q - Q_W) \cdot X_2 + Q_W \cdot X_W}$$

where M_{SC} mass of biomass (activated sludge) in secondary clarifier
Q_W excess sludge flow
X_2 biomass concentration in the final effluent
X_W biomass concentration in the excess sludge stream

FLOODED SOILS

RALF CONRAD
PETER FRENZEL
Max-Planck-Institut für
Terrestrische Mikrobiologie
Marburg, Germany

Wetlands are mainly characterized by standing water, a vegetation adapted to the wetness, and unique soil conditions different from those of upland soils (1). Flooded soils are found in wetlands that are inundated for part of the year. They occur naturally in floodplains and tidal marshes or are created in wetland rice agriculture. Three major types of wetland rice exist: deepwater rice that is covered by more than 50-cm water depth, irrigated rice that is permanently flooded by artificial irrigation, and rain-fed rice that is flooded only after heavy rainfall (2). Wetlands are of great ecological importance, for instance, by constituting unique habitats for plants and animals (1); by contributing the largest source in the atmospheric methane budget, thus affecting global climate (3); and in the case of rice agriculture, by providing the food for one-third of the human population (1).

In general, wetland soils are characterized by unique biogeochemical cycles of carbon, oxygen, nitrogen, sulfur, iron, and phosphorous and unique microbial communities when compared with upland soils (1,4). Besides the various modes of organic matter input, the biogeochemistry of wetland soils is largely controlled by the restricted availability of oxygen. Flooded soils, in particular, have a microflora that is adapted to the change between submergence and drainage. In addition, biogeochemistry of rice soils also is influenced by plowing and by domination of only one plant species. In these respects, rice soils differ from marsh soils or aquatic sediments.

This article focuses on the biogeochemistry and microbiology of irrigated rice soils. In contrast to other wetland soils, irrigated rice soils are manageable and thus accessible to experiments in the field and the laboratory. Thus, they constitute a relatively simple model system. In addition, they cover an area of about 73 million hectares worldwide and annually (in 1997) produce 520 million tons of rice (5). This production must be increased in the future (by 65% until the year 2020) to cover the demand of food by the growing human population (2). On the other hand, they emit about 60 million tons of methane into the atmosphere (3). Although increasing atmospheric methane may cause severe environmental problems by global climate change, a future problem is to increase rice production for the growing human population and simultaneously mitigate methane emission (5,6). This challenge can only be met by a better understanding of the functioning of soil microbial communities.

Biogeochemical processes in flooded soils have previously been reviewed with respect to microbiology (7–9), soil chemistry (10–12), and methane emission (2,13–17). Important early studies published in Japanese have been reviewed by Kimura (9).

BIOGEOCHEMICAL CYCLING

The biogeochemical cycling in flooded soils is driven by the input of organic carbon and of oxygen and by the availability of oxidants (i.e., nitrate, Mn(IV), Fe(III), and sulfate) in the soil. If oxygen or other oxidants are available, organic carbon is oxidized to carbon dioxide. If oxygen or oxidants are not available, organic carbon is disproportionated to CO_2 and CH_4. Availability of organic carbon, O_2, and oxidants in the flooded soil varies with time, space, soil type, and management. The major habitats of microorganisms in rice soils related to availability of O_2 and organic substrates are shown in Figure 1. The major microbial catabolic reactions that are active in rice soils are shown in Table 1.

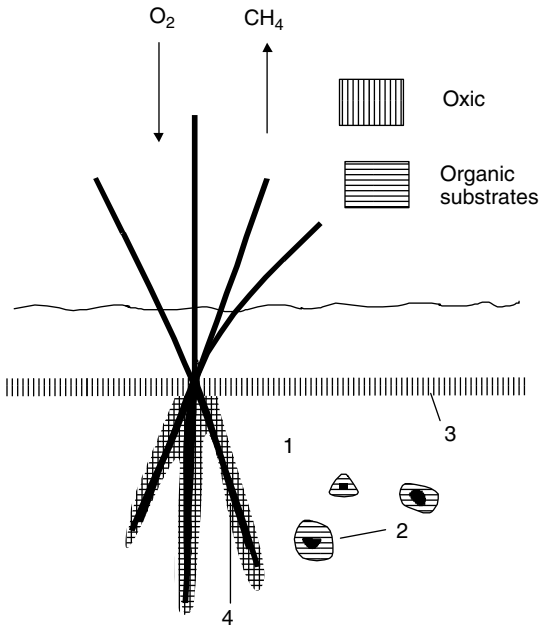

Figure 1. Scheme of a flooded rice field showing the different habitats for biogeochemically active microorganisms: (*1*) bulk soil (anoxic & substrate-limited), (*2*) decomposing straw (anoxic & increased organic substrates), (*3*) surface soil (oxic), and (*4*) rhizosphere (partially oxic & increased substrates).

Table 1. Major Biogeochemical Reactions Catalyzed by Aerobic and Anaerobic Microorganisms and the Standard Gibbs Free Energy Changes ($\Delta G^{\circ'}$) and Standard Redox Potentials ($\Delta E^{\circ'}$)[a]

(a) Aerobic microbes using O_2 as electron acceptor

No.	Phenotype	Reaction	$\Delta G^{\circ'}$ (kJ mol^{-1}) per O_2	$\Delta G^{\circ'}$ (kJ mol^{-1}) per Substrate
1	Heterotrophs	$C_6H_{12}O^b{}_6 + 6O_2 \rightarrow 6CO_2 + 6H_2O$	−479	−2, 872
2	H_2 oxidizers	$H_2 + 0.5O_2 \rightarrow H_2O$	−474	−237
3	Methanotrophs	$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O$	−409	−818
4	Sulfide oxidizers	$HS^- + 2O_2 \rightarrow SO_4{}^{2-} + H^+$	−398	−796
5	Iron oxidizers[c]	$FeCO_3 + 0.5O_2 \rightarrow FeOOH + CO_2$	−380	−190
6	Ammonium oxidizers	$NH_3 + 1.5O_2 \rightarrow NO_2{}^- + H^+ + H_2O$	−192	−288
7	Nitrite oxidizers	$NO_2{}^- + 0.5O_2 \rightarrow NO_3{}^-$	−148	−74

(b) Anaerobic microbes using inorganic electron acceptors[d]

No.	Phenotype	Reaction	$\Delta G^{\circ'}$(kJ mol^{-1}) per e-acceptor	$\Delta G^{\circ'}$(kJ mol^{-1}) per Substrate	$\Delta E^{\circ'}$(mV)
8	DNRA bacteria[e]	$4H_2 + NO_3{}^- + 2H^+ \rightarrow NH_4{}^+ + 3H_2O$	−600	−150	+363
9	Denitrifiers	$2.5\ H_2 + NO_3{}^- + H^+ \rightarrow 0.5N_2 + 3H_2O$	−560	−224	+747
10	Sulfate-reducers	$4\ H_2 + SO_4{}^{2-} + H^+ \rightarrow HS^- + 4H_2O$	−152	−38	−217
11	Methanogens	$4\ H_2 + CO_2 \rightarrow CH_4 + 2H_2O$	−131	−33	−244
12	Iron reducers	$0.5\ H_2 + FeOOH + CO_2 \rightarrow FeCO_3 + H_2O$	−48	−95	+78
12	Homoacetogens	$4\ H_2 + 2CO_2 \rightarrow CH_3COO^- + H^+ + 2H_2O$	−48	−24	−290

(c) Fermenting microbes disproportionating organic substrates

No.	Phenotype	Reaction	$\Delta G^{\circ'}$, (kJ mol^{-1}) per Substrate
13	Homoacetogens	$C_6H_{12}O_6 \rightarrow 3CH_3COO^- + 3H^+$	−311
14	Propionate producers	$C_6H_{12}O_6 \rightarrow 4/3CH_3CH_2COO^- + 2/3CH_3COO^- + 2H^+ + 2/3CO_2 + 2/3H_2O$	−311
15	Butyrate producers	$C_6H_{12}O_6 \rightarrow 2/3CH_3CH_2CH_2COO^- + 2/3CH_3COO^- + 4/3H^+ + 2CO_2 + 8/3H_2$	−248
16	Ethanol producers	$C_6H_{12}O_6 \rightarrow 2CH_3CH_2OH + 2CO_2$	−235
17	Lactate producers	$C_6H_{12}O_6 \rightarrow 2CH_3CHOHCOO^- + 2H^+$	−198
18	Acetoclastic methanogens	$CH_3COO^- + H^+ \rightarrow CO_2 + CH_4$	−36
19	Theoretical	$C_6H_{12}O_6 + 6H_2O \rightarrow 6CO_2 + 12H_2$	−26
(d) Syntrophs reducing protons to H_2			
20	Lactate utilizers	$CH_3CHOHCOO^- + H_2O \rightarrow CH_3COO^- + CO_2 + 2H_2$	−49
21	Ethanol utilizers	$CH_3CH_2OH \rightarrow CH_3COO^- + H^+ + 2H_2$	+10
22	Butyrate utilizers	$CH_3CH_2CH_2COO^- + 2H_2O \rightarrow 2CH_3COO^- + H^+ + 2H_2$	+48
23	Propionate utilizers	$CH_3CH_2COO^- + 2H_2O \rightarrow CH_3COO^- + CO_2 + 3H_2$	+71

Note:
[a]Calculated from the Gibbs free energies of formation taken from Thauer et al. (18), except for siderite ($FeCO_3$) and ferrihydrite (FeOOH) which were taken from Stumm and Morgan (19).
[b]$C_6H_{12}O_6$ = glucose.
[c]The Gibbs free energy strongly depends on the type of iron mineral used for formulating the reaction.
[d]The reactions are given with H_2 as electron donor. Reactions (12) and (19) can be used to replace H_2 by acetate or glucose, respectively.
[e]DNRA = dissimilatory nitrate reduction to ammonia.

Origin of Organic Carbon

The organic carbon in flooded soils is replenished by exudation and decay of roots and by incorporation of straw and other organic matter. Addition of rice straw or compost is common practice in rice agriculture and results in a strong stimulation of CH_4 production (20–22). The half-life of rice straw in flooded soils is about two years (23). Organic matter is also provided by the plant roots through exudation of part of the photoassimilated carbon, sloughed off cells, and decaying roots (24). Pulse-labeling studies showed that about 5% of the photoassimilated $^{14}CO_2$ was converted to CH_4 within a few days and reemitted into the atmosphere (25). Experiments with ^{13}C-labeled straw and carbon dioxide quantified the contribution of different carbon sources to CH_4 emission from irrigated rice (26–29). Without straw addition, plant photosynthesis accounted for more than 80% of CH_4 emission; the rest was due to decomposition of soil organic matter. Addition of straw stimulated CH_4 production, but the percentage contribution of straw carbon to total CH_4

production declined with time, so that over the entire season straw, plant photosynthesis, and soil organic matter contributed about 40%, 40%, and 20%, respectively (29).

Input of Molecular Oxygen

There are two paths of oxygen input into flooded soils: diffusion from the floodwater and transport through the plant-vascular system. In the first path, O_2 penetrates only 2 to 3 millimeters deep into the soil because of active O_2 consumption (30). Occasionally, O_2 concentrations on the soil surface can increase because of photosynthetic layers of algae, but O_2 is nevertheless depleted in a few millimeter depth (30,31). On the other hand, in the vegetated soil, O_2 can be detected in deeper soil layers because of plant-vascular gas transport (30). Aquatic plants typically transport O_2 by diffusion or pressurized ventilation from the atmosphere into the roots to allow respiration of root cells in the anoxic soil (32,33). The vascular system also allows gas transport in the opposite direction and thus mediates more than 90% of the emission of CH_4 from rice fields (34,35) and allows the emission of other trace gases (36). In rice plants, the gas transport is by molecular diffusion (37–39). Oxygen leaks from the rice roots into the surrounding soil but is so rapidly consumed that the penetration depth is very thin (<0.4 mm) (40,41). However, the impact of oxygen leakage from roots on soil biogeochemical cycling becomes significant during the season as the plants develop (42).

The rhizosphere, or more specifically the ectorhizosphere, is the volume of soil influenced by roots (43). Although the outer boundary of the ectorhizosphere may be difficult to define, the rhizoplane (root surface) and endorhizosphere (the various cell layers of the root itself) are easily distinguishable. The plant-vascular system, the aerenchyma, allows a very efficient gas exchange even by molecular diffusion alone (44). The primary function of root aeration is to support the plant tissue with O_2 for aerobic metabolism, but some O_2 will be released into the ectorhizosphere. However, O_2 release along a root is not homogenous (45–47). No O_2 is released at the root tip. Only a few millimeters from the tip aerenchyma formation starts, and the highest O_2 release rates are found along this zone. More proximally, radial O_2 release rate decreases again (40,46). This zone of low O_2 release correlates with the suberization of the exodermis and the development of a layer of sclerenchymatous fibers on the external side of the cortex, causing a barrier for O_2 diffusion (48). Temporal changes in the rhizospheric redox potential, which were recorded close to a growing rice root, agreed well with the described zonation and suggest an "oxygenation window" for the zone behind the root tip forming for about two to three days (49). Free O_2 has been found repeatedly in the rooted soil of flooded rice microcosms (30,40,50,51). However, at elevated temperatures, when O_2 consumption is accelerated, the occurrence of O_2 seems to be restricted to the very root surface (31).

Oxygen concentrations measured in the rooted soil of microcosms at 100 days after planting (dap) were lower than at 50 dap (30). This result is consistent with the observation that Fe(III) precipitates are formed around young roots (see following section) but dissolved later when the root grows older (52). Hence, the O_2 supply seems to be higher in the early season than in the late season. However, the O_2 supply also was found to be influenced in the following ways: (*1*) in vitro, O_2 release from rice roots is stimulated by the inoculation with nitrogen-fixing *Azospirillum* (53); (*2*) reducing soil conditions may favor both aerenchyma formation and O_2 release (54); (*3*) in potassium-depleted soils, the oxidizing power of rice roots is increased by K fertilization (55). To summarize, the O_2 supply in the rhizosphere is highly variable in space and time.

Sequential Reduction and Redox Gradients

Besides O_2, a number of inorganic soil constituents contribute sequentially to the oxidation of organic matter. The sequence is determined by thermodynamics as compounds with higher redox potential are reduced first, that is, $O_2 > NO_3^- > Mn(IV) > Fe(III) > SO_4^{2-} > CO_2$ (Table 1) (10,56). Note that the redox potential of natural ferric iron minerals is substantially lower (around 0 mV) than that of aqueous Fe^{3+} (770 mV) (57). After flooding of soil, O_2 generally is depleted within one day; nitrate usually is depleted within a few days; on the other hand, reduction of Fe(III) can require weeks to complete (10,56). The time required for reduction depends on the concentration of each oxidant in the soil and thus is a factor of soil type and soil management. In general, Fe(III) is by far the most quantitatively important oxidant in rice field soils and thus determines the phase during which the organic matter is oxidized to carbon dioxide (58). In iron-rich acidic sulfur soils, for example, this phase extends over practically the entire season and CH_4 production never starts. In other soils, vigorous CH_4 production generally starts when reduction of Fe(III) and sulfate is largely completed (59). This event usually (details follow) coincides with a decrease of the redox potential (measured with a platinum electrode) to <−150 mV (60). At this time, the soil redox conditions are dominated by the reduction of carbon dioxide to either CH_4 or acetate (61). The total amount of CH_4 produced during the season and the maximum rate of CH_4 production are constrained by the availability of degradable organic matter and oxidants, usually Fe(III) (58,62,63). It also depends on temperature as the time required for sequential reduction increases with decreasing temperature (64–66).

The sequential reduction of soil oxidants is also seen in the form of vertical spatial gradients in the flooded soil under quasi-steady state conditions. Nitrate is usually depleted below a few millimeter depth (51), Fe(III) below about 0.8-cm depth (67), and sulfate below about 1- to 5-cm depth (68,69). The presence of plants, however, that introduce O_2 into deeper soil layers can complicate the vertical profiles, because nitrate, Fe(III), and sulfate are regenerated by oxidation with O_2 from their reduced forms (see following).

ANAEROBIC DEGRADATION OF ORGANIC MATTER TO METHANE

The methanogenic degradation of organic matter is accomplished by a complex microbial community, the functions of which are similar in all kinds of anaerobic environments such as sediments, anaerobic digesters, rumen, or flooded soils. The functions of such a microbial community consist of (*1*) hydrolysis, (*2*) fermentation, (*3*) syntrophic degradation, (*4*) homoacetogenesis, and (*5*) methanogenesis and are illustrated in Figure 2 (70–74). Hydrolysis is the largely extracellular enzymatic cleavage of polymers to monomers, for example, polysaccharides to sugars, proteins to amino acids, and so on. Fermentation is the microbial degradation of the monomers to simpler compounds. This is basically a disproportionation of the substrate to reduced plus oxidized compounds connected to the conservation of energy. Syntrophic degradation is the oxidation of primary fermentation products, such as fatty acids, alcohols, or aromatic compounds, to acetate plus carbon dioxide with protons as oxidant, thus forming H_2 as reduced product. Syntrophic reactions are typically endergonic under thermodynamic standard conditions and thus only proceed if the concentrations of the products, especially of H_2, are kept at a very low level. This is accomplished in syntrophy with the methanogenic microorganisms. Methanogenesis also can convert H_2 plus CO_2 to CH_4 and cleaves acetate to CH_4 plus CO_2. Methanogenesis can also convert formate, methanol, trimethylamine (TMA), or dimethylsulfide (DMS) to CH_4. Syntrophic microorganisms also produce formate instead of H_2 as reduced product. Methanol, TMA, and DMS are negligible degradation products in flooded soils. Homoacetogenesis is a special type of fermentation that produces acetate as sole product (75). Sugars, for example, can be directly converted to acetate, thus bypassing the syntrophic function. Many primary fermentation products as well as H_2 plus CO_2 also can be converted by homoacetogens to acetate as sole product.

In flooded soils, anaerobic methanogenic microbial communities degrade the organic matter that is available, that is, straw and other organic amendments, root exudates and root material, and the indigenous soil organic matter. The methanogenic degradation operates preferentially when oxidants other than CO_2 and H^+ are not available (see below). The degradation process has been studied in anoxic bulk soil, on straw particles, and on the surface of rice roots.

Hydrolysis and Fermentation

Rice straw consists of cellulose (32–37%), hemicellulose (29–37%), and lignin (5–15%) and, in addition, contains silica (76,77). Soil organic matter, on the other hand, is chemically not well defined. In soils into which straw is regularly incorporated, part of the soil organic matter likely consists of partially degraded straw particles, which apparently are hydrolyzed and fermented in a similar way as fresh straw (78). Changes in the composition and quality of soil organic matter, the phenolic content in particular, were observed in intensified rice cultivation where fields are kept flooded for prolonged periods (79,80). Only

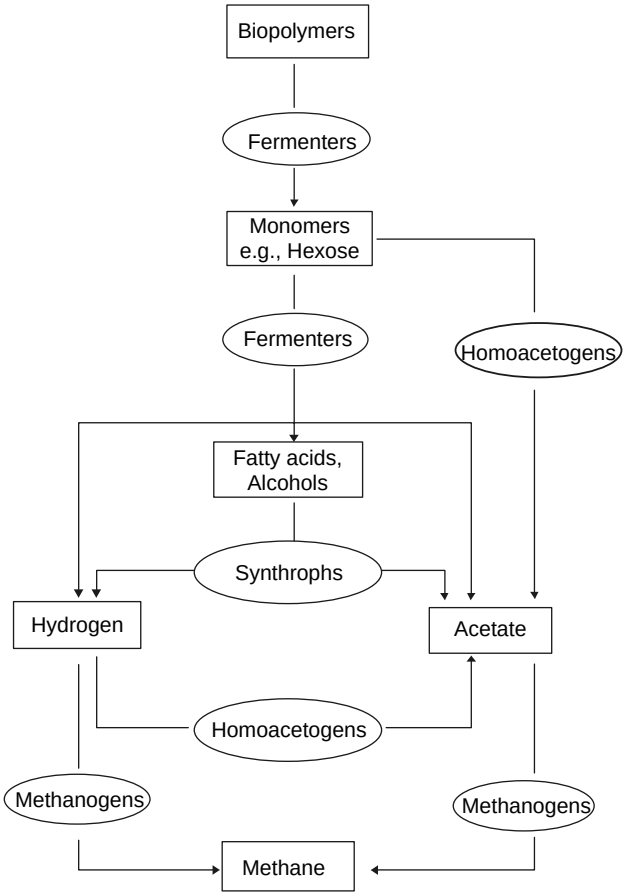

Figure 2. Pathway of anaerobic degradation of organic matter to methane [taken from Conrad 1999 (109)].

3 to 17% of the soil organic carbon is degraded to gaseous products during one season (58,76). The degradation process seems to result in changes of the oxidation state of the organic matter, which, however, are so slight that they are detected only by mass balance of oxidized and reduced compounds (81,82).

Rice straw is colonized by microorganisms, and the structure of the leaf blades and sheaths gradually disintegrates. The visible disintegration process becomes most apparent after three weeks of exposure in flooded soils (83,84). Molecular characterization of the straw-colonizing bacteria in an Italian rice field soil by targeting their ribosomal rRNA genes showed that most of the active bacteria were clostridia (55%), mainly belonging to the clostridial clusters I, III, and XIVa; others belonged to the genus *Bacillus* (1%), the *Cytophaga/Flavobacterium* cluster (5%), and the *Proteobacteria* (4%) (85). These bacterial groups also were found in flooded bulk soil, both by sequence information from clone libraries and by isolation of the dominant anaerobes (using the highest dilution steps of soil) (86–88). Saccharolytic bacteria were found to represent 50% of the total microorganisms (determined microscopically), representing about 10^8 bacteria per gram dry soil. These saccharolytic bacteria were able to grow on xylan, pectin, and various sugars, whereas bacteria able to grow on cellulose were about two orders

of magnitude less numerous. Isolates of the saccharolytic bacteria fermented sugars preferentially to acetate and propionate (87). Bulk Italian rice soil also contained bacteria belonging to the following phylogenetic groups: *Verrrucomicrobia*, *Actinobacteria*, clostridial cluster IX, and *Chlorobiaceae* (86,87). Hence, the straw-colonizing bacteria are possibly a subset of the bacterial community found in the bulk soil. The diversity of the straw-colonizing bacterial community increased immediately after exposure of the rice straw to anoxic soil but became constant after about 15 days (85). A difference in the bacterial community was also observed between dry rice soil and flooded rice soil, indicating community changes after flooding (88,89).

The fermentation pathway of straw components was found to be similar to that of the organic matter in unamended soil with acetate and carbon dioxide as major and propionate as minor fermentation products (78,90–92), that is, the same fermentation products that are observed in the dominant bacterial isolates (87). Only shortly after addition of rice straw to the flooded soil, additional fatty acids transiently accumulated to a significant extent, that is, butyrate, isobutyrate, valerate, isovalerate, caproate (78), and unidentified compounds (probably phenolic compounds) (76). Acetate and carbon dioxide were the major fermentation products of cellulose degradation (93), although small amounts of propionate were produced during fermentation of glucose, the monomer of cellulose (94). However, most of the propionate must be produced from other soil organic compounds or plant residues, possibly from xylan and pectin (95,96) or proteins (97).

Glucose is the most abundant sugar in hydrolysates of rice straw (98) and in the flooded rice soil (99). It is fermented via the Embden-Meyerhoff pathway with turnover times of more than 1 hour (94,99). Acetate is the major fermentation product, the concentration of which is effectively controlled by the equilibrium between glucose fermentation and methanogenic acetate consumption.

Rice roots are also colonized by microorganisms (100), including fermenting bacteria, but the composition of the microbial community seems to be completely different from that in the bulk soil or decomposing rice straw (101). Sequences of the 16S rRNA gene cloned from DNA extracts of rice roots showed a dominance of members from the following phyla: *Cytophaga/Flavobacterium/Bacteroides* (CFB)-phylum, the α-subgroup, β-subgroup, and δ-subgroups of the *Proteobacteria*, the *Holophaga/Acidobacterium* Phylum, and the gram-positive bacteria with low G + C content. Interesting was the detection of *Myxococcaceae* (*δ-Proteobacteria*), a bacterial group that usually lives on the lysis products of microbial and plant cells.

Little is known about the fermentation processes operating on the root surface. Pulse-labeling experiments with $^{14}CO_2$ showed that plant roots release organic material, which is converted to lactate, propionate, and acetate, probably in a sequential fermentation (25). Excised plant roots rapidly produce H_2, which subsequently is consumed by carbon dioxide reduction (102,103). Production of H_2 probably is due to fermentation processes being initiated by the exudation of soluble compounds from the roots or by the decay of the roots. Cellulose, glucose, and xylose are all rapidly fermented on excised rice roots, with acetate as the major fermentation product and propionate as the minor fermentation product (104). Hence, the fermentation pattern of excised rice roots apparently is not much different from that of rice straw and soil organic material, although the bacterial community seems to be completely different.

Syntrophy

In irrigated rice soil, propionate is the most important compound that is syntrophically degraded in the absence of oxidants other than CO_2 and H^+. Propionate accumulates in flooded soil when methanogenesis is inhibited or when high H_2 concentrations are applied, demonstrating that its turnover is controlled by thermodynamic conditions (92). However, propionate degradation proceeds at rather high Gibbs free energies (-7 to -15 kJ mol^{-1} of propionate) (105) that generally are considered as insufficient for microbial energy conservation (74). Low rates of propionate degradation were also observed under formally endergonic conditions, that led to the conclusion that propionate is degraded in soil microniches (e.g., in microbial aggregates) that are shielded from the thermodynamic conditions in the bulk soil (106). Propionate is degraded by a randomizing pathway, the succinate pathway, to one CO_2 product, one acetate product, and three H_2 as stoichiometric products (107). By producing H_2, propionate degradation can account for most of the CH_4 production from H_2 plus CO_2 (107). Propionate degradation on rice roots has not yet been studied, but the reverse process (i.e., the synthesis of propionate from H_2, CO_2, and acetate) seems to operate (103,104). The microorganisms responsible for propionate degradation in flooded soils are not known. Inhibition studies indicate the involvement of sulfate-reducers (107,108).

Homoacetogenesis

Methanogenic archaea convert the final products of fermentation and syntrophic degradation to CH_4. In the absence of homoacetogenesis, degradation of polysaccharides finally results in the production of 2 acetate, $4H_2$ plus $2CO_2$ per hexose monomer (109). Acetate is cleaved by acetotrophic methanogens to CH_4 plus CO_2. Hydrogenotrophic methanogens convert $4H_2$ plus CO_2 to CH_4. Hence, $3CH_4$ are produced from 1 hexose, two of which are produced by acetotrophic (67%) and one is produced by hydrogenotrophic methanogens (33%). In the presence of homoacetogenesis, on the other hand, more acetate instead of H_2 plus CO_2 is produced from hexose fermentation, or some of the H_2 is used to reduce carbon dioxide to acetate. In this case, more than two of the three CH_4 are produced from acetate.

Indeed, hydrogenotrophic methanogenesis frequently contributes less than 33% to total CH_4 production in anoxic rice soil, suggesting that some of the polysaccharides are fermented by homoacetogenesis (61,110–112). Homoacetogenic bacteria of the genus *Sporomusa* do occur in Italian rice field soil in numbers of up to 10^8 per gram dry soil (113). *Sporomusa* species usually are

chemolithoautotrophic, which may explain why some of the acetate (<10%) in rice soil seems to be produced by reduction of carbon dioxide (61,111). The thermodynamic conditions for the reduction of carbon dioxide to acetate usually are not favorable unless H_2 concentrations are elevated (92). Elevated H_2 concentrations and vigorous carbon dioxide reduction to acetate have, for example, been observed on excised rice roots (103,104). Also, 16S rRNA gene sequences characteristic of the homoacetogenic genus *Sporomusa* have been detected in DNA extracts from rice roots (101). In flooded soil, on the other hand, elevated H_2 concentrations and carbon dioxide reduction to acetate usually occur only if methanogenesis is inhibited (112,114). In addition, production of acetate from H_2 plus CO_2 seems to be favored over hydrogenotrophic methanogenesis when temperatures are low (e.g., 15 °C), probably because the resident homoacetogens are more psychrotolerant than the methanogens (92,115,116).

Methanogenesis

Methanogenic archaea occur in rice soils in numbers of up to 10^7 cells per gram dry soil and do not decrease significantly when the flooded soil is drained until the next season (117–119). Numbers of methanogens in rooted soil (that is assumed to receive some O_2, see earlier section) and in anoxic bulk soil are nearly the same (120). Most of the methanogenic archaea in rice soil even survive desiccation and exposure to oxygen (121). The methanogens are even able to decrease the redox potential of their medium to a compatible level (about +50 mV) if substrate is available to initiate CH_4 production (122). Obviously, the methanogens in flooded soils are not easily killed by exposure to O_2, contrary to what most textbook state, and thus are perfectly adapted to their changing environment.

So far, methanogens were isolated or enriched from rice soils belonging to the genera *Methanobacterium* (115,123–125), *Methanobrevibacter* (123,126), *Methanoculleus* (124), *Methanosarcina* (124,127,128), and *Methanosaeta* (129). Molecular techniques also demonstrated the presence of most of these genera in Italian rice field soils (129). Short fragments of the 16S rRNA genes of *Methanogenium* and *Methanoculleus* species were detected in Japanese rice soils (130). Furthermore, 16S rRNA gene sequences of novel archaea (named *Rice cluster I* and *Rice cluster II*) were detected in Italian rice soils (131,132) that fall in between the phylogenetic radiations of the *Methanosarcinales* and *Methanomicrobiales* and have a methanogenic phenotype (133,134).

Although numbers of total culturable methanogens stay fairly constant in rice soil, the individual populations change dynamically with time of anoxia and temperature. Thus, the percentage contribution of *Methanosarcinaceae* within the total methanogenic population increases during 17 to 25 days after onset of anoxic conditions in soil slurries (135,136). This relative increase may be caused by the usual increase of acetate concentrations during this period, given the fact that *Methanosarcina* species can only use acetate concentrations greater than 200 μM (137). After longer periods (90–120 days) of anoxia, acetate concentrations usually decrease, as does the percentage of *Methanosarcina* in the methanogenic population that is then dominated by *Methanosaeta*, which has a much lower threshold (about 10 μM) for utilization of acetate (116). Interestingly, *Methanosaeta* dominates in anaerobic enrichment cultures on cellulose inoculated with Italian rice soil at 15 °C, whereas *Methanosarcina* dominates at 30 °C, at conditions where acetate is nonlimiting (138). The *Methanosaeta* populations in Italian rice soil seem to be more psychrotolerant than the *Methanosarcina* populations. On the other hand, if rice soil slurries are incubated at more than 40 °C, rice cluster I is becoming the dominating methanogenic population (139).

The 16S rRNA gene sequences characteristic for Rice cluster I and Rice cluster II have been discovered on rice roots (131,133). This was surprising because rice roots had originally been considered to be largely oxic habitats (see preceding). Nevertheless, roots produce CH_4 when incubated under anoxic conditions (140) and methanogens inhabit the root surface in numbers of 10^6 cells per gram dry root and produce CH_4 predominantly from H_2 plus CO_2 (133). However, acetotrophic methanogenesis is also possible on rice roots if phosphate concentrations are lower than 20 mM (141). Interestingly, *Methanosaeta* species have so far not been detected on rice roots, although they are abundant in the soil, but acetotrophic *Methanosarcina* species are present (129,131,133). Acetate concentrations probably are much higher on roots than in the bulk soil, thus allowing *Methanosarcina* species to be active.

Clone libraries of archaeal 16S rRNA genes demonstrated the presence in rice soil and on rice roots of novel deeply branching phylogenetic lineages. Novel phylotypes were found among the *Euryarchaeota* and were named *Rice cluster III* and *Rice cluster V*. Even more novel phylotypes were found among the *Crenarchaeota* and were named *Rice cluster IV* and *Rice cluster VI* (131,132,135,136). The sequences of rice clusters III to VI are unrelated to any known bacterial isolate. Hence, it is not known which phenotypes these novel phylotypes have and which functional role they play in the flooded soils. There are also only few related sequences from clones that were obtained from other environments, for example, from lake sediments and anaerobic digestors (related to Rice cluster IV) and from other soils and lake sediment (related to Rice cluster IV) (summarized in 135,142).

MICROBIAL OXIDATION OF METHANE

In flooded soils, CH_4 and CO_2 are the end products of organic matter degradation. However, not all of the produced CH_4 is released into the atmosphere, as it is oxidized by methanotrophic bacteria to carbon dioxide. This oxidation process is possible when O_2 becomes available, that is, at the surface of soil and plant roots.

Scavenging of Methane at the Soil Surface

Vertical concentration profiles in flooded rice soil show that the CH_4 and O_2 gradients overlap at about 2- to 3-mm depth, that is, the lower end to which O_2 diffuses from the surface (31,40). At this depth, CH_4 is

oxidized, thus reducing the diffusive CH_4 flux by about $81 \pm 15\%$ (143). However, if CH_4 production rates are high and if the produced CH_4 cannot evade via the plant gas vascular system (see preceding), gas bubbles form and result in ebullition of CH_4 that is not scavenged by CH_4 oxidation (144). In planted soils, however, gas bubbles may be trapped in the rooted zone where part of the CH_4 can be oxidized. The vertical CH_4 concentration profile seems to be slightly affected by bioturbation of small animals living in the soil (144). However, the net effect of bioturbation is very small; even addition of chironomid larvae to flooded rice soil did not significantly change the flux of CH_4 across the sediment–water interface, although, methanotrophic activity in the walls of the chironomid burrows was significantly higher than in the soil (145).

The methanotrophic bacteria occur in numbers of 10^4 to 10^7 bacteria per gram dry soil (40,50,146–150). The methanotrophs possessing a soluble methane monooxygenase (*mmoX* gene) in addition to the particulate methane monooxygenase (*pmoA* gene) can be detected by naphthol utilization (147). Type I (*γ-Proteobacteria*; family *Methylococcacea*; genera *Methylobacter, Methylocaldum, Methylococcus, Methylomicrobium, Methylomonas, Methylosphaera*) and type-II (*α-Proteobacteria*; family *Methylocystaceae*; genera *Methylocystis, Methylosinus*) methanotrophs can be distinguished, among others, by the sequence of their 16S rRNA and *pmoA* genes and by phospholipid profiles (151). Both groups were detected in flooded rice field soil (152–154).

Methane Oxidation in the Rhizosphere

Methane concentrations in the rooted soil are lower than those in the bulk soil. However, the concentrations at the microsites where O_2 and CH_4 overlap are not known. From studies of CH_4-oxidizing bacteria growing in agar columns in countergradients of O_2 and CH_4, it is known that they consume their substrates to extremely low levels (155). This seems to be less plausible in the rice rhizosphere, because the equivalent CH_4 mixing ratio should not be less than that measured in the aerenchyma. At mixing ratios of 5,000 to 10,000 ppm_v in the aerenchyma, the rhizospheric CH_4 concentration corresponds to 6 to 12 μM CH_4, a concentration quite higher than the apparent K_m known from pure cultures and rice soil (156). Hence, O_2 seems to limit the activity of CH_4 oxidizers more than CH_4 does.

Methane oxidation in flooded soils usually is expressed in percentage of CH_4 production. The first reports of CH_4 oxidation in rice fields were published in 1985 (34), but the quantification later proved to be rather difficult. One method is to measure CH_4 production rates in soil samples and to compare these rates with the CH_4 emission rates in the field (34,157). The difference is taken as the oxidation rate. However, the production rate in a soil sample may be biased by the handling (e.g., cutting of roots), rendering the derived oxidation rate unreliable. For example, rice roots may be cut during the sampling and result in stimulation of CH_4 production by decaying root pieces. As an alternative approach, various inhibitors have been used to block CH_4 oxidation. With these techniques, the difference between the increased emission after application of an inhibitor compared with that before the application of an inhibitor is taken as the oxidation rate. Common methods include the elimination of O_2 (30,34,50,158) or the application of acetylene (C_2H_2) (34,159,160), a suicide inhibitor of the CH_4 monooxygenase (161). However, some authors found that CH_4 emission was reduced (162,163), possibly because C_2H_2 inhibited methanogenesis (164,165). Some authors have favored methyl fluoride (CH_3F) (166–170). However, since CH_3F also inhibits acetoclastic methanogenesis, it also may bias the results (112,140,171). Instead, difluoromethane (CH_2F_2) has recently been used as an inhibitor of CH_4 oxidation (172,173). This inhibitor did not affect methane production in vitro and was applied successfully to laboratory microcosms and flux chambers installed in the rice field (42,154). Regardless of the inherent methodological problems, most numbers published during the last years on CH_4 oxidation rates in vegetated rice soil are in the range of 10 to 50% (42,170,174,175). Compared with the oxic surface of a lake sediment with about 90% CH_4 oxidation (176) or to that of rice fields with about 80% (143), the CH_4 oxidation in the rhizosphere, therefore, seems to be quite ineffective.

The reason for this may be the competition between rice plants and rhizospheric bacteria for nutrients. In greenhouse experiments it could be shown that nitrogen deprivation limits the rhizospheric CH_4 oxidation. A treatment with ammonium-based fertilizers stimulated CH_4 oxidation (153,177), and in a field study in Italian rice field a positive correlation between potential CH_4 oxidation and the availability of ammonium was found (42). Hence, nitrogen fertilization may be an option to reduce CH_4 emission from rice fields. In a first field experiment, however, the stimulation of CH_4 oxidation after urea fertilization was counterbalanced by simultaneous stimulation of CH_4 production, resulting in zero net effect (178).

In contrast, the situation in nonflooded upland fields is quite different. Upland soils are exposed only to atmospheric CH_4 concentrations and show mostly an inhibition of CH_4 oxidation following nitrogen fertilization (179–182). However, even the reaction of upland soils is not consistent, with some published evidence for stimulating or inducing effects of ammonium fertilization on CH_4 oxidation in low CH_4 (146,183–185) and in high CH_4 environments (186,187). Interestingly, this stimulation seems to depend on the natural ammonium level because it is observed in low-ammonium but not in a high-ammonium soil (146).

Methane-oxidizing bacteria have been detected in putatively oxic rhizospheric soil, in the rhizoplane, and even in surface-sterilized rice roots and shoots (40,50,188). They were counted in relatively high numbers of 10^6 to 10^8 per gram dry soil or root biomass. The detection inside rice roots or shoots points to the ability of these bacteria to invade the rice plants, that was confirmed by study of gnotobiotic roots using confocal laser scanning microscopy (189). The number of CH_4-oxidizing bacteria in the rooted soil may or may not increase with time, but the total root-associated population increases largely in parallel to the development of the root system with ongoing season (40,50,154,188). Type II methanotrophs

seems to have a quite stable population size, but type I methanotrophs react fast upon favorable conditions, as shown by analysis of 16S rRNA genes and phospholipid fatty acids (153).

Methane oxidation was repeatedly found to occur also under anoxic conditions in marine sediments (190–194). Although CH_4 turnover in flooded rice fields can be interpreted without assuming an anaerobic CH_4 oxidation process, there are hints that it nevertheless may exist, possibly being correlated with the reduction of sulfate and/or iron (195–197).

Oxidation of Atmospheric Methane

In flooded soils, the methanotrophs act as a filter for the evading CH_4, which is supplied to the upper soil surface layer in micromolar concentrations. Nevertheless, flooded soils still act as a net source for atmospheric CH_4 (Fig. 3). In upland soils, on the other hand, the methanotrophs consume atmospheric CH_4 that is available at nanomolar concentrations. These soils act as a sink for atmospheric CH_4 (36,198,199). The diffusion of CH_4 from the atmosphere to the soil is mainly controlled by texture and moisture (200,201). The methanotrophic populations acting as CH_4 filter versus those consuming atmospheric CH_4 can be distinguished by the CH_4 oxidation kinetics, that is, their apparent K_m being in the micromolar and nanomolar ranges, respectively (36,202).

Fields cropped with upland rice and rain-fed rice (for definition, see 2) can act as sinks for atmospheric CH_4, when the soil moisture decreases to sufficiently low levels (149,203,204). Fields cropped with irrigated rice are also turned into actual upland soils when the flooded fields are drained, and they remain in this state during the fallow period until they are flooded again. Nevertheless, this type of field has so far not been observed to become a net sink for atmospheric CH_4. The residual CH_4 production activity in drained soil, although low, was always found to be higher than the CH_4 oxidation activity, thus resulting in a small net release of CH_4 (205). Hence, it is the balance between production and oxidation of CH_4 that determines the direction of CH_4 flux, which is emission in drained flooded soils but uptake in dry upland soils. The methanotrophic community resident in flooded soils was found to be more sensitive to drying than the methanogenic community was. Nevertheless, the methanotrophs were able to utilize atmospheric CH_4 with a nanomolar apparent K_m (205) and display a dramatic population dynamic in the upper soil layers upon drainage. Type-I methanotrophs (*Methylobacter*, *Methylomonas*, and *Methylococcus*), in particular, reacted with population growth, as identified by the increase of the 16S rRNA and *pmoA* gene content (206).

MICROBIAL CYCLING OF OXIDANTS

In addition to CH_4, other reduced compounds are formed in flooded soil, in particular, Fe(II) and reduced nitrogen and sulfur compounds. Analogously to CH_4, these compounds can be oxidized if O_2 is available and thus effectively regenerate nitrate, ferric iron, and sulfate in the soil (Fig. 3). These regenerated oxidants can subsequently serve as electron acceptors for reduction reactions. Hence, redox cycling of N, Fe, and S is taking place. During this process, N-containing and S-containing trace gases are produced and released into the atmosphere.

Cycling After Intermittent Drainage

Intermittent drainage is a common practice in floodwater management of irrigated rice or incidentally happens after water shortage. Drainage allows O_2 to penetrate deeper into soil, resulting in an increase of the redox potential (207). This increase in redox is brought about by oxidation of Fe(II) to Fe(III) and of sulfide to sulfate, which in turn suppress CH_4 production. Because it takes quite some time after the short-term drainage to reduce the produced Fe(III) and sulfate again, CH_4 production stays suppressed for a while (208,209). Thus, intermittent drainage is an effective option to mitigate CH_4 emission from flooded soils (207,210,211).

Availability of O_2 during intermittent drainage also allows the oxidation of ammonium and consequently the

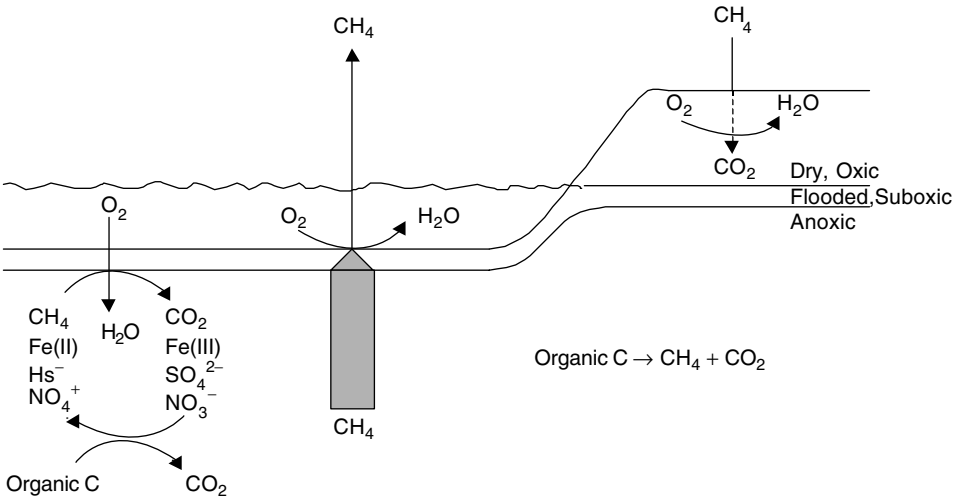

Figure 3. Scheme of redox cycling at the oxic–anoxic interface of flooded soils, of CH_4 oxidation attenuating the emission of CH_4 into the atmosphere, and of CH_4 oxidation acting as sink for atmospheric CH_4.

production of NO and N_2O during nitrification itself and during the subsequent denitrification of the produced nitrate (212). Nitrous oxide (N_2O) is an even more effective greenhouse gas than CH_4 and, in addition, results in the destruction of stratospheric ozone (3,36,213). However, nitrification and production of N_2O only operates if ammonium is available. In vegetated rice fields, the plants rapidly take up ammonium, thereby limiting soil nitrogen (51). Hence, it is not surprising that intermittent drainage results in increased N_2O emission only if the soils are well fertilized (209,214–216).

Cycling in the Rhizosphere

The cycling of matter in the rhizosphere is characterized by the relative abundance of organic matter provided by root exudation and root decay and by the availability of O_2 leaking from the plant aerenchyma system. The O_2 allows oxidation of reduced compounds such as organic substrates, ammonium, ferrous iron, and reduced sulfur, whereas the organic substrates supply electron donors for reduction processes such as the reduction of O_2, nitrate, Fe(III), and sulfate. The stimulation of both oxidation and reduction processes potentially allows for an intensive cycling of C, N, Fe, and S in the rhizosphere.

The cycling of electron donors and acceptors in the rhizosphere has a spatial and temporal component; radial gradients of the different compounds are formed around an individual root, but these gradients change with time and may even collapse at the root surface in a senescing plant. Aerobic and anaerobic processes may be mutually exclusive or may overlap to some extent, but no high-resolution studies have been undertaken as yet. Nevertheless, experimental evidence suggests that rice roots are inhabited by microbial communities that allow the conversion of nitrogen by coupled nitrification-denitrification (51,217,218), the cycling of Fe(II) and Fe(III) (67,219), and the cycling of sulfur by sulfur oxidation and sulfate reduction (69).

Nitrogen Cycling

In wetland rice agriculture, nitrogen fertilizer efficiency is rather poor, with an apparent nitrogen recovery of less than 40% (79,220). The main reasons for fertilizer inefficiency are nitrogen losses by both volatilization of NH_3 and coupled nitrification-denitrification. Nitrogen loss by volatilization of NH_3 is a physical process, caused by algal photosynthesis that increases pH in the flood water (221). Nitrogen loss by denitrification to N_2 is a microbial process that depends in a wetland soil on nitrification, the microbial formation of oxidized nitrogen species from ammonium. Once oxidized, nitrogen (mainly as nitrite and nitrate) is reduced by denitrifying bacteria. Among the processes described earlier, nitrification may compete with rice plants for N sources, but evidence is growing that nitrification and subsequent denitrification play a major role for only a limited time after fertilization. The problem is recognized in agronomic practice, and split-fertilization or deep placement of fertilizers is used to reduce the imbalance between ammonium supply and plant uptake (222). The application of wax-coated calcium carbide (a slow-release source of the nitrification inhibitor C_2H_2) has also been tested (162,163,223).

Nitrogen cycling in rice fields is characterized by spatially heterogeneous substrate concentrations that change unpredictably with time. The activities of nitrifiers and — because of the tight coupling — of denitrifiers are dependent on the presence of O_2 and ammonium. Both substrates may be limiting for nitrification. With the ongoing season, nitrogen is rapidly depleted in the rooted soil layer where the rhizosphere of different roots overlaps, ending up at nearly undetectable concentration of ammonium, nitrite, and nitrate. Nitrification and subsequent denitrification become active only if an imbalance between nitrogen supply to and nitrogen demand of the rice plant allows for increased ammonium concentrations in the rhizosphere (Fig. 4).

Nitrifying bacteria are aerobic bacteria and are assumed to be active in the same microhabitats

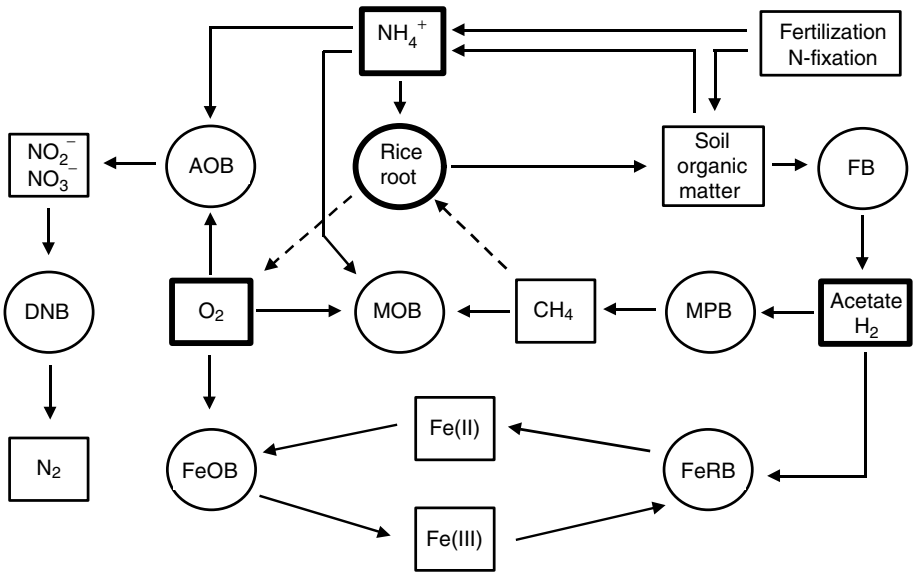

Figure 4. A simplified scheme of the interactions between microbial carbon and nitrogen cycling. Processes and/or organisms are symbolized by circles and substrate pools by boxes. Fluxes of substrates are symbolized by solid arrows with the exception of the diffusion of the gases O_2 and CH_4 into and from the aerenchyma of the root, which are marked by dashed arrows. For sake of clarity, abiotic redox processes, aerobic mineralization of soil organic matter to carbon dioxide, and dissimilatory nitrate reduction to ammonium are omitted. FB = fermenting bacteria; MPB = methane producing bacteria; MOB = methane oxidizing bacteria; AOB = ammonium oxidizing bacteria; DNB = denitrifying bacteria; FeOB = iron oxidizing bacteria; FeRB = iron reducing bacteria.

as the CH_4-oxidizing bacteria. The ammonium-oxidizing genera belong to the *β-Proteobacteria* and *γ-Proteobacteria* (224,225). Ammonium is activated by the ammonium monooxygenase, which is phylogenetically related to the particulate methane monooxygenase of methane-oxidizing bacteria (226,227), and both enzymes are inhibited by the same compounds, (e.g., C_2H_2) (226). Aerobic ammonium oxidizers can be characterized by the gene encoding for the ammonium monooxygenase, the *amoA* (228). DNA extracts from rice roots showed the presence of *amoA* sequences characteristic of the genus *Nitrosospira* (228,229). *Nitrosospira* species are also the most dominant ammonium oxidizers in the rhizosphere of the aquatic grass *Glyceria maxima* (230) and in nonflooded soils (231,232). The numbers of culturable ammonium-oxidizing bacteria in bulk soil and rhizospheric rice soil are approximately 10^4 to 10^6 per gram dry soil (177).

Methanotrophic bacteria are able to activate ammonia with the methane monooxygenase and exhibit nitrification activity (227). Indeed, it was found that CH_4-oxidizing bacteria could contribute substantially (>50%) to nitrification in ammonium-limited rice field soil (177,233). It is not known whether the recently discovered phenotype of anaerobic ammonium oxidation, represented by species of the order *Planctomycetales*, play any role in flooded soils (234–236).

Nitrification activity starts shortly after fertilization with $(NH_4)_2HPO_4$ or urea, resulting in millimolar pore water concentrations of nitrite and nitrate in the rooted soil layer (51). However, such high concentrations are locally restricted and disappear after a few days, when ammonium is again used up by the rice plant and the soil microorganisms. It is not certain whether ammonium oxidizers or methanotrophs are responsible for the nitrification activity following fertilization. However, methanotrophic bacteria are quite sensitive to nitrite (237). Ammonium oxidizers are known to preserve a high-energy charge even during ammonium deprivation (238) and to become reactivated immediately after fertilization (239). Hence, ammonium-oxidizing bacteria probably cause the rapid onset of nitrification after fertilization.

The aerobic nitrite-oxidizing genera belong to the *α-Proteobacteria* (*Nitrobacter*), *γ-Proteobacteria* (*Nitrococcus*), *δ-Proteobacteria* (*Nitrospina*) (225,240), and a deeply branching class (*Nitrospira*) within the domain *Bacteria* (241). The numbers of culturable nitrite-oxidizing bacteria in bulk soil and rhizospheric rice soil are on the order of 10^5 to 10^7 per gram dry soil (177). Phylogenetic analyses of the nitrite-oxidizing community in rice field are so far lacking.

Once nitrite or nitrates have been formed, they may diffuse from the rhizosphere into the anoxic bulk soil, where they will be reduced. Rice field soils contain populations of nitrate-reducing bacteria, denitrifying bacteria, and bacteria capable of dissimilatory nitrate reduction to ammonium (DNRA) (reviewed, see 9). The nitrate reducers (producing nitrite) and the denitrifiers (producing N_2) are mostly facultative anaerobes. The DNRA bacteria are mostly anaerobes. The phenotypes are all polyphyletic, so that reliable molecular tools based on the 16S rRNA gene are not available for environmental studies. Molecular techniques based on functional genes that are unique for the specific phenotypes are also not available yet, so that community analyses of the populations active in nitrate reduction, denitrification, and DNRA are not possible at the moment. The current picture, recently reviewed by Kimura (9), indicates that potential nitrate reducers and denitrifiers contribute up to 16 and 0.9%, respectively, of the total viable counts in rice field soil and that the rhizosphere is more densely populated than the bulk soil. Denitrification activity is obvious in rice field soil, but most studies indicate that DNRA plays no significant role. Hence, the oxidized ammonium is lost mainly by denitrification (if not taken up by the plant) and is not recycled (Fig. 4).

The coupling of nitrification with denitrification in the rice rhizosphere has been shown by balancing nitrogen addition with nitrogen recovery from plants and soil (242), by application of ^{15}N-labeled urea (217,243), and by measurements of N_2, the end product of denitrification (218). Radial profiles measured in different positions along individual rice roots have shown that net nitrification occurs closely behind the root tip at some distance from the root surface and that it was confined to the very root surface in the basal zone (51).

A simplified scheme of how nitrogen and carbon cycling in a rice field are interconnected is shown in Figure 4. The root drives microbial activity by releasing labile organic carbon (exudates, decaying cells, and so on) into the pool of soil organic matter also containing refractive material such as straw, stubble, and humic substances. Organic matter is degraded in the anoxic soil by fermenting bacteria to acetate and H_2 (for details see Fig. 2). If oxidized iron is available, acetate and H_2 are used by iron-reducing bacteria or by CH_4-producing bacteria. Organic nitrogen from the soil organic matter will end up as NH_4^+. Methane-oxidizing bacteria, ammonium-oxidizing bacteria, and iron-oxidizing bacteria compete for O_2. Iron oxidation and reduction together form an internal redox cycle (see following section). Ammonium-oxidizing bacteria produce NO_2^- and NO_3^- that will be reduced in the surrounding anoxic soil by denitrifying bacteria to N_2, making the coupled oxidation and reduction to a nitrogen sink. This loss has to be compensated for by microbial N_2 fixation and by fertilization. All organisms compete for NH_4^+, with the rice root as the top competitor, followed by methane-oxidizing bacteria. The latter may outcompete the ammonium oxidizers for ammonium. For the sake of clarity, abiotic redox processes, aerobic mineralization of soil organic matter to carbon dioxide, and dissimilatory nitrate reduction to ammonium are omitted.

Iron Cycling

Iron is a major component in soils. In fact, iron reduction dominates the redox processes in rice field soils shortly after flooding and often accounts for more than half of the electron balance over the entire rice-growing season, thus being a process that is even more important than methanogenesis (58).

Profiles of Fe(III) in unplanted rice microcosms showed a maximum in a depth of 2 to 4 mm close to the zone of highest O_2 consumption in about 2-mm

depth (67). However, iron oxidation was not an exclusively aerobic process but instead was caused in part by the reduction of nitrate (244) that was available below 2-mm depth (51,244). In slurry experiments using the same rice field soil, substantial amounts of Fe(III) were produced after addition of NO_3^- or N_2O (245). Bacteria able to couple the reduction of NO_3^- to N_2 with the oxidation of Fe(II) to Fe(III) have been found in different sediments (246–248) and are also present in rice fields in most probable numbers of about 10^6 per gram dry soil (244).

Iron-reducing bacteria are abundant in rice field soils. Ferrihydrite-reducing bacteria occur in numbers that are about 10-fold higher than those of methanogens and use H_2, acetate, and lactate as electron donors. Isolates from rice field soil were phylogenetically diverse, belonging to the α-, γ-, and δ-*Proteobacteria* (Schnell, personal, communication).

Rice roots tend to form a dense root mat within the top 3 cm (120). These roots are often covered with reddish iron plaques, making the reoxidation of Fe(II) to FeOOH quite obvious (219,249). Oxidation of Fe(II) has positive effects for the rice plant (250) because high amounts of Fe(II) are detrimental, being a major constraint for rice agronomy in Fe-rich soils (251). Iron plaques are also present in older root segments, where the measured O_2 release is comparably low. Numbers of iron-reducing bacteria are slightly higher in the rhizosphere than in bulk soil (Schnell, personal, communication). Hence, it is likely that iron is cycled on the rice roots by coupled oxidation-reduction of iron, or at the least roots stimulate iron cycling.

Iron(III) is also common in the rooted soil layer between the surface and a depth of at least 3 cm in microcosms (120) and in the field (42). CH_4 production in this layer is low and acetate is mainly oxidized to carbon dioxide (42). In vitro, methanogenesis is not totally suppressed in this soil. However, it is only after reduction of Fe(III) after 25 to 40 days that acetate concentrations reach the threshold values for methanogens and vigorous CH_4 production resumes (120). It is also during the period of iron reduction that sulfate is available in concentrations that are sufficiently high to support sulfate reduction (120), possibly caused by sulfide oxidation coupled to Fe(III) reduction (252).

Sulfur Cycling

As found for reduced nitrogen and iron, reduced sulfur compounds also can be oxidized in the rhizosphere. Indeed, sulfate concentrations are found to be highest in the rhizosphere and in the surface soil layers, indicating that oxidation of reduced sulfur compounds takes place at these oxic sites (25,68,69). Sulfur-oxidizing bacteria are present in bulk and in rhizosphere soil at numbers of 10^5 to 10^6 per gram dry soil and actively oxidize reduced sulfur species, thus regenerating sulfate (253). Isolates of sulfur-oxidizing bacteria are phylogenetically related to *Thiobacillus thioparus* (β-*Proteobacteria*) and to various genera within the α-*Proteobacteria* (253).

Sulfate reduction was studied in rice microcosms with a planar root mat (69). Rates were highest in 0- to 1.5-mm distance to the root mat. Washed excised rice roots showed sulfate reduction potential when incubated in anaerobic medium, indicating a close association of sulfate-reducing bacteria with the roots. Hydrogen-using sulfate-reducing bacteria were present at 10^7 cells per gram fresh root biomass and were related to the genus *Desulfovibrio* (254). The genus *Desulfotomaculum* (potentially utilizing acetate) accounted for 1% of the total bacterial rRNA on rice roots (255). It was suggested that the sulfate-reducers were limited by the availability of sulfate rather than electron donors, the latter would be provided by root exudation.

Traditionally, sulfate-reducing bacteria are considered to be strict anaerobes. However, they may tolerate or even respire O_2. Many of them form aggregates, resulting in a higher tolerance to oxygen exposure (256,257); fast-growing species respire with O_2 that is preferentially used when present together with other possible electron acceptors (257,258). Aerobic respiration is coupled to proton translocation (259) and ATP conservation (260), but aerobic growth in pure culture is poor or absent (261–263). Hence, sulfate-reducing bacteria are well adapted to survive in an environment like the rhizosphere that may become oxic from time to time.

In rice soils, the number of sulfate-reducers range between 10^3 and 10^7 per gram dry soil, depending on soil conditions and substrate used for cultivation (68,264). Isolates were phylogenetically affiliated with the genera *Desulfovibrio*, *Desulfobulbus*, *Desulforhabdus*, *Desulfobotulus*, and *Desulfotomaculum* (254). Dot blot hybridization showed that *Desulfotomaculum* accounted for about 0.5% of the bacterial rRNA (255). Rates of sulfate reduction were highest at about 3- to 5-mm depth. In the top layers, where O_2 was present, sulfate reduction was low but detectable; in depth below 6 to 7 mm, it was limited by sulfate. The major product of sulfate reduction was acid-soluble sulfur (i.e., H_2S and FeS), whereas chromium-reducible sulfur (i.e., S^0 and FeS_2) was a minor product (69). Hence, sulfur was mainly in a labile form. The concentration of pyrite (FeS_2) was less than about 1% of the iron content, so that sulfate reduction in rice soil contributes little to the iron cycle.

Volatile reduced sulfur compounds such as dimethyl sulfide, carbonyl sulfide, and carbon disulfide also are produced in flooded rice fields and are emitted through the rice plant into the atmosphere (265). Production of these trace gases is stimulated by addition of organic sulfur compounds, but the exact mechanism of production is not clear. The production rates of these volatile sulfur compounds are less than 0.1% of sulfate reduction rates (69).

ISOTOPE EFFECTS

Both CH_4 and its precursors show distinct isotopic signatures. In the case of CH_4 formed by methanogens, the distribution of carbon (mainly ^{12}C and ^{13}C) and hydrogen isotopes (H and D = deuterium) depends on the isotopic signatures of the source materials and on the kinetic isotope effect. Isotope data are given in δ notation ($\delta^{13}C$, δD) and expressed in per mill:

$$\delta = [(R_{\text{sample}}/R_{\text{standard}}) - 1] \cdot 10^3$$

where R is the ratio of the isotopes (e.g., $^{13}C/^{12}C$) in the sample and the standard, respectively. In short,

the molecules with the lower isotopic mass diffuse and react more rapidly than the isotopically heavier species, resulting in a kinetic effect. In the case of the carbon atom, this discrimination against ^{13}C results in its depletion in microbially produced CH_4 relative to the precursor substrates. The isotope fractionation factor ε (δ^{13}C-substrate $\rightarrow \delta^{13}CH_4$) is specific for the different methanogenic pathways and takes values from $\varepsilon = 24–27‰$ for acetoclastic (δ^{13}C-acetate $\rightarrow \delta^{13}CH_4$) and $\varepsilon = 55–58‰$ for hydrogenotrophic ($\delta^{13}CO_2 \rightarrow \delta^{13}CH_4$) methanogenesis, respectively (266). Fractionation factors in rice field soils have been investigated by Sugimoto and Wada (267,268).

Isotopic fractionation also occurs during CH_4 oxidation because methanotrophs prefer the isotopically lighter CH_4, causing an enrichment of ^{13}C and deuterium in the residual CH_4 (269–271). The isotope fractionation factor for CH_4 oxidation ($\delta^{13}CH_4 \rightarrow \delta^{13}CO_2$) is $\varepsilon = 7–31‰$ (265). Because production and oxidation have different effects, analysis of the isotopes of CH_4 may be a useful tool to quantify methanogenic pathways and the importance of CH_4 oxidation in situ. In the past, simply the isotopic signature of pore water CH_4 has been used to draw such conclusions (for review see, 266,272). Using more detailed sampling, some authors found signals in natural wetlands that were consistent with plant-associated CH_4 oxidation (273–275), whereas in other situations no rhizospheric oxidation could be detected (275).

Knowing the isotopic signature of pore water and of emitted CH_4, it should be possible to draw conclusions about the underlying microbial pathways and processes. However, it must be taken into account that the isotopically lighter CH_4 diffuses faster than its heavier counterpart. Because in rice the plant-mediated transport of CH_4 is mainly diffusive (37–39), it has a major impact on the signature of emitted CH_4. Hence, the isotopic signature of CH_4 in the aerenchyma also must be taken into account. Only a few studies have used this approach to analyze the CH_4 turnover in rice fields (276–278). These field studies have shown the potential of stable isotopes to unravel the interaction of methanogenic pathways and processes. The magnitude of CH_4 oxidation calculated from isotopic signatures agreed surprisingly well with that derived from other methods (278), but data available as yet are quite scarce. Additionally, the isotopic signatures of CH_4 from the rooted soil, the aerenchyma, and the emission seem to be difficult to interpret with respect to root-associated CH_4 production and oxidation (276–279). The interpretation becomes even more complicated if one takes into account that different groups of CH_4-oxidizing bacteria may discriminate differently against $^{13}CH_4$ and that even within one strain of *Methylococcus capsulatus* the isotope effect largely depends on the currently active soluble or particulate methane monooxygenase (280). Similarly, strain-specific or enzyme-specific discrimination may occur in methanogens. To summarize, measuring naturally occurring isotopic signatures provides a useful tool for the analysis of CH_4 turnover, but it should be applied in combination with other biogeochemical and microbiological methods.

COMPETITION AMONG MICROORGANISMS

Microorganisms require for growth and maintenance a source for energy, carbon, and nutrients. Given the limited availability of these compounds in soil, competition for these resources arises and may significantly affect biogeochemical cycling (13,14). In particular, microorganisms compete for substrates that are generated by anaerobic degradation of organic matter and for electron acceptors and nutrients.

Anaerobes

The microorganisms involved in the anaerobic degradation of organic matter typically are limited by energy. Hydrogenotrophic methanogens, for example, consume their substrate H_2 to levels that are at the thermodynamic threshold for energy conservation. The H_2 partial pressure in anaerobic environments such as flooded soils typically is in a range of only 1 to 7 Pa (58), which allows for the methanogenic reaction ($4H_2 + CO_2 \rightarrow CH_4 + 2H_2O$) a Gibbs free energy change of only 6–7 kJ mol^{-1} H_2 or about −25 kJ per reaction (59). This free energy change is just sufficient to generate one-third ATP per reaction (74). Because H_2 also can be used by bacteria that reduce nitrate, ferric iron, or sulfate, these bacteria compete with methanogens for the available H_2. Since the reduction of nitrate, ferric iron, or sulfate is more exergonic than the reduction of carbon dioxide by methanogens, these bacteria are able to effectively decrease the H_2 partial pressure below the threshold of methanogens (Table 2). This results in the suppression of CH_4 production from H_2 plus CO_2. This suppression often (but not always) coincides with an increase of the soil redox potential that can be analyzed with a platinum electrode. The suppression basically depends on (*1*) the availability of nitrate, ferric iron, or sulfate and (*2*) the presence of active microorganisms able to reduce these oxidants.

Immediately after flooding of soil, H_2 partial pressures increase as a result of the onset of hydrolysis and fermentation. The relatively high H_2 partial pressures allow exergonic CH_4 production from H_2 plus CO_2 until nitrate reducers, iron reducers, and/or sulfate-reducers become active. These bacteria then decrease the H_2 partial pressure until methanogens become suppressed. Suppression of CH_4 production holds on until nitrate, ferric

Table 2. Standard Gibbs Free Energy Changes and Thresholds of H_2-Utilization in Anaerobic Microbes Using Different Inorganic Electron Acceptors

Microorganisms	$\Delta G^{o'}$ (kJ $mol^{-1}H_2$)	H_2 threshold (Pa)
Homoacetogens	−24	43–95
Methanogens	−33	2.5–10.0
Sulfate-reducers	−38	0.8–1.9
Iron reducers	−95	0.05
Nitrate reducers[a]	−150	0.02–0.03

Note:

iron, and sulfate are depleted. Then, H_2 partial pressures increase again and methanogenesis resumes (59,283).

A similar chain of events takes place after intermittent drainage (209) or when nitrate, ferric iron, or sulfate is added to the flooded soil (284). The bacteria-reducing nitrate, ferric iron, or sulfate can also successfully compete with methanogens for acetate and thus suppress acetotrophic methanogenesis (42,114,208,285). The suppressive effect of the oxidants is partially alleviated when degradable organic matter is in excess (284). However, nitrate reducers also compete with fermenting bacteria for sugars (285). Indeed, nitrate fertilization effectively decreased the concentration of dissolved organic carbon and eventually the concentration of dissolved CH_4 and the rate of CH_4 emission (286). During the reduction process, nitrate reducers produce nitrite, N_2O, and NO as transient intermediates, which exert a toxic effect on the methanogenic archaea in addition to competition (245,287,288).

Competition between methanogens and bacteria-reducing nitrate, ferric iron, and/or sulfate certainly also takes place in the rhizosphere of vegetated soil, where nitrate, ferric iron, and sulfate are more or less continuously recycled (Figs. 3 and 4). This recycling of oxidants explains why single additions of Fe or S to irrigated rice can result in rather strong suppression of CH_4 emission that is much larger than expected from the stoichiometry between its reduction and CH_4 production (34,63,120,289–291). Addition of Fe is especially effective because little is assimilated by the plants, lost to the floodwater, or removed by pyrite formation. Effective suppression of CH_4 production by iron has also been observed in vegetated littoral soils (292). In contrast, nitrate is regenerated from ammonium but is released as gaseous product following denitrification. These losses must be compensated for by nitrogen fixation in natural wetlands and by fertilization in wetland agriculture (Fig. 4).

Aerobes

Little is known about the competition among aerobic organisms. An important example is that ammonium oxidizers compete for ammonium with the rice plant and with heterotrophic bacteria (293,294). Furthermore, methanotrophic bacteria are able to successfully compete for ammonium, accounting for most of the detectable ammonium oxidation (177,233). Competition for O_2 is also possible among ammonium oxidizers, nitrite oxidizers, CH_4 oxidizers, ferrous iron oxidizers (Fig. 4), and all the other aerobic organisms, and even with O_2-consuming chemical reactions. Nitrate may be assimilated by the rice plant or reduced by bacteria.

Besides competition, the role of predation, parasitism, and disease in controlling populations and stabilizing the coexistence between potential competitors should not be overlooked, but little is known for flooded soils (294,295).

INTERACTION BETWEEN MICROORGANISMS AND PLANTS

Besides serving as a habitat for microorganisms, there are also more intense interactions between rice plant and microorganisms, the economically most important one being symbiotic N_2 fixation (296). Strains of *Azoarcus*, a nitrogen-fixing genus belonging to the *β-Proteobacteria*, are able to colonize rice roots endophytically (297,298). Bacteria invade the roots, colonize the cortex, and penetrate deeply into the vascular system, allowing systemic spreading into the rice shoot. *Azoarcus* cells inside roots of rice seedlings express nitrogenase, making this bacterium to a possible source of plant-available nitrogen. *Burkholderia vietnamiensis* is a root associate that has a high nitrogen-fixing potential, too. The exact interaction with the rice plant is notknown, but inoculation with a certain strain of this bacterium increased grain yield by 13 to 22% (299).

CONCLUSION

The microbiology of flooded soils is characterized by a large functional diversity that is seen in the numerous microbial phenotypes that occur in this ecosystem (Table 1). This functional diversity is mainly due to the many different ecological niches created by gradients between oxic-anoxic and substrate-rich–substrate-poor zones in the soil. These gradients are created by the limitation of the O_2 transport from the atmosphere into the soil because of slow diffusion and microbial respiration and by the deposition of organic matter into the soil by root exudation and decay of plant debris (Fig. 1). This situation results in element cycling between oxidized and reduced states within the ecosystem occurring in the soil on a microscale. The cycles of iron and sulfur are more or less closed and are driven by the reduction of O_2 and the oxidation of organic matter to CO_2 (Fig. 3). Nitrogen cycling leads to losses caused by denitrification that must be compensated for by microbial N_2 fixation or fertilization (Fig. 4). Because of O_2 limitation, part of the organic matter is disproportionated to CO_2 and CH_4, the emission of the later being of great significance for the atmospheric CH_4 budget. The relative ratio of the CH_4 : CO_2 produced and emitted matters a lot as CH_4 is a much more powerful greenhouse gas than CO_2 is. This relative ratio of CH_4 : CO_2 produced is the result of the complex microbiology of flooded soils.

The first articles describing the use of fluorescent in situ hybridization (FISH) for the analysis of bacteria were published in 1989 (1) and in the early 1990s (2–5), and since then the technique has become increasingly widely used (6,7 and references therein). Using the "mosaic" sequence structure of small and large subunit ribosomal RNA, FISH has enabled the targeting and enumeration of specific microbial populations in a enormous variety of different ecosystems, just a few examples of which are soil (8–10), hot springs (11,12), the rumen (13), aquatic environments (14,15,16), and activated sludge (17,18,19,20). Moreover, recent technological developments have included the combined use of FISH with microautotadiography (21) and with microelectrode measurements (22).

This article focuses on the practical applications of this technique ranging from the initial nucleic acid database related probe design through sample preparation, hybridization, microscopy (including conventional epiflourescence and laser-scanning confocal microscopy), and finally image analysis and interpretation. Also included is a discussion of how recent technological advances have resulted in the broadening of the methodology to many different applications. The pros and cons of the technical aspects of FISH are discussed. In doing so, we will also cover the molecular approaches required for the in situ analysis of ribosomal RNA, messenger RNA, functional genes, and proteins.

TECHNICAL BACKGROUND

Nucleic Acid Databases and Probe Design

The exponential increase in the quantity and availability of sequence information, together with the availability of supporting software on the internet, and the ability to rapidly synthesize DNA oligonucleotides has revolutionized the design and use of DNA hybridization probes. The main source of nucleic acid sequence data is the European Bioinformatics Institute (EBI) database (23), which in collaboration with the DNA Database of Japan (Mishima) and Genbank, NCBI, Bethesda, Maryland (24), maintains and distributes the EMBL Nucleotide Sequence Database (25). There are also databases that specialize in phylogenetic sequence information, such as the Ribosomal Database Project (RDP) (26) and ARB (27). These contain extensive sequence information for the small subunit (SSU) ribosomal RNA (rRNA) genes of microorganisms and to a lesser extent the large subunit (LSU) genes of microorganisms.

In a move toward an integrated center for microbial data, the Ribosomal Database Project is now hosted by the Center for Microbial Ecology at Michigan State University. This Integrated Microbial Database (IMD), which is accessible through the World Wide Web, contains up-to-date phylogeny and taxonomy, gene sequences (including genomes), biochemical, ecological and phenotypic data, and metabolic models (28).

In addition to the sequence data, some of these databases also provide supportive software from alignment editors for phylogenetic analysis. The RDP offers various software programs for handling, analyzing and displaying alignments, and trees. It is also possible to check the phylogenetic groups that putative rRNA-targeted oligonucleotide DNA probes complement. ARB

has a probe design function where rRNA-targeted oligonucleotide probes can be designed at any taxonomic level chosen within a phylogenetic tree. The oligonucleotide probe database is a resource designed to unify oligonucleotide-probe nomenclature and as a record for probe submission following publication. Many of the probe sequences available on this site have been used for fluorescent-labeling and whole-cell hybridization (29).

The procedure for developing a 16S or 23S rRNA probe for a species or genus of bacteria can be conveniently laid out in the following format:

- Comparison of target organism sequences by computer alignment
- Identification of a target sequence (usually 12–25 oligomers in length) that is unique for the taxanomic group of interest
- Chemical synthesis of complementary nucleic acid probes
- Attachment of fluorescent label to the 5′ end of oligonucleotide
- Experimental evaluation of the probe to determine practical specificity of probe. Differences in the secondary and tertiary structure of both the SSU and LSU rRNA molecule may result in steric hindrance that prevents effective probe binding. This can be even more of a problem when fluorescent labels with a large molecular weight are attached to the probe.

Fluorescent Labels and Attachment to Probe

Fluorescent dye molecules are attached to the 5′ end of an oligonucleotide via an aminohexyl linker molecule. Among the most frequently used dyes are fluorescein isothiocyanate (FITC), tetramethylrhodamine 5-isothiocyanate (TRITC), Texas Red, and the hydrophilic sulfoindocyanine dyes CY3, CY5, and CY7. Also used are bodipy complexes and coumarin-phalloidin. Absorption max, extinction coefficients, and emission wavelengths are shown in Table 1. Conveniently, oligonucleotide probes can be obtained prelabeled from the supplier, however, manufacturers will also provide "easy-to-use" labeling kits.

Such fluorescently monolabeled probes might fail to detect cells with small numbers of ribosomes. One or a combination of the following approaches can be adopted to improve fluorescence, thereby improving sensitivity:

Table 1. Spectroscopic Properties of Selected Fluorophores

Fluorophore	Absorption Max	Extinction Coeff.	Emission Max
Fluorescein	490	67	520
Tetramethyl rhodamine	554	85	573
Texas Red	596	85	620
CY 3.18 amine	554	130	568
CY 5.18 amine	652	200	672
CY 7.18 amine	755	200	778
Bodipy	500–581	80	510–591
Coumarin-phalloidin	387		470

indirect-labeling, the use of more sensitive labels, or multiple labeling. The rational behind indirect-labeling is that rather than directly attaching a fluorescent molecule to the oligonucleotide probe, a reporter molecule is attached. Following hybridization, this reporter is detected in a single step by a labeled binding protein. Reporter molecules include digoxigenin or biotin (30). Biotin-labeled rRNA-targeted oligonucleotides have been used to detect *Pneumocystis carinii* in lung sections with alkaline phosphatase-labeled streptavidin (4).

It is also possible to detect whole-cells with oligonucleotides that are covalently linked to enzymes, such as horseradish peroxidase, a more sensitive label. Compared to using FISH with probes labeled directly with fluorochrome, the use of horseradish peroxidase (HRP)-labeled probes followed by treatment with fluorescent tyramide was recently reported to increase the sensitivity of FISH by a magnitude of 10 to 20 (31). One potential restriction of the use of HRP is adequate permeabilization of bacterial cell walls because HRP is a high molecular mass enzyme with a molecular mass of 44 kDa, whereas fluorescein has a molecular mass of only 330 Da. For the HRP to enter bacteria, they must first be permeabilized with cell wall degrading enzymes, for example, lysozyme. This is particularly important for gram-positive bacteria because of their thick cell walls.

The requirement for permeabilization is considered a real problem for the characterization of complex bacterial communities most frequently encountered in environmental microbiology (31). Interestingly, the nonpermeability of bacterial cells to large HRP labeled-probes has been exploited to estimate the condition of bacterial cell walls (32). The rationale behind this approach was that the expression of intracellular, peptidoglycan-hydrolysing enzymes like autolysins would permeabilize the cell wall, making cells detectable by FISH. As a result, intact cells would not be labeled, whereas those with damaged walls would be. The effect of phage infection on the ability of the gram-positive bacterium *Lactococcus lactis* to hybridize to a general eubacterial HRP-labeled 16S rRNA-targeted probe (6) was used as a model. The results indicated that the application of FISH with HRP-labeled probes was a sensitive method for determining the state of bacterial cell walls. The relevance to the complex samples often encountered in environmental microbiology is likely to remain restricted until the problem of permeabilization is fully addressed.

There have also been several attempts to increase the sensitivity of whole-cell hybridization by directing multiple fluorescent labels to one ribosome (33). Using several monolabeled oligonucleotides to different target sites on the rRNA molecule more fluorescence is directed to the target cells. However, the application of this methodology is restricted by the limited availability of target sites with identical specificity.

Sample Preparation and Physical Sectioning for Whole-Cell Hybridization

Pure cultures, mixed cultures of bacteria grown in liquid media, or environmental samples for which the investigator does not require preservation of a three-dimensional

structure can be placed directly on a microscope slide for subsequent whole-cell hybridization. However, most environmental samples are not homogenous solutions, and preservation of structure and spatial relationships are required for a true in situ analysis. To process environmental samples, usually some pretreatment is required, the extent of which will reflect the robustness of the sample being processed.

An example of resilient structures that have been investigated using whole-cell hybridization are the sludge granules involved in the breakdown of waste organic matter (34,35). These samples are so rigid that they maintain their structure during the fixing process, with the granules washed in phosphate-buffered saline, and allowed to settle naturally before the fixation process. Less resilient samples such as feces, rumen fluid, or plant roots may first be set in an agarose gel before the embedding processes are carried out. To set the fixed mixture in agarose, the suspension is warmed to 37 °C and mixed in equal proportions with a 2% solution of agarose in phosphate-buffered saline cooled to 45 °C. The mixture is then rapidly cooled on ice. The fixation procedure is then performed as documented below. The core stages for the processes of sample preparation and physical sectioning for fluorescent in situ hybridization are: fixation, dehydration, embedding, sectioning, mounting, and washing. Each of these will be discussed in detail in the following section.

Fixation. For any successful whole cell hybridization, it is first necessary to achieve sufficient penetration of the cell membrane via a permeabilization and/or fixation step. When characterizing the microbial populations/activity in a specific environment, it is advisable to fix the samples on-site, thereby gaining a truer "snapshot" of the microbial population in situ. Fixation techniques have not changed substantially over the 10 or so years since they were first introduced for environmental applications (1,5). However, these techniques do have limitations, with the failure to permeabilize many gram-positive cells being well documented (8,20,36). As a consequence, a number of different permeabilization pretreatments have been developed including exposure to: xylene (37), lysozyme (8,38) diethyl ether (39), hydrochloric acid (36), and lipase (20). However, it should also be noted that these permeabilization techniques that may be necessary for laboratory cultured bacteria are often not required for the same organisms when analyzed in situ. Permeabilization of cultured *Streptomyces scabies* necessitated a lysozyme pretreatment, whereas the cells were easily detected via the regular 4% paraformaldehyde fixation with no pretreatment in soil (8). Similarly, a mild acid permeabilization step was required for detection of cultured actinomycetes (36), a treatment that proved unnecessary when for the successful hybridization of the same bacteria located on a root surface (9).

The fixation procedure detailed in the next section is applicable to a wide range of environments. Samples are collected and suspended in a paraformaldehyde-based fixative and left for approximately six hours at 4 °C. To prepare the fixative 33 ml H_2O of water is placed in a 150 ml flask and heated to 60 °C, one drop of 10 M sodium hydroxide solution is added, followed by 2 g of paraformaldehyde, then 16.5 ml of triple-concentrated phosphate-buffered saline is added. The pH is adjusted to 7.2, and the solution filtered through a 0.45-μm filter. This is stored on ice and should be used within 24 hours. The fixed sample is then washed in phosphate-buffered saline (PBS 0.13 M NaCl, 10 mM NaH_2PO_4, pH 7.2) to remove the paraformaldehyde that autofluoresces at many of the wavelengths used for whole-cell hybridization microscopy. At this point, samples can be stored in a 1 : 1 (v/v) mixture of phosphate buffer and ethanol at −20 °C.

Dehydration and Embedding. Where preservation of the three-dimensional structure is not required, a sample can be placed directly onto a gelatin-coated microscope slide precleaned in potassium hydroxide in 95% ethanol, then immersed (5 × 1 min) in hot distilled water containing gelatin (0.1% w/v) and $KCr(SO_4)_2$ (0.01% w/v), then dehydrated through ethanol or water baths (5 min in 50 : 50 v/v, then 80 : 20 v/v, and finally 96 : 4 v/v). The dehydrated sample is then ready for FISH. When preservation of the three-dimensional structure is required, the sample on the microscope slides is then dehydrated using ethanol and xylene baths. Subsequently, the sample is embedded in melted paraffin wax.

Sectioning. Each sample is then sectioned into a specified thickness ranging from 2 to 10 μm using a rotary microtome, the thickness of the sample depending on the subsequent microscopic approach. This is considered in the next section.

Mounting and Washing. Each section is placed on a gelatin coated microscope slide. The paraffin wax is removed by sequential washes in xylene and alcohol baths, starting with 100% xylene and ending with 100% ethanol to remove the xylene. Once they have been air-dried, the sections on the slides are ready for hybridization.

The main advantage of thin sections (1–3 μm) is the small cross section the light transverses, reducing the amount of light scattering from out-of-focus images originating from sample material above and below the plane of focus. One disadvantage of sectioning is that the three-dimensional reconstruction requires that each individual slice needs to be bought into focus. An alternative approach is to prepare thicker sections, however, this increases the amount of light scattering, although with the growing use of confocal laser scanning microscopy (CLSM), optical sectioning is rapidly becoming established as an alternative to such physical sectioning.

Hybridization Techniques

Once the sample has been physically fixed onto a microscope slide and prepared for hybridization, it is ready for the addition of the fluorescent-labeled oligonucleotide probe. The first stage in this procedure is the creation of an area around the sample on the slide that will maintain it in contact with the hybridization buffer and probes. Slides with indentations can be used for hybridization, and in this case the sample is placed in the indentation and

no further preparation is required. However, if ordinary slides are used, a wax ring can be placed around the sample. A test tube or similar object of a suitable diameter is warmed in a flame, dipped in wax, and then the wax end of the tube used to form a ring surrounding the sample on the slide. The subsequent stages in this procedure are presented below:

Hybridization. To each well is added 9 μl of hybridization solution (20–40% formamide (Table 2), 0.9 M sodium chloride, 0.1% sodium dodecyl sulfate, 100 mM Tris (pH 7.2)) and 1 μl of probe (25–50 ng μl^{-1}). This is mixed gently with a pipette tip to evenly distribute the probe taking care not to scratch the surface of the sample. An alternative means of ensuring even distribution of the probe for multiple hybridizations is to prepare a master mix of hybridization solution and probe. The concentration of formamide is varied depending on the temperature of dissociation (Td) of the probe used in the hybridization (Table 2). This is left overnight at 37 °C in a screw cap plastic tube (50 ml volume) placed horizontally in a hybridization oven with tissue paper soaked in distilled water to prevent evaporation of buffer.

Washing. The hybridization fluid is removed with a quick rinse in 25 μl double-distilled water. This is followed by a wash in wash solution I (20–40% formamide, 0.9 M sodium chloride, 0.1% sodium dodecyl sulfate, and 100 mM Tris (pH 7.2)) for 20 min at 37 °C. Wash solution I is removed with a pipette and wash solution II is added (0.9 M sodium chloride and 100 mM Tris (pH 7.2)) for 15 minutes at 37 °C. Finally, the well containing the sample is rinsed in distilled water for 10 minutes at room temperature and left to air-dry in the dark. At this point, samples can be stored dry and away from light until analysis by fluorescence microscopy.

Mounting. Before fluorescence microscopy, to retard bleaching, it is advisable to mount the sample using an antifadent. These are supplied by a number of manufacturers and include, for example, Citifluor™ (Citifluor Ltd., U.K.) and "Slowfade®" (Molecular probes, Inc, U.S.A.).

Microscopy

Conventional Epifluorescence. Fluorescence is the emission of light from a molecule in which an electronically excited state has been produced (40). Specifically, when light strikes a molecule capable of fluorescence, a quantum of light is absorbed by that molecule (in $\sim 10^{-15}$ seconds), electrons are raised to a higher excited state, and energy in the lowest vibrational state is rapidly dissipated with the lowest vibrational level of the excited singlet state obtained. The electron returns to the ground electronic state with the emission of energy (fluorescence) (41). The reemission of light is usually at a higher wavelength (Stokes fluorescence) than the initial excitation wavelength. Any fluorescent molecule will have two characteristic spectra, excitation (the relative efficiency of different wavelengths of exciting radiation that cause fluorescence) and emission (the relative intensity of radiation emitted at various wavelengths) (41). Any portion of such a spectrum where absorption occurs can produce a fluorescent light, which will be the same irrespective of the excitation wavelength; however, the fluorescence intensity will vary with the relative strength of the absorption (41).

Table 2. Concentration of Formamide Included in Hybridization Fluid in Relation to the Calculated or Experimentally Determined Td of the Oligonucleotide Probe

Formamide (% w/v)	20	25	30	40	45	50
Td of probe (◦C)	20	25	30	40	45	50
Volume of reagents	μl	μl	μl	μl	μl	μl
Sodium chloride (5 M) (μl)	180	180	180	180	180	180
Tris Cl. (1 M, pH 7.2)	100	100	100	100	100	100
Formamide	200	250	300	400	450	500
SDS (100 gl^{-1})	10	10	10	10	10	10
Distilled water	510	460	410	310	260	210

Fluorescent in situ hybridization utilizes fluorophores (fluorescent light-emitting molecules) tagged onto oligonucleotide probes. In epifluorescence microscopy, the fluorophore is illuminated by the light source, usually a mercury high-pressure lamp, the light from which passes though a excitation wavelength filter, and is then directed through the objective lens by a dichroic mirror onto the sample (Fig. 1a). Light emitted by the fluorophore is then collected by the same objective lens and picked up by the eyepiece or camera. This can be done using either upright or inverted microscopes. A principal advantage of using the inverted microscope is that it provides a stable platform for complementary physiological studies (42).

Before sample analysis using epiflourescence microscopy, it is recommended that the user locates the sample using transmitted or phase-contrast light microscopy. In this way, any excess photobleaching of the samples as a result of overexposure to fluorescent light will be avoided, and the likelihood of successful location of any probed bacteria will be maximized. Images from conventional epifluorescent microscopes can be captured on film with exposure dictated either by the user or by the fluorescence intensity. Examples of such images are presented in Figures 2 and 3. To maximize detection of fluorescence, a charge coupled device (CCD) camera can be used. A CCD is a light-sensitive silicon solid state device composed of many small pixels. The light falling on a pixel is converted into a charge pulse. The output gate of the CCD can either be connected to an analog to digital converter, to digitize the picture, or can provide a standard video signal that can be captured. The computer-reconstructed digitized images are easy to store in the computer memory before any application of image analysis software.

As a less disruptive alternative to thin sectioning, thicker sections can be used for the analysis of the in situ hybridization. When this approach is taken, submicron images of sections are reassembled to reconstruct the biological structure using image analysis software. This reconstruction is called volume rendering (43). This converts a serial collection of image sections into a 3-dimensional representation called the image stack. These stacks can be rotated or spliced to study the structure

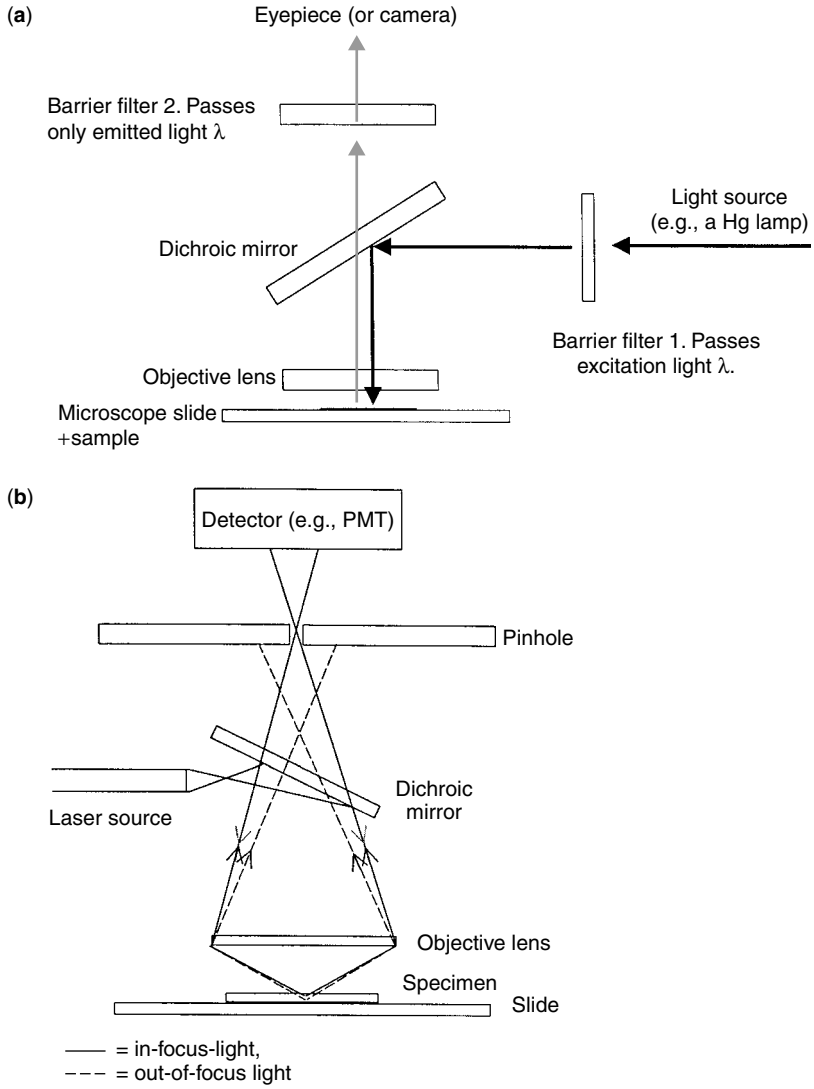

Figure 1. Schematic of (**a**) the optical system in an upright epifluorescence microscope, (**b**) the confocal laser scanning microscopy CLSM.

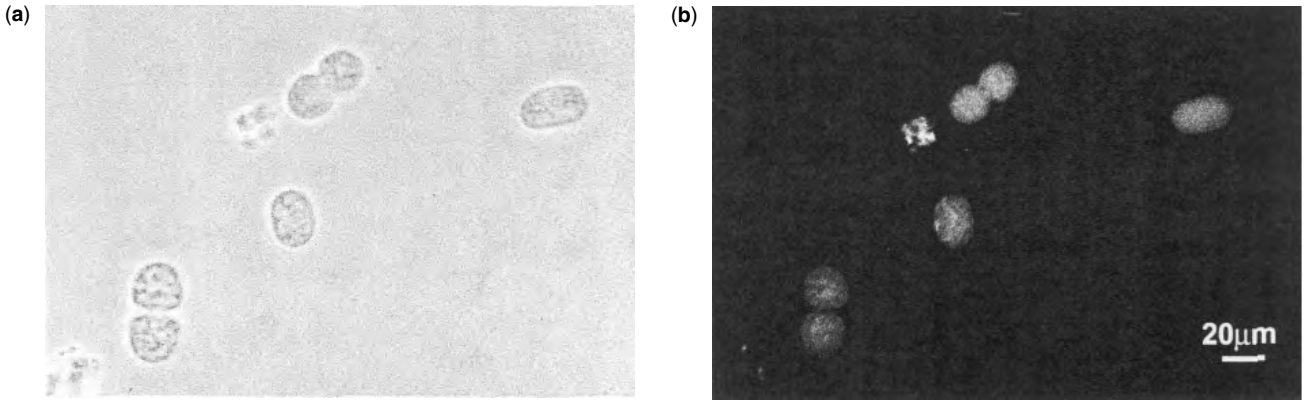

Figure 2. *Achromacia* sp. probed with fluorescently labelled 16S rRNA-targeted oligonucleotide probes visualized using conventional epifluorescence microscopy. of the biological sample. The files for these stacks are cumbersome, however, that is less of a problem with constant advances in computer hardware. Image analysis software has been written for Macintosh, MS-DOS, UNIX workstations, and Silicon Graphics computers (SGI). A list of image analysis software available for public use is available from NIH Image (National Institute of Health, Bethesdam, MD, U.S.A.).

Confocal Microscopy

The introduction of confocal laser scanning microscopy (CLSM) has provided for significant advances in successful utilization of FISH. Increasingly widely used, CLSM has resulted in vastly improved resolution and three-dimensional image analysis. As with conventional epiflourescence microscopy, the use of an antifadant is recommended for mounting FISH samples.

With epifluorescence microscopy, the image obtained from a thick sample is blurred because of out-of-focus fluorescence. In common with conventional epifluorescence, CLSM uses reflected rather than transmitted light; moreover, sample thickness has less effect on the ability to obtain high-resolution images. CLSM enables the researcher to scan through a sample resulting in thin, nonblurry section images (44). Figure 1b shows a schematic of the basic CLSM set up. Argon or Krypton Argon lasers are most commonly used for FISH, covering as they do a broad range of emission lines. Unlike conventional epifluorescence microscopy, a single point of excitation light is scanned across the specimen in CLSM. With only a single point illuminated at any moment, the illumination intensity falls off above and below the plane of focus, thereby reducing the excitation of fluorescence of out-of-focus sample. The fluorescent light then passes back though the dichroic mirror and passes through a pinhole aperture situated in a conjugate focal plane to the sample. Any light emitting from above or below the focal plane will not pass though the pinhole, resulting in a further removal of any out-of-focus fluorescence. The light that passes though the pinhole is then detected by a photomultiplier tube (PMT). Sample scanning (in X, Y, and Z directions) is controlled by use of computers, which also control the image assembly and display functions. It is the Z-scan function (the optical sectioning function) that enables creation of three-dimensional images.

To produce a 3D image, the upper and lower limits of the sample fluorescence can be set manually, following which the section thickness and the number of sections to be scanned are decided. The depth of sections is dictated by the numerical aperture and magnification of the lens used and by the thickness of the sample. The images are then collected from each section (for e.g., on the Leica TCS-NT CLSM the galvanometer driven Z-stage is able to move at a minimum of 10-nm steps though a sample), thereby providing a set of optical sections that can be viewed either as a tableau of images or projected as a three-dimensional image (Fig. 4). Following Z sectioning, the CLSM also enables production of images through the ZX plane. A CLSM system will be coupled to a conventional epifluorescence microscope, enabling the researcher to locate and roughly focus the CLSM on the sample under investigation, before CLSM analysis.

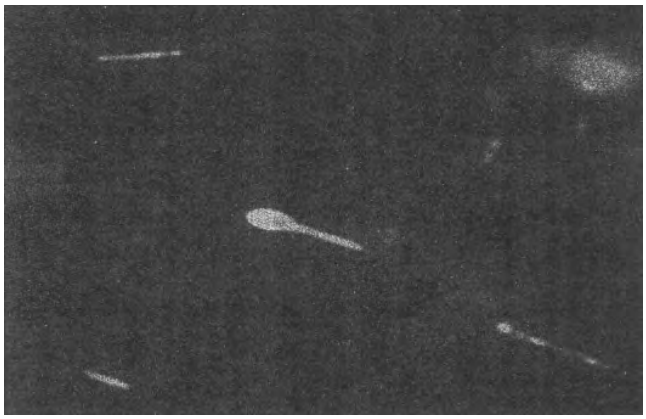

Figure 3. A fecal sample probed with a Fluorescein isothiocyanate-labelled oligonucleotide probe specific for the bifidobacteria genus (S-G-Bif-164-a-A-17) (29) visualized using conventional epifluorescence microscopy. (Dr. G. W. Welling, University of Groningen, The Netherlands). See color insert.

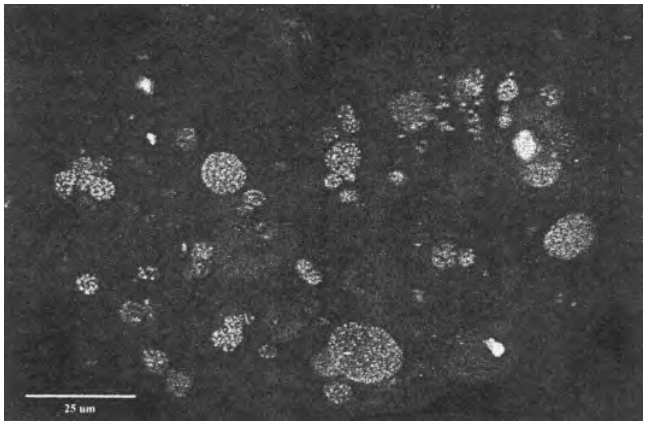

Figure 4. A reconstructed confocal image of an activated sludge floc labelled with fluorescien labelled Nso 1225 (S-*-Ntros-1225-a-A-20) (29) visualized using confocal laser-scanning microscopy (CLSM). (Dr. G. Coskunner and Dr. T. Curtis, The University of Newcastle upon Tyne). See color insert.

Pros and Cons of FISH

Problems associated with the use of FISH can be conveniently broken down into two main areas. First are those directly related to the application of the rRNA analysis in microbial ecology, and to the development of the appropriate oligonucleotide probes. Second are the methodological issues relating to the application of the technology with environmental samples. Although there are extensive databases containing the rRNA gene sequences for several thousand prokaryotes (5S, 16S, and 23S sequences), important weaknesses associated with successful application of FISH lie in this most fundamental area. The difficulties associated with the use of the polymerase chain reaction (PCR) to recover rDNA sequences from complex mixed environmental samples have been well documented (45,46,47). Among these are

chimera formation and the fact that the current database represents only a very small fraction of the extant diversity, therefore limiting primer choice. Chimeric rDNA sequences are formed when a PCR reaction combines two or more sequences derived from different bacteria into one product that is then reamplified throughout the remaining PCR. The probability of chimeric sequences forming is increased when the template DNA used for PCR is very fragmented, resulting in partial length rDNA fragments. Premature termination of elongation during PCR will also have the same effect. Using high-molecular weight, DNA as template has been found to produce chimeric clones at the rate of about 2% (2 out of 113) (45). Chimeras can be detected by performing comparative sequence analysis on different regions of the rDNA sequence. The ribosomal database project at the Center for Microbial Ecology provides an on line chimera check program (26).

Another disadvantage of the direct analysis of rDNA is that the DNA of minor members of the microbiota or of organisms that are recalcitrant to release their DNA using conventional DNA extraction techniques are unlikely to be detected by PCR using universal- or domain-specific rDNA-targeted primers. However, the retrieval of less common sequences can be facilitated using more taxonomically specific PCR primers for PCR amplification. These problems of accurate sequence retrieval for a comprehensive range of microorganisms have serious implications for the design of accurate rRNA-targeted fluorescent probes. Probe design on the basis of incomplete sequence information results in the likelihood that bacteria comprising substantial proportions of the microbial community will not be detected using FISH.

Second, in addition to the limitations to the PCR technique that can result in inaccurate sequence retrieval not reflective of the extant microbial community, there are other more specific methodological problems associated with FISH. Low-fluorescent signal intensity is frequently encountered during in situ hybridization. Such low intensity can be caused by a number of factors including: low ribosome number, low organism number, and insufficient accessibility of the target rRNA molecules.

The correlation between cellular ribosome concentration and bacterial growth rate was a key discovery of microbial physiology (48). In principle, this idea can be applied to environmental samples. Probe-conferred fluorescence should correspond to bacterial numbers and for single cells it should correspond to cell ribosome content and, by inference, to single cell activity. However, there is limited published data relating change in ribosome abundance to growth rate for environmentally isolated bacteria (49).

Problems with target accessibility are usually either related to limited cell wall probe accessibility (common in gram positive bacteria, see permeabilization section) or interference through the tertiary structure of the ribosomes. The problem of restricted accessibility because of the tertiary structure of ribosomes can be reduced by the inclusion of formamide to the hybridization buffer. Formamide is a solvent that weakens the effects of hydrogen bonds. Although the higher-order structure of ribosomes is well known, there is a great deal of variation between taxanomic groups, with some regions inaccessible in some groups, indeed shifting the target site just a few nucleotides can dramatically increase the signal (6).

MOLECULAR APPROACHES TO IN SITU ANALYSES

Ribosomal RNA-Targeted Oligonucleotide Probes

Background. The high abundance of ribosomes has ensured that rRNA is the most commonly used target for fluorescently labeled probes. Moreover, targeting of particular regions of the rRNA sequence enables phylogenetic specificity to be varied from the universal to the subspecies level (1,50,51,52). The genes that code for rRNAs (5S-, 16S-, and 23S-) are also very highly conserved. Regions of the molecule have remained sufficiently conserved through evolution to permit probe design for the three domains, whereas the more variable regions allow for discrimination between genera, species, and even individual strains. The 5S rRNA molecule (approximately 120 nucleotides) provides relatively little sequence information and is therefore of less value in the study of phylogenetic relationships and probe design. The larger 16S molecule provides more sequence information and is the most widely used for FISH. The 23S rRNA molecule (approximately 3000 nucleotides) contains twice as much information as 16S rRNA, however, it is used less frequently for probe design, but has been of value in resolving phylogenetic relationships between microorganisms that have proved to be closely related in terms of their 16S rRNA (53).

There are two different ways to use phylogenetically based oligonucleotide probes for investigating microbial populations. Firstly, quantification of a certain SSU rRNA compared with total SSU rRNA can be obtained by slot-blot hybridizations of a directly isolated mixture of RNAs (tRNA, LSU rRNA, SSU rRNA, and mRNA) with SSU rRNA-targeted oligonucleotide probes specific for the taxonomic group of interest and a universal probe. The relative abundance is calculated by dividing the amount of a specific probe bound to a given sample by the amount of hybridized universal probe. This approach was first used to determine the relative abundance of cellulose-degrading populations of the bovine rumen (54). Subsequently, this technique has been used to determine the abundance of several rumen bacterial populations (55), methanogens in bioreactors (56), microbial mat communities (57), and predominant microbial populations in human feces (58).

Second, to visualize intact organisms within their environment, whole-cell FISH is used. Analysis at this single-cell level provides a more detailed picture than does slot-blot hybridization. This microscopic identification of single cells was first performed with radioactively labeled oligonucleotide probes (59). These have been largely superseded by the use of fluorescent labels that can be instantaneously detected by epifluorescent microscopy.

Fluorescently labeled rRNA-targeted oligonucleotide probes allow the detection of individual cells that makes them a suitable tool for determinative, phylogenetic, and environmental studies in microbiology. This technique is now commonly used for analysis of a diverse

range of environmental microbial populations, such as leaf surfaces (52), sludge granules (35,60), nitrifying bioreactors (61), full-scale biofilters (62), mixed-culture biofilms (63), ruminal bacteria (64), and cricket hindguts (65).

The Use of rRNA-Targeted Probes to Identify Unculturable Organisms

An important caveat to this technology is the in situ identification of previously unidentifiable populations. The restricted number of morphological types or lack of distinct morphological features often limits in situ identification of different organisms in mixed communities. The general description rod-shaped anaerobe, potentially encompasses several thousand bacterial species. This together with the problems of isolating many prokaryotes in pure culture for identification purposes explains why FISH has become such a popular and important tool in environmental microbiology for the direct identification of organisms. As an example, members of the species *Xanthomonas* are important in environmental microbiology, in phytopathology, and in human pathogenesis. Members of this genus are difficult to identify, especially if the origin of the isolates is uncommon (62,66). In comparison to time-consuming methods based on isolation techniques, in situ hybridization has facilitated identification procedures. In a study of biofilters, the dominant bacterial populations identified in full-scale bioreactors and laboratory-scale biofilters were members of the *Xanthomonas* branch of the class *Proteobacteria*, which forms a monophyletic cluster close to the root of the γ-*Proteobacteria* (62). Previously designed probes that are specific for the γ-*Proteobacteria* did not give a positive FISH signal when hybridized with many of the *Xanthomonas* isolates found in the bioreactor samples, indeed none of the 18 tested representatives hybridized with these probes. This indicated that they were new species not previously isolated. Therefore, to allow in situ identification of these bacteria and quantification new probes had to be designed based on new SSU rDNA gene sequences of the new isolates. The new *Xanthomonas*-specific probe presented was an efficient tool for detecting species of *Xanthomonas* in subsequent bioreactor studies and for identifying potential phytopathogens.

The Use of rRNA-Targeted Probes to Study the Spatial and Temporal Relationships of Organisms

In addition to the identification of microbes in situ described in the previous section, FISH is increasingly used in environmental microbiology to study spatial and temporal relationships both within a single population and in mixed populations. In studies of spatial relationships great care must be taken when sampling to minimize disturbance of the microbial populations. This is probably one of the most critical and limiting factors to consider, rather than the microscopy of such samples where that introduction of CLSM has simplified and improved the analysis enormously. Particularly resilient structures that have been investigated in this way are the sludge granules involved in the breakdown of waste organic matter (35,60). The anaerobic degradation of organic matter leads to the intermediate formation of alcohols and fatty acids. The subsequent oxidation of these products under methanogenic conditions is coupled to proton reduction and can only proceed at low-hydrogen partial pressures and low formate concentrations. A low concentration of these metabolic intermediates is maintained by interspecies hydrogen transfer of hydrogen or formate between synthrophic consortia of bacteria. This complex metabolic relationship between different trophic levels of organisms requires a precise spatial organization of the microorganisms, usually the inner layer is composed of methanogens and the outer layer is comprised of fermentative bacteria (67). Additionally, the syntrophic bacteria are in a close juxtaposition with the methanogens.

The beginning of an understanding of how these sludge granules function to breakdown organic matter has been achieved through a combination of FISH and immunohistochemical techniques (68). However, the mosaic of microbes within the granules still requires extensive studies, particularly in relation to the location of bacteria at the genus and species level. A study on mesophilic and thermophilic sludge granules combined FISH with confocal-laser scanning microscope to elucidate the spatial distribution of particular species of methanogens and bacteria that were previously detected by whole microbial community 16S ribosomal DNA (rDNA) cloning analysis (35). Probes were designed for a cluster of bacteria closely related to *Syntrophobacter* species and for a group of unidentified green non-sulfur bacteria. Using these probes, the *Syntrophobacter* species hybridized with cells in the inner layer of the mesophilic sludge granules, whereas the unidentified green non-sulfur bacteria were found to be filamentous cells in the outermost layer of the thermophillic sludge granule sections.

Messenger RNA-Targeted Oligonucleotide Probes and Structure-Function Relationships

An important factor in understanding community level processes is the relationship between structure and function in microbial communities. Therefore, an obvious progression from the detection and visualization of organisms in their environment using fluorescently-labeled rRNA-targeted oligonucleotides described so far, is to determine the metabolic function of organisms in situ. Previous attempts to address this problem have been by a number of means, for example, the metabolic role of unculturable bacteria has been inferred from the spatial location of particular morphologies determined by in situ hybridization in the example described earlier. Another approach in environmental microbiology has been the use of microelectrodes to measure microbial processes. This approach has been of particular value in the study of sulfate-reducing bacteria in microbial mat communities (57). Here the distribution and abundance of sulfate-reducing bacteria and eukaryotes within the upper 4 mm of a cyanobacterial mat community were characterized using a combination of group-specific hybridization probes to measure ribosomal abundance and microelectrodes to determine dissolved-oxygen concentrations.

FISH has been successfully combined with microelectrode measurements to study the processes of sulfate

reduction in trickling filter biofilms (22) and nitrification in microbial flocs of a nitrifying fluidized bed reactor (69). Similarly, the use of microsensors for nitrate in combination with rRNA probes for ammonia- and nitrite-oxidizing bacteria showed that nitrification was restricted to the top layers of a trickling-filter biofilm. In these layers, ammonia and nitrite oxidizers were found in proximity to each other (69). The combination of the two methods provided reliable information relating in situ microbial activity and the occurrence of specific microorganisms in complex microbial consortia.

A more direct approach for studying the functional relationships of organisms in situ is to investigate the expression of particular genes. It is important to note that the information derived from rRNA-targeted oligonucleotide probes on the abundance of RNA for a particular population cannot be used as an indication of a specific kind of activity. Excepting members of a few highly physiologically restricted bacterial lineages, such as the ammonia oxidizers belonging to the β-proteobacteria, the apparent identification of a bacterial species in situ does not provide much information about its function in its habitat. Often, one population has the potential to catalyze different transformations, and one genotype is linked to several phenotypes. More importantly, one phenotype may be linked to several genotypes, for example, a wide range of genotypes of bacteria express cellulase enzymes. Additionally, just because a particular genotype is present in an environmental sample does not necessarily mean that it will be expressing a characteristic phenotype. Information regarding the phenotype of an organism is of more value than the actual abundance of the bacteria. A direct and sensitive means of studying the phenotype of bacteria is to study mRNA expression. Prokaryote synthesis of mRNA commits the bacteria to expression of the gene product. If there is sufficient sequence information, then probes can be designed for regions of the mRNA for particular gene products. These probes are then used to identify specific mRNAs in the pool of extracted mRNAs (70). A method for detecting RNAs in single bacterial cells by an in situ PCR has been developed (71).

It is important to note, however, that mRNA is incredibly labile and difficult to handle, particularly in environmental samples that are notoriously rich in nucleases. An alternative approach to mRNA detection is the use of genetic reporters, such as the *lux* or *lac* Z-genes. This approach has been used in a number of areas of environmental microbiology, such as the study of bacterial infection of root hairs (72), surface regulation of alginate production (73), and the monitoring of nitrogen or phosphate starvation (74).

An alternative strategy to studying structure–function relationships in bacteria is the use of radiolabeled substrates in combination with microautoradiography. This permits the analysis of the metabolic activity of prokaryotes under conditions that approach in situ conditions by direct visualization of microorganisms with active uptake systems within a complex community. To date a major limitation of microautoradiography has been an inability to correlate the activity detected with identification and detection of a responsible organism. However, the recent combination of microautoradiography with FISH performed with rRNA-targeted oligonucleotide probes permits simultaneous identification and determination of substrate uptake patterns of individual microbial cells within complex microbial consortia (21). This methodology was first evaluated by using defined artificial mixtures of *Escherichia coli* and *Herpetosiphon aurantiacus* with [^{3}H] glucose. Subsequently, this was used to visualize the uptake of organic [^{14}C] acetate and [^{14}C] butyrate) and inorganic [^{14}C] bicarbonate and [^{33}P] radiolabeled substrates in probe-defined populations from complex activated sludge microbial communities. In summary, this combined technology allows the direct analysis of the in vivo uptake of substrates by probe-identified microorganisms in environmental samples.

Fluorescent Proteins as Reporters for In Situ Gene Expression

Unfortunately reporter genes, such as the *lux* or *lac Z*-genes described earlier are not suitable for use in FISH, however, the successful cloning and heterologous expression of green fluorescent protein of *Aequorea victoria* (75) provided a suitable reporter for use with the FISH approach (63). Green fluorescent protein has become a useful tool for measuring and monitoring bacterial gene expression (76). The biggest potential application of this methodology in environmental microbiology is the monitoring of microorganisms exploited for bioremediation, biocontrol, and plant growth enhancement. This will be of particular value for genetically engineered microorganisms that potentially share their phylogeny with many existing environmental microorganisms and so cannot be differentiated with fluorescently labeled rRNA-targeted probes. An advantage of green fluorescent protein is that unlike other biomarkers, it does not require any substrate or additional cofactors in order to fluoresce. Single cells tagged with green fluorescent protein can easily be visualized by microscopy; normally a single copy integrated into the chromosome is sufficient for visualization of cells. It is the active component of a bacterial population that is the most important, because this is the fraction that exerts an effect on the environment.

Green fluorescent protein has been used in conjunction with FISH to study in situ gene expression in mixed-culture biofilms and to provide evidence of metabolic interactions between community members (63). In the biofilms, bacterial identity was determined by in situ hybridization with fluorescent labeled 16S rRNA targeted probes, while gene expression was simultaneously visualized using green fluorescent protein as a marker for the expression of enzymes involved in the catabolism of toluene. However, there are still problems with the use of green fluorescent protein. As discussed earlier not all the viable cells in a population are metabolically active and the green fluorescent protein phenotype does not indicate the metabolic status of the cells. Additionally, green fluorescent protein is a very stable protein, and therefore reflects the history of gene expression in the cell rather than expression at any one time.

An alternative marker protein for use in conjunction with FISH is β-glucuronidase. This is another promising

tool for ecological studies of biocontrol agents in soil-based environments such as the rhizosphere. It has been transformed into *Trichoderma harzianum*, a widely used biological control agent for soil-borne plant-pathogenis fungi (77). However, while there are many advantages to using this marker protein it does require an exogenous substrate that green fluorescent protein does not and some background activity of β-glucuronidase may be present in some systems.

CONCLUSION

The use of FISH with rRNA-targeted probes has evolved rapidly over the past decade from a technique to qualitatively identify microorganisms to one that provides answers concerning some of the more complex issues in environmental microbiology. With access to the appropriate microscope facilities, it is a simple and robust technique and has been and is being used in environmental microbiological laboratories the world over. Insights into the architecture of complex microbial communities are now being provided. Together with the use of marker proteins to signal particular gene expression and so relate structure to function, the opportunities for this technique in environmental microbiology are particularly valid.

FREE-LIVING AMEBAS PRESENT IN THE ENVIRONMENT CAN CAUSE MENINGOENCEPHALITIS IN HUMANS AND OTHER ANIMALS

F. L. Schuster

Members of the protozoon genera *Acanthamoeba*, *Naegleria*, and *Balamuthia* are free-living, nonparasitic amebas. Some are, however, capable of causing disease as

opportunistic pathogens in humans and other animals. *Acanthamoeba* and *Naegleria* have a wide distribution in soil and water and can be readily isolated from either of these sources. It is believed that *Balamuthia* amebas also share the same habitat as *Acanthamoeba* and *Naegleria* but have yet to be isolated from environmental samples. Since their recognition as potential human pathogens, these organisms have come to occupy an increasingly important place in the fields of environmental microbiology and clinical medicine. Although they share a similar ecological niche in nature, the amebas have different phylogenetic histories and taxonomic positions. Several comprehensive reviews of these organisms and their pathogenic potential have been published over the years (1–7).

The concept that *Acanthamoeba* and other small free-living amebas can cause disease in humans and other animals was suggested by the late Dr. Culbertson in the early 1960s. Culbertson and colleagues, while growing poliomyelitis virus in monkey kidney cell cultures for vaccine purposes, noticed cleared areas or plaques in the control cell cultures. The culture supernatant, when injected into experimental animals, caused death of the animals with typical symptoms of meningoencephalitis, such as ruffled fur, aimless wandering, coma, and death. Culbertson and coworkers isolated an ameba from the culture supernatant and brains of the dead and dying animals and designated it as *Acanthamoeba* Lilly A1 strain (8). This isolate was subsequently named as *Acanthamoeba culbertsoni* (3). Culbertson and colleagues also isolated from nature several different strains of *Acanthamoeba* with varying degrees of virulence. Based on these studies, Culbertson suggested that human infections with these amebas might occur naturally (3,8). A few years later, Fowler and Carter in Australia reported meningoencephalitis in an Australian boy attributed to *Acanthamoeba*, which was later identified as *Naegleria fowleri* (3,9). Currently, it is well known that several species of *Acanthamoeba*, *Balamuthia mandrillaris*, and *N. fowleri* cause infection in humans and other animals (2,3,7).

Acanthamoeba causes a spectrum of diseases, including granulomatous amebic encephalitis (GAE), *Acanthamoeba* keratitis, skin and nasal abscesses, and bone infection. Typically, infections caused by *Acanthamoeba* occur in immunocompromised hosts, including persons with the human immunodeficiency virus and/or the acquired immune deficiency syndrome (HIV/AIDS). In contrast, *N. fowleri* causes primary amebic meningoencephalitis (PAM) in previously healthy children and young adults with a history of water-related sports. The third member of this group of amebas, *B. mandrillaris*, causes granulomatous encephalitis and skin abscesses and sinus infections in both immunocompetent and immunocompromised persons. In this review, we describe the biology and epidemiology of the amebas, their modes of infection, and mechanisms of pathogenesis, and appropriate antimicrobial therapy in the treatment of these infections, emphasizing recent advances in knowledge concerning these opportunistic pathogens (3).

Acanthamoeba spp.

Biology

The life cycle of *Acanthamoeba* includes a trophic or feeding stage, the trophozoite, and a resistant cyst stage. The trophozoite has sluggish locomotion and measures about 20 to 30 μm in diameter and is characterized by the presence of pointed pseudopodial projections, the acanthopodia. In nature, amebas feed on bacteria, a feature that makes it relatively easy to isolate and culture them in the laboratory. When food is scarce or when facing desiccation or other environmental stresses, the amebas round up and encyst. The cyst has two walls, the outer wall (ectocyst) is wrinkled and the inner wall (endocyst) is stellate, polygonal, oval, or round. At the junction of the ecto- and the endocyst are pores or ostioles and these are covered with opercula. Upon return to favorable growth conditions, the dormant ameba is activated to leave the cyst and become once again a trophic form (10).

Acanthamoeba has worldwide distribution and is commonly found in soil, dust, fresh water, sewage, swimming pools, and hot springs. It has also been isolated from tap water, salt water, ocean sediments, heating, ventilating and air conditioning (HVAC) units, hydrotherapy baths in hospitals, dental irrigation units, eye wash irrigation units, home aquaria, humidifiers, thermal and nuclear cooling tower effluents, bacterial, mycotic, and mammalian cell cultures, vegetable matter, contact lens paraphernalia, and human tissue. Given their environmental ubiquity, many opportunities exist for humans to come into contact with trophic amebas or cysts (3,4,6,11). *Acanthamoeba* is tolerant of a wide range of osmolarities, enabling it to survive in distilled water, tissue culture media, mammalian body fluids, and seawater. Strains isolated from human cases of *Acanthamoeba* infections generally grow optimally at 37 °C, although a number of clinical isolates grow better at about 30 °C. The pathogenic potential and virulence of environmental isolates can be determined by instilling amebas into the nasal passages of mice. Infected animals exhibit signs such as ruffled fur and aimless wandering, coma, and die within 1 to 4 weeks indicating the virulence and/or the pathogenic potential of the isolate. The cytopathic effect (CPE) caused by amebas on tissue cultures is another possible mode of assessing virulence (4,5) of the strain.

The taxonomy of the genus is unsettled. Until relatively recently, species were created on the basis of morphological criteria, including such features as size of trophozoites and cyst morphology. Based on such criteria, *Acanthamoeba* isolates were separated into three groups: I, II, and III. Members of group II are most frequently isolated from the environment and, perhaps because of their relative abundance in nature, are most often implicated in human infections. Increasingly, isoenzyme patterns and/or a molecular approach using 18S rRNA gene, is being investigated to improve upon the taxonomy of the genus *Acanthamoeba* and determine its phylogenetic relationships (12).

In addition to their involvement in human disease, *Acanthamoeba* spp. have also been identified as agents

of GAE in gorillas and other old-world primates, other mammals like sheep and horses, as well as in lower animals, including fish and lizards (3,4,6).

Growth and Nutrition

Acanthamoeba spp. can be readily grown and maintained in the laboratory using a variety of media. As bacteria are their major food source, they will grow in the laboratory on nonnutrient agar plates covered with bacteria such as *Escherichia coli* or *Enterobacter aerogenes*. They show a preference for bacteria that are not encapsulated, the presence of a mucoid capsule inhibiting phagocytosis by the amebas. The use of nonnutrient agar covered with a bacterial lawn is the recommended technique for isolation of amebas from both clinical specimens such as brain tissue and corneal scrapings, as well as environmental samples. Amebas feed upon the bacteria until almost all the food is gone and then encyst. Cysts remain viable for prolonged periods of time, especially if the agar plate is sealed to prevent drying and kept at a reduced temperature (4).

Acanthamoeba can also be readily established in bacteria-free or axenic culture by harvesting amebas from a bacterized culture, washing them by centrifugation in distilled water or saline to eliminate most of the bacteria, and then inoculating the washed cells to a suitable growth medium containing antibiotics. A combination of penicillin-streptomycin or gentamicin is effective in inhibiting or killing any residual bacteria present in the ameba inoculum. A medium consisting of 2% proteose peptone, 0.5% yeast extract, and 0.5% glucose will support axenic growth with yields of 10^6 amebas/mL or more. A number of the isolates from human *Acanthamoeba* infections appear to require further medium enrichment with calf serum and a standard tissue culture vitamin mixture. Also, several different species of *Acanthamoeba* have been grown in chemically defined media (4,11).

Endosymbionts

For reasons that are not known, *Acanthamoeba*, more so than other soil amebas, is often likely to harbor endosymbiotic bacteria. According to one study it is estimated that approximately 20 to 24% of clinical and environmental isolates of *Acanthamoeba* spp. harbor endosymbiotic bacteria. Many, if not most, of these bacteria cannot be cultured outside of the ameba and appear to be obligate endosymbionts. Whether endosymbiont-bearing *Acanthamoeba* serve as reservoirs for these bacteria, some of which are potential pathogens for humans, is unknown at this time.

Acanthamoeba spp. that are found in HVAC units (discussed earlier), might serve as hosts for bacteria such as *Legionella* spp., the causal agent of legionellosis and Pontiac fever. *Legionella* have complex growth requirements yet survive in nutritionally deficient environments, perhaps because of an association with amebas or other protozoa. *Legionella* are intracellular parasites of human mononuclear phagocytes and, in the course of infection, destroy their host cells. They apparently do the same to *Acanthamoeba*, proliferating within phagosomes after uptake and causing lysis of amebas. While most of this work has been based upon in vitro studies, *Acanthamoeba* infection with *Legionella*-like bacteria has been found in amebas isolated from soil samples. It is estimated that approximately 30% of the *L. pneumophila* contained in these samples were viable but nonculturable, based on DNA amplification and hybridization. *Mycobacterium avium*, another bacterium found in water supplies, was able to survive saprophytically in vitro in association with *Acanthamoeba* trophozoites. Both *M. avium* and *Legionella* have been found to survive within the ameba cyst, as has *Afipia felis*, a potential human pathogen. Further, it has been shown that *Acanthamoeba* harboring *M. avium* and *Legionella* were more virulent than noninfected amebas to mice after intranasal instillation. Likewise, in another study, increased cytopathogenicity for tissue culture monolayers by amebas harboring endosymbionts was shown when compared with those lacking endosymbionts. Other bacterial pathogens that have been shown to proliferate in vitro within *Acanthamoeba* trophozoites are: *Listeria monocytogenes*, causal agent of meningitis and septicemia in humans; *Burkholderia pseudomallei*, agent of meloidosis in humans'; and *E. coli* serotype 0157, cause of hemolytic uremic syndrome in humans. Obligate intracellular pathogens such as *Chlamydia* and *Chlamydia*-like bacteria have been found in approximately 5% of *Acanthamoeba* isolates, and *C. pneumophila*, a respiratory pathogen, can survive and grow within *Acanthamoeba*. A feature common to all the prokaryotes that can develop within amebas is that they are obligate or facultative parasites of human phagocytic cells, suggesting that pathogenesis for humans may have evolved from infection of amebas and perhaps other protozoa, and that amebas may have an important role in the etiology of several bacterial diseases (14–17).

ACANTHAMOEBA GAE

Granulomatous amebic encephalitis (GAE) caused by *Acanthamoeba* is an insidious, chronic infection of the central nervous system caused by *Acanthamoeba* spp. The precise portal of entry is not clearly known, but the wide dissemination of these amebas in the environment allows for many possible modes of infection. Trophic amebas and/or cysts of *Acanthamoeba* have been isolated from the nasal mucosa of healthy persons, suggesting a nasopharyngeal route as one means of invasion, and amebas may also enter the body through breaks in the skin or trauma or injury to the corneal epithelium because of a foreign body or use of contact lenses. Amebas were also found in a biopsy specimen from a patient's perforated gastric ulcer, suggesting that entry was via an oral route. From skin lesions, amebas can be transported by hematogenous spread to other organs and organ systems of the host. Of particular interest is that most, if not all, persons who develop GAE are immunocompromised, including AIDS and transplant patients. However, there have been a few

cases described in which there was no underlying immune suppression (2–5,18,19).

Pathology and Pathogenesis

Definitive identification of amebas usually follows upon brain biopsy and visualization of trophic or cystic amebas in hematoxylin and eosin (H&E)-stained brain tissue sections, or upon culturing amebas from clinical other samples. In formalin-fixed, paraffin-embedded and H&E-stained tissue sections, amebas can be distinguished from host cells by their prominent densely staining central nucleolus. *Acanthamoeba* is found in either the trophic or cystic stage in tissue sections. Additionally, indirect immunofluorescence testing using anti-*Acanthamoeba* serum is also helpful in the recognition of amebas in brain tissue. Characteristic cysts can be readily recognized after cultivation on agar plates (2–7).

Mechanisms of Pathogenesis

Much of the damage done by *Acanthamoeba* trophozoites in the course of corneal or brain infections is probably the result of several different pathogenic mechanisms. *Acanthamoeba* lacks the specialized feeding cups that are found in *Naegleria* amebas (discussed later), though phagocytosis of host cells is undoubtedly involved in damage to host tissues. Several studies have described enzymes produced and secreted by *Acanthamoeba* that may facilitate spread of amebas by opening avenues for invasion and providing nutrients in the form of lysed host cells (3,20,21).

Host Response

Much of the information about the host immune response to *Acanthamoeba* is from in vitro and mouse experimental studies. The alternative complement pathway and antibody formation are both important defense mechanisms that activate neutrophils to destroy invading amebas. Once stimulated, neutrophils release lysosomal enzymes and reactive oxygen intermediates, including hypochlorite and hydrogen peroxide, thus promoting destruction of amebas. Other studies also indicate that although *Acanthamoeba* activated the complement pathway, it was shown to be resistant to complement-mediated lysis. Furthermore, it has been suggested that microglial cells produce a variety of interleukins (IL-1a and b, and tumor necrosis factor) when cultured with *Acanthamoeba* and thus may be responsible for the killing of the amebas. Different conclusions reached in these studies are probably owing to a number of factors including species and strains of *Acanthamoeba* used and the growth conditions employed (22,23).

ACANTHAMOEBA KERATITIS

Acanthamoeba keratitis is the other major infection caused by these amebas. In contrast to the systemic nature of GAE, keratitis is an acute, localized infection involving the cornea. Unlike GAE, it occurs in immunocompetent persons following corneal trauma or, more commonly, as the result of poor hygiene in the care of contact lenses or contact lens cases (24,25). Wearers of contact lenses are a high-risk group for *Acanthamoeba* keratitis, with most of the cases resulting from use of nonsterile tap water in preparation of contact lens solutions, and/or failure to keep lens storage cases clean. Amebas proliferate wherever bacteria are found as a potential food source; once established in the lens storage case, amebas can transfer to the lens surface and, ultimately, to the corneal surface, in which they are difficult to eradicate with antimicrobial treatment. In the presence of an antimicrobial agent, trophic amebas encyst and can survive the course of therapy. No case of GAE has ever been reported to progress from a case of amebic keratitis, although a case of uveitis was associated with fatal GAE. Amebas isolated from keratitis infections generally have lower temperature optima than GAE isolates, consistent with their superficial location. Among the species that have been implicated as etiologic agents are *A. castellanii*, *A. polyphaga*, *A. rhysodes*, *A. culbertsoni*, and *A. hatchetti*. Symptoms of infection include severe pain, lacrimation, photosensitivity, and the appearance of ring infiltrates. Corneal transplants have been used to repair corneal damage and eliminate infection; enucleation has been performed in cases of treatment failure. This infection may be confused with viral keratitis with resultant delay in initiating appropriate therapy to eliminate the amebas. Definitive diagnosis is based on visualization of amebas upon microscopic examination of corneal scrapings or biopsies or their cultivation from affected tissue (11). Recently, confocal microscopy has been used as an aid in the diagnosis of *Acanthamoeba* keratitis (26).

ANTIMICROBIAL THERAPY

Use of antimicrobial agents against GAE has not been particularly successful, in large part owing to the spread of infection before the causal agent can be identified. Diagnosis is, more often than not, postmortem. No single drug has been effective in clearing an infection and combination drug therapy is often employed. Among the drugs used in the treatment of GAE with varying degrees of success were pentamidine isethionate, 5-fluorocytosine, itraconazole, fluconazole, and sulfadiazine (3,27,28). Other drugs that have been used include amphotericin B, rifampin, and ketoconazole. A combination of intravenous pentamidine, oral fluconazole or itraconazole, and azithromycin along with topical applications of chlorhexidine, and ketoconazole cream, were effective in treatment of skin nodule infections (3,27,28). In some cases therapy had to be discontinued because of undesirable side effects of the medications. Drugs effective against *Acanthamoeba* generally have little effect upon *Naegleria*.

Treatment of *Acanthamoeba* keratitis has been more successful than GAE. A variety of drugs have been used in treatment, including chlorhexidine, polyhexamethylene biguanide, propamidine isethionate, dibromopropamidine isethionate, neomycin, paromomycin, polymyxin B, clotrimazole, ketoconazole, miconazole, and itraconazole (3,11,29,30). Brolene, a commercially available eye

medication (in United Kingdom) containing propamidine isethionate and dibromo propamidine isethionate was found to be effective in the treatment of *Acanthamoeba* keratitis infections but may be accompanied by drug toxicity and resistance. As is the case for GAE infections, treatment of amebic keratitis often employs a combination of drugs. Currently, the drugs of choice for *Acanthamoeba* keratitis are chlorhexidine gluconate, PHMB, and propamidine isethionate (brolene).

Other compounds have been screened for efficacy against *Acanthamoeba* spp. in vitro. These include a variety of diamidine compounds, synthetic maganin compounds combined with silver nitrate, imidazole and triazole compounds, and azithromycin, phenothiazines, and povidone-iodine (31,32).

NAEGLERIA FOWLERI

Biology

The genus *Naegleria* comprises a group of amebo-flagellate protozoa. The ameboid form, the trophozoite, is the feeding and dividing stage in the life cycle, but the ameba transforms into a nondividing, nonfeeding flagellate when conditions change, for example, when its habitat is diluted by rain water. In the laboratory, transformation from the ameba to flagellate stage can be induced by washing trophic amebas in distilled water. The flagellate stage is transitory and soon reverts to the trophozoite form. A cyst stage is also found but the cysts are not as resistant to environmental stresses as those of *Acanthamoeba* (10). Although widely distributed in soil and water, *Naegleria* are not as common as *Acanthamoeba*. Both pathogenic (*N. fowleri*) and nonpathogenic isolates (*N. gruberi*, *N. lovaniensis*, and others) can be recovered from environmental samples. Another species of *Naegleria*, *N. australiensis*, isolated from environmental samples, is pathogenic to mice, but is not known to cause amebic meningoencephalitis in humans. There are, however, nonpathogenic *Naegleria* species (*N. lovaniensis*) and other ameba species that can also tolerate elevated temperatures. Pathogenic strains are more often recovered from warm water lakes, streams, spas, and thermally polluted bodies of water. These same bodies of water have often been sites for infection of humans with *N. fowleri*. *Naegleria* amebas have not been recovered from seawater, suggesting sensitivity to elevated osmolarities (4). In nature they feed upon bacteria, and can be isolated from both environmental and clinical specimens using nonnutrient agar spread with bacteria. *Naegleria* can be isolated from many of the same sites, such as swimming pools, as *Acanthamoeba* and other free-living amebas (1–7).

Growth and Nutrition

Naegleria fowleri, like *Acanthamoeba*, can be grown in the laboratory on nonnutrient agar plate coated with bacteria, such as *E. coli* or *E. aerogenes*. *Naegleria fowleri* can be identified based on its eruptive locomotion, ability of trophic amebas to transform into flagellates when suspended in distilled water, and the characteristic vesicular nucleus that remains intact throughout mitosis. *Naegleria fowleri* can also be established in axenic culture by washing amebas from a bacterized culture by centrifugation and transferring them to an antibiotic-containing medium, omitting the antibiotic once the bacteria have been eliminated. A chemically defined medium has also been developed for *N. fowleri* (4).

Endosymbionts

Naegleria fowleri, like *Acanthamoeba*, can support the growth of *Legionella pneumophila* in the laboratory. But there have been no reports in the literature of environmental or clinical isolates of *Naegleria* amebas harboring endosymbiotic bacteria. Given its somewhat more restricted distribution and a greater sensitivity to environmental stresses than *Acanthamoeba*, *Naegleria* probably plays a minor role in dissemination of bacteria in nature (4,15).

PAM Caused by *N. fowleri*

Naegleria fowleri causes an acute and fulminating primary amebic meningoencephalitis (PAM). The onset is sudden and the disease progresses rapidly and death usually occurs within a week or less. With perhaps a few exceptions, all cases of PAM reported in the literature have been fatal (3).

Pathology and Pathogenesis

As with *Acanthamoeba* encephalitis, amebas can be seen in necrotic brain tissue and within the perivascular space. Evidence points to the nasal passages as the portal of entry, and most victims of PAM have a history of swimming in freshwater lakes, streams, or pools, or washing in tap water containing the amebas. Amebas are aspirated into the nasal passages and, after attaching to the nasal mucosa, migrate across the cribriform plate to the brain via the olfactory nerves, causing extensive damage to the frontal lobes of the brain. This has been documented at the light microscopic and ultrastructural levels by infections via the intranasal route in the mouse model. Diagnosis of PAM can be made by microscopic examination of freshly collected CSF, and seeing amebas actively moving about (3).

Mechanisms of Pathogenesis

It is not clear why *N. fowleri* amebas are so highly virulent and/or invasive, causing such extensive damage in so short a period of time. Based upon, for the most part, in vitro studies, several possible explanations have been offered. In tissue culture, *Naegleria* amebas destroy the cell monolayer by causing the Cpe, and "nibbling" away at the tissue culture cells by producing suckerlike appendages. Other studies suggest the amebas produce toxins or enzymes or a cytolytic factor that causes destruction of tissue culture cells or presence within *Naegleria* amebas of a cytopathic protein that triggers the apoptosis pathway in susceptible tissue culture (3,4).

Host Response

Given the rapid onset and progression of PAM in humans, there is little opportunity for an effective humoral response to develop against the amebas. However, in one case, a 9-year-old who survived PAM, a high titered (4,096) anti-*N. fowleri* antibody of the IGM class, was found at 7, 10, and 42 days and the antibody persisted for 4 years (3,4,33). While *N. fowleri* causes a fulminating and fatal disease in some, many more humans are presumably exposed to this ameba than the small fraction that develop Pam. What distinguishes those who contract Pam from those who do not is an intriguing question, assuming that all persons are similarly exposed. That most of the victims of PAM are young and have been swimming or engaged in other aquatic activities has suggested that it might be owing to greater activity in the water, namely diving and prolonged periods of immersion with a greater opportunity of aspirating amebas into the nasal passages. Based on serologic studies carried out at different laboratories, it is believed that large numbers of humans are exposed to *Naegleria* and the antibody titer reflected the degree of environmental exposure to amebas (3,4). Domestic and wild animals, having a closer association with soil and water than humans, might be expected to show higher antibody levels. Serologic studies have shown that cattle and swine have low titered antibodies, whereas wild animals such as raccoons, rabbits, rats, and voles had high titers (34). Reports of a South American tapir and cattle dying of PAM caused by *N. fowleri* have been published (35). A recent report suggests that a number of Holstein cattle in California died of PAM probably contracted from drinking untreated river water (36). The conclusion to be drawn from these studies is that both humans and other animals are exposed to *Naegleria* amebas and develop antibodies against them. Whether these antibodies are protective remains unclear.

The laboratory mouse is an ideal animal model to study PAM. Mice can be inoculated intranasally or intracerebrally with a suspension of amebas and most die within the week. Differences in time-to-death arise because of the size of the inoculum, culture history, and virulence of the particular strain of ameba being used, and the age of the mouse. The intracerebral route is more certain than the intranasal route to establish infection, and even low virulence strains can cause PAM when so inoculated. Adult mice are less likely to become infected than young animals. Pathogenic isolates from PAM patients tend to lose their virulence with repeated subculture. Virulence, however, can be restored or enhanced by animal passage or even by culturing amebas on tissue culture monolayers (4).

Antimicrobial Treatment

Naegleria fowleri is highly sensitive to amphotericin B, and hence it is the drug of choice for treating PAM cases. Among the few cases reported to have survived PAM, only one well-documented case, that of a 9-year-old girl, was rapidly diagnosed and treated early in the course of infection with intravenous and intrathecal amphotericin B, miconazole, and oral rifampin (33). The authors suggested, based on in vitro testing, that amphotericin B and miconazole had a synergistic action, while rifampin was without effect on the amebas.

BALAMUTHIA MANDRILLARIS

Biology

Balamuthia is the third member of the pathogenic free-living amebas and the most recent of the group to be recognized as a pathogen (2,3,7,37,38). There had been reports in the literature over the years of encephalitis caused by amebas that were neither *Acanthamoeba* nor *Naegleria* by immunofluorescence staining. Ultimately, the isolation of amebas from the brain of a mandrill baboon that died in the San Diego Wildlife Park enabled infections of these non-*Acanthamoeba-Naegleria* cases to be diagnosed (37,38). The ameba, which is larger (12 to 60 μm in length) than either of the other two genera, has a cyst stage but no flagellate stage. The cyst is a triple-layered structure lacking pores. The ameba resembles in many of its features the leptomyxid amebas included in the genus *Leptomyxa* (37). Recent evidence, however, based upon sequencing of 16S-like rRNA suggests that *B. mandrillaris* may have phylogenetic affinity with the genus *Acanthamoeba* (39). With the identification of the baboon ameba, human cases were soon discovered and additional strains of the ameba were isolated (3).

Growth and Nutrition

The amebas grow well and abundantly when inoculated on to monkey kidney or rat glial cells but do not grow on bacteria as *Acanthamoeba* and *Naegleria* amebas do. Thus, attempts to isolate this organism from environmental samples (soil and/or water) using the conventional technique of nonnutrient agar and bacteria (3,37,38) do not work. This may in part be owing to (*1*) the relatively long generation times (>20 hours) of *Balamuthia* isolates in vitro and (*2*) the many other organisms (protozoa and fungi) in the environmental samples that overgrow potential *Balamuthia* isolates. Tissue culture monolayers have served as an excellent growth substrate for the amebas isolated from brain tissue samples of victims. The amebas feed on the cell monolayer, decimating it within several days. Using trophic amebas from these tissue culture monolayers, a cell-free medium has been formulated that produces approximately 5×10^5 amebas/mL. Several isolates have been adapted to grow in this medium with doubling ranging from 21 to 28 hours. In culture, the organism is sensitive to changes in osmolarity and does not readily tolerate either hypo- or hyperosmotic conditions (40).

GAE Caused by *B. mandrillaris*

The disease *B. mandrillaris* causes is similar to GAE caused by *Acanthamoeba*, and occurs in immunocompromised hosts, including AIDS patients and intravenous drug users. But it has also been reported from immunocompetent persons. In addition to the typical GAE,

B. mandrillaris may infect the sinus cavities and skin causing abscesses and lesions. The disease is chronic, developing over a period from about 2 weeks to 2 years. Humans over a wide age range from a few months to greater than 50 years have developed infections. Almost all cases of GAE caused by *B. mandrillaris* have resulted in death. Little is known about the source of these infections and *B. mandrillaris* has not been isolated from an environmental source (3,37,38).

Pathology and Pathogenesis

There is a pronounced similarity between *Balamuthia* encephalitis and that caused by *Acanthamoeba*. The amebas are found in similar locations in the brain causing hemorrhagic necrosis in the midbrain, thalamus, brainstem, and cerebellum (3). Most infections have developed in immunosuppressed or immunocompromised persons, including those suffering from AIDS, or malnourished individuals including chronic alcoholics. *Balamuthia* GAE has occurred in the very young or older persons or in patients with HIV/AIDS. Some of the *Balamuthia* GAE cases had facial skin lesions and/or rhinitis with infections of the sinus cavities or otitis media (3). Symptoms in children and adults have included headache, nausea and vomiting, fever, myalgia, weight loss, and seizures. The duration of symptoms has ranged from several days to 2 years and the period from onset of symptoms to time of death has ranged from about 1 week to greater than 2 months. Like its *Acanthamoeba* counterpart, the disease is of a chronic nature, developing slowly and insidiously. The disease has also been reported in animals, particularly those in zoological parks. Several of the cases have occurred in primates, including the original mandrill baboon, gorillas, gibbon, and monkeys as well as horses and sheep. An animal model using SCID (severe combined immunodeficient) mice has also been established (3,13,37,38).

Host Response

Limited information is available about host response to *Balamuthia*. As the infections have been of a chronic nature, it is likely that an antibody response would have occurred in the host. Recent studies to identify serum antibody response to *B. mandrillaris* in patients with or without GAE indicate that some people do mount a humoral response to these amebas (41).

Antimicrobial Therapy

Effective antimicrobial therapy is virtually nonexistent. The organism does not respond well to the drugs that are of limited efficacy in treating PAM and GAE caused by *Acanthamoeba*. Little information is available about the efficacy of antimicrobial agents in treating *Balamuthia* GAE. Most of those diagnosed as having the disease had been treated empirically with antibacterial, antifungal, or antiviral agents but these had minimal effect upon disease progression. Recently, however, a 60-year-old patient from California has survived the infection, but with severe neurologic deficits, after treatment with a combination of sulfadiazine, clarithromycin, fluconazole, and 5-fluorocytosine (Dr. Thomas Dietz, personal communication to G.S.V.). In vitro studies have shown that pentamidine and propamidine isethionate at a concentration of 1 μg/mL inhibit growth of amebas by 82 and 80%, respectively (31). The drugs, however, were amebastatic but not amebicidal. Amphotericin B, effective against *Naegleria*, had little effect upon *Balamuthia*. Among other drugs tested were macrolide antibiotics, azole compounds, gramicidin, polymyxin B, trimethoprim, sulfamethoxazole, and a combination of trimethoprim-sulfamethoxazole (3). Given the problems with diagnosis of infection and the lack of effective antimicrobial agents, the prognosis for victims is bleak.

CONCLUSION

It is estimated that more than 100 known infectious agents can cause encephalitis. Encephalitis caused by *Acanthamoeba*, *Naegleria*, and *Balamuthia* is not a major public health problem as relatively few cases have been diagnosed. Yet because of its high mortality and because children are often victims (PAM), it is of concern. Most of the amebic encephalitis cases described in the literature have been from countries in which a well-developed medical establishment is available for identifying these cases. It can be assumed that many more cases occur on a global scale, in humans as well as animals, which go undiagnosed and unreported. Amebic keratitis, caused by *Acanthamoeba*, is a very different type of infection that targets mainly the wearers of contact lenses. Although devastating in its impact, at least effective drugs for treatment are available. Areas that are in need of further investigation are (*1*) developing diagnostic procedures for early identification of the agents of PAM and GAE, (*2*) finding safe and effective antimicrobial agents for treating these infections, (*3*) developing effective molecular and/or serologic probes for the diagnosis of the infective agents, and (*4*) finding the ecologic niche of *Balamuthia* in nature.

Acknowledgments

The authors are pleased to thank Dr. T. H. Dunnebacke-Dixon, California State Department of Health, for a critical reading of the manuscript and Dr. A. Julio Martinez, Pittsburgh University School of Medicine for helpful suggestions.

FREEZE DRYING: PRESERVATIONS OF MICROORGANISMS BY FREEZE-DRYING

JOHN H. CROWE
LOIS M. CROWE
University of California
Davis, California

Preservation of microorganisms by freeze-drying is widely practiced (1–12), but usually with an enormous loss of viability; in fact, the death rate is so severe that it is often given in log units (13–16). The literature on survival of microorganisms in the dry state is extensive (17), therefore all of it is not reviewed in this article. Instead, findings over the past decade that have provided new insights into freeze-drying technology and are likely to dramatically improve viability of microorganisms in the dry state (some of which have been published in the last few months) are discussed.

LESSONS FROM NATURE

The major sites of damage from dehydration are membranes and labile proteins (3). We have learned a great deal about how to obviate this damage by studies on organisms that normally survive dehydration. A usual feature in the biochemistry of such organisms (a phenomenon known as anhydrobiosis) is that they accumulate large amounts of disaccharides, the most common of which are sucrose and trehalose (18–28). Survival in the dry state is often, but not always (29), correlated with the presence of one of these sugars. (Some additional interesting exceptions to this observation will be described in the following text.) Over the past 20 years we and others have provided evidence that these sugars stabilize membranes (30) and proteins (31–37) in the dry state, most probably by hydrogen bonding to polar residues in the dry macromolecular assemblages (30,32,33). This direct interaction results in maintenance of dry proteins and membranes in a physical state similar to that seen in the presence of excess water (38–40). For example, when a phospholipid bilayer is dried, the liquid crystalline to gel phase transition temperature rises sharply, often by as much as 70 °C (40). Thus, the membrane will be in gel phase at physiological temperatures in the dry state (Fig. 1). This phase transition may lead to leakage across the bilayer (41–45) and to phase separation of membrane components (46), both of which may be catastrophic events for an intact cell. Disaccharides have the ability to

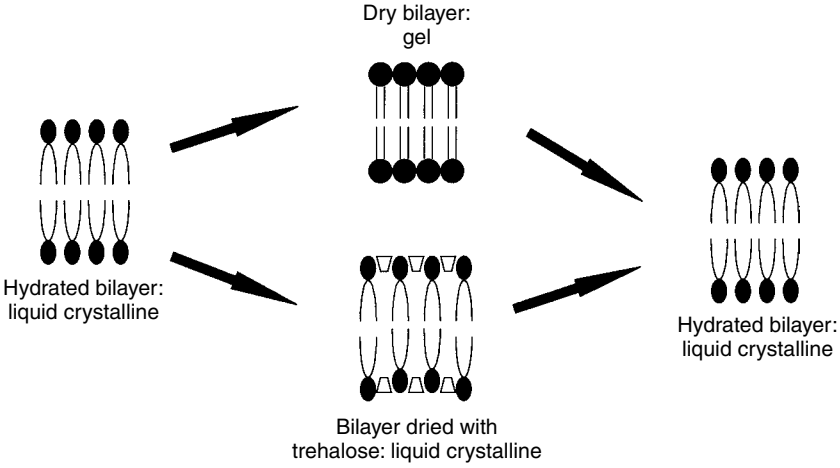

Figure 1. Diagram illustrating effects of dehydration on the gel to liquid crystalline phase transition temperature in a phospholipid dried with and without trehalose. During rehydration, the membrane dried without trehalose undergoes a phase transition, leading to temporary defects across the bilayer and to leakage of solutes (adapted from J. H. Crowe et al., in W. H. Dantzler, ed., *Handbook of Physiology*, Section 13, Comparative Physiology, vol. II, Oxford University Press, Oxford, U.K., 1997, pp. 1,445–1,477). The polar head groups are represented by the filled circles and the acyl chains by the adjacent lines. Trehalose is represented by the trapezoids between the polar headgroups in the bilayer dried with trehalose.

reduce this transition temperature (T_m) in the dry state, sometimes well below the transition temperature seen in the fully hydrated bilayer (30). We have suggested that this interaction is responsible for the stability of membranes in dry organisms (30). Because T_m is driven down below T_m in the fully hydrated bilayer, it seems clear that residual water in the sample cannot be responsible for creating this effect, but there is direct evidence as well that water cannot be involved; the dry samples contain at most 0.1 moles water/mole lipid (41). Similar observations have been made concerning the interaction between the sugars and dry proteins (32,33), with comparable arguments about the role of the stabilization of proteins in intact cells. There is some evidence in the literature that a major site of damage in freeze-dried microorganisms is the cell membrane (13,47), but evidence concerning stability of other cellular components during drying of microorganisms is lacking.

THE ROLE OF SUGAR GLASSES IN STABILIZATION

Glass Formation Is Required for Stabilization

Bruni and Leopold (51) have suggested that the glassy state may assure quiescence and stability in a living system for long periods. Indeed, it appears that maintenance of the cell in the glassy state is required for long-term stability of model systems such as liposomes (58,59) and for intact cells (55,56). The role of glasses in this regard appears to be immobilization of cellular components, thus preventing close approach of surfaces that would normally be separated by bulk water.

Properties of Glasses

A glass is a liquid of such high viscosity that it is capable of slowing chemical reactions or even, for all practical purposes, stopping them altogether (48–50). The viscous glass can, nevertheless, be readily melted by addition of water, thus restoring conditions permissive for normal metabolism. This latter point is particularly important in considerations on stability of cells in the dry state, therefore it is discussed in the following text. Excellent reviews on the properties of glasses can be found in Slade and Levine (48–50).

A glass typically is spatially homogeneous, but without any long-range lattice order (48). Glasses show temperature-dependent transitions, during which they pass from a glassy mechanical solid to a state with markedly decreased viscosity. This transition, called T_g, is a second-order transition (as opposed to a first-order transition such as a crystalline melt). It can be detected by a change in heat capacity or by direct measurement of mechanical relaxation of viscosity. Operationally, T_g is most often measured with differential scanning calorimetry (DSC), differential mechanical analysis (DMA), electron spin resonance (ESR), nuclear magnetic resonance (NMR) (48–50) or, most recently, Fourier transform infrared spectroscopy (52). The latter method is particularly useful because it permits detection of glass transitions even in single cells. With DSC, which is the most widely used method, a change in the baseline is seen at T_g, which represents the change in heat capacity.

T_g is strongly affected by the addition of plasticizers such as water. In sucrose glasses, for example, T_g falls from about 70 °C to −70 °C with the addition of water (Fig. 2). Such a diagram of the relationship between T_g and water content, known as a state diagram, has fundamental importance in the study of glasses. Construction of the state diagram for a pure solute requires some care, but it is nevertheless a straightforward procedure involving the addition of small amounts of water to the dry glass, with measurements of T_g at each increment. State diagrams for mixed solute systems are considerably more complex; a three-dimensional state diagram has recently been prepared for a ternary system, sucrose, glycine, and water (53), which yielded a three-dimensional glass transition "surface" (rather than the two- dimensional state diagram seen in a binary system). On the basis of such results, it would seem hopeless to attempt to construct state diagrams for, for example, sugar-protein mixtures, let alone sugars in intact cells. Nevertheless, it has been possible to do so possibly because the sugar contents of anhydrobiotic organisms are so high, often exceeding 20 or even 25% and sometimes as much as 50% of the dry weight (54), thus restricting the

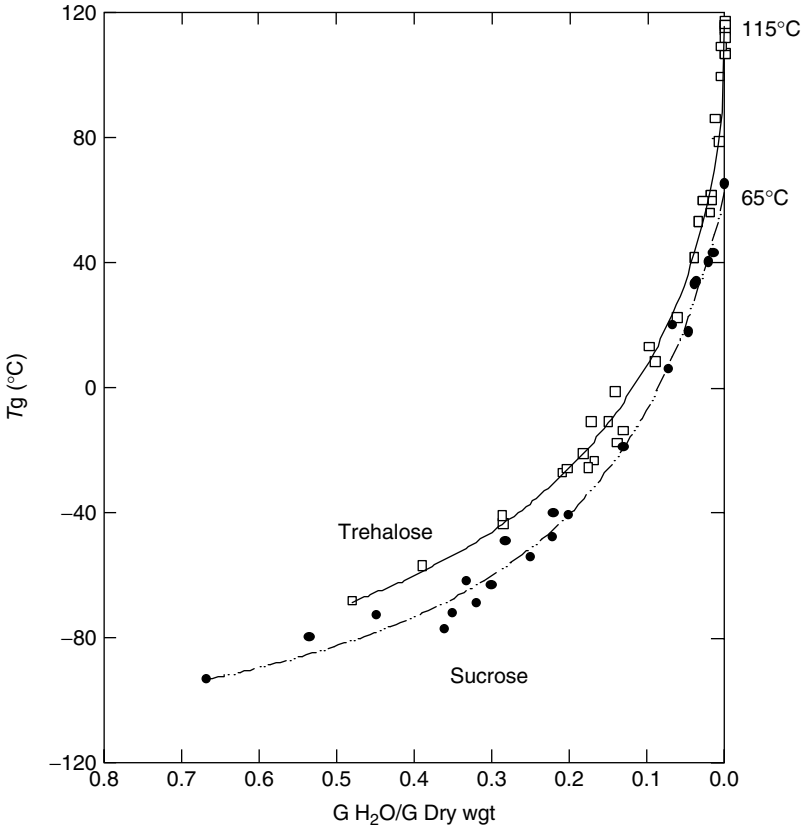

Figure 2. State diagrams for sucrose and trehalose, illustrating the large difference in glass transition temperatures (T_g) for these sugars. Data from L. M. Crowe et al., *Biophys. J.* **71**, 2,087–2,093 (1996).

participation of other compounds in the glass transition of the predominant sugar. Indeed, glasses have been detected in dry plant cells (54–56) and bacteria (57), and full state diagrams have been produced in a few cases.

To put this in practical terms, the sample temperature should not exceed the T_g line (Fig. 2) during processing for freeze-drying or during storage. It must also be noted that the damage that occurs due to devitrification has a kinetic component (60). In the case of membranes, it takes some time for the damage (fusion between adjacent membranes) to occur following devitrification. As a result, the sample may undergo short periods of devitrification without serious damage.

Are polymers useful for vitrification in cells? It would seem a priori that if maintenance of the dry cell in an anhydrobiote in the glassy state was required, an elevated T_g would be advantageous. For instance, it is clear from the state diagram for sucrose shown in Figure 2 that the addition of even modest amounts of water would result in devitrification of the sample at physiological temperatures. In seeds (61) or pollen (45), which contain large amounts of sucrose, devitrification would clearly seem to be problematic. One solution might be to add a third compound at high concentrations that would elevate T_g. Good candidates for such a role can be found among the many polymers that have elevated T_gs. T_g varies with molecular weight in a characteristic and predictable fashion; it increases nearly linearly with molecular weight of the solute, and some polymers have T_gs exceeding 200 °C (48). Thus, it would seem that such compounds ought to be found at high concentrations in anhydrobiotic organisms. Evidence is beginning to accumulate that certain polymers may play such a role in anhydrobiotes either by elevating T_g or by otherwise altering viscosity, although the mechanism is not at all clear (52,59,62,63). Interestingly, Blisett and coworkers (64) and, more recently, Bashan and Gonzalez. (65) showed good survival of microorganisms in dry polymers, but unfortunately the polymers were not characterized sufficiently to suggest a mechanism of preservation. Hill and coworkers (62) reported that *Nostoc* produces an extracellular polymeric glycan that seems to be related to its survival in the dry state. Subsequently, Hill and coworkers (63) showed that this glycan can stabilize membrane vesicles in the dry state provided a small amount of sugar is also present. About the same time, we also reported that mixtures of a large polymer, hydroxyethyl starch and glucose will stabilize membrane vesicles during drying (66). Neither component would provide stability by itself, but the two in combination worked reasonably well. It emerged that the polymer, with its high T_g, prevented fusion during drying but did not affect the lipid T_m. The glucose, by contrast, reduced T_m in the dry lipids but did not prevent fusion (Fig. 3). Thus, the two in concert satisfied both requirements. Such mechanisms may be found in the real world.

Is Vitrification Sufficient?

It is clear from the studies on glasses outlined previously that vitrification is an important aspect of preservation of cells in the dry state. But is it in itself sufficient?

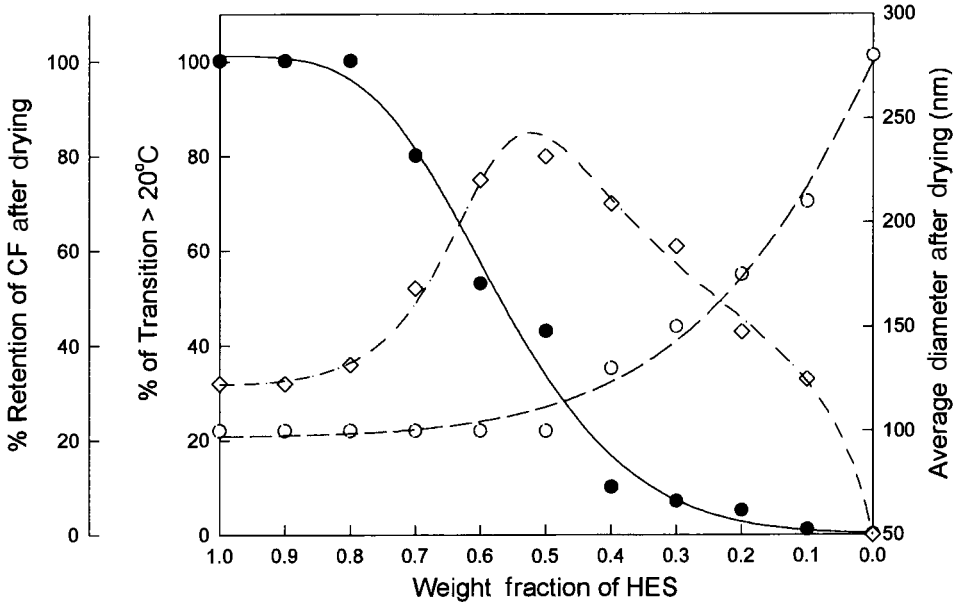

Figure 3. Effects of mixtures of hydroxyethyl starch and glucose on the stability of dry liposomes. Neither component protects the liposomes against leakage of trapped solute [carboxyfluorescein, (CF)] when used alone, but the two compounds in a mixture do so. HES inhibits fusion (because of its high T_g) but has no effect on the phase transition (T_m). Glucose has the opposite effects. Data from J. H. Crowe and et al., *Cryobiology* **35**, 20–30 (1997).

The discussion on studies with liposomes has shown that vitrification by the addition of a polymer with an elevated T_g does not preserve the dry liposomes (66). It is possible that the polymer phase separates from the liposomes (which appears to be the case with multilamellar vesicles), but that does not appear to be so with unilamellar vesicles; the polymers prevent fusion between the vesicles during drying, but have no effect on T_m in the dry lipids (66). The interpretation placed on this finding is that the polymer can prevent fusion by steric hindrance of close approach of adjacent liposomes, but does not affect T_m because the polymer is too large to interact directly with the bilayer. Thus, our own viewpoint on this matter is that although glass formation is required for long-term stability, it is not in itself sufficient (67).

Is Trehalose Special?

Trehalose has been shown by a large number of workers around the world to be remarkably (and sometimes, it is claimed, uniquely) effective in stabilizing dry or frozen biomolecules, cells, and tissues. Others have not observed any such special properties. However, trehalose has a remarkably high T_g compared with other oligosaccharides (Fig. 2). It is not anomalous in this regard because it lies at the end of a continuum of sugars with increasing T_g. Nevertheless, it is unusual in that the addition of small amounts of water does not depress T_g as in other sugars. Instead, a dihydrate crystal of trehalose forms, thus shielding the remaining glassy trehalose from effects of the added water (68). Therefore under less than ideal conditions, such as high humidity and temperature, trehalose does indeed have special properties, which may explain the stability and longevity of anhydrobiotes that contain it. Further, it makes this sugar useful in stabilization of biomolecules and intact cells of use in human welfare.

In summary, we believe that trehalose is the sugar of choice as an excipient for most investigations on freeze-drying biomolecules or intact cells. Under ideal storage conditions (low water content, low temperature, and in the presence of reduced oxygen), other sugars such as sucrose can be just as effective as trehalose. But trehalose not only has the required properties for stabilization under ideal conditions it also works well under storage conditions that are not ideal.

Other additives in combination with trehalose may be useful. Juan de Pablo and colleagues have recently discovered that the effectiveness of trehalose can be increased remarkably by adding borate ions. The addition of one borate ion per mole of trehalose raised T_g by 60 °C (69). The borate apparently accomplishes this by forming a cross-linked network between the sugars. More recently, Conrad and coworkers (70) applied this system to freeze-dry and vacuum-dry *Lactobacillus*, with excellent recovery initially. When the cells were subsequently stored at 37 °C, in air, without protection from light or oxygen, recovery remained as high as 40% even after three months under these vastly suboptimal storage conditions. Thus, de Pablo and coworkers may have discovered the best of both worlds; the trehalose-borate mixture behaves like a trehalose-polymer mixture but without the problems associated with polymers. As shown in the following section, it is possible that the trehalose gets into the cells during chilling, and this entry may be required for preservation. It is also possible that the borate may enter the cytoplasm by the same mechanism, but it is unlikely that a large polymer would do so. These promising results

may well lead to vastly improved methods for freeze drying not only for microorganisms but also other cells. As de Pablo and coworkers point out, the high T_g of this mixture is likely to be particularly useful when the samples must be stored under suboptimal conditions.

TREHALOSE HAS UNUSUAL SOLUTION PROPERTIES

Trehalose Protects Against Effects of Toxins

Several groups have reported that trehalose has unusual properties in solution (76–80). It is not at all clear just what these properties mean for stability of biological systems in the dry state, but it is interesting to note that they may be related to the observation that trehalose reduces ethanol toxicity in yeast cells undergoing fermentation (81–83). This finding may well have applications in the world of fermentation that are currently being explored. Trehalose may have similar effects for other toxic compounds (84), so this may be a generalized protective mechanism against chemical toxins.

Trehalose and Thermal Tolerance

Extensive literature has developed over the past decade suggesting that trehalose synthesis may be involved in thermal tolerance in hydrated microorganisms. Attfield (85) and Hottiger and coworkers (86) first reported that heat shocked yeast cells produce trehalose, a finding that has not been without controversy, although the vast majority of reports now seem in agreement with these original observations (20,87–89). Some workers, notably Wiemken and his colleagues, have proposed that trehalose may actually be a substitute for heat shock proteins in some cells (90–95). Recent reports showed a synergistic effect between trehalose and heat shock proteins such as HSP104 (96–98); therefore, it now seems likely that the trehalose and heat shock protein mechanisms are not mutually exclusive. In fact, the bulk of the evidence now suggests that trehalose synthesis may be a general stress response (83,95,99–104). The observation that heat shock leads to trehalose accumulation may also be useful in inducing cells to make trehalose with a view toward using that induction as a means for increasing survival during drying. In fact, some progress has already been made in that regard (86).

Relationship Between Solution Properties of Trehalose and Dehydration

It is not at all clear as to what is special about trehalose that leads to such interesting properties in solution, although some progress is being made by de Pablo and coworkers (77). However, what is clear is that the solution properties and effects of the sugar during drying do not share a common mechanism; the sugar appears to interact directly with proteins and bilayers during drying, as discussed earlier, but in solution or during freezing, the best evidence suggests that instead of a direct interaction, there is preferential exclusion of the solute from the surface of the protein or membrane (This matter is too complex to cover in detail here; see 105–106 for discussions).

TREHALOSE AND SURVIVAL FOLLOWING DEHYDRATION IN YEASTS: A CASE STUDY

Saccharomyces cerevisiae synthesizes trehalose during the stationary phase and survives drying (air-drying or freeze-drying) after trehalose synthesis is complete. In our hands, more than 40% survival can be obtained in cells dried in this fashion. By contrast, cells taken from log-phase cultures showed poor survival. Here again, survival is clearly correlated with trehalose synthesis. Studies on yeasts and the role of trehalose have yielded the following useful observations.

Membrane Lipid-Phase Transitions and Survival of Drying

It has long been known that when commercially dried yeasts are rehydrated, they must be placed in warm water, a requirement that is also shown in the data in Figure 4. This puzzling result might be explained as follows, according to Leslie and coworkers (107). Suppose the yeast cell membranes are in the gel phase at temperatures less than about 40 °C. Thus, when the cells are put in cold water they undergo a phase transition as they rehydrate, leading to leakage of solutes across the membrane. By contrast, when they are placed in warm water, the lipids would be expected to undergo the phase transition before the waterfront reached the membranes. We tested this model by measuring the leakage of cytosolic components from cells rehydrated at different temperatures and phase transitions in the dry cells. The results (Fig. 4) showed that with increasing temperature of rehydration leakage from the cells was abated in concert with the increased survival. At about the same temperature, the cell membranes were seen to undergo a gel to liquid crystalline phase transition in the dry state, suggesting that the model proposed may be correct.

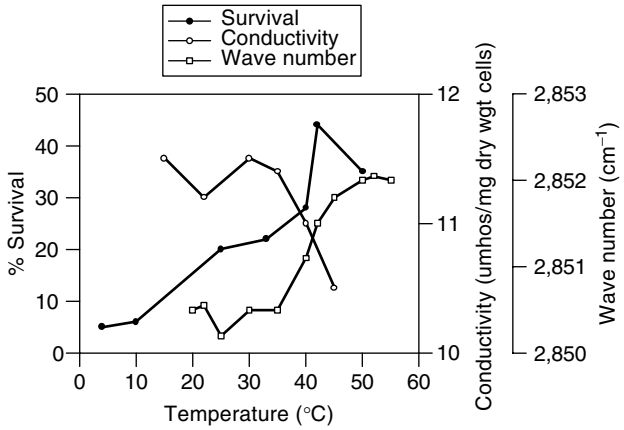

Figure 4. Survival of dry yeast cells rehydrated at the indicated temperatures. Also shown is a measure of the lipid-phase transition made with infrared spectroscopy (wave number) and leakage of solute as a function of rehydration temperature. Adapted from S. B. Leslie and coworkers, *Biochim. Biophys. Acta* **1,192**, 7–13 (1994).

Does Trehalose Depress T_m in Membranes in Dry Yeast Cells?

When membranes were isolated from yeast cells and dried with and without trehalose, the results shown in Figure 5 were obtained. In the membranes dried with the sugar, T_m was centered on about 42 °C, in good agreement with the results seen in intact cells (Fig. 4). But with the membranes dried without the sugar, T_m was seen to rise to nearly 70 °C (Fig. 5). Thus, it appears that the sugar is responsible for depressing T_m in the dry cells to a range at which it is physiologically possible to rehydrate the cells without killing them (107). If T_m were more than 50 °C (above the lethal temperature for the hydrated cells), this would clearly not be possible.

A trehalose transporter is required for yeast cells to survive drying. *S cerevisiae* has a proton-dependent trehalose transporter (108), the function of which was not at all clear until recent years. The transporter will work as a mechanism for taking up trehalose from the medium, but trehalose is rarely found in the medium surrounding these cells, so its existence was puzzling. Panek and coworkers (108,109) have provided an explanation. They produced a mutant strain in which the transporter was missing. This strain synthesizes trehalose normally, but will not survive drying. However, if trehalose is introduced outside the cells they survive. Panel and coworkers inferred from these observations that the transporter may be used to get trehalose outside the cells during the drying process. They then produced a mutant deficient in trehalose synthesis. As predicted, those cells did not survive drying unless trehalose was added outside, in which case they transported the sugar to the inside, and the cells then survived drying. These results, summarized in Figures 6–7, suggest the importance of having trehalose on both sides of the membrane, in keeping with results from liposomes showing that the sugar must be on both sides of the bilayer to achieve optimum stability (30).

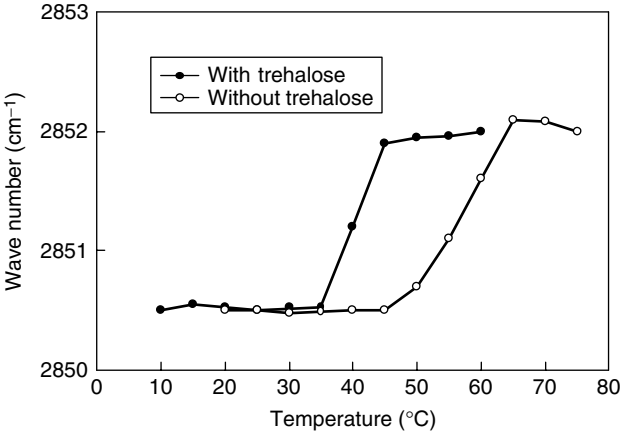

Figure 5. Lipid-phase transitions measured with infrared spectroscopy in membranes from yeasts dried with and without trehalose. The sugar reduces T_m by about 30 °C. Adapted from S. B. Leslie and coworkers, *Biochim. Biophys. Acta* **1,192**, 7–13 (1994).

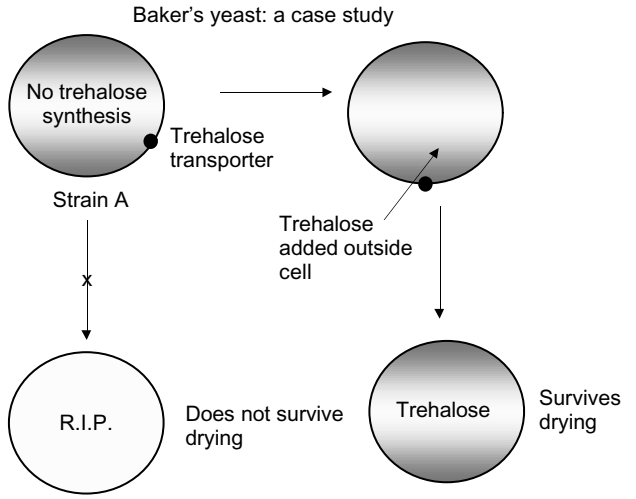

Figure 6. Diagram, illustrating a case study on the relative roles of trehalose synthesis and transport in survival of drying by yeast cells. In this strain, which lacks trehalose synthesis but has a transporter, adding trehalose outside leads to survival following dehydration. Adapted from E. C. A. Eleutherio and coworkers, *Biochim. Biophys. Acta* **1156**, 263–266 (1993).

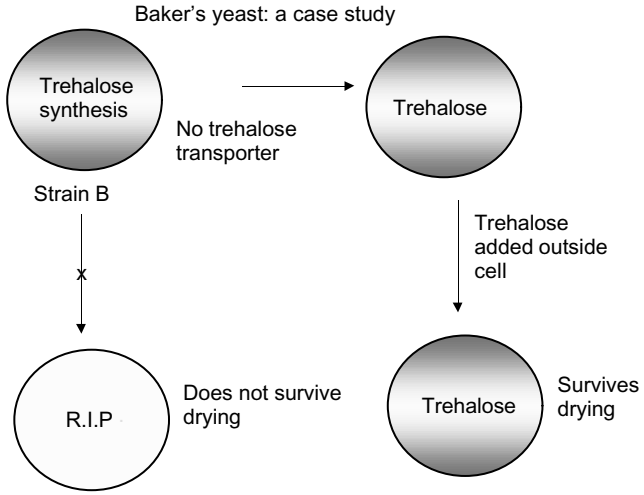

Figure 7. Diagram illustrating a case study on the relative roles of trehalose synthesis and transport in survival of drying by yeast cells. In this strain, which has trehalose synthesis but no transporter, adding trehalose outside also leads to survival following dehydration. Adapted from data of E. C. A. Eleutherio and coworkers, *Biochim. Biophys. Acta* **1,156**, 263–266 (1993).

INTRODUCING TREHALOSE INTO CELLS ARTIFICIALLY

It is clear from the earlier discussion that if a way could be found to introduce trehalose into cells that do not normally make this sugar, cellular survival following drying might be enhanced. In fact, currently it is possible to do this with a number of bacteria, with gratifying results. Several techniques are available, not all of them successful:

Chemical Permeabilization and Electroporation

Both of these widely used methods for introducing solutes across membranes may work with bacteria. We have not

tested either method with bacteria, but others and we have done so with eukaryotic cells, with generally disappointing results. The sugar can be introduced into the cytoplasm, but it appears that the membranes are so destabilized by these treatments that subsequent drying is unsuccessful.

Loading Using Lipid-Phase Transitions

Because membranes are known to become transiently leaky during lipid-phase transitions, Leslie and coworkers (110) suggested that it might be possible to use the phase transition itself to introduce sugar into the cytoplasm. The rationale here is that if one puts a high concentration of sugar outside, the main diffusion vector would be expected to be from outside to inside. Leslie and coworkers (110) reported that at least in some bacterial species, this is a practical solution to the problem. For instance, *Bacillus thuringiensis* surprisingly showed a phase transition between about 0 and 20 °C (Fig. 8). When trehalose was put in the medium around the cells, it was seen to accumulate in the cytoplasm when they were chilled below 20 °C (Fig. 8). When the cells were then freeze-dried, survival increased from less than 10% when they were dried with trehalose on the outside (but without slow cooling through the phase transition) to nearly 70% when they were chilled slowly and the trehalose was allowed to enter the cytoplasm. Lipid-phase transitions were then measured in the cells dried under optimum conditions. When the cells were dried without trehalose T_m rose by about 40 °C compared with the hydrated cells. However, in the cells dried with trehalose T_m was similar to that seen in the hydrated cells. Thus, trehalose reduces T_m in these dry cells by about 40 °C. There is some evidence that this might even work with mammalian cells; Beattie and coworkers (111) reported that mammalian islets of Langerhans were successfully preserved by freezing after trehalose was introduced into the cytoplasm by chilling the cells through a lipid-phase transition.

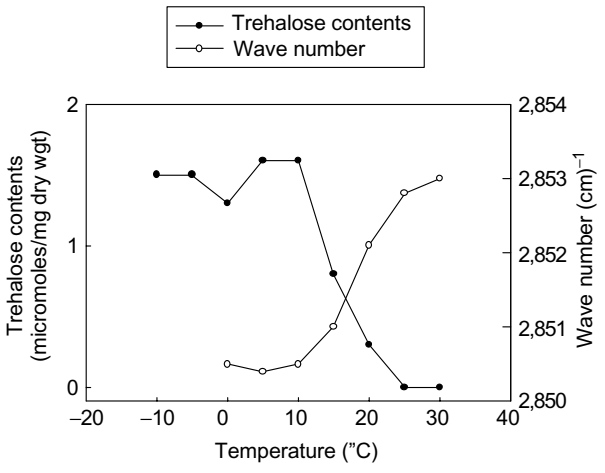

Figure 8. When *Bacillus thurengiensis* was chilled in the presence of trehalose, the sugar entered the cytoplasm between about 20 and 10 °C, coincident with a lipid-phase transition, measured with infrared spectroscopy. Data from S. B. Leslie et al., *Appl. Env. Microbiol.* **61**, 3,592–3,597 (1995).

Transfection with Genes for Biosynthesis of Sugars

The biosynthetic pathway for trehalose synthesis involves two steps (Fig. 9) and thus two enzymes. The genes for those enzymes have been cloned (102,112,113). It should be possible to transfect microorganisms with these genes with an appropriate promoter and thus induce the cells to make their own trehalose. In fact, this has been attempted with plant cells (114) with promising results, which were improved by inhibition of trehalase, which in turn led to increased accumulation of trehalose (28,115) More recently, related results have been obtained with mammalian cells (116), also with promising results. The genes were incorporated into an adenovirus vector, which was then introduced into a mammalian cell line. With multiple infections, the trehalose biosynthesis increased. The cells, which were then dried to a level at which free water was no longer detectable, retained viability for five days. It seems reasonable to suspect that the level of viability might be improved by altering the storage conditions; oxygen, for example, is known to attack dry membranes producing free radicals and free fatty acids that are extremely damaging. The first such study with bacteria was recently published by Billi and coworkers (117), who transfected *E. coli* with the gene for sucrose phosphate synthase. Presumably, the transfected cells produced sucrose phosphate, although that was not confirmed. After freeze-drying or air-drying the transfected cells showed a 10^4 increase in survival compared with controls. Furthermore, lipid-phase transition temperatures were depressed in the transfected cells, similar to the results produced by Leslie and coworkers (110).

An alternative to the pathway shown in Figure 9 that has not been explored is a novel enzyme that converts maltose to trehalose (118,119). The first suggestion of the existence of this pathway was obtained from yeasts by Panek's group (120). That work was forgotten for some years, but its independent rediscovery by two other groups (118,119), and publication of new evidence that this pathway may play a physiological role in yeasts (121) has rekindled interest in it. However, it is not clear how this pathway might be used to increase trehalose synthesis.

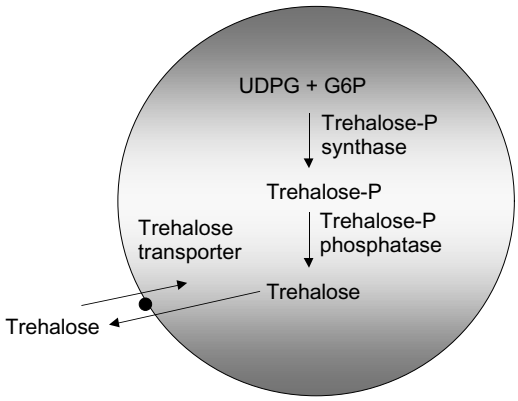

Figure 9. Cartoon, illustrating the trehalose biosynthetic pathway and the trehalose transporter. All three genes have been cloned (see text).

Transfection with the Gene for the Trehalose Transporter

The gene for the trehalose transporter from yeasts has been cloned (122), thus providing another potential pathway for the introduction of trehalose. One can imagine that transfection of cells with the biosynthetic genes and the gene for the transporter may even result in the complete mimicking of the system that occurs naturally in yeasts (Fig. 9). Several groups of investigators in the United States are attempting to do just this with mammalian cells, but so far as we know there is only limited activity in this area with microorganisms.

Use of a Pore Protein to Introduce Trehalose

Eroglu and coworkers (123) recently engineered a pore-forming hemolytic protein, α-hemolysin, so that the pore could be switched on and off. By substituting a number of residues with histidines the pore could be turned off; by adding μM quantities of Zn^{++} the pore could be closed, and by removing the Zn^{++}, the pore could be reopened. Because the pore protein spontaneously inserts into membranes, Eroglu found that they could simply incubate the cells in its presence, add trehalose in the absence of Zn^{++}, and introduce the sugar via the pore. Using this procedure, they were able to obtain very high rates of survival of two lines of mammalian cells in the frozen state. Such studies have not yet been extended to microorganisms.

THERE IS MORE THAN ONE WAY TO ACHIEVE STABILITY

We have concentrated this discussion on trehalose because it is so effective as an excipient. However, there are other routes to the same end. For example, if the rise in T_m in membrane lipids is the key damaging event during dehydration, it should be possible to prevent this damage by mechanisms other than interactions with disaccharides. This appears to be the case. Hoesktra and coworkers (43,44) showed that with certain pollen species the hydrated cells have a T_m so low that it does not rise above physiological temperature during drying. Such cells survive drying with minimal amounts of disaccharides present (43). However, to achieve this low T_m, the membrane lipids are highly unsaturated and are particularly susceptible to free radical attack (1) and to enzymatic deesterification (71–74). Such species have only a brief lifetime in the dry state. More recently, Linders and coworkers (75) showed that a species of *Lactobacillus* can be dried, although it contains only small amounts of disaccharides. When phase transitions were measured in the intact cells, T_m was seen to increase by only a small amount during drying. It emerged that the lipid composition of the membranes is probably responsible for this effect. The membranes have a high concentration of charged lipids, which presumably show electrostatic repulsion and thus a limited rise in T_m during drying. These kinds of adaptations appear to be exceptional.

CONCLUSION

Sugars can be used to freeze-dry microorganisms very effectively, provided they can be introduced into the cell. The means for accomplishing this are at hand as are described here. In fact, it may be possible by genetic engineering methods to mimic the natural system in yeasts. The most effective sugar, at least under less than optimum conditions, is trehalose. Nevertheless, even the relatively high effectiveness of this sugar can be improved by addition of polymers or borate ions, both of which elevate the glass transition and improve stability. The potential for further work in this field is enormous.

FUNGAL ALLERGY AND ALLERGENS

ROBERT K. BUSH
University of Wisconsin–Madison
William S. Middleton Memorial Veterans Hospital
Madison, Wisconsin

Fungi can cause a variety of human diseases. They can act as pathogens, elicit allergic diseases, and cause other types of hypersensitivity diseases such as hypersensitivity pneumonitis, allergic bronchopulmonary mycoses, and allergic fungal sinusitis. This article focuses on the role of fungi as etiologic agents in allergic rhinitis and asthma.

Allergic diseases [e.g., allergic rhinitis ("hayfever") and allergic asthma] are classified as immediate hypersensitivity reaction, or type 1 according to the Gell and Coombs classification (1). Allergic reactions involve the production of immunoglobulin E (IgE), antibodies that are formed in response to a variety of protein or glycoprotein antigens (allergens) of which fungi are a typical example. Generation of IgE antibodies requires the central role of CD4+ T-helper lymphocytes. In the development of fungal allergy, exposure to the allergens largely occurs through inhalation of these proteins carried on spores or other particles into the nose and lung.

EXPOSURE TO FUNGAL ALLERGENS

Exposure to fungal allergens is generally considered to arise from the outdoor environment, but indoor exposure to fungal allergens can also occur. Indoor environmental exposure is a reflection of fungal spores invading the indoor environment through open windows and cracks or following amplification of fungi due to water accumulation in the indoor environment. Certain taxa such as *Penicillium* and *Aspergillus* may be recovered in higher amounts in the indoor environment compared with the outdoor environment; and, therefore, are considered to be predominantly indoor exposures (2). Homes and businesses that have been flooded or have excessive moisture problems are also sites for exposure to fungal allergens.

A number of fungi have been identified as causing allergic disease (allergenic). A listing of some of the identified allergenic fungi is found in Table 1. The best studied allergenic fungi belong to the somewhat artificial group *Fungi imperfecti* (Deuteromycetes), which are now recognized as the asexual forms of Ascomycetes. Fungi belonging to the Basidiomycotina are increasingly recognized as important fungal allergens, although they have not been as well characterized as the fungi imperfecti. Ascomycotina comprise another large group of fungi that on occasion have been shown to be allergenic. Zygomycota appear to be of lesser importance as fungal allergens.

Seasons and weather patterns influence the number of fungal spores in the outdoor air. In the northern areas of the United States, fungal spores appear in the spring as snow cover begins to recede. When the weather warms, the spores become more prevalent, particularly in the months of May and June. Peak spore counts occur in the months of late summer (July through September) with the numbers receding during October and November. In the southern areas of the United States, fungal spores are present throughout the year, although again spore counts peak during the late summer and early fall (June through October; (3). Wet and dry conditions

Table 1. Allergenic Fungi

Myxomycetes	*Coprinus*	*Cephalosporium*
Fuligo	*Dacrymyces*	*Cladosporium*
Lycogala	*Ganoderma*	*Coniosporium*
Stemonitis	*Hypholoma*	*Curvuluaria*
Oomycetes	*Inonotus*	*Dicoccum*
Plasmopara	*Merulius*	*Dreschlera*
Zygomycetes	*Naematoloma*	*Epicoccum*
Absidia	*Pleurotus*	*Epidermophyton*
Mucor	*Ustilago*	*Fusarium*
Rhizopus	*Psilocybe*	*Gliocladium*
Ascomycetes	*Stereum*	*Helminthosporium Stereum*
Chaetomium	*Gasteromycetes*	*Monilia*
Claviceps	*Calvatia*	*Nigrospora*
Daldinia	*Geastrum*	*Paecilomyces*
Erisyphe	*Lycoperdon*	*Penicillium*
Eurotium	*Pisolithus*	*Phoma*
Leptosphaeria	*Podaxis*	*Rhodotorula*
Microsphaeria	*Scleroderma*	*Spondylocladium*
Saccharomyces	*Teliomycetes*	*Sporobolomyces*
Xylaria	*Puccinia*	*Sporotrichum*
Basidiomycetes	*Tilletia*	*Stemphylium*
Hymenomycetes	*Urocyctis*	*Tilletiopsis*
Agaricus	*Ustilago*	*Torula*
Amanita	Deuteromycetes (Fungi Imperfecti)	*Trichoderma*
Armillaria	*Alternaria*	*Trichophyton*
Boletus	*Aspergillus*	*Trichothecium*

also affect outdoor spore recovery from the air. Spores from *Cladosporium*, *Alternaria*, *Epicoccum*, and others predominate during dry weather, especially during windy days (2). *Fusarium*, *Phoma*, Ascospores, and Basidiospores are the predominant organisms recovered during periods of wet weather (2). A seasonal relationship exists between indoor fungal recovery and outdoor fungal levels. Table 2 lists the types of fungi found in the indoor and outdoor environment during various seasons of the year in studies conducted in southern California, Finland, and England.

MECHANISM OF FUNGAL ALLERGY

The first step in the process of the development of fungal allergy consists of the production of IgE antibodies to fungal proteins or glycoproteins. This initial step is termed "*sensitization*." Fungal allergens are taken up by antigen presenting cells in the lung (4). These cells then present the allergen to T-lymphocytes. For the allergen to be recognized by the T cell, it must first be processed into small peptide fragments and presented on the surface of the antigen presenting cell in association with major histocompatibility (MHC) class 2 proteins (5; Fig. 1). Antigen presenting cells capture and internalize the protein. They migrate to draining lymph nodes where the processed peptides are presented on the surface of the cell in association with MHC class 2 molecules. Naïve T cells, through a T cell receptor that has specificity for a particular antigenic peptide, recognize the complex of the antigen and the MHC class 2 molecule. The naïve T cells become activated through a variety of costimulatory signals. The activated T cells then undergo multiple rounds of replication that are controlled by a variety of cytokines. Initially a pool of multi-potential cells (Th0) are produced. Under the influence of the local cytokine milieu these cells can differentiate into Th2 cells.

For allergic diseases, genetic predisposition is present, known as atopy. Individuals are defined as being atopic if they or close relatives have manifestations of allergic diseases such as allergic rhinitis, asthma, or eczema. The genes that control the Th2 type of response have not been discovered at present; however, clear-cut genetic influences do exist.

The production of cytokines by the Th2 cell leads to the production of specific IgE antibodies. IgE antibody has unique biological characteristics. It has the ability to bind to receptors found on mast cells and basophils. These cells contain histamine and other biochemical mediators and are found in abundance in the tissues that are the sites of allergic reactions. These cells are particularly abundant in the eyes and respiratory tract. Interaction between fungal allergens and IgE on the surface of the mast cell or basophil results in its degranulation with release of histamine and other biochemicals that can affect the tissues, which lead to the symptoms of allergy such as sneezing, coughing, and wheezing. These reactions occur rapidly within 10 to 15 minutes after exposure to the fungal allergen to which the individual is sensitive (early-phase response).

In approximately half of the allergic subjects, the so-called early-phase response is followed by a late-phase reaction that occurs three to four hours after the initial exposure to antigen. The late-phase response differs from the early response in that it involves the influx of inflammatory cells from the bloodstream, consisting largely of eosinophils and basophils. A number of cytokines produced by the lymphocytes are potent stimulatory factors for the recruitment of eosinophils. Cytokines and chemokines are important factors in recruiting eosinophils into the site of inflammation. Eosinophils can contribute to further tissue inflammation by releasing their granular proteins, cytokines, and also generate leukotrienes that have profound effects on airway function in patients with asthma.

In summary, the mechanism underlying fungal allergy involves a complex series of events. Genetic factors play an important role in governing the ability of the individual to

Table 2. Distribution of Indoor and Outdoor Allergenic Fungi

	Range-Spores/M^3

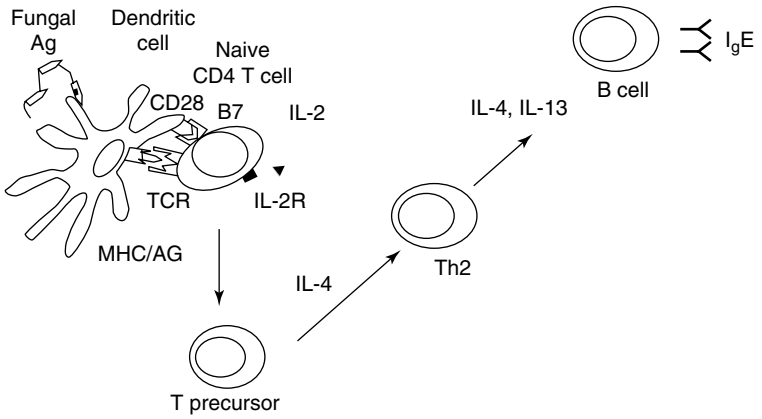

Figure 1. Antigen presentation to naïve T-cells requires recognition of antigen (Ag)/major histocompatibility (MHC) complex by T-cell receptor (TCR) and co-stimulatory signals provided through interaction of CD28 and B7. Differentiation of T-precursor cells into Th2 effector cells is influenced by the presence of interleukin (IL)-4 and IL-3. Modified from C. M. Kiekhaefer et al., In: R. K. Bush, ed., Environmental Asthma, Marcel-Dekker, New York, 2001, pp. 13–31.

develop IgE antibodies. The allergens produced by fungi, through airborne routes, lead to their uptake by antigen processing and presenting cells. These cells interact with T-lymphocytes and in the appropriate cytokine milieu lead to the generation of Th2 helper cells. The Th2 cells elaborate cytokines that are directly involved in the production of the IgE antibodies.

Circulating IgE, which is specific for fungal protein allergies, binds to the surface of mast cells and basophils. Interaction between the fungal allergen and IgE triggers the release of preformed mediators, such as histamine, and the generation of other vasoactive biochemical mediators. These mediators have direct effects on the tissue. Further, production of cytokines and chemokines result in recruitment of inflammatory cells, particularly eosinophils, into the tissue. Eosinophils, in turn, release other mediators and generate leukotrienes that result in the typical inflammation seen in the late-phase allergic reaction. Over time these events may lead to chronic problems such as asthma.

Symptoms of Fungal Allergy

The most common symptoms related to fungal allergy involve the nose, eyes, and lungs. These symptoms are known as allergic rhinitis, allergic conjunctivitis, and asthma, respectively. Nasal symptoms include nasal congestion, runny nose, and sneezing, whereas ocular symptoms include redness, itching, and watery eyes. Asthma is important because this is a potentially fatal condition. Symptoms of asthma consist of cough, wheezing, and shortness of breath. In addition to fungal allergy, individuals with asthma may experience symptoms when exposed to other allergens as well as exercise, cold air, and virus infections.

PREVALENCE OF FUNGAL SENSITIVITY

Allergy to fungi is demonstrated by skin testing with extracts prepared from fungi or by in vitro assays that use radioimmunoassays (radioallergosorbent [RAST]) or enzyme-linked immunoassays [ELISA] to detect specific IgE antibodies to fungi. Although presence of IgE antibodies does not necessarily reflect disease, it is one way of determining the frequency of sensitization and its relationship to respiratory symptoms. Unfortunately, many of the commercially available extracts for detecting fungal allergy are unstandardized materials, and, therefore, give variable results. Until such time as standardized extracts are available, estimates of the true prevalence of sensitivity to fungi will be difficult to establish. Nonetheless, studies in various parts of the world indicate that fungal sensitivity is common, particularly among asthmatics and especially in younger patients. In the general population of the United States, a large-scale epidemiologic study indicated that 3.6% of the population are sensitized to the fungus, *Alternaria alternata* (6). In reports from the United States, up to 80% of asthmatic patients demonstrate positive skin test to one or more fungi (7). In a European study in patients presenting with suspected respiratory allergy, the frequency of positive skin tests to fungi varied from country to country (8). Approximately 3% of patients in Portugal had positive skin tests to either *Alternaria* or *Cladosporium*; in Spain, 20% demonstrated positive skin tests to these allergens. In the United States, a skin reactivity study involving symptomatic patients found that 25 to 33% of these individuals reacted to one or more basidiomycete species (9). In another large-scale epidemiologic study of children with asthma residing in inner cities in the United States, the most common sensitizer was *Alternaria:* 38.3% of asthmatic children had a positive skin test to this allergen, which was comparable to their sensitivities to cockroach and house dust mites (10).

ASSOCIATION OF THE FUNGAL SENSITIVITY WITH ASTHMA

Sensitivity to house dust mites, cockroach allergens, and animal danders are known risk factors for asthma. An accumulating body of evidence suggests that sensitivity to fungi, particularly *Alternaria*, is associated with asthma. Gergen (11) found that *Alternaria* sensitivity was associated with an adjusted odds ratio (an adjusted odds ratio indicates the risk for an event, e.g., asthma is associated with a factor *Alternaria* sensitivity that is 2.3 times greater than chance alone when all other factors have been considered) for having self-reported asthma of 2.3 (95% CI, 1.5 to 3.4). Peat (12) found that children residing in the inner part of Australia who had asthma

were likely to be sensitized to *Alternaria*, which resulted in an adjusted odds ratio of 5.6 (95% CI, 3.1 to 10.1). In a study of children residing in the desert southwest United States, skin test sensitivity to *Alternaria* at age six was associated with persistent asthma and onset of new asthma but this declined by age 11 (13). This age decline in fungal sensitivity in asthmatic patients had previously been noted by Kaufmann (14).

Studies in school age children residing in North Carolina, Virginia, and New Mexico also demonstrated similar effects in that there was a link between *Alternaria* sensitivity and asthma in these populations (15,16). Although positive skin tests or the presence of IgE sensitivity to fungi by in vitro methods indicate a link between sensitization and asthma, it has been more difficult to directly correlate exposure to fungal spores and the development of asthma symptoms in sensitized individuals. Bruce (17) found that autumnal asthma symptoms were correlated with the presence of sensitivity to *Alternaria* by skin tests in approximately 50% of their subjects. In a study of children in southern California, fungal exposure was significantly associated with asthma symptoms (18). The need for inhaled bronchodilators to treat asthma symptoms and asthma symptom scores increased with increasing numbers of spores per cubic meter of air (18). These studies demonstrate the limitations in assessing exposure-response relationships. However, it does appear that fungal spores play a role in asthma symptoms.

ROLE OF FUNGAL EXPOSURE IN ACUTE ASTHMA ATTACKS

Exposure to fungal spores has been associated with emergency room visits for asthma. Nelson (19) reported that emergency room visits for asthma in children was associated with sensitivity to a variety of allergens including *A. alternata*. Epidemics of asthma have occurred at times of high spore counts in the atmosphere. These have been recognized in New Orleans at a time when there was a high basidiomycetes spore count in the air (20). Similar outbreaks have been reported in England and New Zealand during times of high fungal spore counts (21). Fungi may have also played a secondary role in the outbreaks of asthma in Barcelona, Spain, which were attributed to sensitivity to soybean hull (22).

ROLE OF FUNGAL ALLERGY IN SEVERE AND FATAL ASTHMA

Fungal sensitivity and exposure to airborne fungal spores has been associated with severe episodes of asthma. In a study of children and young adults who presented with respiratory arrest due to asthma, 10 of 11 patients were sensitive to *Alternaria* (23). Further, these patients experienced their severe episodes of asthma at the peak of the *Alternaria* season. The adjusted odds ratio was 189 ($CI = 6.5 - 5,535.8$) for a severe, potentially fatal attack of asthma that was highly correlated with *Alternaria* sensitivity (23). The risk of death from asthma has also been correlated with the presence of fungal spores in the atmosphere. In a study of death certificates from asthma in the Chicago area, the adjusted odds ratio for death on a day when the fungal spore counts exceeded 1,000 per cubic meter of air was 2.3 times as high as when the counts were less than 1,000 (24). The odds ratio increased for every increase in the fungal spore count above 1,000 per cubic meter. This observation indicates that fungal sensitivity not only carries an increased risk for the development of asthma but also plays an important role in epidemics of asthma, acute severe life threatening episodes of asthma and asthma deaths.

INDOOR FUNGAL EXPOSURE AND ALLERGIC DISEASE

Most of the studies cited above have concentrated on the relationship of fungal sensitivity to outdoor allergens and its role in allergic disease and asthma. The relationship between fungal exposure and allergic symptoms in the indoor environment is not as well characterized. Several studies have examined the relationship among indoor fungal spore counts, fungal allergen levels, and allergic symptoms. Studies conducted in Ontario, Canada, showed that allergic symptoms were higher in patients living in a damp residence (25). In Dutch children with known allergies, 63% lived in homes that had increased indoor fungal levels (26). The most commonly identified organisms recovered from homes were *Penicillium*, *Cladosporium*, *Aspergillus*, and mycelia sterilia. Peat (27) reviewed the literature for the previous 15 years regarding the relationship between dampness or fungi in the home and respiratory health. Analysis of the data from these studies (Fig. 2) indicates that there is an increased risk for children to have respiratory symptoms in a home that is damp or has visible fungal growth (odds ratio in the range of 1.5–3.5) (27). Verhoeff and Burg (28) also reviewed the association between fungi in homes and health risk. These authors came to virtually the same conclusion as Peat concerning the positive association between damp homes and respiratory morbidity of the occupants (28). In addition to these literature reviews, Beaumont (29) found that half the reported asthmatic symptoms of patients could be attributed to indoor or outdoor fungal spore peaks.

Aside from the home environment, individuals are exposed to fungal allergens in their work environment as well. Studies of Canadian office workers indicate that the office environment is also a potential source of fungal allergen exposure (30). Clearly it is important to account for exposure to fungi in the outdoor environment, home environment, and workplace.

PURIFIED FUNGAL ALLERGENS

Recent advances in molecular biology have led to a better understanding of fungal allergens and their relationship to allergic disease. Previous attempts to isolate fungal allergens by conventional protein techniques have proven cumbersome and difficult. Several major allergens have been identified from important fungal taxa (Table 3).

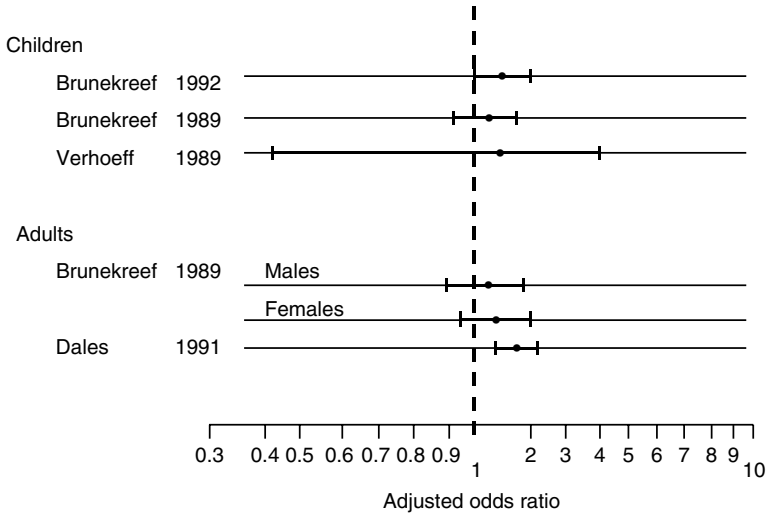

Figure 2. The association between asthma in children and adults exposed to fungal growth in the home. From: R. K. Bush, in environmental Asthma, R.K. Bush, ed, Marcel-Dekker, New York, 2001: 69–90.

Alternaria

A number of *Alternaria* allergens have been isolated. Alt a 1 is a major allergen with a molecular weight of 29 to 30 kD (21,31–33). Fragments of this protein have been molecularly cloned (34–36). The allergen is a two-chain dimer. Ninety percent of *Alternaria* allergic individuals have IgE antibodies to this protein. The biological function of Alt a 1 has not been elucidated. Alt a 2 is another major *Alternaria* allergen that has been molecularly cloned (37). It has a molecular weight of approximately 25 kD. Approximately 60% of *Alternaria* sensitive individuals have IgE antibody directed against this protein. Sequence homology has been demonstrated to a common transposable region and to mouse RNA-dependent eukaryotic initiation factor-2α-kinase. Several other minor *Alternaria* allergens have been identified as well (38). Alt a 3 is a heat shock 70 protein; Alt a 6 is a P2 ribosomal protein; Alt a 7 is homologous with YCP4 yeast protein; and Alt a 10 is an alcohol dehydrogenase. These proteins appear to be cytoplasmic housekeeping proteins that are conserved among several fungal species. GP70 has also been described, which is a 70 kD allergen from *Alternaria* (39). It accounts for 13% of the dry weight of an *Alternaria* extract and elicited positive skin tests in 87% of *Alternaria* sensitive patients tested with it.

Cladosporium

Three *Cladosporium herbarum* allergens have been purified (3). Cla h 1 and Cla h 2 are major allergens with molecular weights of 13 and 23 kD, respectively. Cla h 3 is a ribosomal P2 protein, similar to Alt a 6 (40). In addition, enolases are highly conserved major allergens found in *Cladosporium* and *Alternaria* (41). Enolases are also found to be allergens in *Saccharomyces cervisiae* and *Candida albicans*.

Aspergillus

Aspergillus fumigatus is an important indoor allergen from which several allergens have been molecularly cloned (42,43). Asp f 1 is a cytotoxin homologous with mitogillin (44). This protein is secreted into the surround media only during active growth of the organism. Asp f 2 is a major allergen in patients with allergic bronchopulmonary aspergillosis (ABPA) (45). Asp f 3 is a peroxisomal membrane protein that binds IgE from *Aspergillus* allergic asthmatic patients at a rate of approximately 72% (46). Asp f 4 binds IgE from sera with patients with ABPA (42). Asp f 5 is another secreted protein important in the allergic asthma and is a metalloprotease (42,43). Asp f 6 is a nonsecreted, manganese superoxide dismutase that is important in ABPA (42). Secreted proteins such as Asp f 1, Asp f 3, and Asp f 5 are recognized by IgE antibodies in sera of patients who have *Aspergillus* sensitivity with or without ABPA (42). Using a combination of these allergens, diagnostic sensitivity of 97% for *Aspergillus* allergy has been demonstrated (42). The nonsecreted proteins such as Asp f 4 and Asp f 6 are recognized by the IgE antibodies in patients with allergic bronchopulmonary aspergillosis (42).

Penicillium

Several allergens from *Penicillium citrinum* have been identified (47–50). A 33 to 34 kD alkaline serine proteinase has been isolated, which is cross-reactive with similar allergens from an *Aspergillus oryzase* (49). Approximately 93% of patients with sensitivity to various *Penicillium* species have IgE binding to this protein (49). A heat shock 70 protein has also been identified as an important *Penicillium* allergen (50).

Identification and purification of fungal allergen plays a critical role in improving the diagnostic capabilities for fungal allergy. Further, identification of these allergens provides the basis for development of immunoassays to quantitate allergen exposure in the environment.

ASSESSMENT OF FUNGAL ALLERGEN EXPOSURE

See Bioaerosol Sampling and Analysis, this Encyclopedia, for more information.

Table 3. Some Relevant Allergens from Fungi by Molecular Cloning

Fungal Taxa	Allergen Designation	Molecular Size (KD)	Sequence Homology/Comments
Alternaria alternata	Alt a 1	29–31	Major allergen
	Alt a 2	25	Major allergen, mouse RNA- dependent, eukaryote initiation factor 2-alpha kinase
	Alt a 3	20	hsp 70 protein
	Alt a 6	11	P_2 ribosomal protein
	Alt a 7	22	YCP4 yeast protein
	Alt a 10	53	Alcohol dehydrogenase
	Enolase	46–48	Conserved allergic protein in several fungal species
Cladosporium herbarum	Cla h 1	13	Major allergen
	Cla h 2	23	Major allergen
	Cla h 3	11.1	
	Enolase	46–48	Conserved protein in several fungi species
	hsp 70	70	hsp 70 protein
Aspergillus fumigatus	Asp f 1	18	Major allergen mitogillin
	Asp f 2	34	Important in patients with ABPA
	Asp f 3		Peroxisomal membrane protein
	Asp f 4	30	Important in patients with ABPA
	Asp f 5		Metalloprotease
	Asp f 6	26.7	Important in patients with ABPA Manganese superoxide dismutase
	Asp f 7	11.6	
	Asp f 8		
	Asp f 9	33.7	
	Asp f 10		Aspartic proteinase
	Asp 11		Peptide-prolyl isomerase
	Asp f 12	65	hsp 70 protein
Penicillium citrinum	Pen c 1	33	Alkaline serine proteinase conserved in other fungal species
	Pen c 2	70	hsp 70 protein
	Pen c 3	18	Peroxisomal membrane protein
Psilocyte cubenis	Psi c 1		
	Psi c 2	23	Cyclophilin
Coprinus comates	Cop c 1	8.9	Intermediate allergen

Traditionally, exposure to fungal allergens has been assessed by microscopically identifying and counting the number of fungal spores in the air or by semiquantitative cultures obtained from air or settled dust samples. A number of volumetric samplers are available. In general, suction devices are preferred because they are more efficient in capturing a broader range of particle sizes than impaction samplers. In addition to these methods, immunoassays to detect fungal polysaccharides (51) and markers for total fungal mass such as ergosterol, are available. There is no evidence, however, that either of these fungal products play a pathological role in fungal allergy. Lastly, the most direct way to assess fungal allergen exposure is by the measurement of actual allergen concentrations in airborne or settled dust samples. This technology is not as highly developed as it is for house dust mite, cats, or cockroach allergens, but as more fungal allergens are identified, immunoassays for their quantitation are being developed. Such assays have been developed for *A. alternata* allergens (39,52–54), *A. fumigatus* (55), and *Cladosporium herbarum* (54). Because of a variety of technical limitations of each sampling method, a combination of assays may be necessary to more accurately identify and quantitate fungal allergen exposure.

ABATEMENT MEASURES TO REDUCE FUNGAL ALLERGEN EXPOSURE

On the basis of available information, there is a correlation among fungal exposure, sensitivity to fungi, and development of allergic disease. Therefore, reductions in exposure should lead to decreased severity and incidence of illness attributed to it. This has been demonstrated for allergens such as dust mite and cat, but no controlled trials have been conducted regarding fungal exposure. The recommendations are, therefore, based on intuitive reasoning.

For outdoor fungal exposure, sensitive individuals should avoid exposure to contaminated materials such as decaying vegetation, compost piles, and farming activities.

If these activities must be performed, the use of a dust-mist mask or full respiratory protection may be necessary to reduce exposure.

Indoor fungal exposure occurs in two ways: through infiltration of spores from the outside and through the growth of fungi indoors. Successful strategies to eliminate the problem must consider both sources of contamination. Spores from the outside can be reduced in the inside environment by closing doors and windows and using air conditioning. This can reduce indoor fungal allergens at times when the outdoor levels are high [the use of window air conditioners with the vent closed has been shown to effectively exclude spore infiltration from the outdoor environment (56)]. Interestingly, indoor fungal allergen concentrations are decreased when ventilation (i.e., opening windows) is increased (57). A compromise of providing adequate filtered air and nonfiltered outdoor air ventilation is necessary to reduce spore exposure while at the same time allowing fungal metabolites to vent to the outside.

Indoor fungal growth is dependent on moisture and a carbon source. The fundamental principle for eliminating or reducing fungal growth is controlling the amount of moisture present (58). Several steps can be taken to control indoor moisture problems. (*1*) Use dehumidifiers or air conditioning to maintain indoor relative humidity no greater than 50%, (*2*) seal all leaks to prevent water accumulation, (*3*) increase the use of bathroom and kitchen ventilation by using exhaust fans, (*4*) vent clothes dryer to the outside, (*5*) reduce the number of live indoor plants that have to be watered, (*6*) heat all rooms in the winter and add heating to outside wall closets, and (*6*) use a sump pump in the basement that are prone to flooding.

Carpets, wallpaper, paneling and heating, and air conditioning systems are known to harbor fungal spores. Fungal levels are higher in the presence of old wall-to-wall carpets (57). Vacuuming can reduce fungal spore levels; however, if contamination is extensive or family members are extremely sensitive, more effective measures may be needed such as replacing carpeting with hardwood, tile, or other materials. Washable surfaces that have visible fungal growth can be treated with 5% bleach and detergent solution. However, caution should be exercised when applying this and respiratory protection should be used. Treatment can also be done with commercial antifungal agents, although not all of these products are equally effective (59).

In cases in which extensive flooding has occurred that has led to tremendous amounts of fungal growth in basements or other areas, paneling and other contaminated materials may have to be removed. If contamination is found in air ducts and filters, these may need to be cleaned or replaced to reduce fungal exposure (60).

High efficiency particulate air (HEPA) filters are the most efficient type of filter to remove spores from the air in indoor environments (61). Electronic air cleaners have a moderate effect (62). However, the effectiveness of these air filters in treating allergic disease due to indoor fungal allergy is yet to be established. Heating and air conditioning equipment in homes and the workplace should be inspected and cleaned regularly to avoid fungal contamination that can be circulated through the building.

To a person who is highly sensitive to fungal allergens, a well fitted mask that will filter particles that are less than one micrometer when engaged in activities such as cleaning that can disperse spores into the air can be of benefit. Where extensive fungal contamination exists, cleaning should be performed by individuals who are not allergic or immunocompromised.

Conclusion

Sensitivity to fungal allergens is a common clinical problem. Fungal allergen exposure is associated with the development and severity of asthma in sensitized individuals. Most of the exposure occurs from the outdoor environment, although the contribution of indoor fungal allergen exposure to allergic disease may also play a significant role. Traditional methods of exposure assessment by spore counts in quantitative cultures suggest that indoor fungal exposure indeed contributes to allergic airway disease. Methods to more directly assess fungal allergen exposure by immunoassays are still under development. Presence of fungal growth in the home or workplace suggest a problem with excessive dampness in the environment. Methods to decrease the infiltration of fungal spores from the outdoor environment, controlling indoor moisture problems, and cleaning or removing contaminated materials may be helpful in improving the health of individuals with fungal induced allergic diseases.

FUNGAL CONTAMINANTS

CHIN S. YANG
P & K Microbiology Services, Inc.
Cherry Hill, New Jersey

Fungal spores are recognized allergens (1,2). Over the last 20 years, fungal amplification in the indoor environment, because of leaks and excessively high humidity, and the resulting contamination have increasingly been recognized as a major health risk to building occupants (3–7). In addition to their allergenicity, fungi are known to be capable of causing infections and capable of producing a wide variety of chemicals (3–6,8). These chemicals include irritating volatile organic compounds and highly poisonous mycotoxins. Fungi and their by-products have been suspected of causing adverse health effects ranging from irritation, hypersensitivity diseases, infections, to possibly inhalation mycotoxicosis (4–6). Some chemical by-products of fungi, such as penicillin, cephalosporin, and cyclosporin, are beneficial to humans. The growth and amplification of fungi in the indoor environment may expose building occupants to allergens, fungal glucan and volatile organic compounds (VOCs), and possibly mycotoxins over a long period of time or until the occupants and/or fungal contamination are removed from the environment. The current approach to the assessment and investigation of indoor fungal contamination includes taking notes of water damage history, visual inspection, sampling and testing for fungi in the air and from other possible sources, and, ultimately, remediation (5).

WHAT ARE FUNGI?

Fungi are ubiquitous in nature. They are eukaryotic organisms. Their cells do not contain chlorophyll and, therefore, must rely on external sources for nutrients and energy; that is, they are heterotrophic. There are approximately 70,000 species of fungi known and identified. However, it is conservatively estimated that there are more than 1.5 million species in nature (9). Fungi can form symbiosis with algae (lichens), mycorrhizal associations with plant roots, or cause diseases in plants and animals, including humans. More importantly, a majority of fungi are saprophytes, and decompose litter and organic matter to recycle nutrients. These saprophytes can be found growing in man-made environments in which they grow on many organic building materials with elevated moisture content or water activity because of the availability of excessive moisture or uncontrolled water in the indoor environment.

In the current taxonomy, true fungi may be arranged into four or five phyla (9,10). They are Chytridiomycota, Zygomycota, Ascomycota, Basidiomycota, and Deuteromycota. Many mycologists do not accept the last group as a formal taxonomic category and call them mitosporic fungi (produce spores by asexual mitotic division). Most taxa of the Deuteromycota are also called *microfungi*, or *molds*, because of their small sporocarps. Many members of the Deuteromycota have sexual states (termed teleomorphs) in either the Ascomycota or the Basidiomycota. However, a significant number of taxa in the Deuteromycota have only anamorphs (asexual state) and no known teleomorphs, and can not easily be assigned to either the Ascomycota or Basidiomycota without using molecular and ultra-structural techniques. Therefore, the anamorphic or asexual names are used in this text. Although the majority of fungi found to be associated with indoor contamination are in the Deuteromycota, a few members of the Zygomycota, Ascomycota, and Basidiomycota have also been identified growing in the indoor environment.

Fungal spores are cosmopolitan. They are in soil, in water, or in the air, and have been reported from the Arctic, the Tropics, and the Antarctic. They are known to contain allergens, and may carry mycotoxins (1,4,5,7,8). More significantly, they are propagules and will germinate and grow into colonies under suitable conditions outdoors as well as indoors. Numerous cases of fungal growth and amplification have been reported in the indoor environment (3–5). Reports of illness and adverse health symptoms have been related to mold growth and exposure to mold allergens, mycotoxins, and possibly fungal VOCs in water-damaged and moldy environments (5,11–14).

Microfungi may produce spores in dry form or in slimy masses (15). Dry spores are powdery and easily become aerosolized. Their primary dispersal mechanism is through air. Common dry-spored fungi found indoors include species of *Alternaria*, *Aspergillus*, *Cladosporium*, *Paecilomyces*, and *Penicillium*. Dry spores may be released into the air by passive means or by an active discharge mechanism. Spores of *Aspergillus*, *Cladosporium*, and *Penicillium* become airborne by air movement, whereas *Epicoccum nigrum* and *Sporobolomyces salmonicolor* are known to discharge their spores by a shooting mechanism. The slimy spores are dispersed primarily through running water, small animals or insects, and occasionally through air when they become dry and disturbed or when they are attached to other particles. Species of *Acremonium*, *Fusarium*, *Stachybotrys*, and *Trichoderma* are well-known slimy-spored fungal contaminants found indoors. Both dry- and slimy-spored fungi can be found in the same indoor environment.

FUNGI IN THE INDOOR ENVIRONMENT

Fungal growth in the indoor environment is not new. Wood microbiologists have studied wood decay by fungi for many years (16,17). *Aspergillus versicolor* and *Scopulariopsis chartarum* were reported to grow on wallpaper as far back as the 1930s (18,19). *Chaetomium* species were found damaging ammunition dumps in the Pacific during World War II. *Aspergillus* species and other molds are known to grow and damage optical instruments in the humid tropical environment. In the indoor environment, fungi have been found to grow on wood products, paper products, carpets, wallpapers (20), and insulation materials of the heating, ventilating, and air-conditioning (HVAC) system (21).

Fungi require moisture, organic nutrient, oxygen, light, and reasonable temperature to initiate and sustain growth in the indoor environment. Nutrients are usually plentiful, oxygen is normally in relative abundance, sunlight and artificial lights are required indoors for human functions, and temperature is often suitable or ideal in indoor environments. These factors usually do not pose a problem in the indoor environment. The critical factor to fungal colonization and growth indoors is moisture, particularly the moisture content of materials. Ambient relative humidity does not directly affect mold colonization and growth.

Moisture content in materials may be measured in percentage of water on oven-dry weight or in water activity. However, water content in a material does not imply the actual availability of free water to fungi. A better measurement of water availability to fungi is water activity (22), which is expressed as:

$$\mathrm{Aw} = \frac{\text{vapor pressure of water in substrate}}{\text{vapor pressure of pure water}}$$

Water activity (Aw) in a substrate can selectively allow certain fungal groups to grow. At low water activities (<0.85), xerophilic fungi, such as *Eurotium* species, some species of *Aspergillus*, and *Wallemia sebi*, are often found to dominate the fungal population. In wet substrates, hydrophilic fungi, such as species of *Acremonium*, *Stachybotrys*, *Trichoderma*, and *Ulocladium* are likely to be found. Slimy-spored species are likely to be found in a high water activity environment because of their requirement of water for spore dispersal.

Fungi can obtain their nutrients from the indoor environment. Wood and paper products, skin flakes, pollen grains, insect parts, and organic dusts are commonly available indoors (23). Wood and paper products are the

most abundant nutrients available. In fact, they are so abundant, many cellulolytic fungi, such as *Stachybotrys chartarum*, *Trichoderma species*, *Chrysosporium pannorum*, and *Chaetomium globosum*, are commonly identified from these sources in the indoor environment. Pollen is another good nutrient source for fungi. Some fungi have been found capable of attacking and using pollen for a supplementary source of nitrogen (24). Insect parts may also harbor fungi. In studies of samples collected indoors, entomophagus *Beauveria bassiana* and *Paecilomyces farinosus* are occasionally found in abundance. Insect and insect parts are very common in dust samples taken in wet and damp environments. Organic dust, including soil, compost, and mulch, is also a good source of nutrients for fungal growth.

Fungi are aerobic but may grow in reduced oxygen conditions. However, the lack of oxygen in water may actually limit fungal growth when materials are soaked deep in the water even though Aw is at 1. In the indoor environment, oxygen is highly unlikely to be a limiting factor to fungal colonization and growth.

Some fungi require light for spore production; however, light may affect some vegetative growth. Without light, some fungi, such as species of *Alternaria* and *Epicoccum*, are known to fail to sporulate. The myth that fungi grow better in total darkness was based on layman's observations. Dark places are often associated with lower temperature, higher humidity, and dampness. It is the moisture that permits fungal growth in such conditions (5). It is not uncommon to observe fungal growth on the walls of occupied spaces, although heavier fungal growth may be found in the wall cavity side of the surfaces.

Fungi may grow at temperatures below freezing to 35 °C or higher. Some of them are thermophilic (50 °C or higher) but most fungi prefer the room temperature range (20 to 30 °C). A few fungi, such as *Aspergillus fumigatus*, grow best at a temperature close to 35 °C. Several species of *Cladosporium* (*C. herbarum*, *C. cladosporioides*, and *C. sphaerospermum*) and *Penicillium corylophilum* are known to germinate and grow at relatively low temperatures (25). These fungi are commonly encountered growing in HVAC systems (21), particularly near the cooling coil where the temperature can be as low as 10 °C.

HEALTH EFFECTS

Fungi are known to cause a number of adverse health effects to humans. Four types of diseases are generally recognized: (*1*) infection in living tissues by fungi (mycosis), (*2*) allergic and hypersensitivity diseases, (*3*) mycotoxicosis owing to ingestion of foods containing toxins produced by fungi or inhalation of mycotoxin-containing spores, and (*4*) irritation caused by chemicals produced by fungi.

Fungal Infections

Of over 70,000 species of fungi, no more than 300 species have been directly implicated as causing human disease. Approximately 90% of all fungal infections are caused by fewer than a dozen fungi (26). *Aspergillus fumigatus* is the most notorious and most often encountered in fungal infections among the immune-deficient population, causing aspergillosis. This fungus can grow at a wide temperature range with the optimum near human body temperature. In addition, it produces several mycotoxins, which may facilitate invasion of the fungus. Outbreaks of aspergillosis caused by this fungus are not uncommon in hospitals and health care facilities, particularly in bone marrow or organ transplant units and in critical care units. *Aspergillus fumigatus* is not a common colonizer of the indoor environment. However, its spores are among the smallest among microfungi at approximately 2 to 3 μm (27), allowing them to easily infiltrate the air space of a building. A few other species of *Aspergillus* have also been reported to cause aspergillosis.

Dermatophytic fungi, such as species of *Trichophyton*, *Epidermophyton*, and *Microsporum*, grow on and utilize keratin in hair, skin, and nails for food. Because of their nutritional requirements, their attack rate is higher in institutions or in overcrowded conditions. Although dermatophytoses are normally not life threatening, they are the most common fungal infections in the world.

Soil-borne infectious fungi, such as *Histoplasma capsulatum, Blastomyces dermatitides*, and *Coccidioides immitis*, are usually found outdoors. However, *H. capsulatum* and *Cryptococcus neoformans* are often found in association with bird and bat droppings, or with soils enriched with bird droppings or poultry manure. Occasional outbreaks of histoplasmosis in the indoor environment have been reported because of indoor contamination by nesting birds (28). Transmission is by air. *Coccidioides immitis* causes valley fever or coccidioidomycosis. This fungus is primarily found in southwestern United States in arid, alkaline soil. Except for reports of infections in laboratory workers, there has been no report of infections in the indoor environment (26,29).

Allergic and Hypersensitivity Diseases

Fungal spores of various species have been associated with hypersensitivity diseases, such as mold allergy, rhinitis, bronchitis, asthma, and hypersensitivity pneumonitis (6). The significance of fungal spores as allergens in the indoor environment has not been fully appreciated until recently. The fungal spore is a known cause of allergic diseases (2) and has been identified as one of the major indoor allergens (1). Fungal levels comparable to outside background levels are usually well tolerated by most people. However, as atypical fungal spore levels increase because of recurrent water leaks, home dampness and high humidity, an increased frequency of respiratory problems (allergy and "sick building syndrome"-like symptoms) can be found (13,30–37). Many allergenic fungal spores are common outdoors. Because of their concentration and prevalence outdoors, these spores are the ones most likely to invade and grow in the indoor environment. Species of *Acremonium, Aspergillus, Alternaria, Chaetomium, Cladosporium, Paecilomyces, Penicillium, Phoma, Rhodotorula, Sporobolomyces, Stachybotrys, Trichoderma, Tritirachium*, and *Ulocladium*, have been

encountered and reported to grow in the indoor environment. Many of these fungi have been reported to cause allergies and hypersensitivity diseases.

The reported percentage of the human population that is allergic to fungi and molds varies from 2 to 18%. Approximately 80% of asthmatics were reported to be allergic to molds (14). The incidence and prevalence of allergic diseases are on the rise (1). In clinical allergy, patients can be specifically tested for mold allergy using skin or serological tests, and appropriate advice and treatment can then be prescribed. Patients with an atopy (a genetic trait of increased allergen sensitivity) are frequently allergic to multiple fungal species and manifest type I reactions (asthma, rhinitis, eczema, and hay fever).

All fungi may be allergenic depending on the exposure situation and dose (1). The relevant route of exposure is inhalation and the adverse effects are related to duration and intensity of fungal exposure. However, typical for allergic reactions is that once an individual develops an allergy to certain fungi, even small airborne concentrations can trigger an asthma attack or other allergic reactions. Allergy threshold levels to common mold, have been reported at 100 CFU/m^3 for *Alternaria* and at 3,000 CFU/m^3 for *Cladosporium* (2).

Hypersensitivity pneumonitis (HP), also called *extrinsic allergic alveolitis*, is a well-recognized allergenic, occupational disease, including malt worker's lung, woodworker's lung and wineworker's lung, It is characterized by symptoms of dyspnea, cough, abnormal chest X-ray, abnormal lung functions, high antibody precipitins, and possibly pulmonary fibrosis (6).

Mycotoxicosis

Many fungi produce a number of secondary toxic metabolites. These chemicals, known as *mycotoxins*, are toxic to animals and humans. Symptoms of mycotoxicosis may include skin rashes, loss of appetite, dizziness, nausea, immune-suppression, neurotoxicity, hemorrhage of the lungs and brain, birth defects, and cancer. Although mycotoxicosis can be caused by ingestion, inhalation, or skin contact of mycotoxins, the majority of our knowledge on mycotoxicosis has been learned from ingestion exposure. The significance of inhaled mycotoxins to human health is not well defined and currently is under scientific investigations. It is, however, prudent to limit exposure to such potent toxic chemicals (5), particularly when significant fungal growth and amplification is found indoors. It is conceivable that multiple forms of exposure, including ingestion, inhalation, and skin contact, are very likely when an indoor environment is infested with fungi. In addition to causing mycotoxicosis, mycotoxins may be involved in fungal infection. It was recently suggested that gliotoxin produced by *A. fumigatus* may facilitate the invasion of animal and bird lungs (38).

Organic dust toxic syndrome (ODTS), also called *toxic pneumonitis*, is a nonallergic, noninfectious form of an acute inflammatory lung reaction to fungal dust exposure (38). The differences between HP and ODTS can be difficult to distinguish. A table is available to compare differences and symptoms of HP and ODTS (6). High dosage exposures to fungal spores (possibly mycotoxins), glucans, or endotoxins are usually associated with ODTS. The significance of ODTS in occupational health is such that preventive measures have been recommended for certain occupations, such as agriculture and food processing industries, by the National Institute for Occupational Safety and Health (NIOSH). The measures include the use of industrial hygiene controls, special protective equipment, ventilation and respiratory protection (40).

Irritations

Actively growing fungi may produce VOCs with unpleasant odors. Some people consider these odors to be offensive and irritating. It has been suggested that exposure to fungal VOCs (possibly also bacterial VOCs) may be related to poor air quality (14). However, there is very little clinical data to relate exposures to fungal VOCs and symptoms of disease (5).

Strains of toxigenic *Stachybotrys chartarum* were found to induce hemolysis on blood agar incubated at 37 °C but not at 23 °C (41). Although the significance of this finding is yet to be determined, hemolysins produced by pathogenic bacteria are known virulent factors in the disease causing process. The production of hemolysin(s) by this fungus was suggested to play a role in the pathophysiology of idiopathic pulmonary hemorrhage (41).

Beneficial Fungal Chemicals

Fungi are also known to produce a number of useful chemicals and compounds. These include alcohol, organic acids, enzymes, antibiotics (such as penicillin and cephalosporin), immunosuppressive medicine (such as cyclosporin), and many anticancer agents (5,8). Some fungal chemicals also have estrogenic effects on humans (8).

ASSESSMENT AND INVESTIGATION

The most important step in the assessment and investigation of fungal contamination in a building is to visually inspect and evaluate the building structure and the HVAC system. If information regarding building water damage history is available, it may be helpful in developing an evaluation method, formulating a sampling strategy, and possibly relating water damage and fungal contamination to reported health effects. The visual inspection may include, but not be limited to, the following points. They are: (*1*) detection of moisture and leaks, (*2*) identification of sources and causes of moisture migration, (*3*) identification of structures that are conducive to moisture migration, (*4*) identification of the moisture-damaged areas and coverage, (*5*) identification of hidden moisture damage, (*6*) assessment of hygienic conditions of the HVAC system, and finally, (*7*) collection of source samples to confirm fungal growth, and to identify the types of fungi. After careful review of the building history and visual inspection of the building structures and the HVAC system, samples of various types may be collected to confirm fungal growth. This approach not only identifies the sources of fungal contamination, but also facilitates medical diagnosis and eventual remediation and control of fungal growth.

Various types of sampling may be used. Air sampling has been commonly used in the assessment of airborne fungal contaminants. However, no standard protocol is currently available. Various types of air sampling equipment are commercially available. In a medically based assessment, air sampling may help to decide whether airborne fungal spores may be the offending agents. Air sampling for culturable fungi or total spore counts is often used to determine potential human exposure (42). Air sampling for culturable fungi provides accurate identification of fungi but often underestimates airborne spore concentrations because of nonviable spores, dormant spores, or unsuitable collection media (15). Air sampling for total spore counts may provide a better estimate of airborne concentrations of fungal spores; however, identification of fungal spores is presumptive at best. A recent comparative study showed that higher fungal levels were derived from an air sampling cassette analyzed using the total spore count method when compared with samples collected with an Andersen single stage sampler and analyzed for culturable fungi. The total spore count method also had a better detection frequency of spores that have difficulty competing with fast-growing fungi on nutrient media (42).

Currently available air sampling technology and the analytical methodology are capable of sampling for a short period of time. The results are affected by the normal fluctuations of airborne fungi and usually do not reflect the temporal and spatial variations. Efforts to improve sampling efficiency and analytical capability are being pursued. Recent reports suggest that the newly developed Polymerase Chain Reaction (PCR) technology may identify species-specific DNA sequences of some important indoor fungi. The technology can be applied in the detection of specific fungi in air or in substrate, (43,44). The technology also has much better detection sensitivity than the currently used techniques.

In addition to air sampling, source sampling, by taking surface wipes, bulk material, vacuum dust samples, is used to detect and confirm the presence of fungal reservoirs and growth, and to identify the types of fungal contaminants. Because fungi do not grow in the air, source sampling and testing is necessary to locate and detect the sources of fungal growth and contamination. The samples can be processed and analyzed using conventional extraction and serial dilution techniques, or by the PCR or DNA fingerprinting technology (43,44).

To quickly confirm fungal growth, a piece of clear cellophane sticky tape can be used to remove fungal "growth" from surfaces. The tape sample is prepared and examined under a compound microscope for fungal structures. This technique provides qualitative, descriptive results. A competent mycologist may identify fungi to the genus or species level, depending on the presence of fungal structures and fungal characters. The viability of identified fungi, however, is unknown unless further tests or culturing are performed. This method has been extensively and successfully used by field personnel in building assessment and inspection for fungal contamination.

The results of various samples are used to determine and locate fungal growth and contamination, as well as the types of fungi and their levels. Properly collected data can be helpful to physicians, who make the diagnosis and relate exposure to disease. A mycologist or a microbiologist with mycology training is useful in assisting in the interpretation of results. Results of air samples require careful and systemic approach to the interpretation. There are no generally accepted numeric guidelines or standards for assessment of fungal bioaerosol exposure in the indoor environment. Comparative sampling is necessary and is the currently accepted approach (45). For practical purposes, outdoor samples and samples collected from indoor nonproblem locations are taken as a reference for comparison. Although the American Conference of Governmental Industrial Hygienists (ACGIH) had previously suggested numeric guidelines for interpretation of fungal bioaerosol data, the current 1999 publication does not support any existing numeric criteria for interpreting fungal bioaerosol data (5). In keeping with the current ACGIH recommendations (5) as well as the industry-wide approach, interpretation of possible indoor fungal exposures should focus on:

1. comparison of indoor versus outdoor concentrations,
2. comparison of species composition indoors and outdoors,
3. determination of the presence of marker species in the indoor environment, such as *Aspergillus versicolor, Penicillium aurantiogriseum, Ulocladium botrytis*, and *Stachybotrys chartarum*, which are relatively uncommon in outdoor air, and
4. determination of the origins, whether indoor or outdoors, of the identified airborne fungi based on the natural niches and habitats of the fungi.

In general, indoor fungal concentrations should be similar to or lower than outdoor concentrations. Residential buildings are usually leaky and tend to have fungal levels similar to outdoor levels. It must be kept in mind that comparison of indoor and outdoor fungal sample results requires both expert and commonsense approach. For example, in subfreezing, snow-covered weather, outdoor fungal concentrations are very likely lower than indoor levels. If significantly higher levels of total fungi as well as marker species are found indoors, this often suggests indoor fungal amplification. Furthermore, the detection of some slimy-spored fungi in the air, even at low levels, may require further evaluation. The detection of slimy-spored toxigenic fungi, such as *S. chartarum* or *Fusarium verticillioides* (syn. *F. moniliforme*), often suggests an indoor contamination source. In addition, the consistent detection of some marker fungi, such as species of *Aspergillus, Paecilomyces, Penicillium* and *Wallemia*, may indicate water damage or excessive humidity, and fungal amplification.

PREVENTION AND CONTROL

Although fungal spores have been known to be an allergenic agents for many years, their significance to human health in general and to humans in the indoor environment in particular has been mostly overlooked

and misunderstood. They produce allergens and a wide range of chemicals and compounds that can induce various health effects and responses. More importantly, in a moldy indoor environment, humans are likely to be exposed to multiple fungal types as well as a mixture of various chemicals and toxins via various exposure routes (inhalation, ingestion, and skin contact). The best treatment for the exposures is to avoid or minimize such exposures by preventing fungal growth and removing any existing fungal growth as soon as it is discovered.

Fungal growth indoors is usually the result and symptom of moisture problems. Although fungal spores are common in indoor environments, fungi normally do not grow in a dry clean building. However, they can quickly establish their presence when there is sufficient moisture. Many fungi that have been found to grow indoors are ubiquitous and fast growing. A few fungi, such as *Chaetomium globosum* and *Stachybotrys chartarum*, are found growing indoors because of their preference for cellulose-rich substrates. Any unwanted moisture may allow fungal spores to germinate and grow into colonies. It is critically important to keep water, moisture, and excessive humidity in a building under control.

In a contaminated building, moldy materials must be removed, in addition to controlling moisture and humidity and to keeping the building dry (46). Because most fungal spores are very small (mostly 2 to 10 μm), isolation and containment must be installed during remediation to avoid and minimize migration of aerosolized spores and secondary contamination. Any residual spores may last for a few years; therefore, the building environment must be kept dry to starve the spores of moisture, thus preventing their germination and growth. Biocide treatments are usually not recommended because of potential toxicity to humans and house pets, and possibly long-term residual effects. Furthermore, biocide treatments without moisture control are only a temporary solution. Fungi will grow back in a few days if moisture presence persists.

Assessment Services
Olympia, Washington

A number of fungi and microbes have been recognized to have importance in clinical medicine. These have been described to cause infections of the skin and other body organs, allergy, inflammatory or irritant effects, and toxicosis. Infections are discussed only briefly because these are commonly described in more detail in standard medical textbooks (1,2). Specifically, fungi not normally found in the interior of buildings and their chemical by-products such as (1–3)-ß-D-glucan, mycotoxins, and microbial volatile organic compounds (MVOCs) have also been implicated in conditions commonly known as "sick building problems" or building related diseases (3–5). Health problems from biological aerosolized pollutants can also be related to animal dander, dust mites, bacterial endotoxins (lipopolysaccharides or LPS) (6), viruses, *Legionella*, and protozoa, which will be discussed in other articles in greater detail.

Fungal spores and other microbial products can be deposited in the dust on various indoor surfaces (organic dust) and may be become airborne in the indoor environment and result in air contamination (bioaerosols). Such bioaerosols have been defined as microscopic organisms and biologically significant materials that are transported through the atmosphere and deposited in areas that may have "consequences for life" (7). Organic dust comprises materials of vegetable, animal, and microbial origin such as bacteria and fungi (8). Microbial materials and components in dust are made of a variety of substances including fungal spores and hyphae, actinomycetes spores, endotoxins (lipopolysaccharides from gram-negative bacterial cell walls), mycotoxins, (1–3)-ß-D-glucan, and MVOCs. Organic dust has been recognized as containing causative agents for airway disease (e.g., sinusitis, asthma), allergy and toxic reactions (7). The term *sick building syndrome* (SBS) refers to poorly defined physical conditions or nonspecific symptoms (primarily sensory complaints) that are related in time and location to a "problem building," but no definite or specific cause (exposure) can be identified in an industrial hygiene evaluation of the work area (9–12). SBS is typically a multifactoral problem that includes building factors, ventilation system problems, volatile organic compounds (from carpets, glues, office supplies, or microbes), work-organization, and job stress and dissatisfaction, among others. Common complaints and symptoms in SBS cases can vary in their clinical presentation, prevalence, and their relationship to the time the building investigation is carried out. The term *building-related disease or illness* signifies a category of clinical diagnoses that are related in time and place of occurrence to an identifiable, known hazardous exposure in a building. Such illnesses have distinct clinical findings and laboratory or imaging test abnormalities. The pathogenesis of specific building-related illnesses has been related to infectious, immunological, or toxic exposures (13–17).

Fungi (or molds) have been related to building complaints for both SBS and building related illness. There are many nutrient sources in buildings that fungi can utilize for food, such as wood, paper, paint, mineral oil, and various modern building materials. If moisture from leaks or defective ventilation intrudes into such nutrient-rich environments, fungi and bacteria can grow to levels not encountered in outdoor environments. Bacteria and fungi contribute to degradation of materials, and can lead to health problems if they become airborne and are inhaled or touched by occupants. Many fungal spores are in the respirable size of 2–20 μm and may be trapped in the human airways, including the lungs. Maximal airborne dispersal will frequently occur under dry building conditions, if fungi and bacteria and their products are not removed after moisture intrusion has been ameliorated. Fungi detected on damp and wet building materials (so-called "atypical fungi") detected in past building investigations and identified utilizing different sampling methods are listed in Table 1.

INFECTIONS

Infections caused by fungi are called mycoses, specifically, endemic mycosis and opportunistic mycosis. Opportunistic fungal pathogens have medical importance, especially in persons with immunodeficiencies, organ transplants,

Table 1. Fungi Found on Damp and Wet Building Materials (So-called "Atypical Fungi")

Alternaria alternata
Aspergillus niger
Aspergillus versicolor
Aspergillus ochraceous
Aspergillus sydowii
Aspergillus versicolor
Aureobasidium pullulans
Chaetomium globosum
Cladosporium herbarum
Eurotium herbariorum
Eurotium repens
Memnoniella echinata
Paecilomyces variotii
Penicillium aurantiogriseum
Penicillium brevicompactum
Penicillium chrysogenum
Penicillium citrinum
Penicillium commune
Penicillium corylophilum
Penicillium expansum
Penicillium spinolosum
Penicillium viridicatum
Stachybotrys chartarum (atra)
Trichoderma viride
Wallemia sebi

and patients with immunosuppressant pharmacological treatments (20). Endemic mycoses are related to the geographic distribution of certain fungal pathogens. This type of infection is caused by the inhalation of airborne spores or conidia found in regions that have a high occurrence of such fungi because of unique soils, climate, and flora or fauna. Fungi and the endemic infections that may occur through air transmission are listed in Table 2.

Opportunistic infections are secondary illnesses that occur in patients with an altered or weakened immune system. Patients at risk for fungal infections usually have major systemic diseases or health suppressed conditions such as complicated diabetes mellitus, cancer, HIV/AIDS, severe liver or kidney diseases, organ transplantation, or burn injury. These patients may be on immune-suppressive medication. These infections are not contagious and the fungi are not considered obligatory pathogens. Secondary fungal infections and medical complications related to airborne fungal contamination in hospitals and transplant units have been reported. Immune-compromised patients may be at an increased risk of contracting opportunistic infections if pathogenic fungi become airborne and a route of entry exists. Among the fungi of concern are *Aspergillus* spp., such as *A. fumigatus*, *A. flavus*, and *A. niger*. Soil, bird and bat droppings, water-damaged materials, or rich organic substrates in buildings, may be a reservoir for these fungi. Other clinically important fungal infections are candidiasis, with local mucocutaneous or disseminated systemic organ manifestations, and skin mycoses. Among fungal skin infections (dermatophytoses) are tinea corporis, capitis, curae, and barbae (named depending on the body region infected) that are caused by fungal genera such as *Microsporum*, *Epidermophyton*, and *Trichophyton* that manifest as dermatitis. Invasive fungal diseases of the paranasal sinuses may also be associated with allergic sinusitis in patients (22). Often *Aspergillus* species are involved. Noninvasive forms may be colonizing preexisting body cavities and may be asymptomatic as long as some immunological resistance can be maintained.

An increased rate of respiratory, ear, or gastrointestinal infections can be found in people who are exposed to unusually high concentrations of fungi in the indoor environment. This is possibly the result of an altered or weakened immune system caused by cytotoxic fungi. Epidemiological studies have shown that among children, especially those in daycare centers or in schools, the rate of upper respiratory infections, bronchitis, and ear infections increases with excessive mold or dampness in buildings. Among adults in such environmental situations, an increased risk of bronchitis and sinusitis has been documented.

Correct diagnosis, therapy, and prevention of opportunistic infections may be difficult for those who are not well trained and experienced in this field. Early recognition, preventive building engineering, proper hygiene, and public health intervention can reduce the incidence

Table 2. Diseases Transmitted by Airborne Fungi and Affected Tissues

Fungi	Disease	Affected Organ/Tissues
Histoplasma capsulatum	Histoplasmosis	Lung, eye, (skin & bone.)
Cryptococcus neoformans	Cryptococcosis	Lung, central nervous system, meninges, skin and viscera.
Coccidioides immitis	Coccidioidomycosis	Lung, multi organ dissemination (skin, bone, meninges, joints).
Blastomyces dermatitidis	Blastomycosis	Lung, skin & mucous membrane, bone, joints.
Aspergillus spp.	Aspergillosis	Lung, bronchial airways and sinus cavities, ear canal, eye (cornea).
Sporotrix schenkiie	Sporotrichosis	Granulomatous pneumonitis (rare), skin, joints, central nervous system, eyes
Mucorales, Zygomycetes	Mucormycosis	Nose, sinuses, eye, lung (brain & other organs), gastrointestinal system.

(*Source:* 21)

of mycoses, especially those acquired in institutional care facilities.

ALLERGY

Many fungi are known to cause an immune pathology with an exaggerated or inappropriate immune response called hypersensitivity reaction or common allergy. Fungal spores are a known cause of allergic disease and have been identified as one of the major indoor allergens (23–26). Significant methodological problems in the production of reliable allergen extract from fungi exist compared to, for example, a cat, dust mite, or cockroach allergens. Extracts that are available correspond poorly to the fungi found frequently in indoor surveys (27). Population studies have shown that prolonged indoor exposure to some fungi can result in hypersensitivity reactions and chronic allergic diseases. Most people usually tolerate mold concentrations comparable to outside levels. Normal or typical indoor molds may vary depending on climate variations and geographic regions. However, as mold levels that are atypical in the indoor environment increase because of recurrent water leaks, home dampness, and high humidity, the prevalence of allergy and respiratory problems also rises (28–30). Many epidemiological studies have shown associations between damp and moldy buildings and cough and asthma among the occupants (31). Damp building materials, particularly those containing cellulose are prone to fungal contamination. Among the most common fungal contaminants of damp and moldy buildings are *Penicillium*, *Aspergillus*, *Chaetomium*, *Ulocladium*, *Stachybotrys*, and *Cladosporium* (32).

The reported percentages of populations allergic to molds vary from 2% to 18%. The incidence and prevalence of allergic diseases is on the rise. Approximately 80% of asthmatics were reported to be allergic to molds (33). A recent study of patients diagnosed with allergic fungal sinusitis found a very high incidence of mixed fungal contamination in nasal mucus (up to 96%) together with eosinophilia, but no type I hypersensitivity (34).

In clinical allergy, patients can be tested for specific mold allergy using skin or serological tests (IgE-RAST) and specific advice and treatment can then be given. Because of the low sensitivity of some of the commercially available mold extracts, false negative test results are common. Patients with atopy (a genetic trait of increased allergen sensitivity) are frequently allergic to multiple fungal species and manifest type I reactions (e.g., asthma, rhinitis, eczema, and hay fever).

All fungi may be allergenic depending on the exposure. However, the sensitivity of clinical laboratory tests to confirm allergy or prior exposure may vary with the individual patient and his or her immune system. Atopic individuals typically have a higher rate of positive skin reactions after provocation tests and serological allergy tests that measure antibody precipitins (IgE). Some individuals with known allergy may not develop any measurable biological marker. Diseases such as allergic bronchopulmonary aspergillosis (ABPA) (35) and allergic fungal sinusitis (AFS) possibly require additional host factors that are not well documented and may be the result of a combined reaction of allergenic inflammation and the immunotoxic effect of fungal metabolites. The pertinent route of fungal exposure is inhalation. Fungal mycotoxins have been found to inhibit the motion of respiratory cilia, slowing or preventing clearance of particles including viruses and bacteria from the respiratory tract (36), which may be important in the pathology of rhino-sinusitis. Allergically sensitized individuals have a lower tolerance to airborne concentrations of fungal allergens. Such sensitivity differs categorically from an inflammatory response to fungal toxins, which has a dose-response relationship that depends on concentrations of toxins breathed in, and does not require prior sensitization. Allergy threshold levels to common molds have been reported, but variations in sampling strategies and methodological limitations make these very unreliable in practical settings (37,38). Experts agree that currently acceptable safe threshold limits for fungal indoor exposure cannot be established and it generally is recommended that unnecessary fungal exposures are avoided or minimized (39,40).

HYPERSENSITIVITY PNEUMONITIS (HP) AND ORGANIC DUST TOXIC SYNDROME (ODTS)

The clinical findings and laboratory results of allergic and inflammatory toxic reactions to airborne microbial exposure are often difficult to separate in clinical practice (41–43). Hypersensitivity pneumonitis, called extrinsic allergic alveolitis outside the United States, is a well-recognized occupational lung disease. In serious cases, it may lead to lung fibrosis (scarring of the lungs). Organic dust toxic syndrome, also called toxic pneumonitis, is a nonallergic, noninfectious form of an acute inflammatory lung reaction to high fungal or other organic dust exposure (44). The differences between HP and ODTS can be difficult to distinguish. Table 3 lists comparative features of HP and ODTS.

In the early or subclinical stages of the disease, laboratory findings, pulmonary function tests, or radiological abnormalities may not be present. In these cases, the patient's history is vital for early diagnosis. The significance of ODTS in occupational health is such that the National Institute for Occupational Safety and Health (NIOSH) has recommended preventive measures for ODTS. The measures include the use of industrial hygiene controls, special protective equipment, ventilation of the workspace, and respiratory protection (45).

Workers in several occupations are at risk of acquiring these diseases although the number of affected people may not be very high. Farming and the agricultural industry, lumber and wood industry, and waste management are included in the occupations at risk. Large-scale composting of organic waste is a new, growing technology in municipal waste management (46). Environmental monitoring suggests possible high exposure risks to several pathogenic fungi, bacteria, and viruses. Immunological

Table 3. Comparative Features of Hypersensitivity Pneumonitis and Organic Dust Toxic Syndrome

	Hypersensitivity Pneumonitis (Extrinsic Allergic Alveolitis)	Organic Dust Toxic Syndrome (Toxic Pneumonitis)
Immune responses	Type IV delayed hypersensitivity, cell mediated immune reaction	Nonallergenic, noninfectious, lack of IgG.
Affected tissue/organ	Lung alveoli, forming granulomas	Inflammatory lung reaction
Exposure levels	106–1,010 CFU/m^3 of thermophilic actinomycetes or fungi	High concentrations of fungi, >109 spores/m^3 of (1–3)-ß-D-glucan or >1–2 $\frac{1}{4}$ g/m^3 of endotoxins.
Clinical features	Dyspnea, cough, fatigue, poor appetite, weight loss, abnormal chest X-ray, abnormal pulmonary functions, high antibody precipitins; may cause pulmonary fibrosis long term.	Dyspnea, cough, headaches, fever, chills, malaise, acute inflammatory lung reaction, negative chest X-ray; may recover after exposure cessation.

blood changes (such as IgG antibody elevation) can be can observed in waste handling workers or other occupations with high fungal exposure (47).

INFLAMMATION AND IRRITATION OF THE AIRWAYS

Prolonged exposure to fungi and their products can result in inflammation of the skin and mucous membranes, and of the airways (nonallergic asthma, bronchitis) (3,48,49). Skin contact with fungal materials can cause skin irritation and lesions that are often difficult to distinguish from other chemical-contact dermatitis, unless history of exposure can be established (50). Symptoms of burning eyes, nasal irritation, sore throat, hoarseness, and irritant cough are common after repeated exposure to airborne fungi. Typically, these complaints subside once the exposure is stopped. After inflammation of the airways, patients may be more intolerant to other airborne agents or pollutants, such as tobacco smoke, perfume, diesel exhaust, and strong chemical odors. A possible pathway of the mechanism of the effects of microbial organisms and its products are shown in Figure 1. It illustrates the important systems and mediators of the lung defense.

MYCOTOXINS

Several fungi found in our environment, in household dust, and agricultural products, produce toxins termed *mycotoxins*. Most of the information on mycotoxins comes from studying ingestion-related poisoning or from animal studies (50,52–56). The control of mycotoxins in food and feed is an important public health task and has great economic importance. Food-borne diseases affect animals or cause regional outbreaks of human disease (57). Historically, mycotoxins have been known to be a problem to farmers in Eastern European and developing countries, who have problems related to wet weather and storage (58). *Claviceps purpurea*, one of the first mycotoxin producers identified, produces the substance ergot, which causes ergotism. Ergot toxins caused food poisoning outbreaks associated with dry gangrene, loss of limbs, and bizarre behaviors that may have significantly contributed to the population decline in Europe from the fourteenth to the eighteenth centuries (59). Mycotoxin poisoning may have constituted part of the plagues of Egypt in which a series of catastrophes led to scarcity of food, wet storage of grain, and fungal growth of what is believed to be *Stachybotrys*. Subsequently, this led to the death of infants (first born) and elders from ingestion of mycotoxin-contaminated food (60).

Mycotoxins have been called an agent in search of a disease (61) but may be instrumental in a number of diseases. More than 400 fungal metabolites are known to be toxic to animals or humans. Mycotoxins can act directly or as products resulting from metabolism in the body. Break-down products of mycotoxins are more frequently measured in toxicodynamic studies as the parent mycotoxins have short half-lives ranging in hours or less. Important mycotoxigenic fungal species, their mycotoxins, and associated diseases are listed in Table 4.

Mycotoxins are typically small molecules (200 to 500 mass units) that are produced by a taxonomically wide range of fungi and consist of a very diverse group of compounds including polyketides, terpenes, cyclic polypeptides, phenolic acids, and diphenyl quinones, among others. (62,63). Important toxins are aflatoxin, 12-13-epoxytrichothecenes, fumonisins, ochratoxins, and gliotoxins, among others. Examples of fungi and their secondary metabolites are listed in Table 5 (64).

The International Agency for Research on Cancer (IARC) (38) classifies aflatoxin, a toxin discovered in 1961 and produced by *Aspergillus flavus*, *A. niger*, and *A. parasiticus*, as having "sufficient evidence" for human and animal liver carcinogenicity. It may also be involved in occupational respiratory cancers among food and grain workers (65). Aflatoxin-induced disease has been well reviewed (66,67). Carcinogenicity for trichothecene toxins (T-2 toxin, *Fusarium* toxins) was listed with "limited evidence" for animals and "inadequate evidence" (no data

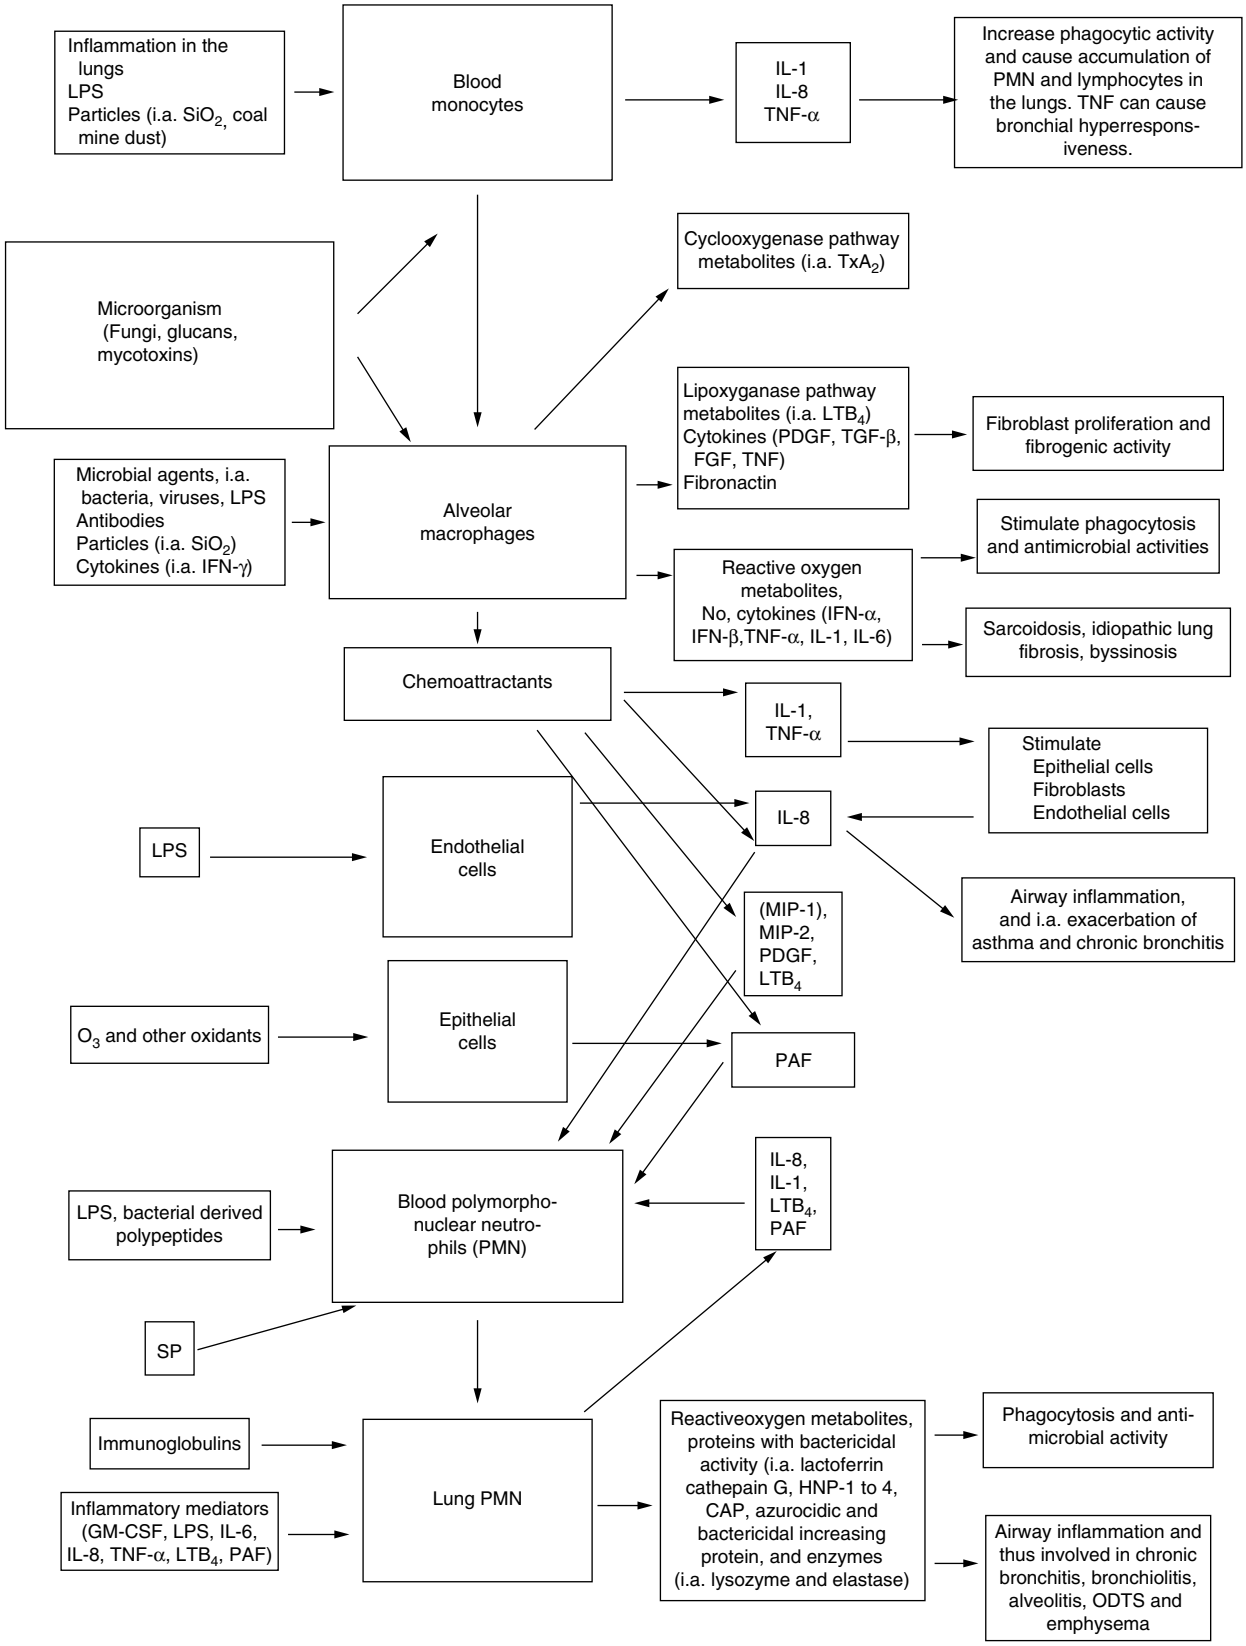

Figure 1. Possible respiratory tract effects from exposure to microbial organisms and products source: (50) G. D. Nielsen, Y. Alarie, O. M. Poulsen, B. A. Nexo. Possible mechanism for the respiratory tract effects of noncarcinogenic indoor-climate pollutants and based for their risk assessment. G. D. Nielsen, Y. Alarie, O. M. Poulsen, and B. A. Nexø, *Scan. J. Work Environ. Health* **21**, 165–178 (1995).

Table 4. Some Toxigenic Fungi, Fungal Chemical Metabolites, and Their Health Effects

Fungi	Chemical Metabolites	Health Effects
Penicillium (>150 species)	Patulin	Hemorrhage of lung, brain disease.
	Citrinin	Renal damage, vasodilatation, bronchial constriction, increased muscular tone. Nephrotoxic, hepatotoxic.
	Ochratoxin A	Neurotoxic.
	Citroviridin	Reduced cellular oxygen uptake.
	Emodin	Lung disease.
	Gliotoxin	Neurotoxic: trembling in animal.
	Verruculogen	Lung, teratogenic in rodents.
	Secalonic acid D	
Aspergillus spp.	Patulin	Hemorrhage of lung, brain disease.
A. flavus &	Aflatoxin B1	Liver cancer, respiratory cancer,
A. parasiticus	Sterigmatocyst	cytochrome-P-450-monooxygenase disorder.
A. versicolor	in	Carcinogen.
A. ochraceus	Ochratoxin A	Nephrotoxic, hepatotoxic

Table 5. Examples of Fungi and Their Secondary Metabolites

Arenaria alternata: tenuazonic acid, alternatiol, alternariol monomethylether, altertoxins
Alternaria, tenuissima: altertoxins
Aspergillus ochraceus: penicillic acid, ochratoxin A, xanthomegnin, viomellein, vioxanthin
Aspergillus flavus: kojic acid, 3-nitropropionic acid, cyclopiazonic acid, aflatoxin B1, aspergillic acid
Aspergillus fumigatus: gliotoxin, verrucologen, fumitremorgin A&B, flumitoxins, tryptoquivalins
Aspergillus niger: naphtho-pyrones, malformins
Aspergillus (Emericella) nidulans: sterigmatocystin, nidulotoxin
Aspergillus terreus: terrein, patulin, citrinin, citreoviridin
Aspergillus versicolor: sterigmatocystin, nidulotoxin
Aspergillus ustus: austamide, austdiol, austins, austocystins
Eurotium amstelodami: physcion, echinulin
Eurotium chevalieri: physcion, echinulin
Eurotium berbariorum: physcion, echinulin
Chaetomium globosum: chaetoglobosins, chetomiin
Cladosporium berbarum: epi- and fagi-cladosporic acid
Fusarium culmorum: culmorin, fusarin C, trichothecenes type B, zearalenone
Fusarium verticillioides: fumonisins, fusaric acid, fusarin C, moniliforme, naphthoquinone pigments
Fusarium solani: fusaric acid, naphthoquinone pigments
Paecilomyces variotii: patulin, viriditoxin
Penicillium aurantiogriseum: penicillic acid, verrucosidin, nephrotoxic glycopeptides
Penicillium brevicompactum: botryodiploidin, (mycophenolic acid)
Penicillium cbrysogenum: roquefortine C. meleagrin
Penicillium citrinum: citrinin
Penicillium commune: cyclopiazonic acid, rugulovasine A & B, fumigaclavine A & B
Penicillium crustosum: roquefortine C, penitrem A, terrestric acid
Penicillium expansum: roquefortine C, patulin, citrinin, communesins, chaetoglobosin C
Penicillium glabrum: citromycetin
Penicillium roqueforti: roquefortine C, isofumigaclavine A & B, PR-toxin, mycophenolic acid
Penicillium rugulosum: rugulosin
Penicillium variabile: rugulosin
Penicillium viridicatum: xanthomegnin, viomellein, vioxanthin, viridic acid, penicillic acid
Trichoderma barzianum: chrysophanol, koninginin A, trichorzianines A+B
Trichoderma viride: alamethicins, emodin, suzukacillin, trichodermin, trichotoxin A
Stachybotrys chartarum (a.k.a. atra): satratoxins, verrucarin J, roridin E and others
Wallemia sebi: walleminol A&B.

available) for humans in 1993. Macrocyclic trichothecenes, such as satratoxin H, have not been classified as carcinogenic. Epidemiological studies suggest a higher rate of upper respiratory tract and lung cancer in workers in the grain and food handling industry with high fungal product inhalation risk (65). The high rate of lung cancer among uranium miners in Silesia (so-called "Schneeberg disease") may have been related to combined effects of high radon and *Aspergillus* exposure in the underground mines (68).

Water-damaged building materials are often contaminated with fungi that produce detectable levels of mycotoxins (69–72) that may become airborne and contribute to indoor air pollution. Air sampling in buildings with fungal growth utilizing high-volume collection methods and assays sensitive to *Stachybotrys chartarum* toxins (Roridin A) showed that a very high percentage of the samples were cytotoxic if *Stachybotrys chartarum* was detected on the paper air-filters (73). Trichothecene and other mycotoxins were isolated by chemical methods (HPLC system) from extracts of samples with *Stachybotrys chartarum* and other fungal growth from buildings with water-damaged gypsum boards or other building materials (74,75). Important toxigenic fungi in damp buildings appear to be: *Penicillium* species, *Aspergillus* species, *Chaetomium*, *Fusarium* species, *S. chartarum* (syn. *S. atra*), *Paecilomyces* species, and *Trichoderma viride* (76). These fungi have been associated with adverse health effects in humans and animals, resulting in diseases that are primarily neither allergic nor infectious in nature. Inhalation of mycotoxins contained in houses appear to have stronger effects than ingestion of mycotoxins (77,78). Several mycotoxins are observed to be cytotoxic even in very low concentration and can inhibit DNA, RNA, and protein synthesis, and cause apoptosis of cells of different body organs. These toxic effects may cause a variety of short-term as well as long-term adverse health effects in animals and humans (79–82). Symptoms thought to be due to mycotoxins or toxin-containing spores (particularly those of *S. chartarum*) include dermatitis, recurring cold and flu-like symptoms, burning and sore throat, headaches and excessive fatigue, diarrhea, and impaired or altered immune function. The ability of the body to resist infectious diseases may be weakened, resulting in opportunistic infections. Certain mycotoxins, such as zearalenone, have been found to cause infertility and stillbirths in pigs and are regulated in food in Canada to prevent developmental effects in humans. Low level complex exposures from a mixture of mycotoxins encountered in typical conditions in wet and moldy buildings, may have synergistic effects. These may result in neuro-endocrine-immune changes that result in complex changes or even damage of the endocrine and nervous system (Fig. 2; 83).

The high-dose exposure to fungi and mycotoxins found in farmers and in food industries was generally considered unlikely to occur in nonfarming activities. However, many toxigenic fungi, such as *S. chartarum* and species of *Aspergillus*, *Penicillium*, and *Fusarium* have been found in high concentrations in buildings with documented indoor air problems and illnesses (84–86). An epidemiological study of adults in damp and moldy buildings suggests that inhalation exposure to mycotoxin-containing fungal spores is significant in the reported cases of building-related mycotoxicoses (87). Building and health investigations associated with toxigenic *Stachybotrys* were reported by Croft and coworkers (88), Auger (89,90). Johanning and coworkers (91) and Hodgson (92). Hemorrhagic lung disease in infants was highly associated with indoor *S. chartarum* exposure in a case cluster investigation in Cleveland (93) and in a case-home investigation in the mid-west of the U.S.A. (94). Subsequently, some consultants for the Center for Disease Control and Prevention (CDC) called for more research to prove the causal relationship of *Stachybotrys* and idiopathic pulmonary hemorrhage in infants on review of the Cleveland study. Exposure of mice to toxigenic spores of *S. chartarum*–induced bleeding from the respiratory tract (95) supporting the association found between toxic spores of this fungus and bleeding lungs in infants made in the Cleveland study. More recently, *S. atra* was isolated from bronchoalveolar lavage fluid of a child with pulmonary hemorrhage (96) and *S. atra* exposure was found in an infant that developed laryngeal spasm and hemorrhage during general anesthesia (97).

One important toxigenic fungus frequently detected in "problem buildings" is *S. chartarum*, which produces a series of potent cytotoxins such as trichothecenes (satratoxins) and spirolactones, as well as a variety of other compounds affecting the immune system (98,99). Table 6 lists chemical metabolites derived from *Stachybotrys* and reported health effects that may be related to the chemical properties.

A case study of health effects and changes in immunological laboratory values related to indoor exposure to trichothecenes and possibly other mycotoxins noted disorders of the respiratory and central nervous system, (100–102).

Trichothecenes are potent small molecule inhibitors of protein synthesis that act through inhibition of peptidyl transferase activity (103,104). These toxins can cause alveolar macrophage defects and affect phagocytosis. They have been investigated for use in cancer treatment (105) but also for use in chemical-biological warfare. The presence of fungal chemical metabolites has been reported in several cases of animal and human ingestion–related mycotoxicosis, occasionally resulting in death of animals and humans (106,107). Mycotoxins, such as Satratoxin H of the macrocyclic trichothecene group, have been shown to suppress T- or B-lymphocyte activity, suppress immunoglobulin and antibody production, reduce complement or interferon activity, and impair macrophage-effector cell function of human neutrophils (108).

Changes in laboratory measured levels of immunoglobulins (IgA, IgE, IgG, and IgM) have been reported in workers handling mycotoxin contaminated foodstuff (primarily deoxynivalenol or vomitoxin) (109). Renal failure, with deposition of IgG in the glomeruli, in a farmer who inhaled mycotoxins, primarily deoxynivalenol (vomitoxin) from *Aspergillus ochraceus*, has also been reported (110).

The treating physician may not recognize signs of mycotoxicosis because symptoms often overlap several known syndromes and exposure circumstances, and presence of certain mycotoxins are often not noted in the patient's history. Establishing exposure history and the presence of toxigenic fungi will be of importance to the differential diagnosis. Newer analytical methods involving immunoassays and cell line cytotoxicity analysis may be able to provide rapid information about the

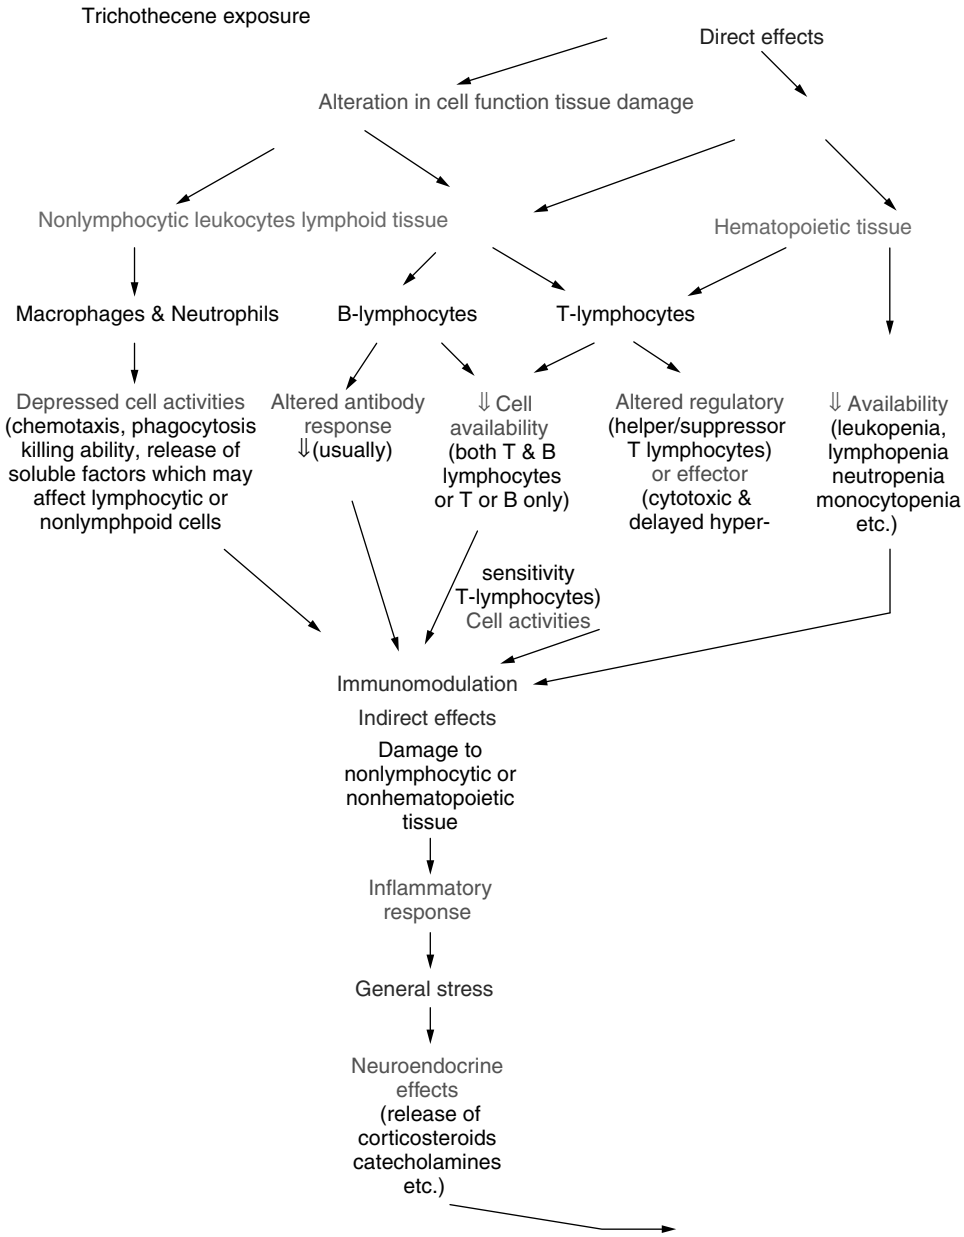

Figure 2. Immune system effects of Stachybotrys mycotoxins (trichothecenes) [*Source:* H. M. Ammann, in E. Johanning, ed., *Bioaerosols, Fungi and Mycotoxins: Health Effects Assessment, Prevention and Control*, Eastern New York Occupational and Environmental Health Center, Albany, 1999, pp. 520–521. See color insert.

presence of mycotoxins in fungus-contaminated environments (111).

MICROBIAL VOLATILE ORGANIC COMPOUNDS (MVOCS)

Fungi in active growth produce microbial volatile organic compounds (MVOC's) that are typically noticed as a mildew odor. Indoor measured MVOC levels, however, are typically low, and possible health risks are uncertain. Related mucous membrane and trigeminal nerve irritation may trigger unpleasant reactions and annoyance. Olfactorial reactions and memory formation may result in psychophysical reactions by subjects with a history of prior exposure.

Measurement of MVOC may be an indicator of excessive fungal growth indoors (112). A number of VOCs have been identified from fungi common in indoor contamination. Most of these fungal VOCs are derivatives of alcohols, ketones, hydrocarbons, and aromatic compounds. Most studies of MVOCs have been done on fungi that contribute to off-flavors and odors in food. Fungal species such as *A. niger* and *A. flavus*, isolated from indoor environments, produce the alcohols 1-octen-3-ol and 2-octen-1-ol that together account for the characteristic odor of these species (113). In a recent report, Larsen and Frisvard (114)

Table 6. Chemical Metabolites Derived from Stachybotrys and Reported Health Effects

Fungi	Chemical Metabolites	Health Effects
Stachybotrys chartarum & *Fusarium* species	Trichothecenes* (more than 50 derivatives known): T-2, nivalenol, deoxynivalenol, diacetoxyscirpenol, satratoxin H, G, other macrocyclic trichothecenes	Immune suppression and dysfunction, cytotoxic, bleeding, dermal necrosis; high dose ingestion = lethal (human case reports); low dose, chronic = potentially lethal); teratogenic, abortogenic (in animals). Hemorrhage.
		"Alimentary toxic aleukia" (ATA) reported in Russia and Siberia.
		"Staggering wheat" in Siberia.
	Spirolactone	"Red mold disease" in Japan.
	Zearalenone	Neurotoxic/nervous behavior abnormality.
		Cocarcinogen/chemotoxic.
		Anticomplement function.
		Phytoestrogen may alter immune function; stimulates growth of uterus and vulva, atrophy of ovary.
Claviceps spp.	Ergot alkaloids	Prolactin inhibitor, vascular constriction, uterus contraction promoter.

studied the in vitro production of fungal volatiles from 47 *Penicillium* taxa and detected alcohols, ketones, esters, small alkenes, monoterpenes, sesquiterpenes, and aromatics. Little is known about VOCs of other common indoor fungal contaminants.

CONCLUSION

Fungi in indoor environments may play a more important role than previously thought. Fungal contamination has been recognized as a major problem in buildings in which moisture control is poor or significant water intrusion has occurred. Synergistic inhalation effects of fungi and its by-products, such as mycotoxins in fungal spores, beta-glucans, or perhaps fungal MVOCs released into the surroundings are potentially irritating, toxic, teratogenic, carcinogenic, and immune-suppressive. Immunotoxicological effects probably depend on the exposure conditions, dose, and timing. Some immunological effects may only be transient, of short duration, and difficult to detect in routine medical tests. Medical findings often appear nonspecific and overlap several syndromes, and therefore other systemic diseases or causes need to be ruled out by the experienced clinician. Furthermore, risk assessment of human exposure to these fungi and their by-products is complex because multiple agents, hypersensitivity reactions, and different disease outcomes are involved. Several methods exist to assess and characterize exposure conditions (115). Exposure to fungi and their by-products at varying levels is ubiquitous in some indoor environments. Sampling techniques applied in building investigation should be selected on the basis of an established hypothesis, namely, on the goal and purpose of the testing. Human sensitivity and susceptibility to fungi, and microbial contaminants in general, varies from individual to individual. Some of the health implications from inhalation exposure of many fungal metabolites are not well understood, particularly at low concentrations. Little is known concerning the consequences of short- or long-term human inhalation exposures to toxic fungal metabolites. Although it appears that for most people adverse health effects are limited, reversible and not severe, there are notable exceptions that pose clinical challenges. However, based on the information available currently, it is prudent to counsel avoidance of any unnecessary exposure to infectious, allergenic potential toxic fungi. Control of moisture problems is key to preventing further growth and the potential for exposure. Because allergic and toxic properties of fungi remain even if the organisms are no longer viable, removal of molds and microbial dust from buildings is also necessary. Minimizing and avoiding indoor exposure to pathogenic fungi will generally result in resolution of any symptoms and related diseases in otherwise healthy people. A good understanding of fungal biology in the indoor environment and its impact on human and animal health will help in better diagnosis, appropriate treatment, and will contribute to the improvement of public health.

Biotechnology, the application of living organisms and/or their components to industrial processes and products, is expanding rapidly because of advances in genetic engineering. These advances allow for the possibility of "tailoring" organisms or their components to specific needs such as optimizing performance in the production of important metabolites, increasing stability to broaden or improve their application to a desired process, or the ability to translocate genetic material from one organism to another. Biotechnology has had, and will continue to have, a large effect on a wide variety of industries by providing the potential to lower the energy requirements and associated costs of an industrial process, and providing the means to move the process toward a base of renewable raw materials. Some of the most important organisms used in biotechnology are fungi (Table 1). The use of fungi is not new. Historically, fungi have been used as a food source or in food preparation. It is only in the past 100 to 150 years that humanity has harnessed the power of fungi and applied them to the areas of industry, medicine, agriculture, and the environment.

Evidence of the prehistorical use of fungi is limited to a few archeological relics and extrapolation from cultural practices that have survived to recent times. An example of the use of mushroom from evidence was found in the frozen, partially mummified remains of a 5,000-year-old stone age man discovered in the Tyrolean Alps. Among his possessions were fragments of three types of shelf fungi. One species was probably used as tinder, a practice that was common throughout Europe before the advent of matches. The purpose of the other two fungi is not known, but speculation suggests they may have served medicinal purposes. Another example of an ancient use of mushrooms is evident in Norse history. The Vikings ate the mushroom *Amanita muscaria* in preparation for battle. They believed that the mushroom gave them special ability to fight. In actuality, it was the psychogenic effect of the toxins in the mushroom that reduced their perception of fear and lent them their ferocity in battle. This mushroom was also used as a pest control agent in the Northern Hemisphere during the Middle Ages.

THE ROLE OF FUNGI IN BIOTECHNOLOGY

Mushroom production has a long history of importance as a food in many countries. The Romans and Greeks considered a variety of mushrooms as delicacies, which

Table 1. Selected Examples of Fungi and Their Biotechnological Uses

Organism	Use in Biotechnology
	Production of Antibiotics
Cephalosporium acremonium	Cephalosporin C
Emericellopsis sp.	Penicillin N
Fusidium coccineum	Fusidic acid
Paecilomyces varioti	Variotin
Penicillium chrysogenum	Penicillins G and V
Penicillium patulum, Khuskia oryzae	Griseofulvin
Tolypocladium inflatum	Cyclosporin
	Production of Medicinal Compounds
Claviceps purpurea	Ergotamine
Rhizopus nigracans, Phytophthora infestans	Steroid transformations
Aspergillus terreus	Lovastatin
Ashbya gossypii	Riboflavin
Blakeslea trispora, Phycomyces blakesleanus	β-Carotene
	Production of Organic Acids
Aspergillus niger	Citric acid, Gluconic acid
Aspergillus terreus	Itaconic acid
Penicillium stoloniferum	Mycophenolic acid
Rhizopus oryzae	Fumaric acid, Lactic acid
	Production of Industrial Solvents
Candida acidothermophilum	Ethanol
Pichia farinosa, Trigonopsis sp.	Glycerol
	Production of Enzymes
Aspergillus sp.	Lipase, Pentosanase, Proteases,
Aspergillus niger	β-Glucanase, Cellulase, Glucose oxidase, Lactase, Glucoamylase, Pectinase, Catalase
Aspergillus oryzae	α-Amylase
Fusarium sp.	Penicillin acylase
Penicillium sp.	Dextranase, Catalase
Trichoderma reesei	Cellulase, Hemicellulase
	Use in Food and Beverages
Saccharomyces cerevisiae	Various beers and wines, Kefir, breads
Saccharomyces bayanus	Champagne
Saccharomyces sake	Sake
Aspergillus oryzae	Sake, Miso, Shoyu
Candida holmii	Sourdough bread
Penicillium camembertii, P. roquefortii	Blue cheese
Monascus albidus	Tofu (fermented bean curd)
Candida sp., *Fusarium* sp.	Edible protein substitutes
Agaricus sp., *Morchella* sp., *Pleurotus* sp.	Edible mushroom cultivation
	Use in Agricultural Compounds and Applications
Giberella fujikuroi	Giberellin
Various species of Hyphomycetes and Zygomycetes	Bioinsecticides
Various species of Hymenomycetes and Gasteromycetes	Forestry
Puccina sp., *Phragmidium* sp., *Entyloma* sp.	Bioherbicides
Trichoderma sp.	Biofungicides

were served only to the most privileged people. The European community has a rich history of hunting the prized truffle. Eastern cultures have cultivated mushrooms for more than two thousand years. Today mushroom farming has grown to be a very large economic concern around the world. The types of fungi grown for consumption within particular regions have expanded from a single species (i.e., *Agaricus bisporus* in the United States) to include more exotic types that are popular in other countries, such as the oyster mushroom (*Pleurotus ostreatus*), which has typically been grown in the Orient. Other traditional food uses have exploited the fermentation properties of fungi to make beer, wine, and spirits, to leaven bread, to add flavors to cheeses, and to produce foods such as shoyu (soy sauce), miso, and tofu (Table 1). Modern uses of fungi in the food industry have been in the production of flavors, coloring agents, and as a protein supplement used to mimic meats.

Traditional industrial uses of fungi began early in the twentieth century with the production of citric acid from *A. niger*. Today the industrial use of fungi has increased to a variety of applications that include other organic acids, industrial solvents, and industrially important enzymes such as cellulase, amylase, and lactase (Table 1). Novel industrial uses of fungi also exist, which include coal solubilization, delignification, and bleaching of paper pulp, and removal of metal ions from solutions.

Development of fungal technology has been closely tied to the importance of fungi in medicine. In 1928, Alexander Flemming discovered penicillin, the first and most important of the medically useful antibiotics (1). With the advent of World War II, the industrial process of fungal fermentation was applied to *P. chrysogenum* to produce the penicillin required to meet the demands of the Allied Forces. Since that time, a wide variety of antibiotics and medicinally useful compounds have been isolated from fungi (Table 1). The medicinal uses of fungi are expanding because of the power of genetic engineering. Genetically engineered fungi are being used to produce, transform, or modify a variety of medicinally important compounds. Some of the proteins produced in fungi are insulin, human α-interferon, and hepatitis B surface antigen used in vaccines. Compounds that are transformed or modified by

fungi include various steroids and antibiotics. Additional compounds produced or modified by fungi are listed in Table 1.

The use of fungi in agriculture is rapidly developing. Attempts are being made to use fungi as bioinsecticides or bioherbicides and to improve crop yields (2). The advantages of using fungi as bioinsecticides and bioherbicides are related to the broad spectrum of environments that fungi can colonize and host range specificity that may decrease the possibility of undesirable secondary affects on the environment. Additionally, it is possible to permanently establish these fungi in an ecosystem, thereby sustaining long-term control over a pathogen and decreasing costs.

There are three major areas that are being investigated for the use of fungi to improve crop yields: mycorrhiza association, fungal metabolites, and genetic transformation (3). *Mycorrhiza* (fungus-root) is the term used to describe the association of fine feeder roots with root-inhabiting fungi. This association is symbiotic in nature, providing nutrients and protection from stress to both species. Current research is exploring the use of mycorrhiza-forming fungi with commercial crops to improve crop health and productivity. Many of the fungi associated with plants produce chemical compounds that are plant growth regulators. These chemicals, which include gibberellins, cytokinins, and ethylene, are currently being produced industrially for application on crops with high commercial value. These plant growth regulators have been shown to improve crop quality, increase yield, and alter harvest time of the plant product, thereby increasing a crop's economic value. Genetic manipulation is often used to increase or introduce an economically desirable trait into a plant to increase yield or resistance to stress. Traditional methods for genetic transformation have used *Agrobacterium* to introduce foreign DNA into plants. Researchers are currently investigating the use of a mycorrhizal fungus (*Olpidium brassicae*) for genetic transformation. The wide host range for this fungus, which includes grasses and many broadleaf plants, makes it a useful vector for many crops such as beans and lettuce (4).

The broad diversity of applications illustrates the important role that fungi have in biotechnology. This gives importance to understanding fungal ecology, biochemistry, physiology, and genetics to realize the full biotechnological potential of fungi. This knowledge, combined with the ability to manipulate fungal DNA, will expand the application of fungi to environmental concerns.

FUNGI IN ENVIRONMENTAL BIOTECHNOLOGY

Environmental use for fungal biotechnology has been largely devoted to the treatment of hazardous wastes and bioremediation of soils. Most significant of these applications has been the use of wood-degrading white-rot fungi. White-rot fungi are a group of ubiquitous fungi from the class Basidiomycetes that have the ability to depolymerize lignin in wood and to mineralize it to carbon dioxide, thereby making cellulose available for use as an energy source. Various species of white-rot fungi have been studied for their ability to degrade lignin and are used in a variety of biotechnological applications. Among these are *Pleurotus eryngii* (5,6), *Trametes versicolor* (7), *P. ostreatus* (8), *Bjerkandera* species (9), *Phlebia radiata* (10), *Ceriporiopsis subvermispora* (11), and *Phanerochaete chrysosporium* (12). Of these, *P. chrysosporium* has been extensively studied and shown to have the ability to degrade a variety of persistent environmental pollutants such as munitions (11,13–15) synthetic polymers (16,17), pesticides, and various organic compounds (18). This ability is related to the nonspecific, free-radical mechanism, which evolved to degrade lignin (19). The lignin-degrading enzymes can catalyze both oxidative and reductive reactions utilizing highly reactive, nonspecific redox mediators. The versatility of these enzymes to degrade a large number of diverse chemicals gives white-rot fungi great potential for application in environmental biotechnology.

Lignin

The lignin-degrading ability of white-rot fungi evolved owing to the unique nature of lignin. Unlike most biopolymers, lignin does not contain identical, readily hydrolyzable, repeating linkages that occur at regular intervals. The biosynthesis of lignin is the result of peroxidase-catalyzed polymerization of three precursor alcohols: coumaryl alcohol, coniferyl alcohol, and synapyl alcohol (20–22). Peroxidases oxidize these phenylpropanoid compounds to generate phenoxyl radicals that randomly combine to form an irregular, three-dimensional polymer that has no precise chemical structure (3,21–25). The relative concentration of each monomer, which differs with each plant species, determines the final structure of the lignin. Therefore, the final structure of lignin will vary greatly from species to species. The unusual structural features of lignin, that of being bulky, nonlinear, three-dimensional, and stereo-irregular, make its degradation a complicated process that requires a system that is extracellular, nonspecific, and nonhydrolytic.

Wood-Degrading System of White-rot Fungi

Although lignin degradation has been studied for more than 40 years, it was not until the early 1980s that the lignin-degrading system of white-rot fungi was discovered. Early work showed that ligninolytic activity was related to H_2O_2 production (26,27). The isolation of ligninase from the white-rot fungus *P. chrysosporium* soon followed (28–30). Ligninase was shown to contain a heme prosthetic group and was called lignin peroxidase (LiP) (31). Subsequent research identified that some of the ligninase activity detected in the extracellular fluid of the fungal cultures was dependent on Mn^{2+}, leading to the discovery of manganese peroxidase (MnP) (32). Ten extracellular peroxidases, six isoenzymes of LiP, and four isoenzymes of MnP have been purified from cultures of *P. chrysosporium* (33). The enzymes of the lignin degradation system are defined as the ligninases (LiP and MnP), hydrogen peroxide producing enzymes and laccases. Together with other small molecules produced by the fungus or found in wood, such as veratryl alcohol (3,4-dimethoxybenzyl alcohol, VA), oxalate, and manganese, white-rot fungi can efficiently degrade lignin. The

production of the lignin-degrading enzymes occurs during secondary metabolism of the fungus when nutrients such as carbon, nitrogen, or sulfur are limited (12,28,30). Wood is considered to be a nitrogen-poor medium (34). Other enzymes produced by white-rot fungi for wood degradation are cellulases and cellobiose dehydrogenase (CDH). These two enzymes are primarily produced when the fungi are grown on cellulose as the carbon source (35).

Peroxidases

The types of peroxidases are structurally similar. Their sequences are 48% homologous and the overall fold and organization of their secondary structure are nearly identical (36,37). The enzymes contain a penta-coordinate heme and two structural calcium ions. The heme of both LiP and MnP are coordinated by a histidine as the proximal axial ligand, whereas the distal ligand to the iron is open and comprises the hydrogen peroxide-binding site formed by a histidine and an arginine. Both LiP and MnP contain four conserved disulfide bonds, whereas MnP contains an additional disulfide bond located in the C-terminal end of the protein (37). This disulfide bond was proposed to facilitate MnP activity by providing an access channel to the substrate-binding site by moving the C-terminal tail away from the body of the protein (37).

The substrate-binding sites of LiP and MnP differ, providing the basis for the distinct activities of these two similar enzymes. Unique to MnP is a proposed Mn^{2+} substrate-binding site, formed by the carboxylate oxygen atoms of two glutamates (E35, E39) and aspartate (D179) amino acids, a heme propionate oxygen, and two water oxygen atoms (37,38). Lignin peroxidase lacks two of these carboxylic amino acids and the C-terminus tail of the protein blocks access to the gamma-meso edge of the heme (36). Experimental support for the proposed Mn^{2+}-binding site has been provided by mutation of the substrate-binding site amino acids (39,40) and modification of the heme propionates (41).

The substrate-binding site of LiP has not been well defined. Because LiP can directly oxidize a broad range of substrates, from small compounds to bulky substrates such as lignin and ferrocytochrome *c*, the substrate-binding site was proposed to be located at the protein surface and includes aromatic or nonpolar residues (42). Using the crystal structure of cytochrome *c* peroxidase as a template, homology-modeling studies identified two sites centered on tryptophan residues (W17 and W171) on the surface of LiP (42). An additional substrate-binding site was proposed in the access channel near delta-meso edge of the heme (36). Site-directed mutagenesis experiments have shown that W171 (43) and amino acids of the heme access channel (44) are important for substrate oxidation and may reflect two independent substrate-binding sites. In particular, it was shown that W171 was required for the oxidation of VA and a wide variety of other substrates (45,46).

The peroxidase catalytic cycle is shown in Figure 1. In the catalytic mechanism, hydrogen peroxide removes two electrons from the ferric enzyme, generating the enzyme intermediate compound I. One electron is taken from the ferric iron group, forming the oxoferryl [Fe(IV) = 0] species and the other electron is removed from the porphyrin, generating the porphyrin-cation radical (47,48). Compound I is converted to compound II by the one-electron oxidation of a redox mediator. This oxidation quenches the radical on the porphyrin, yielding the oxoferryl enzyme intermediate and a substrate radical. Reaction with a second redox mediator reduces compound II back to the ferric enzyme, releasing the bound oxygen as hydroxide and a second substrate radical, thus completing the catalytic cycle (49). The reduction of compound II is generally the rate-limiting step of peroxidase catalysis when hydrogen peroxide is saturating. It is usually one order of magnitude slower than compound I reduction (48).

Peroxidases can catalyze the one-electron oxidation of a variety of substrates because of the high reduction potentials of hydrogen peroxide and the catalytic intermediates of the enzymes. Hydrogen peroxide has a reduction potential of 1.8 and 1.3 V at pH 0 and 7, respectively (50,51), whereas the reduction potentials of compound I and compound II for LiP and MnP are as great as 1.4 V (52).

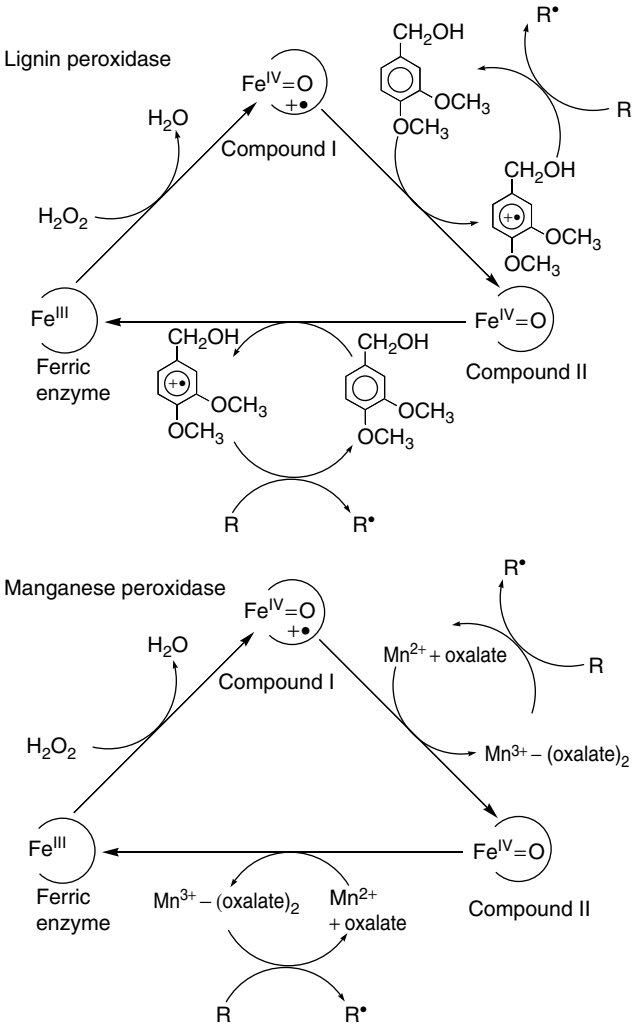

Figure 1. Mechanisms of catalysis and mediation by lignin peroxidase and manganese peroxidase from *Phanerochaete chrysosporium*.

Although LiP has been shown to directly oxidize a variety of bulky substrates (46), it is the indirect redox reactions catalyzed by these enzymes that are considered important for the degradation of lignin and environmentally persistent pollutants (53). Consequently, research has focused on identifying small redox chemicals that can mediate the oxidation of these chemicals.

The physiological substrates for LiP and MnP are VA (54,55) and Mn^{2+} (56,57). Veratryl alcohol is a by-product of lignin degradation (58) and is synthesized and secreted by the fungus during secondary metabolism (59). When VA is oxidized, it is converted to the veratryl alcohol cation radical (60) with a reduction potential of 1.4 V (52). Although it is not believed that the veratryl alcohol cation radical can diffuse away from LiP because its stability in water is believed to be very limited (61), it was shown to mediate the oxidation of other chemicals (62). Manganese occurs naturally in wood (63) and its availability increases as the wood decays (64). Manganese peroxidase oxidizes Mn^{2+} to Mn^{3+}, which is believed to act as a diffusible redox mediator to facilitate the biodegradation of lignin and pollutants (65). Unlike LiP, the catalytic cycle of MnP has a unique requirement for chelated Mn^{2+} to reduce compound II to ferric enzyme (57). Although many organic alpha-ketoacids may act as effective chelators for Mn^{2+} (62,66), it is believed that oxalate is the physiological chelator in vivo (57). Once manganese is oxidized, the chelator acts to stabilize Mn^{3+} by providing electron density to the manganese. The stabilized Mn^{3+}-oxalate complex is then able to diffuse away from the enzyme and oxidize less accessible areas of wood or other chemicals (66). The reduction potential of the Mn^{3+}-oxalate complex has been estimated to be 0.9 to 1.2 V (67,68).

Hydrogen Peroxide Generating Enzymes

Hydrogen peroxide is an oxidative substrate for the peroxidases and is required for catalysis. White-rot fungi appear to have developed a number of mechanisms to produce hydrogen peroxide. Hydrogen peroxide generation by white-rot fungi may, in part, consist of intracellular enzymes, glucose-1-oxidase, glucose-2-oxidase, and methanol oxidase (69–71), and two extracellular enzymes, glyoxal oxidase, and aryl alcohol oxidase (72–75). Glucose-1-oxidase, the first enzyme implicated in hydrogen peroxide formation in white-rot fungi, is produced during secondary metabolism (69). Glyoxal oxidase is also produced during secondary metabolism and can utilize glyoxal, methyl glyoxal, and other alpha-hydroxyl carbonyl and dicarbonyl compounds to produce hydrogen peroxide (72). The involvement of intracellular glucose-2-oxidase and methanol oxidase in extracellular hydrogen peroxide production is not known (70,71), although speculation suggests that the fungi secrete the hydrogen peroxide (69,71,73). Aryl alcohol oxidase reduces molecular oxygen to oxidize aromatic alcohols that are both secreted by the fungi and produced during lignin degradation to aldehydes to generate hydrogen peroxide (73,74). There are also some minor enzymatic and nonenzymatic pathways that may contribute to hydrogen peroxide formation. Cellobiose dehydrogenase is capable of generating hydrogen peroxide through the direct or indirect reduction of molecular oxygen (76). Cellobiose dehydrogenase can also reduce iron, which can react with molecular oxygen to form superoxide, and ultimately, hydrogen peroxide (76,77). Additionally, molecular oxygen can be reduced by carboxylate anion radical generated upon the oxidation of oxalate and glyoxylate by Mn^{3+} produced by MnP-dependent reactions (78,79). The relative contribution of each of these mechanisms to the production of hydrogen peroxide is not clear; however, it is proposed that it is the generation of hydrogen peroxide that is the rate-limiting step in biodegradation (80).

Laccase

Laccases are phenol-oxidase enzymes containing four copper ions, produced by white-rot fungi during primary metabolism (81). These proteins catalyze the one-electron oxidation of phenols to phenoxyl radicals with the concurrent reduction of molecular oxygen to water (81,82). Additionally, laccases can also oxidize nonphenolic lignin model compounds in the presence of a proper redox mediator (82,83). Laccases, or enzymes similar to laccases, are also used by higher plants to produce lignin and are used by many fungi to help in lignin depolymerization (81–83). The role of laccases in lignin degradation is not well understood. Laccases are produced at different levels by a variety of white-rot fungi. High levels of laccase are produced by *Pycnoporus cinnabarinus*, whereas *P. chrysosporium* produces only low levels of the enzyme and only under conditions in which the fungus is grown on cellulose (81). The potential of laccases in bioremediation has not been well characterized.

CDH

It has been proposed that the degradation of lignin and highly oxidized environmental pollutants may require reductive pathways (18). Cellobiose dehydrogenase is a two-domain enzyme containing FAD and heme (76). It is secreted by *P. chrysosporium* and other fungi when cellulose is used as the nutrient carbon source and it catalyzes the oxidation of cellobiose and the reduction of quinones, which are produced during lignin degradation, and other electron acceptors such as molecular oxygen, iron, and manganese dioxide (76). These redox reactions may have significant consequences on biodegradation by the formation of oxidative and reductive free radicals. Figure 2 shows the mechanism of free-radical production by CDH. Although the physiological role of CDH is not known, there are a number of proposed functions for the enzyme. Among these are cellulose depolymerization, lignin depolymerization, and diminished product inhibition of cellulases by oxidizing cellobiose. In addition, CDH can generate free radicals to promote a variety of redox reactions, which can enhance MnP activity by dissolving precipitated manganese dioxide, creating cellobionic acid to chelate Mn^{3+}, and reducing quinones (76). The potential for redox cycling between the peroxidases and CDH is alleviated by its proteolytic cleavage when the fungus enters secondary metabolism (84). The independent flavin domain retains most of the activities of

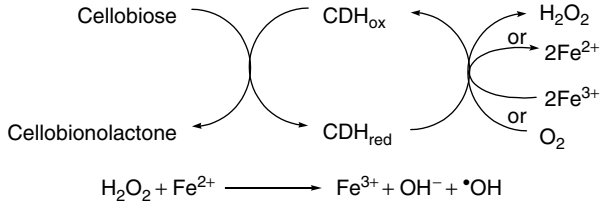

Figure 2. Proposed mechanism for hydroxyl radical production by cellobiose dehydrogenase.

CDH, but does not inhibit LiP and MnP, as intact CDH does (84).

Cellulase

Fungi produce cellulases when cellulose is used as the nutrient carbon source (85). There are several classes of cellulases that work together to depolymerize cellulose through hydrolysis reactions. Some cellulases work from the terminal ends of the cellulose and are referred to as exoglucanases. Cellulases that can hydrolyze glucose monomers located in the interior of the polymer are referred to as endoglucanases. Most endoglucanases bind to areas of imperfection in the cellulose matrix. These enzymes also differ in their ability to depolymerize carboxymethlyated cellulose with only endoglucanases capable of catalyzing its hydrolysis (86). Cellulases are receiving increased attention from government and academic researchers for use in the bioconversion of green waste to ethanol.

Methylation

White-rot fungi have a methylation system that is important in the degradation of phenolic pollutants and phenolic lignin degradation products (87,88). Methylation occurs during ligninolytic and nonligninolytic conditions. The physiological methyl donors are proposed to be S-adenosylmethionine and methyl chloride, the latter being synthesized from S-adenosylmethionine (89). The resulting methylated product can then be oxidized such that the aromatic ring is opened. This mechanism is believed to limit the ability of phenols to redox cycle, providing a mechanism for degradation instead (90). Methylation of phenol yields the corresponding anisole (18). This is of particular importance in alleviating the toxicity of some polychlorinated phenols (PCP) because some PCP are potent inhibitors of oxidative phosphorylation and are highly toxic to microorganisms.

Transmembrane Redox Potential

Fungi possess a transmembrane redox potential, and the membrane redox potential of *P. chrysosporium* has been shown to reduce a number of chemicals (Fig. 3). The transmembrane redox potential is believed to be responsible for the reduction of 2,4,6-trinitrotoluene (TNT) (91). Physiologically, the transmembrane redox potential may be important for the protection of the fungal hyphae from free radicals produced by peroxidases during lignin breakdown. It may also be involved in quinone reduction, reducing quinones in proximity

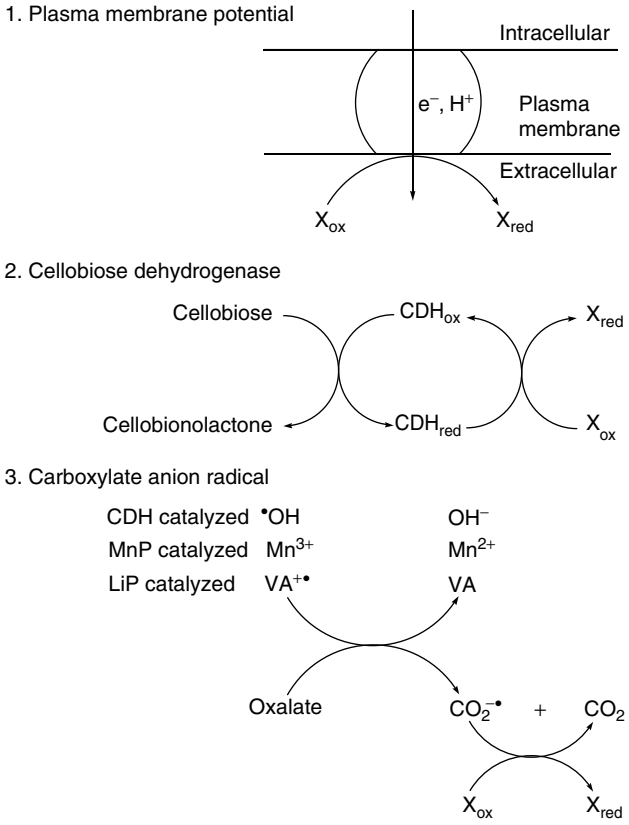

Figure 3. Reductive reactions catalyzed by the white-rot fungus *Phanerochaete chrysosporium.*

to the transmembrane methylase for methylation and subsequent degradation rather than redox cycling (92).

OTHER WOOD-DEGRADING FUNGI

Brown-Rot Fungi

There are many known species of brown-rot fungi. Brown-rot fungi are characterized by their ability to remove the cellulose, hemicellulose, and xylan from wood without the complete degradation of the lignin as seen with white-rot fungi. The remaining, partially oxidized lignin is brown. A percentage of the lignin degraded by brown-rot fungi is hydroxylated and demethylated (93,94). Brown-rotted wood has a rapid decrease in its properties of strength even before there is a significant weight loss. After brown-rot decay, there is an increase in the weight percentage of the wood that is alkali soluble. This increase is characteristic of brown-rot decay. Specific enzymes responsible for wood degradation have not been isolated but it is generally accepted that degradation involves the hydroxyl radical. It should be pointed out that most of the evidence for hydroxyl radical-mediated degradation is circumstantial (95).

Brown-rot fungi tend to maintain the extracellular pH between 1.7 and 3.5, whereas white-rot fungi typically maintain the pH between 4 and 6 (96,97). It has been proposed that the low pH allows ferri-reductases to generate hydroxyl radical without damage to the

fungi (98). The low pH decreases the affinity of organic acids for iron. This increases the reduction potential of the iron and decreases the reactivity of ferrous iron for molecular oxygen. The reduced iron diffuses away from the fungi into areas with higher pH. The iron then reduces molecular oxygen to ultimately yield hydroxyl radical at a safe distance from the fungal mycelia (98).

Soft-Rot Fungi

Soft-rot fungi are the most recently discovered group of wood-degrading fungi. Wood that has been degraded by soft-rot fungi has an increased ratio of lignin to carbohydrate when compared with undegraded wood (99). Soft-rotted wood usually has distinctive longitudinal cavities created in the wood. Some soft-rot fungi have the ability to erode lignin, but not to the extent of white-rot fungi. In contrast to white-rot fungi, wood degradation does not appear to be in response to nutrient limitation. As with brown-rot fungi, the enzymes responsible for lignin degradation have not been determined; however, many soft-rot fungi secrete CDH and some express laccase activity. These enzymes may be responsible for wood degradation (99).

Soft-rot fungi tend to degrade wood at slower rates than either white- or brown-rot fungi, but they are well adapted to adverse environments (100). Soft-rot fungi do not have peroxidases and do not cause wood to be alkali soluble, leading to the conclusion that soft-rot fungi have a different mechanism of wood decay than either white- or brown-rot fungi (99).

GENETIC MANIPULATION OF FUNGI

The application of any fungi to a specific area of concern will require a proper understanding of the genetics and physiology of the species or class of fungi. The tools of genetics have increased our knowledge greatly, and the advances in this field, from recombinant DNA techniques and microarray gene analyses to elucidating entire genome sequences, will hasten the understanding of the principles that will govern biotechnological advancements. The ability to genetically manipulate fungi has permitted researchers to improve microbial strains by alteration of the fungi's genetic code, production of proteins outside their natural host, exploration of the relationship of protein structure and function, and design of new functions into proteins. The list of fungi and the products (Table 1) that are isolated from them is evidence of the biotechnological potential of this technology.

During the late 1980s, when the traits of white-rot fungi were recognized for having great potential for degradation of environmental pollutants, researchers sought to find the best strain of fungus to degrade lignin. Early work with *P. chrysosporium* used screening to find naturally occurring mutants of the fungus that exhibited useful traits. Several strains of *P. chrysosporium* that exhibited an enhanced ability to degrade lignin or oxidize phenols were identified (3). Currently, through recombinant DNA techniques we are no longer constrained to the traditional methods for fungal strain improvement of mutation, screening, and selection. The discovery that microorganisms carry plasmids (101), which are independently inherited DNA molecules, has permitted researchers to transform microorganisms, manipulating how and where genes are expressed. The genes for the peroxidases of *P. chrysosporium* have been identified (3) and placed into plasmids for expression of recombinant proteins. The peroxidases have been expressed in prokaryotic and eukaryotic organisms. The recombinant enzymes are currently being expressed in bacteria, *Escherichia coli* (102,103), other fungi, namely, *A. oryzae* (104), and the natural host, *P. chrysosporium* (105,106).

Expression of recombinant peroxidases in prokaryotic systems has the potential to produce target protein in quantity in a short period and at low cost (107). Unfortunately, bacterial expression systems do not always produce active recombinant proteins (108,109) and thereby require additional processing steps to obtain active enzymes (109,110). Lignin and manganese peroxidases have been expressed in bacterial systems. However, as are many other plant or fungal peroxidases, these proteins are produced in an inactive form, requiring the introduction of heme and calcium to form active enzyme (102,103). Because of the limitations of bacterial systems for protein expression, eukaryotic systems remain indispensable for the production of many recombinant proteins by providing an environment that permits the production of active enzymes (111,112). Transformations of yeast and higher fungal species have provided for the recombinant expression of many useful proteins (Table 2). The use of yeast has dominated the area of heterologous protein expression as a result of the ease in which these organisms can be manipulated compared with the higher fungi. Recombinant MnP and LiP have been produced in the natural host *P. chrysosporium* by placing the genes under the control of the glyceraldehyde-3-phosphate dehydrogenase promoter, allowing peroxidase expression in nutrient-sufficient culture conditions (105,106). The reintroduction of the peroxidase genes into *P. chrysosporium* illustrates the power of genetic engineering to, hopefully, direct the improvement of fungal strains for specific characteristics. These expression systems have advantages and disadvantages for the development of an organism or enzyme for biotechnological applications.

The tools of crystallography, genetic engineering [Polymerase Chain Reaction™ (PCR) and site-directed mutagenesis], and enzyme kinetics have opened the door to understanding how enzymes function on a molecular level. From crystallographic data researchers can identify structural features that may contribute to the function of an enzyme. Site-directed mutagenesis and PCR allow researchers to make changes in the genetic code to alter a protein's structural features. Enzyme kinetics are used to evaluate the effect of the structural changes on enzyme activity. Using these tools, researchers have made significant advances in understanding the structural features that contribute to the activity of the enzymes from white-rot fungi. With this knowledge researchers can design features into proteins to obtain an enzyme with desired properties. Protein engineering has been applied to the peroxidases from *P. chrysosporium* to

Table 2. Examples of Heterologous Proteins Expressed in Fungi

Organism	Protein

Trichoderma reesi	pH 2.5 acid phosphatase (*A. niger*)

increase the thermal stability of recombinant protein (41) and to introduce veratryl alcohol oxidase activity (45,46) into MnP.

POLLUTANT DEGRADATION

The diverse and partially redundant mechanisms of the extracellular, nonspecific, free radical–based lignin-degrading system used by white-rot fungi enables the fungi to degrade a wide variety of environmental pollutants (Table 3; 18). Central to this ability are the enzymes LiP, MnP, and CDH. These enzymes can produce a number of free radicals that allow for the mediated oxidation or reduction of recalcitrant chemicals (62,113). Lignin peroxidase and MnP can use their respective substrates, veratryl alcohol and manganese, to mediate the oxidation of other chemicals (62,114). These two oxidized substrates can also oxidize oxalate to form the carboxylate anion radical that can be used for reductions (Fig. 3). The carboxylate anion radical can also be formed by CDH (76). The carboxylate anion radical can reduce molecular oxygen or iron to generate oxygen radicals, that is, superoxide (115–117). Superoxide can dismutate to form hydrogen peroxide, which in the presence of reduced iron can generate the hydroxyl radical, a potent oxidant.

The ability to form both oxidative and reductive species gives white-rot fungi the capability to degrade a variety of pollutants. Many pollutants might require reduction for effective degradation or have metabolites that must be reduced for efficient bioremediation. Three extracellular reductive mechanisms can be described for *P. chrysosporium* (Fig. 3). The reductive potential of the plasma membrane potential, or CDH, has been shown to reduce chemicals that are easily reduced. However, some highly oxidized pollutants such as carbon tetrachloride and trichloroethylene are relatively stable and cannot be reduced directly by the plasma membrane redox potential or by CDH. Also, because of the oxidation potential required to further oxidize these chemicals, they are resistant to oxidative remediation by the peroxidases. However, the highly reductive carboxylate anion radical formed by LiP, MnP, and CDH can reductively dehalogenate carbon tetrachloride and trichloroethylene (60,113,118,119), leading to their mineralization.

The various metabolites formed by the many different mechanisms of wood degradation do not inhibit the activity of the different enzymes involved. For example, the peroxidases have been shown to oxidize, either directly or indirectly, a variety of small and large compounds such as cyanide (120), polycyclic aromatic hydrocarbons, many phenols (18), iodide, ferrocyanide, and cytochrome c (46). Yet their oxidized substrates, Mn^{3+}-oxalate or the veratryl alcohol cation radical, are reduced by the reducing sugars, glucose and cellobiose, products of cellulose metabolism (17). This was unexpected, but considering the natural environment of white-rot fungi, it would be unproductive for cellobiose to act as a reductant, and therefore an inhibitor, for the peroxidases.

However, there is potential for these multiple redox reactions to compete and form futile cycles. For example, veratryl alcohol can be oxidized to quinones by LiP (121,122) that can be subsequently reduced by CDH to the hydroquinone (92). Hydroquinones are readily oxidized back to the quinone by Mn^{3+}, which results in a zero net metabolism. However, the reactions catalyzed by the fungus have evolved to work together to prevent redox cycling and promote degradation. For example, quinones can be reduced to hydroquinones and these phenolic compounds can be methylated at the cell surface (88), resulting in a compound that could be oxidized to a cation radical,

Cyanides	

which would be susceptible to further oxidation resulting in mineralization.

Transformation of insoluble and toxic chemicals can be a potential problem for bioremediation. White-rot fungi may have significantly fewer difficulties in accomplishing this than bacterial systems because of the extracellular degradation system they have evolved. The oxidative and reductive compounds produced by CDH and the peroxidases were shown to efficiently depolymerize insoluble polyacrylate polymers (16,17), transforming them to a soluble product that was easily metabolized by the fungi. Additionally, many of the extracellular reactions that lead to mineralization result in the detoxification of chemicals. In the degradation of pentachlorophenol, one of the first steps is its methylation to pentachloroanisol, which can be further metabolized (88). Highly oxidized compounds, such as TNT, can be very toxic to microorganisms. The fungus is able to detoxify these chemicals by first reducing them by a transmembrane redox potential (91). The detoxification reactions take place at the cell surface and thus are dependent on mycelial mass to effectively overcome the toxic effects of these chemicals.

The biodegradation of the munitions TNT, hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX), and octahydro-1,3,5,7-tetranitro-1,3,5,7-tetraazocine (HMX) by white-rot fungi has generated a great deal of interest in recent years (11,13–15). Degradation of all three munitions in both soil and liquid cultures of *P. chrysosporium* have been shown. Manganese^{III}, produced by MnP, oxidizes each of these munitions (15). Additionally, TNT and RDX could be directly reduced by CDH (13). Reduction of TNT to its amino and diamino derivatives is quickly catalyzed by the transmembrane redox potential (91). TNT reduction is seen with almost all fungi, but only wood and litter-degrading fungi are able to oxidatively transform the aminodinitrotoluenes and mineralize them (91,123). Lignin peroxidase has been shown to directly catalyze the transformation of aminodinitrotoluenes (15). Cultures of *P. chrysosporium* have been shown to efficiently mineralize even high concentrations of TNT to carbon dioxide (11). In the case of RDX, nearly 100% of the carbon was oxidized to carbon dioxide (13). In soil cultures, higher concentrations of RDX caused increased rates of RDX disappearance. In liquid cultures, mineralization rates were proportional to RDX concentration until RDX became saturating (13).

The mechanisms used by white-rot fungi for the degradation of wood make it an exceptional candidate for the bioremediation of complex mixtures of pollutants. Intech180 (North Logan, Utah) has commercialized white-rot fungi technology and has overseen the application of the fungi in a number of field tests. EarthFax Engineering, Inc. (Salt Lake City, Utah) conducted a recent field

application at a wood treatment facility in southeastern U.S.A. that was predominately contaminated with PCP, dioxin, and lindane (124). Bioremediation resulted in the reduction of contaminating PCP, dioxin, and lindane to levels below EPA industrial and residential standards. Successful bioremediation should lead to the restoration of a contaminated site to use. An advantage to using white-rot fungi is that the fungal inoculum consists of fungus grown on woody by-products, and its degradation results in the formation of humus. Thus, bioremediation of soils results in the improvement of many soil factors, making it suitable to use for agricultural or landscaping purposes.

CONCLUSION

The use of fungi for some biotechnological development has one basic goal, to provide a cost-effective alternative to some specific industrial process. The development of *A. niger* to produce citric acid was driven by labor-intensive, and thus expensive, methods of isolating the acid from lemons. Many other industrial applications of fungi were developed for similar reasons; the product was less expensive to produce or a compound's structure was unknown and thus unable to be synthesized, as was the case with penicillin. Today the definition of "cost-effective" extends beyond economic concerns to include political and environmental considerations. Governments are passing increasingly restrictive legislation that controls contaminating emissions of many industrial processes. As restrictions increase, alternative processes will need to be developed to meet the current requirements for a product. A prime example is the development of "biofuels" to replace our dependency on imported oil and to stop generating the pollutants associated with their use. Biofuels are alcohols made from cellulosic biomass (green waste from agriculture and forestry). The vision of the Department of Energy National Biofuels Program is "to realize the large-scale use of environmentally sound, cost-competitive, biomass-based transportation fuels. . .." This vision clearly reflects the philosophy of a "green" biotechnology, to begin with a renewable resource to make a product by a process that is friendly to the environment.

Each of the industrial fungal processes introduced earlier may impact the environment either by reducing the level of a pollutant that is made or by removing the source of pollution. Many times the by-products of a fungal process can be used for other purposes. As in the example of bioremediation with white-rot fungi, the end product can be reintroduced into the environment for a productive use. There are many areas in which fungi can be applied: industry, agriculture, food science, medicine, and bioremediation. In all cases, the biotechnological development of fungi should, hopefully, have a positive impact upon our environment.

FUNGI IN FRESHWATER ECOSYSTEMS.

See WATER FUNGI AS DECOMPOSERS IN FRESHWATER ECOSYSTEMS

FUNGI IN MARINE/ESTUARINE WATERS

STEVEN Y. NEWELL
University of Georgia
Sapelo Island, Georgia

Eukaryotic mycelial decomposers (organoosmotrophs) of marine ecosystems were until recently all termed "fungi," but they are not all members of the kingdom Fungi (1); some belong to the kingdom Straminipila (2) (alternative spelling: Stramenopila), whose members have zoospores (biflagellate swimmers) as propagules (Table 1; 3–5). This article focuses on the marine mycelial fungi and straminipiles that are decomposers of vascular-plant material. The most clearly important of the fungi with respect to marine-ecosystem functioning are the ascomycetes (3,4,6–8) that are secondary producers using the lignocellulose of extraordinarily productive intertidal vascular plants [e.g., saltmarsh grasses (9,10)]. There are only a very few species of marine mycelial basidiomycetes [ca. 2% of all known species of marine mycelial fungi (7)]; the ecological role of marine basidiomycetes is likely to be the same as that of marine ascomycetes. The importance of the marine straminipiles, mostly species of *Halophytophthora*, is not well established, but may be analogous to that of the marshgrass ascomycetes — the principal substrates for the halophytophthoras are leaves that fall into the marine environment [e.g., mangrove leaves (4,11)]. A few species of marine fungi and straminipiles are potentially important parasites or pathogens of macroalgae and animals (4,12), including corals (13,14).

The mostly nonmycelial, unicellular marine chytrids, the only members of the kingdom Fungi that have zoospores (posteriorly uniflagellate) as propagules, also include symbionts, for example, of seagrass (16), but marine chytrids as a group are not known well enough for inclusion in this article (3). Note that the two books that still must be used for chytrid identifications date from 1960–1977 (17). The marine yeasts [unicellular ascomycetes and basidiomycetes in the kingdom Fungi (3,18)] as well as the nonmycelial straminipiles [Labyrinthulomycota: thraustochytrids and labyrinthulids (3,19,20); parasitoidal marine intertidal lagenidialean straminipiles (21–23)] and the maritime vesicular-arbuscular mycorrhizal fungi (zygomycotes; 24) are also excluded here.

THE MARINE-DECOMPOSER ASCOMYCETES AND STRAMINIPILES

Marine mycelial ascomycetes include representatives of several ascomycetous taxonomic groups (1,8,25), with the largest number belonging to the perithecial

Table 1. Contrasting the Two Major Types of Marine Mycelial Organoosmotrophs[a]

Taxon	Typical Substrate	Key Morphocharacteristics
Kingdom Fungi, Phylum Ascomata	Intertidal plant shoots, driftwood	Haploid chitinous mycelium, porous septa, complex sexual structure, nonmotile propagules (ascospores), accumulation of biomass in substrate (5–30% of total mass)
Kingdom Straminipila, Phylum Oomycota	Fallen leaves, e.g., of mangroves	Diploid nonchitinous mycelium, septal plugs, no complex sexual structure, motile propagules (zoospores), no accumulation of biomass (<1%) in substrates[b]

[a]See also references (1–3,5,7–9,15).
[b]Biomass information for oomycotes tentatively estimated, based in part on unpublished findings (transmission electron microscopy) of D. Porter, E. A. Richardson and S. Y. Newell for submerged decaying mangrove leaves.

order Halosphaeriales, many species of which produce ascospores bearing appendages (some quite elaborate) that are likely to serve as substrate-attachment devices (7,26,27). Many of the ascomycetes most important in secondary production in marine intertidal zones are pseudothecial ascomycetes [loculoascomycetes (1,28)] (Fig. 1; 7,9). Keys to the marine ascomycetes are available (6,7). Examination of rDNA base sequences has revealed that marine ascomycetes evolved from terrestrial ancestors into marine habitats (29). The fact that principally important ascomycetes of decaying saltmarsh grasses are members of the same genera common as agents of diseases of cereal grasses (e.g., *Phaeosphaeria* and *Mycosphaerella*) indicates that it is likely that at least some marine intertidal ascomycetes evolved into the sea with their substrate plants (30).

The marine mycelial straminipiles of plant-decomposition systems are members of the family Pythiaceae, and most are members of the genus *Halophytophthora* (4,5). The most common species worldwide is *Halophytophthora vesicula* (Fig. 2). A key to the species of *Halophytophthora* is available (33). The most common nonhalophytophthoran marine species is *Pythium grandisporangium* (34). The wide range of morphologies and behaviors (e.g., peculiarities of zoospore-release mechanisms) of the halophytophthoras indicate that *Halophytophthora* is a catch-all (polyphyletic) genus (4). Cooke and coworkers (35) examined rDNA base sequences for *Halophytophthora batemanensis* [probably = H. *vesicula*

Figure 1. Typical deposit of ejected ascospores of two species of loculoascomycetes from naturally decaying smooth cordgrass leaf blades of Georgia saltmarshes (9). The smaller (about 7 μm wide), hyaline, 2-celled spores are of *Mycosphaerella* sp. 2 [Kohlmeyer and Kohlmeyer (31)] (Dothideales), and the larger (about 11 μm wide), dark, 4-celled spores are of *Phaeosphaeria spartinicola* (Pleosporales). The spores were explosively expelled at a rate of hundreds per square centimeter per hour, onto a capture glass placed in front of a wetted decaying leaf, and many have germinated to hyphae. These two species are nearly always intimately mixed in the leaf-decay system, and may be mutualists (9,30,32).

(4)] and concluded that the halophytophthoras may be more closely related to the genus *Pythium* than to *Phytophthora*. However, sequencing of mtDNA (*cox2*) (D. Hudspeth, M. Hudspeth and S. Newell, unpublished) from six strains of *H. vesicula* (both "delicate" and "robust" varieties; Fig. 2) indicates that these six form a single clade that is closer to *Phytophthora* than *Pythium*.

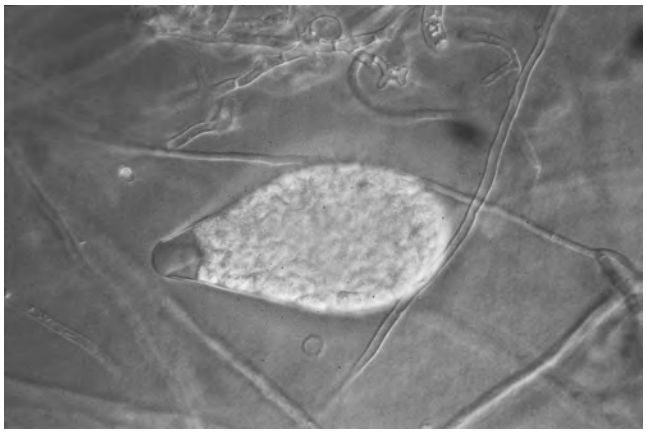

Figure 2. Zoosporangium of the cosmopolitan marine oomycote *H. vesicula* (about 40 μm wide at the widest point) (4,36). This is the "delicate" variety; see References 11 and 37 for photos of the "robust" variety. Species of *Halophytophthora* are common and rapid pervaders of fallen mangrove leaves (34,36,38,39). At full maturity, the inverted cone visible at the tip of the sporangium (left end) everts into a delicate, ephemeral release vesicle, and the biflagellate zoospores seen crammed against one another in the sporangium swim away through the vesicle.

Life histories of the marine ascomycetes and the marine straminipiles are quite different from one another (Table 1). The predominant ploidy for the ascomycetes is haploid. Haploid mycelia pervade the plant substrate, lyse and digest it, and convert it into new fungal mass [at high efficiency ($\geq$50% yield) at least in some cases (9)]. Some of the fungal digestate is used to construct ascomata (commonly spheroidal, dark-colored tissues embedded in the decaying plant material) in connection with sexual fusion of female and male hyphal or spermatial entities. Binucleate (dikaryotic) ascogenous hyphae are formed, and from these, multiple asci (usually cylindrical containers of ascospores) grow upward within the ascomata. Ascospores are formed after nuclear fusion, meiosis, and subsequent mitosis (usually eight spores per ascus). The ascospores are released, in some cases explosively expelled, from the asci, out away from the decaying plant, and some of these ascospores attach to new substrates to complete the cycle. See References 1,8,9, and 25.

The predominant ploidy for the marine straminipiles is diploid (Table 1). Haploid sexual organs are formed by meiosis, and these soon fuse in compatible pairs to form zygotes in the female partner. The zygotes mature into usually thick-walled oospores. The oospores germinate to yield new diploid hyphae that can propagate vegetatively by diploid zoospore formation. The zoospores swim and/or are transmitted through water currents to new substrates (commonly fallen leaves) to which they attach and penetrate by germination into new diploid hyphae. Some of the marine straminipiles may not undergo sexual reproduction. See References 1, 5, 36 to 38, 40 and 94.

Methods of collection and isolation of marine ascomycetes and marine straminipiles are given in reference (4) (see also 7,36,38,41). Central methods for ascomycetes involve capture and culture of ascospores expelled away from the plant material collected in the field, often as standing-decaying shoots (Fig. 1). Alternatively, ascomata can be microexcavated from decaying material, squashed with fine forceps, and dragged across agar to spread ascospores for subsequent germination and transfer. For straminipiles, samples are collected as submerged decaying leaves and small subsamples are placed on oomycote-selective medium (containing strong selective inhibitors of fungi and bacteria). When oomycotes appear, single sporangia or hyphal tips are removed to new culture plates. It is very important that investigators working with marine-mycelial decomposers keep in mind that culture of mycelial eukaryotes on common laboratory agar media, with transferring, will commonly lead to loss of natural physiological capabilities and capability for sexual reproduction (42).

MARINE ADAPTATION OF EUKARYOTIC MYCELIAL DECOMPOSERS

Neither marine mycelial ascomycetes nor straminipiles have a large presence in the plankton (11,43). Mycelial fungal biovolume concentrations are less than 0.2% of biovolumes of bacterioplankters, even in saltmarshes, where fungal volume would be expected to be maximized (9). Mycelial straminipile contribution to flagellate-plankton volume has been estimated to be only about 10^{-5} to 10^{-6} that of total flagellates, even close to the mangroves, where marine oomycotic contribution would be expected to be greatest (44). Even the single-celled fungi [yeasts (3,18)], which one might expect to be adapted to life in liquid suspension, and therefore potentially having planktonic impact (45), are present in the saltmarsh plankton at levels 10^{-8} those of bacterioplankters and at total biovolumes at most 10^{-5} those of bacteria [using generous yeast-cell volumes (*Pichia spartinae*; 18) and bacterial-cell volumes from Reference 46]. [Note that the appearances of yeasts in natural plankton samples, e.g., in direct-epifluorescence microscopic fields, are unknown; because marine-planktonic yeasts have not been direct-microscopically enumerated as have bacteria, it is possible that the above estimates of yeast cell concentrations (culture-based) are not accurate.]

Mycelial fungi are exquisitely well adapted to pervasion and lysis of solid substrates, through turgor-pressurized tip growth and lytic-enzyme release, among other capabilities (47,48). They would not be expected, therefore, to have the plankton as a major habitat, one where their relatively weak dissolved-substrate affinities ($>10^{-6}$ M) put them at a severe competitive disadvantage to the ultramicro planktobacteria, whose affinities are commonly as strong as 10^{-8} M (47,49). It is in the solid, aboveground parts of dead intertidal vascular plants (e.g., saltmarsh grass and rushes) in which marine ascomycetous decomposers have the opportunity to pervade, lyse polymeric solids, and produce new mass, with minimal competition from prokaryotes or predators (Table 1; 9,11,49,50). This does not appear to apply to parts of marine vascular plants that are permanently submerged (seagrasses) or to leaves that fall and then decay in a permanently submerged location (mangroves), unless the dead parts break away and then decay in the intertidal zone (16,51,52). Although submerged wood is known to be a substrate for many species of marine fungi (4,6,7), the extent to which submerged wood serves as a substrate for marine-fungal production is not yet clear (3).

Marine mycelial straminipiles may not build large masses in their solid substrates (fallen, submerged leaves, e.g., mangrove leaves; Table 1). They do penetrate and grow within fallen, submerged leaves [although not apparently within leaves produced within the inter- or subtidal zones (4,39,43)], but there is some evidence (see next section) for the hypothesis that they soon convert newly synthesized mass into zoospores that rapidly depart the decaying leaf system (11,53).

Marine mycelial ascomycetes are not dramatically different from their terrestrial and freshwater counterparts, perhaps in part because mycelial fungi in general are capable of countering low external water potential by production or absorption of compatible solutes such as glycerol and membrane protectants such as trehalose (54–56). These compatible solutes and membrane protectants serve equally well to provide physiological functionality in the face of desiccating conditions or salty

conditions; for this reason, it is not a simple matter to find evidence of physiological adaptations to seawater salinity using agar cultures (57,58). Therefore, the definition that has been adopted for the marine eukaryotic decomposers is "fungi that grow and sporulate exclusively in a marine or estuarine habitat" (4,31). This definition excludes species of fungi that might be capable of germination and inextensive hyphal growth, but that are capable of neither extensive substrate pervasion nor ascomatal or conidial formation in marine substrates in nature (11). It also excludes species such as *Schizophyllum commune*, which can form basidiomatal brackets on dead wood in salty, maritime environments, and exhibit resistance to salt in agar culture, but which also produce basidiomata on dead wood in nonsalty terrestrial environments (59). There are, however, subtle physiologically adaptive characteristics of at least some marine fungi, including membrane-transport enzymes that function optimally in the presence of seawater ions and the alkaline seawater carbonate-buffering system (54,60–62). It may be marine adaptations of this nature that can restrict normal propagule production to the marine environment (54,63), along with specific adaptations to high sulfate availability and to the marine substrates that are occupied and lysed (e.g., finely targeted lytic enzymes, competitive characteristics targeted to potential marine combatants, mutualisms evolved with marine invertebrate litter comminuters). Adaptations to marine substrates probably include selective adherence by seawater-borne ascospores bearing appendages (4,6,7,26,27).

Marine mycelial straminipiles generally show mycelial growth and zoospore production patterns with broad optima at salinities above that of freshwater, and it has been suggested that this, along with cuing of zoospore release by dilution and mild drying, is a sign of adaptation to intertidal zones, where salinities would be expected to be variable, along with occasional exposure of substrates to air (36,37,53,64). Straminipiles generally can respond to increasing salinity by production of compatible solutes (proline; 54). There are no reports of the characteristic marine mycelial straminipiles (halophytophthoras) from freshwater or terrestrial habitats (but see 36), so the definition given in the previous paragraph for marine mycelial ascomycetes also applies to the mycelial straminipiles (4).

BIOMASSES AND PRODUCTIVITIES

A barricade that blocked collection of data for marine mycelial biomasses and productivities was the opacity of their solid substrates. This obstacle was overcome by development of methods for chemical extraction and measurement of biochemical proxies for living fungal (membrane-containing) mass and total-fungal (cytoplasm-filled and empty hyphal) mass (especially ergosterol and glucosamine, respectively) (65–67). Subsequently, the ergosterol method was expanded such that it became possible to measure instantaneous fungal production rates (66,67). The expansion involves monitoring the flow of radiolabeled acetate into ergosterol.

There are no published methods for biochemical-proxy measurement of the biomass or productivity of marine straminipiles, primarily because the straminipiles do not synthesize ergosterol, nor do most species have glucosamine as a monomer of cell wall polymers (3,66,68). It may be that immunoassays for terrestrial, plant-pathogenic straminipiles could be adapted for measurement of mass of marine mycelial straminipiles (66).

Because marine ascomycetes are capable of high-efficiency conversion (ca. 40–60% yield) of intertidal vascular plant material, which is highly photosynthetically productive, the productivity of marine ascomycetes in saltmarshes is substantial (Fig. 1; 30,32,69,70). For smoothcordgrass (*Spartina alterniflora*) saltmarshes in Georgia, U.S.A., annual fungal productivity (3-year average) was 535 g m^{-2} of marsh. Standing dead shoot parts are essentially converted *from within* into new entities that are substantially fungal in nature, although this is not patently obvious in gross aspect (9,50). Surprisingly, fungal productivity was higher in winter and spring than in summer and autumn in Georgia (latitude 31°N) (32). Autumnal productivity of marshgrass ascomycetes at a standard temperature of 20 °C did not show decreases with increasing latitude from 29 to 43°N, and the same major species of ascomycetes were involved over the whole transect (71). Bacterial productivities on standing-decaying marshgrass leaves were approximately 1% of the fungal productivities inside the leaves (9).

High productivities of saltmarsh ascomycetes led to high content of fungal nitrogen and phosphorus in standing decaying leaves (33–88% in living fungal mass); saltmarsh-fungal production may partially drive import of nitrogen by saltmarshes (32). Bacterial nitrogen fixation in decaying marshgrass shoots may also be facilitated by fungal/bacterial consortia, and saltmarsh ascomycetes have been implicated in the lytic release of volatile organosulfur compounds from within the decaying shoots (9).

There is no published information yet for biomasses or productivities of marine mycelial straminipiles. However, three findings suggest that these oomycotes do not have a mass accumulative strategy like the marine mycelial ascomyetes (see previous section): (*1*) carbon dioxide output rates do not rise in decaying leaves containing high frequencies of marine oomycotes to the level that they do in leaves containing high concentrations of marine-ascomycete mass (39,69); (*2*) frequencies of oomycotic occupation of and rates of oomycotic zoospore release from submerged decaying mangrove leaves fall early in the decay process (53); (*3*) transmission electron microscopy has shown high densities of mycelia of marine ascomycetes in naturally decaying saltmarsh grass blades, but no clear evidence (in a preliminary study) of such densities of hyphae of oomycotes in naturally decaying mangrove leaves (50; Porter, Richardson, and Newell, unpublished).

FATES

The mass produced by marine ascomycetes (at least those of saltmarshes) has the same sort of fate as does

that produced by fungi in forest floor litter: (*1*) output to shredding invertebrates; (*2*) output as sexual propagules (ascospores); (*3*) output as remnant mycelia in small particles, breaking away from the litter decay system and moving into a sediment bacterial/meiofaunal system (9,32,72). In the saltmarsh, principal, at least partially mycophagous, shredding invertebrates are snails, amphipods, and probably crabs, but it is likely that others remain to be identified (9,72). It has been suggested that one cause of lower summer plus autumn fungal productivity in saltmarshes is higher tides that would permit greater access of mycophagous invertebrates and bacterial competitors than in winter plus spring (32). It is not known whether marine straminipiles serve as food for litter-associated invertebrates. If they do not accumulate substantial masses within decaying leaves, as hypothesized earlier, then it may be that the main output avenue for marine mycelial straminipile mass is for zoospore stages in the plankton to serve as food items for invertebrates, perhaps principally the protozoplankton.

POLLUTION AND MARINE FUNGI

There is a large literature for terrestrial ecosystems on the impacts of both: (*1*) pollutants on fungi and (*2*) fungi on pollutants (73,74). Much less is known about marine mycelial ascomycetes and straminipiles and anthropogenic contamination of the marine environment. Recent examinations of urban saltmarsh sites that had received gross pollution by toxic chemicals (Hg, Cr, PCBs, PAHs, multichlorinated insecticide) showed that saltmarsh ascomycetes in the marshgrass decay systems were not detectably impacted (75,76). Two implications of these findings are: (*1*) toxic contaminants may readily move through the fungal decay system into the coastal-marine foodweb; (*2*) because saltmarsh ascomycetes are lignocellulolytic, they may be candidates for bioremediation strategies in which polyaromatic pollutants are present (50).

FURTHER READING

For more information on mycelial ascomycetes and straminipiles pertinent to understanding of their marine ecology, additional references (77–85,15,86–94) can be consulted.

GALLIONELLA FERRUGINEA: AN IRON-OXIDIZING AND STALK-FORMING GROUNDWATER BACTERIUM

KARSTEN PEDERSEN
LOTTA HALLBECK
Göteborg University
Göteborg, Sweden

HISTORY AND TAXONOMIC COMMENTS

The genus *Gallionella* is characterized by its chemolithotrophic growth with ferrous iron and its production of a twisted stalk consisting of a bundle of numerous fibers that makes *Gallionella* very easy to identify. *Gallionella* has been described under several different names such as *Spirophyllum ferrugineum* (1,2), *Didymohelix ferrugineum* (3), *Gloeosphera ferruginea* (4), and *Gallionella filamenta* (5). Most, if not all, of the attempts to categorize species of the genus *Gallionella* under various names arise from observed differences in the appearance of the stalk. The current phylogenetic position of the family *Gallionellaceae* is based on the only 16S-DNA sequence for *Gallionella* available in DNA databases. Additional strains must be sequenced before the diversity of other possible species or genera within this family can be determined.

Ehrenberg was the first to discover the stalks of *Gallionella* more than 160 years ago while studying ochre masses in 1836. In his description (1), Ehrenberg referred to *Gallionella* as a *fossil infusorian*, which he called *die Eisenochertierchen*, the small iron ochre animals. Haeckel (6) presented the first phylogenetic tree that included the kingdom Monera for unicellular organisms in 1866. Zopf (7) first included *Gallionella* with the bacteria in 1879. *Gallionella* has been observed and described by many more scientists from early days and there has been a continuous discussion about its morphology and physiology, but most studies have focused on the stalks. For a summary of the first 100 years of discussions about the intriguing characteristics of *Gallionella*, see Beger and Bringmann (8) and van Iterson (9). Winogradsky (10,11) proposed an autolithotrophic life of the so-called *iron bacteria* including *Gallionella* and listed *Leptothrix, Cladothrix*, and *Gallionella* as examples of lithotrophic iron bacteria. Adler (2) found only small amounts of *Gallionella* in fresh water from Karlspader, but when the water had been left in bottles for several days, the *Gallionella* reproduced profusely or, more precisely, the stalks had become elongated. Lieske (12) succeeded in cultivating *Gallionella* in carbonic water with metallic iron as the ferrous iron source. In 1924–1929, Cholodny made microscopic studies on cover slips that had been submerged in habitats of *Gallionella* (13,14). Admirably accurate sketches of cells attached to the ends of stalks were drawn, showing that the stalk was excreted by the cell and was not a living part of it. Teichmann (15), growing cultures according to the method described by Lieske (12), found a great number of bean-shaped cells in the fluid. This observation influenced Pringsheim (16) to suggest that it is "not impossible that motile cells are formed under certain conditions," a conclusion in accordance with today's knowledge of free-living cells in the exponential growth phase.

In 1953, Beger and Bringmann (8) made comparisons between earlier drawings of the stalk of *Gallionella* and their own transmission electron microscopy studies of stained whole cells and stalks. They proposed that the genus *Gallionella* consisted of five species. Vatter and Wolfe in 1956 (17) presented transmission electron microscopy images of metal-shadowed cells with stalks directly placed upon grids. One year later, Kucera and Wolfe (18) introduced an excellent growth medium containing iron sulfide as the source of ferrous iron. Wolfe could have succeeded in his work with *Gallionella* but for his premature conclusion that "these organisms (i.e., iron bacteria) are too difficult to be profitable" (19). In 1958, a thesis on *Gallionella* presented by van Iterson (9) produced excellent electron microscopy images of the organism using a methodology similar to that used by Kucera and Wolfe described earlier, and it suggested that the stalk was a living part of the organism, with sporangia in the form of membrane sacs on the stalk. Balashova (5,20–22) studied the stalk using transmission electron microscopy with chromium-stained preparations and concluded that it may have zoological forms and budding cells on its cell walls. In 1989, Hanert (23) made detailed light microscopy studies on stalk elongation using single cells and measurements of iron oxidation in both natural samples and laboratory cultures. Evidence of intracytoplasmatic membranes and autotrophic growth was presented. In 1990, Lütters-Czekalla (24) reported growth of *Gallionella* with reduced sulfur compounds instead of ferrous iron as electron donor. This observation remains to be confirmed. In 1990–1995, Hallbeck and coworkers (25–28) reported the 16S-rDNA sequence of *Gallionella*. They showed that, in the exponential growth phase, *Gallionella* has a free-living stage without a stalk. The authors demonstrated chemolithotrophic growth, with carbon dioxide as the sole carbon source, and mixotrophic metabolism. They also demonstrated an organic composition of the stalk and found that the stalk was important for survival in the environments in which *Gallionella* is found. A thesis summarizing these results was published in 1993 (29).

ENRICHMENT, ISOLATION, AND CULTIVATION PROCEDURES

Growth Medium

Various media for enrichment and cultivation of *Gallionella* have been tested. To create proper growth conditions, the medium must contain ferrous iron and carbon dioxide. Lieske (12) designed a culture medium composed of carbonic water and metallic iron. The use of iron sulfide as a source of reduced iron was first suggested by van Niel (17). In 1957, Kucera and Wolfe (18) published a growth medium composed of a salt solution and iron sulfide, which made it possible to obtain pure cultures of *Gallionella*. The salt solution was initially prepared with tap water because the medium lacked a crucial component. This component was later found to be calcium. The ferrous iron medium has since then been widely used, with some minor modifications. Wolfe's modified medium is prepared as follows. Screw-capped tubes (180 × 16 mm) are filled with 10-ml salt medium consisting of 1.0 g NH_4Cl (ammonium chloride), 0.4 g $MgSO_4$(magnesium sulfate) × 7 H_2O, 0.1 g $CaCl_2$(calcium chloride) × 2 H_2O, 0.05 g K_2HPO_4 (Potassium phosphate mono basic) and one liter double-distilled water. The salt medium is autoclaved, chilled to 5 °C and infused with sterile, filtered CO_2 (carbon dioxide) to pH 4.6 to 4.8. A ferrous sulfide or ferrous carbonate precipitate (0.5 ml) is added slowly to the bottom of the tubes with a Pasteur pipette and the tubes are left for 4 to 6 hours to allow gradient conditions to establish before inoculation. The ferrous sulfide and ferrous carbonate have to be prepared in the laboratory. Ferrous sulfide is prepared by dissolving 7.8 g $FeSO_4$ $(NH_4)_2SO_4$ (Mohr's salt) and 4.8 g sodium sulfide each in 200-ml boiling distilled water, and subsequently pouring the ferrous solution into the sulfide solution. Two 500-ml Erlenmeyer flasks are used, and mixing is done with a glass rod. The flasks are filled to the top and sealed with a rubber stopper to prevent oxidation of the ferrous iron. The iron sulfide sediment needs at least 4 hours to settle and is then washed five times with boiling water before it is centrifuged at high velocity. The iron sulfide is collected in small bottles, filled up with water, closed with an airtight lid and sterilized at 121 °C for 20 minutes. The medium is stored cool in airtight vials.

Ferrous carbonate is prepared by dissolving 3.9 g $FeSO_4(NH_4)_2SO_4$ (ferrous sulfate ammonium sulfate complex) and 1.0 g anhydrous Na_2CO_3 (sodium carbonate) each in 100-ml boiling distilled water, and subsequently pouring the carbonate solution into the ferrous solution, preferably under a nitrogen atmosphere. The precipitated ferrous carbonate is then washed five times with boiling double-distilled water, sterilized in closed vials at 121 °C for 20 minutes and stored cool in airtight vials. It is recommended that all solutions used for preparation of the medium and source of ferrous iron are filtered (using a 0.2-μm filter) to remove any cells or particles that may give a background during microscopic counts.

Isolation

Gallionella strains have been isolated successfully by serial dilution and serial transfer. The isolation procedure starts with washing one colony, if the enrichment culture contains colonies attached to the walls of the culture tubes (23). Thereafter, the colony is suspended in 10-ml fresh, sterile medium and inoculated into new test tubes with Wolfe's modified medium at serial dilutions in ten times increments. The dilution series is made up to ten times the inverse of the total number of cells per ml. One milliliter is used as inoculum from each dilution and introduced into several parallel culture tubes. Five to ten serial transfers, each starting from one colony, are necessary to achieve pure cultures in this manner. This procedure requires up to ten weeks but is quite certain to continually reduce the number of contaminants and obtain a pure culture. Purity is checked microscopically using a variety of heterotrophic and autotrophic media, such as yeast extract bouillon, nutrient agar, *Nitrosomonas* medium, and *Thiobacillus ferrooxidans* medium.

Maintenance

Pure stock cultures of *Gallionella* strains can be maintained for years using the described culture conditions with serial dilution transfers every four to eight weeks. Nunley and Krieg (30) reported preservation of *Gallionella* culture material for at least 13 weeks by freezing at −80 °C in 15% glycerol, although this procedure did not result in survival of the strain cultured by the authors.

DESCRIPTIVE CHARACTERS

Morphology

The size, shape, and ultrastructure of *Gallionella* are illustrated in Figures 1 and 2. The cell is gram-negative, bean-shaped, and usually 0.5–0.8 × 1.6–2.5 μm in size. It secretes an extracellular twisted stalk from the concave side, 0.3 to 0.5 μm in width and up to 400 μm or more in length. The stalk is composed of

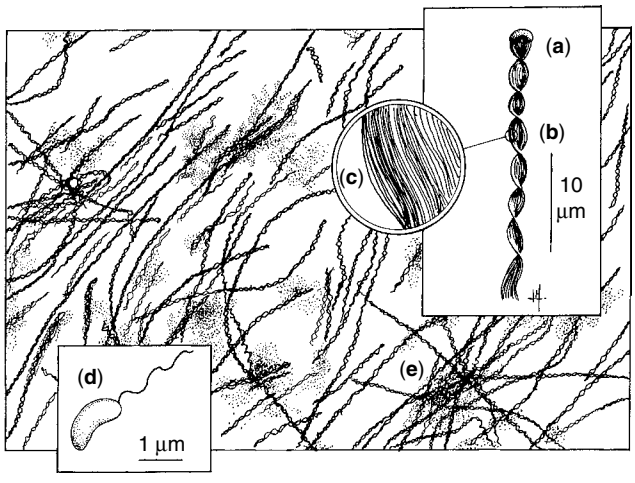

Figure 1. *Gallionella ferruginea* cell morphology, flagella position in cell suspension, and stalk arrangement. The bean-shaped cell of *G. ferruginea* (**a**) forms stalks (**b**) of a bundle of 2-nm wide fibers (**c**). Motile cells with one polar flagellum (**d**), and without a stalk, have been reported. Iron hydroxides precipitate on and around the stalks (**e**).

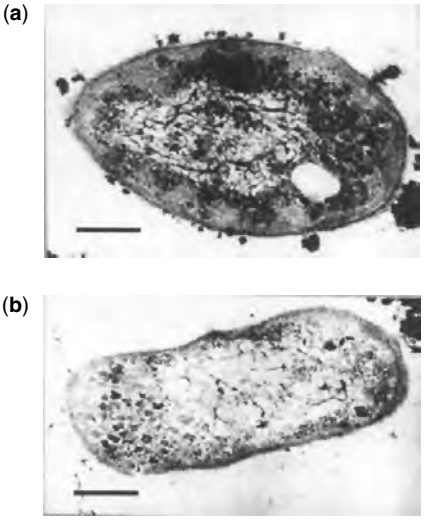

Figure 2. Ultra-thin section of *G. ferruginea* strain Johan in the stationary phase. (**a**) Cross-section of strain Johan with outer cell wall membrane. Bar = 0.2 μm. (**b**) Longitudinal section of strain Johan. Bar = 0.25 μm.

a number of 2-nm wide fibers and is produced under microaerophilic conditions when cells are in the late exponential or stationary growth phase. Cells may have a polar flagellum (17). The stalk becomes continuously encrusted with precipitated ferric iron oxides that may totally cover old stalks. The composition of the stalk has not been conclusively demonstrated, but inorganic as well as organic compositions have been suggested. Hanert (23) proposes that the stalk consist of colloidal ferric hydroxide based on observations of it being dissolved in 0.12% sodium thioglycolate. Hallbeck and Pedersen (27) reported a higher carbon-to-nitrogen ratio (C : N = 6.8) in stalk-forming cultures compared with a non-stalk-forming culture (C : N = 4.8), and concluded that the stalk is composed of an extracellular carbon skeleton, probably a carbon polymer.

Two strains of *Gallionella* have been described and published (Table 1). Strain BD from a drainpipe in Braunschweig was described by Hanert (23) and strain Johan from a 60-m deep drinking water well was described by Hallbeck and Pedersen (25–27) and Hallbeck and coworkers. (28). Strain BD was reported to have intracytoplasmatic membranes (23), whereas strain Johan does not have such membranes (Fig. 2). The isolation procedure for *Gallionella* is by serial dilution and the possibility of contaminants contained in the cultures cannot be excluded conclusively. Serial-thin sectioning should show a stalk connected to the sectioned cell to confirm it to be a cell of *Gallionella*, as in Figure 3(a–c). Inclusions that may be poly-β-hydroxybutyrate have been noted but apart from this, strain Johan does not show any specific fine intracellular structures (Fig. 2).

Growth and Physiology

Gallionella can be cultured in vitro in screw-capped test tubes using oxygen and ferrous iron concentration gradients in a salt medium, with carbon dioxide as sole carbon source (Fig. 4), as described earlier. Solid-phase ferrous iron is placed at the bottom of the tube in a fresh, autoclaved and oxygen-free salt medium. Iron sulfide or iron carbonate can be used as a source of ferrous iron. With this procedure, the concentration of dissolved ferrous iron will decrease from the bottom of the tube and upward as it dissolves and diffuses away from the solid phase. Oxygen will decrease in concentration from the top of the tube

Table 1. Differential Characteristics of *Gallionella Ferruginea* Strains Johan and BD

Character	Strain Johan[1]	Strain BD[2]
Cells bean-shaped	Yes	Yes
Diameter (μm)	0.5–0.8	0.5–0. 7
Length (μm)	1.6–2.5	0.8–1.8
Motility without stalks	Yes	Yes
Motility with stalks	No	No
Temperature range for growth (°C)	5–25	ND[a]
Optimum temperature (°C)	20	17
pH range for exponential growth	5.0–6.5	ND
Generation time in exponential growth (h)	8.3	ND
Stalks not produced in exponential growth phases	Yes	ND
Maximum cell number in in vitro culture (cells/ml)	5×10^6	ND
Length of stalks (μm)	Average 60 per cell	Up to 400 for one cell
Colony form in vitro	A ring on the tube wall	Circular colonies
Growth with carbon dioxide as sole carbon source	Yes	Yes
Growth with ferrous iron as sole energy source	Yes	Yes

[1]Strain Johan was described by Hallbeck and Pedersen (25–27), and Hallbeck and coworkers. (28).
[2]Strain BD was described by Hanert (23).
[a]Not determined.

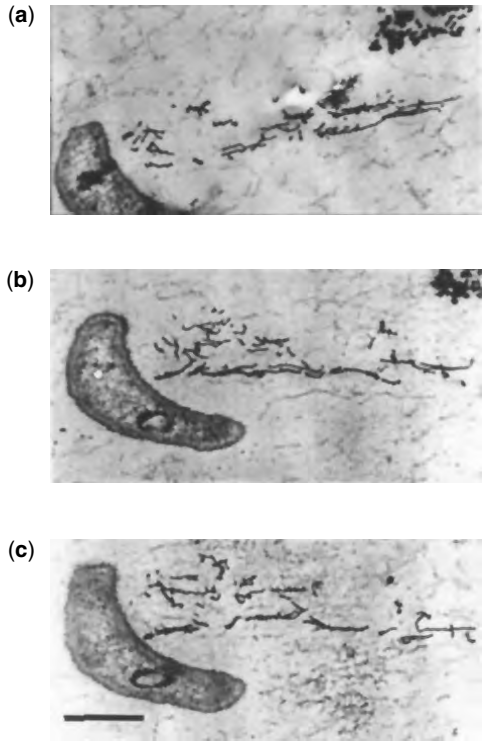

Figure 3. Serial-thin sections of a cell with an adjacent stalk. Bar = 0.5 μm.

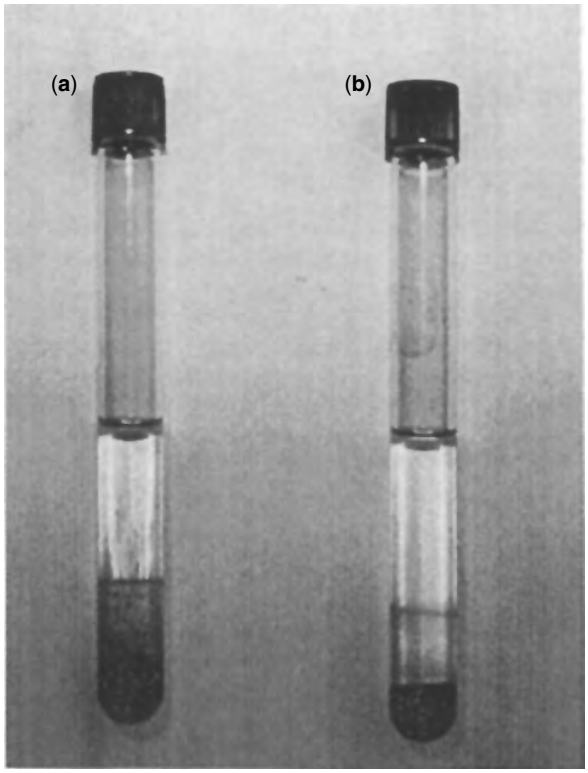

Figure 4. Screw-capped gradient culture tubes with 2-week-old growth of *G. ferruginea*. Iron sulfide as a source of ferrous iron is placed at the bottom of the tubes. (**a)** Growth of a stalk-forming strain. (**b)** Growth of a non-stalk-forming strain.

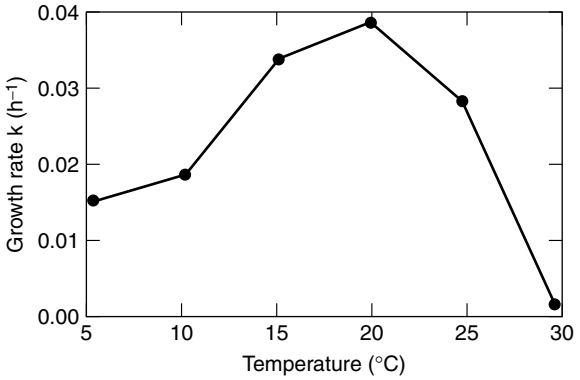

Figure 5. The growth rate (k) of *G. ferruginea* under aerobic culture conditions in the temperature range of 5–30 °C (*Source:* Hallbeck and Pedersen (25)).

downward as it diffuses into the salt medium from the air above. An optimum growth situation will develop in this gradient tube and *G. ferruginea* cells and stalks will appear in the gradient at the position most favorable to growth. Eventually, in the tube additional rings of growth may form in new places as the concentration gradient changes with aging of the culture.

The optimum growth temperature is 17–20 °C and temperatures above 25–30 °C are lethal (Fig. 5). The culture grows to a maximum of 5×10^6 cells/ml culture, which makes many traditional techniques for strain characterization impossible. Strain BD develops small, circular colonies attached to the wall of the tube within three to five days after inoculation. Strain Johan predominantly forms a ring at a specific level in the concentration gradient (Fig. 4). The cells of strain Johan colonize as new rings upward in the tube as the culture gets old, that is, ten days or older. Eventually, most of the tube will be filled with a brittle mass of stalks, iron oxides, and cells. Hallbeck and Pedersen (25) have demonstrated that *Gallionella* strain Johan is free-living in vitro in its exponential growth phase and does not produce stalks until its late exponential and stationary phases, when pH exceeds 6 (Fig. 6). Most stalk formation and iron oxidation occur at circum-neutral pH (31). The generation time at optimum temperature for strain Johan is 8 hours. Stalk production continues for many days in the stationary phase (25). Some cell division may still occur but not at the growth rate observed during the first four to five days after inoculation. The use of the term *stationary phase* implies that cell division ceases, but cell activity does not necessarily cease. Instead, the cell appears to enter a secondary phase, during which it allocates its metabolic activity to stalk production instead of cell formation. This type of metabolic switch is commonly observed among microbes producing antibiotics. The maximum mean stalk length per cell of strain Johan has been determined to be 60 μm in a 16-day-old culture (Fig. 6). Individual cells may produce a much longer stalk, with 400 μm having been reported for a single cell of strain BD (23). With prolonged sub-culturing on iron carbonate as energy source, some of the *Gallionella* strain Johan cultures have been reported to irreversibly lose their ability to form a stalk (28). Their

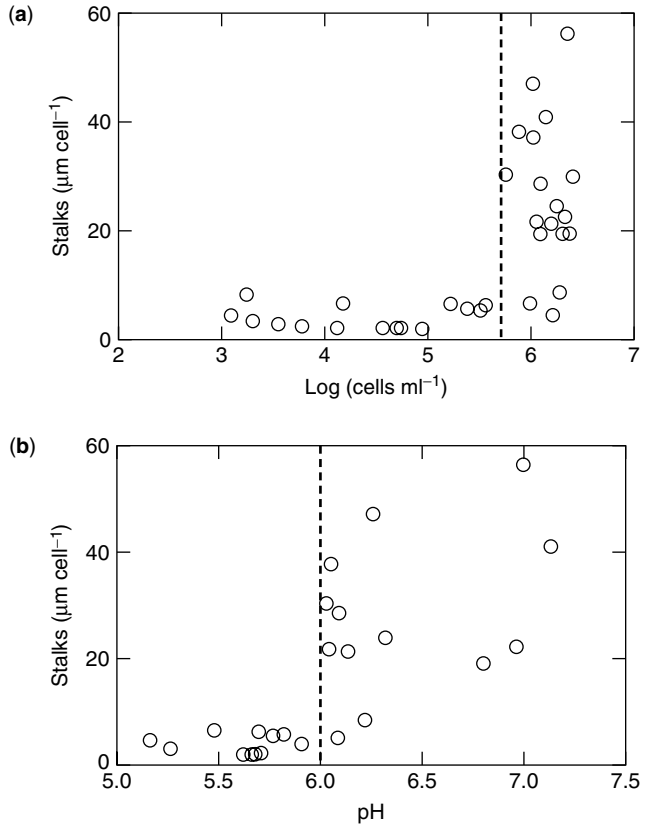

Figure 6. (**a**) Relation between total number of cells and stalk length per cell in growth experiments with *G. ferruginea* under aerobic gradient growth conditions. Data from four experiments. (**b**) Relation between pH and stalk length per cell in growth experiments with *G. ferruginea* under aerobic growth conditions. Data from three experiments (*Source:* Hallbeck and Pedersen (25)).

identity was confirmed by 16S-DNA sequencing. They still form a ring of oxidized iron, as does the stalk-forming variant, but the ring is very thin (Fig. 4).

Gallionella is chemolithotrophic, with ferrous iron as its energy source and electron donor, and with carbon dioxide as its sole carbon source. Carbon dioxide fixation by strain Johan was revealed using hydrogen [^{14}C]-carbonate (26), whereas in vivo activity of the Calvin cycle key enzyme, ribulose biphosphate-carboxylase, has been reported for strain BD (23). Mixotrophic metabolism has been shown on glucose, fructose, and sucrose although growth did not occur on these sugars without ferrous iron and carbon dioxide. Ammonium and nitrate can be used as nitrogen sources; the capacity for nitrogen fixation is not known.

Phylogeny

In 1993, the 16S-rRNA gene of *G. ferruginea* (strain Johan) was published between base numbers 47 and 1405 (*Escherichia coli* numbering) (28) Phylogenetic analysis of this sequence has placed *Gallionella* among the β-proteobacteria. The sequence was distant from other species sequences in the tree, with a 10% difference to the most closely related genus, the chemolithotroph *Nitrosospira multiformis* (32). The remote position of *G. ferruginea* in relation to other species, and its utilization of iron as its energy source and electron donor as opposed to ammonia for the closest gene cluster, *Nitrosomonadaceae*, motivates the designation of a separate family for the genus *Gallionella, Gallionellaceae*. At present, there is only one known species in this family. The capacity of chemolithotrophic iron oxidation among bacteria has previously been suggested to be evolutionarily widespread (33). This is confirmed by, for instance, the phylogenetic distance (85% in terms of its 16S-rRNA gene identity) between *Gallionella* and the iron-oxidizing genus *Thiobacillus*.

Working with *Gallionella ferruginea*

Gallionella ferruginea has a generation time of 8 hours at 20 °C and grows to at most 5×10^6 cells/ml after 80 hours. The difference between working with a slow-growing organism such as *G. ferruginea* and a fast-growing bacterium such as *Escherichia coli* is striking, as demonstrated by the following calculations. A growth experiment with *G. ferruginea* starts with 1×10^3 cells/ml and it grows at most to 5×10^6 cells/ml. An *E. coli* experiment may start at 10^6 cells/ml and within three and a half hours, it easily grows to 10^9 cells/ml. These numbers illustrate that many experiments that can be performed easily with *E. coli*, are difficult or even impossible and in all cases, very time-consuming if applied to *G. ferruginea*. For instance, biochemical analytical procedures commonly require cell amounts in the milligram to gram range. One gram of *E. coli* cells can be obtained by growing 1 l of culture left overnight. To obtain 1 g of *G. ferruginea*, 250,000 culture tubes (Fig. 4) have to be prepared and cultured for five to six days. The cells will be in 2,500 liters of medium, together with more than 50-kg ferrous iron oxide and a great number of stalks. For interest, approximately 12,000 tubes, with about 6-kg iron sulfide and 120 liters of the mineral salt solution, were used to produce the data published in Hallbeck and coworkers (25–28). The total weight of all *G. ferruginea* cells in these experiments was 0.05 g.

ECOLOGY

The environments where stalk-forming *Gallionella* can be found, commonly attached to surfaces, are in slow-flowing groundwater that is rich in ferrous iron but has a low organic carbon content and a low oxygen tension. Typical places to search for *Gallionella* are the insides of drainpipes, storage basins for groundwater from deep wells, and inside tunnels and on rock walls with seeping groundwater. A common feature of these environments is that cold (i.e., below 20 °C), reduced, anaerobic, and ferrous iron–bearing groundwater reaches an atmosphere that contains oxygen. Such environments are suitable for chemolithotrophic growth with ferrous iron as the energy source and the electron donor and with oxygen as electron acceptor. A flow appears to be an absolute prerequisite to the formation of *Gallionella*, continuously

supplying ferrous iron and possibly also carbonate from the groundwater to the attached cells. Under such conditions, the stalk may act as a holdfast and prevent the cells from being washed out to a more oxidized environment that does not contain ferrous iron.

Hallbeck and Pedersen (27) have demonstrated an additional function for the stalk. The iron oxidation that occurs in a typical *Gallionella* environment may be divided into two processes namely: (*1*) the respiratory iron oxidation performed by the cells in their energy metabolism, and (*2*) the nonmetabolic iron oxidation induced by the increasing oxygen tension as the anoxic groundwater reaches the atmosphere. Ferrous iron reacting with oxygen participates in a chain of reactions yielding highly reactive oxygen species such as perhydroxyl (HO_2), hydrogen peroxide (H_2O_2), and the hydroxyl radical (HO) (34). The survival of the stalk-forming (Sta^+) *Gallionella* strain Johan in media with a low or high potential for oxygen radical formation was compared with that of a variant of strain Johan, which irreversibly lost its ability to form a stalk (Sta^-) (27). It was found that *Gallionella* Sta^+ survived longer (nine weeks) than did Sta^- (six weeks) in cultures with a high potential for oxygen radical formation. Therefore it was suggested that the stalk of *Gallionella* protects the cells against the toxic oxygen species discussed earlier, by directing the oxidation of iron to the stalk. This phenomenon could be compared with the action of the protein ferritin, proposed to perform iron oxidation in both prokaryotic and eukaryotic cells (35). Whether the iron oxidation on the stalk is enzymatic or the stalk acts as a surface catalyst for the oxidation reaction is not known.

In conclusion, the stalk acts as a holdfast and gives *Gallionella* the unique possibility of colonizing and surviving in an ecological niche with high contents of ferrous iron and with some oxygen, a niche that is inaccessible to bacteria without a defense system against the oxygen radicals formed during inorganic oxidation of ferrous iron.

Microbial Mats and Biofilms

Systematic studies of *Gallionella* in natural and laboratory environments have been few. Emerson and Revsbech (36) reported the occurrence of *Gallionella* spp. in an iron-oxidizing microbial mat. They found *Gallionella* to predominate closer to where the groundwater emanated from the well. It was here that the water had the lowest concentrations of oxygen, confirming the microaerophilic nature of *Gallionella*. The authors continued their studies in the laboratory, constructing a chamber that mimicked the situation on the studied site (37). They concluded that the studied bacterial consortium was responsible for most of the observed iron oxidation. The other dominating species studied were *Lepthotrix ochracea* and members of the family *Siderocapsa* were also observed.

The formation of biofilms of *Gallionella* on surfaces has been reported earlier (27,38). Water from 40 to 60 m deep wells was pumped over test surfaces and in less than 48 hours, dense biofilms of stalks and cells developed. They were up to 30-μm thick, showing the growth potential of this bacterium. The Äspö Hard Rock Laboratory (HRL) tunnel, Äspö, Sweden (39), is heavily populated with mats of *Gallionella* that can reach 10 cm or more in thickness. Stones and rock surfaces in pools and ditches in the tunnel are commonly covered with moss-like biofilms of *Gallionella*, demonstrating underground tunnels, mines, and so on to be excellent sites for studies of processes related to this organism, such as metal accumulation.

Metal Accumulation on the Stalks

The stalks of *Gallionella* attract large amounts of iron hydroxides and hydroxides of other metals also. The processes governing this coating are not well established, although several intriguing theories exist. It can be anticipated that enzymatic ferrous iron oxidation by *Gallionella* in its extraction of electrons for energy production takes part in the build-up of metal oxides on the stalks. By this process, oxidized, ferric iron from this metabolic process would be expelled and adsorbed on the stalk. In addition, as suggested earlier, the stalk may act as a protective agent against the creation of toxic levels of oxygen radicals. The stalk would then have a ferrous iron oxidation capability and a sorption capacity for ferric iron hydroxides and for other metals. An interesting function of the stalk, which is in line with these assumptions, has been suggested by Banfield and coworkers. (40). This group discovered ferrihydrite nanocrystalline growth in samples containing *Gallionella* stalks and suggested that the stalks attract or flocculate 2 to 3-nm ferrihydrite particles formed by the cells' enzymatic oxidation of ferrous iron. The stalk then governs an aggregate-based growth of polycrystalline materials. Surfaces of nanocrystalline iron oxyhydroxides, for example, goethite formed from ferrihydrite are active adsorption sites for metals at neutral to alkaline pH. Consequently, *Gallionella* may have an important influence on the fate of dissolved metals in natural groundwater, as discussed later.

The transport, chemical speciation, and ultimate fate of dissolved metals in aqueous systems are largely controlled by reactions that occur on solid surfaces (34). Recognition of the importance of solid-phase reactivity in aqueous geochemistry has fostered the development of the surface complexation-precipitation theory (SCPT) as the leading model for understanding the behavior of dissolved metals in pristine and contaminated waters (34,41). This concept embraces the principles of thermodynamics and chemical equilibria to predict when solid-phase partitioning of metal ions is likely to occur in response to sorption, and to quantify subsequent surface precipitation reactions. The SCPT has thus far been applied almost exclusively to minerals, particularly to hydrous iron oxides (41); however, Warren and Ferris (42) recently demonstrated that a continuum exists between ferric iron sorption and precipitation reactions on bacterial surfaces, as anticipated with SCPT. Pedersen and Albinsson (43) reported a similar process with the iron-reducing bacterium *Shewanella putrefaciens*. This is an important step forward as bacteria are at least as widely distributed in aqueous systems and probably as reactive as are many inorganic solids. Moreover, if SCPT is to emerge

as a true guiding paradigm for aqueous geochemistry, it must be firmly established to be applicable to both organic and inorganic solids.

The behavior of bacteria as geochemically reactive solids can be inferred from extensive research documenting their performance as sorbents of dissolved metals, and nucleation templates for a wide range of authigenic minerals (43–46). This reactivity stems directly from the presence of amphoteric surface functional groups (i.e., carboxyl, phosphoryl, and amino constituents), which are associated with structural polymers in the cell walls and external sheaths, capsules, and stalks of individual cells (43). Direct interaction between these surface functional groups and dissolved metals accounts for the sorptive properties of bacteria, whereas surficially sorbed metals provide discrete sites for subsequent mineral nucleation and precipitation reactions (43).

Because of their ubiquitous distribution and reactive surface properties, hydrous iron oxides are considered to be dominant sorbents of dissolved metals in aquatic environments. This perception is somewhat tempered by work that shows that natural iron oxides often contain significant amounts of silica (e.g., siliceous ferrihydrite) and sulfate (e.g., jarosite and schwertmannite), as well as organic matter, including intact bacterial cells (44). This intermixing of compositionally variable iron oxides and organic matter produces composite multiple sorbent solids with highly variable metal retention properties, referred to as *bacteriogenic iron oxides* (BIOS).

Bacteriogenic iron oxides and groundwater samples were collected underground at the Stråssa mine in central Sweden and from the Äspö HRL tunnel. ferrous iron-oxidizing bacteria, including stalked *G. ferruginea* and filamentous *Leptothrix* sp., were prominent in the BIOS samples from Stråssa, whereas *G. ferruginea* dominated in the Äspö HRL samples. The goal of these investigations was to understand the accumulation of various metals by BIOS. Strontium, cesium, lead, and uranium were studied in the Stråssa BIOS (47), and sodium, cobalt, copper, chromium, and zink were studied in the Äspö HRL BIOS (48).

The BIOS samples were found to contain only amorphous hydrous ferric oxide, as determined by X-ray diffraction. Inductively coupled plasma mass spectroscopy revealed hydroxylamine-reducible iron and manganese oxide contents ranging from 55% to 90% on a dry weight basis. Distribution coefficients (K_d values), calculated as the ratio between the BIOS and dissolved heavy metal concentrations, revealed solid-phase enrichments of 10^0 to 10^5, depending on the metal and iron oxide content of the sample. At the same time, however, a strong inverse linear relationship was found between log K_d values and the corresponding mass fraction of reducible oxide in the samples, implying that the metal uptake was strongly influenced by the relative proportion of bacterial organic matter in the composite solids. On the basis of the metal accumulation properties of the BIOS, an important role can be inferred for intermixed iron oxides and bacterial organic matter in the transport and fate of dissolved metals in groundwater systems.

CONCLUSION

Gallionella ferruginea is a gram-negative, bean-shaped, iron-oxidizing bacterium that secretes an extracellular twisted stalk composed of numerous fibers. The stalk is produced under microaerophilic conditions when cells are in the late exponential or stationary growth phase. The phylogenetic position of *G. ferruginea*, as determined by 16S-DNA sequence comparisons, is among the β-proteobacteria. The bacterium is a member of the family of *Gallionellaceae*, with one known species, *G. ferruginea*. The most closely related species, according to 16S-rDNA sequence data, is the chemolithotroph *Nitrosospira multiformis*, which with a 16S gene similarity of 90% is only distantly related. *Gallionella ferruginea* is motile by means of a polar flagellum. Microaerophilic, chemolithotrophic growth can be obtained in vitro by using oxygen and ferrous iron concentration gradients in a salt medium, with carbon dioxide as the sole carbon source. Mixotrophic metabolism has been demonstrated with glucose, fructose and sucrose. *Gallionella ferruginea* can be found where anaerobic groundwater with ferrous iron reaches an environment that contains oxygen. Commonly, large amounts of stalk material are produced, which attract iron hydroxides and many different trace metals, giving it a brown, macroscopic appearance. The stalk and iron hydroxide masses formed may cause severe clogging of ditches, drinking water wells, and any other facilities utilizing iron-bearing, anaerobic groundwater eventually.

GENE EXCHANGE IN BIOFILMS

Stefan Wuertz
Technical University of Munich
Garching, Germany

Microorganisms in many natural and engineered systems grow at solid–liquid, solid–gas, liquid–liquid, or liquid–gas interfaces. These microbial aggregates are called *biofilms* and contain entrapped particles of both organic and inorganic origin, extracellular polymeric substances (EPSs), and water (1). They form spatially differentiated multispecies communities. EPSs are composed of polysaccharides, proteins, nucleic acids, and other amphiphilic polymeric compounds (2); they play a pivotal role in microbial interactions with interfaces and serve in binding cells and other particulate materials together (3). Owing to the close proximity of cells, biofilms are likely candidates for multicellular communication and coordination. One such form of interaction is the exchange of genetic information, and mobile genetic elements represent an important mechanism in the adaptation of populations to environmental changes.

The principle of horizontal gene transfer, that is, a change in the genetic makeup of a cell by means of acquisition of foreign DNA, as compared to vertical gene transfer during cell division in the bacterial domain has been known since the 1940s. At that time Avery and coworkers (4) reinterpreted an earlier experiment by Griffith (5) and first demonstrated the uptake of free DNA, thereby providing evidence that DNA contained hereditary information. In biofilms, horizontal gene transfer among bacteria is beneficial because it increases metabolic capabilities and helps the biofilm community adapt to changing environmental conditions. In natural systems, conditions are frequently oligotrophic and bacterial growth rates are low. Because bacterial cells divide by binary fission, thus enabling vertical gene transfer, with only a handful of daughter cells receiving chromosomal mutation, the evolutionary significance of horizontal gene transfer is considered to be substantial. In open engineered systems, such as wastewater treatment plants, cell densities and growth rates are much higher. Here, the impact of horizontal gene transfer may be compounded by a rapid division of transconjugants passing on their newly acquired genetic information to the next generation.

The role of genetic exchange processes in the environment has only begun to be investigated fairly recently (6), mostly in relation to the biosafety aspects concerned with the release of genetically modified microorganisms. In many ways, the use of bioengineered organisms in applied technologies involving less than absolute control of the employed biota has been hampered by uncertainties regarding the fate of genetic information in the environment. Until quite recently, available information did not

allow an exact estimate of the likelihood of gene transfer in various habitats. This has led to numerous risk assessment scenarios and the use of bacterial plasmids as vehicles for foreign DNA, which are restricted in their host replication range and their ability to be transferred. Horizontal gene transfer in biofilms can be considered highly likely because of high cell densities, the long retention time of cells, their relative immobility, and the fact that DNA can adsorb to surfaces. However, very little research on gene transfer in biofilms has been carried out to date despite the obvious importance of gene flux for microbial taxonomy and ecology. In fact, the existence of a fixed biomass or biofilm has often been ignored in the characterization of environmental samples. In this article, the focus is mainly on the role of gene transfer in natural and engineered systems in which the establishment and role of biofilms has been experimentally verified. Further, a distinction will be made between those studies dealing with gene exchange in biofilms based on average transfer frequencies and rates and recent reports on the extent of transfer as measured microscopically, in situ, at the single-cell level in undisturbed biofilms.

MECHANISMS OF GENE TRANSFER

There are three major mechanisms by which gene exchange in the environment can occur: (*1*) conjugation, in which DNA is transferred from a donor to a recipient cell by cell-to-cell contact; (*2*) transformation, in which extracellular DNA is taken up by competent cells; and (*3*) transduction, in which bacteriophages act as vectors for transfer of bacterial DNA to a new host.

Conjugation

During conjugation, plasmids are transferred from a donor to a recipient cell. This form of gene transfer requires physical contact and places the greatest demands on donor and recipient cells. The information to be transferred must reside on a plasmid or transposon, and both cell types must be metabolically active. Cell contact is established via conjugative pili, which are encoded by the tra genes (Fig. 1). Some smaller, naturally occurring plasmids do not contain a complete tra system. They can be transferred by the process of mobilization (7), provided they carry their own *oriT* site as well as genes required for conjugative DNA processing (mob region) (Fig. 2). Plasmids can also integrate into the host chromosome via recombination. If the plasmid later becomes excised, it may carry chromosomal genes, which will be transferred to a recipient during conjugation. Conjugative transfer can be inhibited by DNA restriction, surface exclusion (8), incompatibility of plasmids, or fertility inhibition (9). It is a relatively nonspecific process, which can occur between distantly related bacteria (10). Certain plasmids belonging to the incompatibility groups IncQ and IncP have been transferred from *Escherichia coli* to bacteria as distant as the Chlorobiaceae, that is, green sulfur bacteria. Conjugation systems in gram-negative bacteria are frequently but not universally repressed, and can be activated by stress factors including temperature, UV-irradiation, or the antibiotic erythromycin.

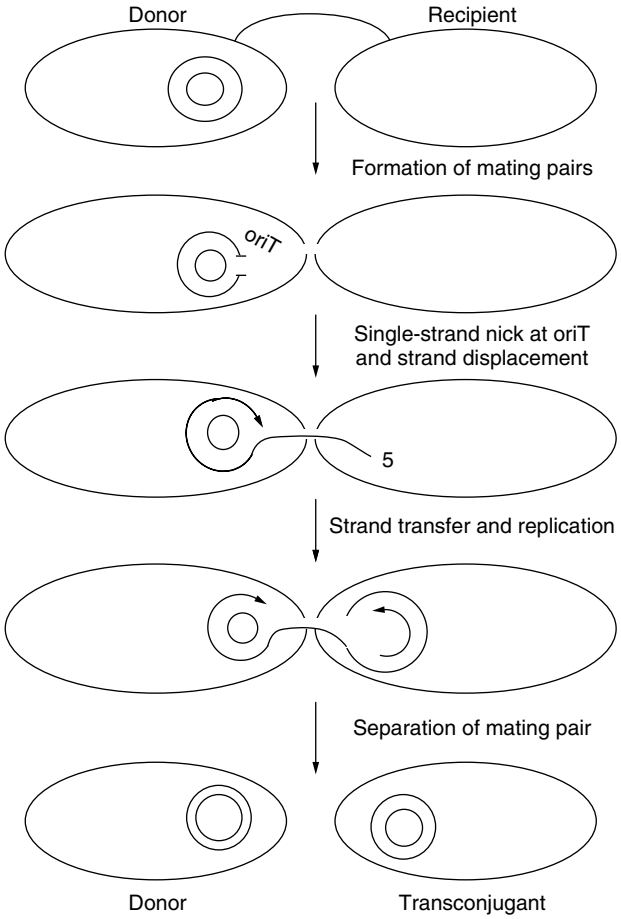

Figure 1. Mechanism of DNA transfer during conjugation. The donor cell produces a pilus, which is encoded by the plasmid and contacts a potential recipient cell that does not contain the plasmid. Retraction of the pilus brings the cells into close contact and a pore forms in the adjoining cell membranes. Formation of the mating pair signals the plasmid to begin transfer from a single-stranded nick at oriT. The nick is made by plasmid-encoded tra functions. The 5′ end of a single strand of the plasmid is transferred to the recipient through the pore. During transfer, the plasmid in the donor is replicated, its DNA synthesis being primed by the 3′ OH of the *oriT* nick. Replication of the single strand in the recipient proceeds by a different mechanism with RNA primers. Both cells now contain double-stranded plasmids, and the mating pair separates. *Source:* redrawn after Ref. 11 with permission from the American Society for Microbiology, © 1997.

Gram-positive organisms including *Streptococcus*, *Staphylococcus*, *Enterococcus*, *Bacillus*, *Streptomyces*, *Nocardia*, and *Clostridium* spp. are known to carry transmissible plasmids, but apparently conjugation does not involve the formation of pili (9). One conjugation system specific for enterococci is inducible by signal peptides ("clumping inducing agents") that are excreted by recipients. These molecules then subsequently entice the plasmid-carrying donor cell to synthesize surface proteins involved in cell clumping. For *Enterococcus faecalis*, clumping is not observed below temperatures of ca. 12 °C. In streptococci and staphylococci, plasmid transfer by conjugation in the laboratory requires a solid surface, but the mechanisms of transfer have not been elucidated.

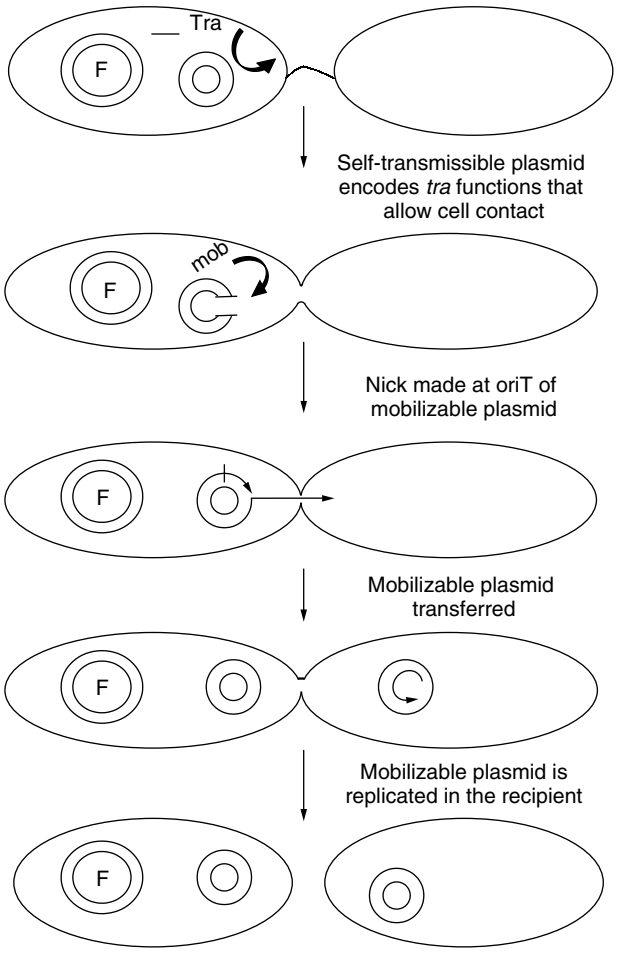

Figure 2. Mechanism of plasmid mobilization. The donor cell carries two plasmids, a self-transmissible plasmid, F, which encodes the tra functions that promote cell contact and plasmid transfer, and a mobilizable plasmid (blue). The mob functions encoded by the mobilizable plasmid make a single-stranded nick at oriT in the mob region. Transfer and replication of the mobilizable plasmid then occur. The self-transmissible plasmid may also transfer. *Source:* redrawn after Ref. 11 with permission from the American Society for Microbiology, © 1997.

Conjugation has been shown to occur in aquatic systems (12), including wastewater and sludge (13–15), in soil (16), on plant leaves (17), and in each of the intestinal, urogenital, and respiratory tracts (18,19); it may be the most important gene transfer mechanism in the environment because many plasmids are known to have a broad host range and the ability to transfer plasmids is widespread among bacteria.

Conjugative transfer of plasmids in biofilms under environmental conditions has been demonstrated with an elegant method called *exogenous isolation* (20). The procedure calls for the addition of a genetically characterized recipient bacterial strain to a mixed natural bacterial community present in the epilithon, the biofilm present on river stones. The method uses suspended cells rather than intact biofilms (Fig. 3), and the new plasmid to be transferred into the recipient is obtained by applying a direct selection for markers, such as Hg resistance (21). Another version of this method involves tripartite exogenous isolation of plasmids (Fig. 3) (22). Here, known recipient and donor strains are mixed with the suspended epilithic community and incubated together. The donor contains a small, mobilizable plasmid, which cannot transfer itself (mob^+tra^-). During incubation with the epilithic community, another plasmid, which is tra^+, must enter the donor strain and then mobilize the tra^- replicon into the plasmid-free recipient. Importantly, this procedure does not involve selective pressure on the tra^+ plasmid, and hence a variety of plasmids are obtained without any predetermined phenotype. This method has also been used successfully under environmental conditions, that is, in a river (23).

To approximate conditions as they occur in biofilms, another method was devised in which donor and recipient bacteria are placed onto membrane filters to be incubated on stones (membrane method, Fig. 4). Alternatively, bacteria have been introduced directly into the epilithic bacterial community on separate stones (stone method, Fig. 4). Next, the two stones are brought into contact in the river. Plasmid transfer is confirmed by plating presumptive transconjugants on selective agar plates. Hence, conjugative plasmid transfer can occur in natural biofilms in an environmental setting such as river stones. The transfer frequencies in various microcosms and in rivers have been assessed using the stone and filter methods. They varied from 10^{-2} to 10^{-8} transconjugants per recipient and were greatly affected by temperature (Table 1). Frequencies were lower or higher in situ than on agar plates in the laboratory depending on the microorganisms tested, indicating that additional species-specific factors influence conjugation in environmental biofilms. Exogenous isolation has also been used on disrupted epilithon and air–water interface samples, which had been filtered onto membranes and floated on artificial seawater (25). Frequencies were in the order of 10^{-8} and 10^{-9} recipients per filter for the biofilm and the air–water interface samples, respectively.

In the terrestrial environment, the rhizosphere (root microenvironment), phylloplane (leaf surface microenvironment), and, to a lesser extent, soil particles may represent favorable conditions for biofilm formation. On the phylloplane, conjugation is stimulated by leaf exudates, such as carbohydrates, amino acids, and organic acids, and takes place primarily in junctions between epidermal cells and in substomatal cavities (17). Similarly, gene transfer is stimulated by root surfaces (32). A minimum water content or relative humidity is important for cell survival, but above this level they do not have a direct effect on conjugation frequencies. Clustering of cells into interstices found on the phylloplane can lead to transfer frequencies that are higher than those found on filters placed on agarose (17). The metabolic activity of bacteria is not rate limiting in specialized niches like the phylloplane and the rhizosphere (33), as long as a certain threshold activity is maintained.

An example of a specialized and selective environment for biofilms is the mammalian intestine (19). Plasmid transfer takes place in the viscous mucus layer covering the epithelial cells. On the basis of selective enumeration of transconjugants in the feces of streptomycin-treated

mice and in the effluent of flow cells with biofilms developing on the glass surfaces, it was reported that conjugative gene transfer occurs rapidly after the addition of donor cells. After this initial burst of activity, no further transfer takes place. Thus, only a fraction of the biofilm microbial population obtains the plasmid, and primary transconjugants do not act as donors for neighboring recipient cells. There is some evidence in support of this hypothesis in the way of microscopic observations based on the detection of the green fluorescent protein (GFP) of transconjugants forming a thin layer on top of recipient microcolonies (34). This bears implications for the relevance of conjugative gene transfer in biofilms, such as those found in the intestine, in which the transient influx of high numbers of plasmid-bearing cells may lead to the transfer of antibiotic resistance and other plasmid-encoded genes to the intestinal flora. If bacterial movement in the mucus layer was restricted by biofilm-like conditions, then the further dissemination of newly acquired genes would be slowed considerably, but yet other environmental factors may play a role in determining secondary transfer. In a biofilm reactor study, the rate of plasmid transfer (expressed as cells/cm^2/hour) initiated by transconjugants was found to be highly dependent on the ambient nutrient levels (35). At the highest substrate concentration used, the rate of secondary transfer surpassed the rate of transfer initiated by the recipients by an order of magnitude. Hence, it is necessary to consider the type of habitat when assessing gene transfer scenarios.

Laboratory-grown biofilms in reactors or flow cells operated under continuous flow conditions have been useful for the study of gene transfer as the environmental conditions can be controlled. In biofilms, there is no homogenous mixing of cells, and contact as required for conjugation occurs only between individual layers of cells. Hence, plasmid transfer cannot be described by the mass action model employed for conjugation events between cells suspended in liquid media (36). Rather, the spatial biofilm structure, that is, architecture, accounts for the difference in transfer frequencies. This is apparent from looking at the effect of nutrient concentrations in a controlled rotating annular biofilm reactor (35). Higher substrate concentrations can dramatically suppress the occurrence of transconjugants over time. As conjugation is an energy-requiring process, there appears to be no physiological reason for this observation. It may be a result of interruption of mating pairs owing to rapidly dividing cells or caused by greatly varying biofilm architecture. Shear stress has a considerable effect on biofilm architecture, according to measurements of biofilm thickness and areal and volumetric density. As a rule of thumb, low shear (0.07 N/m^2) biofilms tend to be thicker and less volumetrically but more areally dense than high shear (0.99 N/m^2) biofilms (37). It also affects the efficiency of conjugative transfer of a plasmid, such as RP4, which tra genes code for rigid pili. In a rotating annular biofilm reactor, conjugation was only observed below a shear of 0.085 N/m^2, which corresponds to a laminar flow regime (38). Besides temperature and

nutrient concentration, the ratio of donors and recipients is important for initial conjugation events, with an ideal ratio of 1 : 1.

Although gene transfer in biofilms is most frequently expressed in terms of frequencies of transconjugants (T) per recipient (R) or donor (D), this does not reflect relative differences in the localization of donor cells or the kinetics of transfer. The total number of transconjugants may be high owing to the growth and division of cells or transconjugant-initiated secondary gene transfer, despite relatively low frequencies of initial horizontal gene transfer. To more accurately account for the role of the donor, the transfer frequency, F, can be expressed as the number of transconjugants divided by the product of recipients and donors (39),

$$F = T/R\,D$$

Despite the fact that there are more chances of cell collisions in suspended systems, there have been reports of higher transfer frequencies in biofilms. For example, a biofilm, which had formed on the surface of glass beads in a reactor, supported much higher frequencies of plasmid transfer under no-flow conditions than did the planktonic population in the liquid phase (40).

Retrotransfer. In the mid-1980s, Max Mergeay and his colleagues in Mol, Belgium, reported a phenomenon occurring in the opposite direction of conjugation as it is commonly defined: the resident plasmid or chromosomal genes of a recipient are transferred to the donor of a conjugative plasmid (41). Hence, the donor cell, which has received DNA from the intended recipient, becomes a *retrotransconjugant*. Retrotransfer has been demonstrated for several plasmids belonging to various incompatibility groups (42). It proceeds unidirectionally in two steps and is de facto mechanistically identical to conjugation. The recipient cell is first converted to a donor cell by receiving a plasmid capable of retrotransfer. The tra genes must be expressed in the recipient before retrotransfer can occur. In a second round of conjugation, a mobilizable plasmid (tra^-mob^+) is transferred back to the original strain that donated the tra^+ plasmid. Even nonmobilizable plasmids (as judged by the lack of conjugation), as well as chromosomal markers, can be retromobilized (43,44). For this reason, retrotransfer is important from the point of view of release of genetically modified microorganisms. The presence of plasmids that can both mobilize and retromobilize other plasmids was confirmed in soil and aqueous systems (45). Until now, there have been few studies to assess the relevance of retrotransfer in biofilms. In a rotating annular biofilm reactor containing a pure culture of *Bacillus azotoformans* with the conjugative plasmid RK2, a donor *Pseudomonas putida* PB2440 harboring the mobilizable plasmid pDLB101 was capable of retromobilizing this plasmid and transferring it to *B. azotoformans* after having first received plasmid RK2 (35). The initial rate (expressed as transconjugant cells/cm^2/hour) was slower than for mobilization, confirming the need for RK2 to be transferred and replicated in strain PB2440 before retrotransfer is possible. After 2 hours, this rate increased considerably and even exceeded direct mobilization rates. When the calculated growth rates of retrotransconjugants were taken into account, the increase in cell numbers of *B. azotoformans* containing both plasmids was because of the growth of retrotransconjugants and not because of the continuous retrotransfer events. As retrotransfer involving plasmids from different incompatibility groups occurs at different frequencies, these studies provide only a glimpse of the potential role of gene transfer in natural biofilms.

Transformation

The uptake of free DNA from the extracellular environment is referred to as *transformation*. Over 40 bacterial species, including representatives of the genera *Acinetobacter*, *Pseudomonas*, *Bacillus*, *Staphylococcus*, *Streptococcus*, *Neisseria*, and *Haemophilus*, are known to be competent of taking up DNA during their natural lifecycle; this phenomenon is referred to as *natural transformation* (10). Other species, such as *E. coli*, can be rendered competent by physicochemical manipulations (e.g., electroporation). The latter form of competence is unlikely to be of importance in the environment. The process of natural transformation (hereinafter referred to as "transformation") in biofilms is sensitive to inhibition by extracellular nucleases and involves the following steps (Figs. 5–7):

1. Release of DNA from dead or viable cells
2. Dispersal of released DNA in biofilms
3. Persistence of the released DNA in biofilms
4. Development of competence in bacterial cells
5. Binding of DNA to potential recipient cells

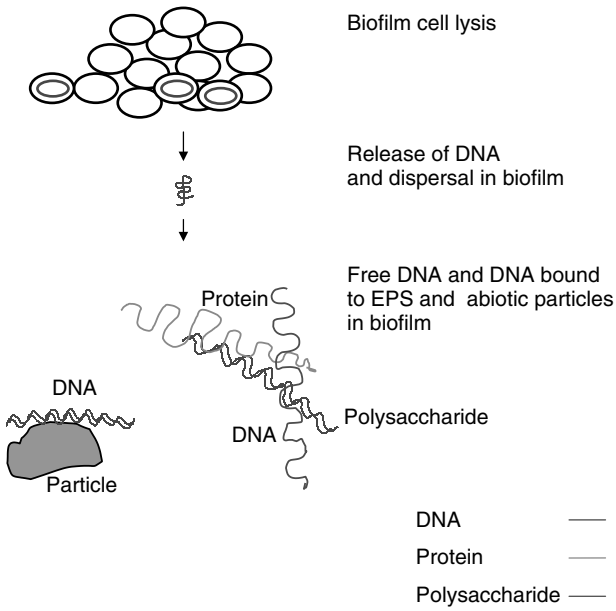

Figure 5. Conceptual view of the fate of DNA after cell lysis in a biofilm, depicting the first three steps in natural transformation (see text for details). The released DNA is either bound to biofilm constituents such as EPSs, cells, and abiotic particles or present as free DNA. See Figures 6 and 7 for uptake of DNA and internal processing by cells. See color insert.

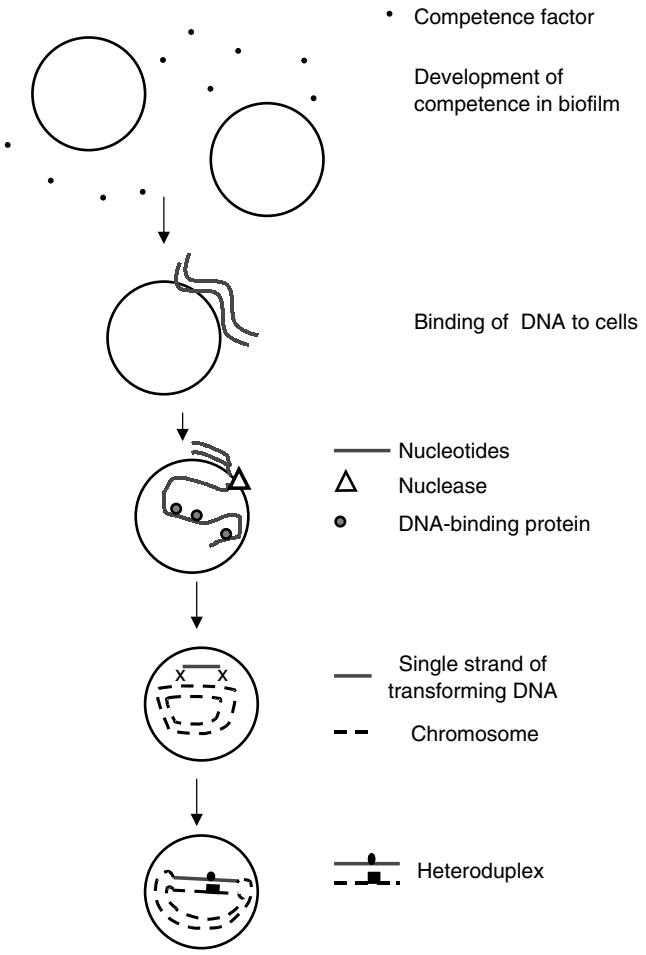

Figure 6. Uptake by and integration of transforming DNA into the chromosome of *Streptococcus pneumoniae*. Competence factors accumulate as the cells reach a high density. Double-stranded DNA binds to the cell and one strand is degraded. The remaining single strand replaces the strand of the same sequence in the chromosome, creating a "heteroduplex," in which one strand comes from the donor and one comes from the recipient. *Source:* redrawn after Ref. 11 with permission from the American Society for Microbiology, © 1997. See color insert.

6. Uptake of exogenous DNA and internal processing by cells
7. Integration of transforming DNA into the chromosome (Fig. 6) or reassembly of a transforming plasmid molecule (Fig. 7)

Transformation is known to be dependent on cellular functions that are distributed on the chromosome and are expressed under certain environmental conditions (46). The state of competency, when nucleic acids are adsorbed at the cell surface and can be taken up by the cell, is transient in liquid culture in most of the organisms studied. Its development and duration are variable among different species. In gram-positive bacteria, it is cell density dependent and occurs as a result of the accumulation of a competence factor in the growth medium of the culture. It is thought to be an inducible state of existing cells and can occur as an immediate response (e.g., *Streptococcus*) or a gradual event (*Bacillus subtilis*). One exception is *Neisseria gonorrhoea*, in which competence is constitutively expressed (47). Important for an assessment of transformation in the environment is the question of accessibility of free DNA because of the widespread occurrence of DNases. In gram-negative bacteria such as *Haemophilus*, *Azotobacter*, *Acinetobacter*, and *Pseudomonas* spp., no competence factor is produced, and the development of competence is controlled internally, for example, by an environmental stimulus leading to unbalanced growth (48). It is probable that the state of unbalanced growth is a fact of life for bacterial cells in the environment and hence, gram-negative cells should be continually competent for transformation. This was shown for *Acinetobacter calcoaceticus* grown in flow cells in the laboratory both under stress and no-stress conditions (Hendrickx, Hausner, and Wuertz, unpublished information). Likewise, the accumulation of a competence factor in biofilms should allow gram-positive species requiring the factor to also reach the state of competency. This may explain why the dental plaque organism *Streptococcus mutans* transformed 10- to 600-fold more efficiently when growing in biofilms than when growing in liquid culture (49).

It is known that DNA adsorbs to mineral surfaces, a phenomenon that protects it from degradation. Bacteria with natural competency, such as *Pseudomonas stutzeri*, may take up this particle-associated DNA by an unknown mechanism (50). For example, the efficiency of DNA uptake by *B. subtilis* was 3,200 times higher at an interface formed by sand particles and water than when the cells occurred in a planktonic state (51). However, two other competent species, *P. stutzeri* and *A. calcoaceticus*, did not display this trait (51). Likewise, *Vibrio* sp. WJT-1C took up more free plasmid DNA in water than in the sediment (52). Overall, it seems that particulate plasmid DNA is less accessible than dissolved plasmid DNA, although chromosomal DNA can increase the rate of transfer when present at the same time (51). In laboratory studies, plasmid DNA was transferred intergenerically from *E. coli* to *B. subtilis* (53). and to a *Vibrio* sp. (54). Interestingly, some forms of transformation require cell contact, but unlike conjugation, the donor cells can be metabolically inactive or dead. However, as the transfer involving live donor cells was inhibited by nalidixic acid or rifampicin, it was hypothesized by Paul (54). that some form of active transport of plasmids was involved in this type of transformation. The process is DNase sensitive and any type of plasmid, including nonconjugative plasmids, can be transferred. Its relevance to transformation in the environment remains to be shown. Clearly, these results are important for the release of genetically modified microorganisms. Little information is available on the rates of uptake in biofilms; this may be because of the lack of knowledge concerning the distribution and availability of extrachromosomal DNA in complex systems (51).

The only direct evidence of biofilm-associated transformation in a natural environment comes from river epilithon (20). Using *A. calcoaceticus*, a genus common in aquatic environments, as the recipient and either lysed

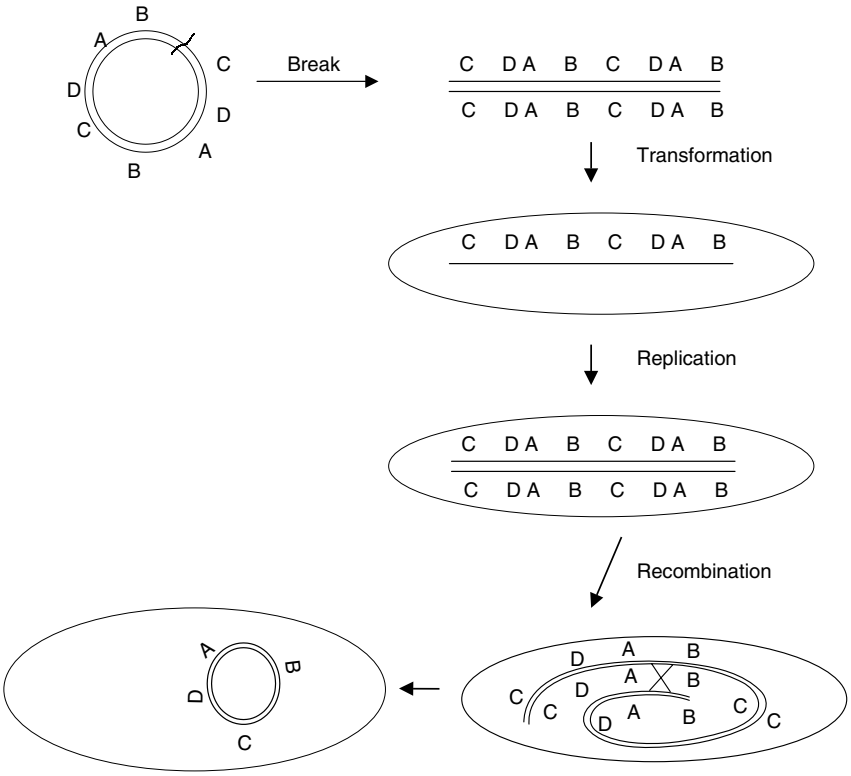

Figure 7. Natural transformation of bacterial cells by dimeric plasmids. After the single-stranded dimeric plasmid DNA is taken up, it can serve as a template to make the double-stranded DNA. The repeated ends can recombine with each other to form a circular plasmid. *Source:* redrawn after Ref. 11 with permission from the American Society for Microbiology, © 1998.

cells or live cells of the same species as the donor, transformation frequencies of 4.0×10^{-4} and 1.7×10^{-5}, respectively, were reported (55). Here, transformation can be considered to have occurred truly in situ. The experimental setup involved placing two nitrocellulose filters, one containing the source of DNA and one the recipient, in contact with each other on the surface of a sterile stone. The stone was placed in a nylon mesh bag and left on the bed of a river for 24 hours before selecting for transformants. The method is similar to the one described earlier for conjugation (Fig. 1) and *A. calcoaceticus* was transformed both by free chromosomal DNA and live donor cells via cell-contact transformation (56). These investigations, although not strictly biofilm studies owing to the lack of EPS, reveal the potential for natural transformation under in situ environmental conditions when high cell numbers are present. It has been reported that high DNase activity in wastewater treatment plants prevents uptake of free DNA. On the other hand, the presence of EPS in biofilms may help bind and protect extracellular DNA (57). In the light of reports of adsorption of DNA to some surfaces such as clay minerals (51), the potential for transformation in biofilms in a variety of environmental settings, including soil, epilithon, phylloplane, rhizosphere, and wastewater reactors, is considerable.

Transduction

Transducing bacteriophages can act as carriers of foreign DNA pieces, which they inadvertently insert into their own DNA structure during lysis of their respective bacterial hosts. During the next infection cycle, a phage can pass on this information to its new host (Fig. 8). This process may be *generalized* transduction, in which a phage can contain any piece of donor chromosomal or extrachromosomal DNA as a result of general cell lysis, or *specialized* transduction, in which a lysogenic bacteriophage, after having integrated into the host chromosome, may transduce genes that are adjacent to its insertion site upon the onset of the lytic cycle. Transduction is specific, as bacteriophages have a very limited host range (10). Hence, this form of gene transfer is only possible between closely related species (58). The fact that the number of viruses in the aquatic environment is much higher than previously thought, that is, up to 10^8 particles per milliliter in marine waters (59), gave rise to speculation by investigators that about one-third of the bacterial population can be attacked by bacteriophages within 24 hours. T4 bacteriophages can infect *E. coli* cells in laboratory-grown biofilms (60), and similar scenarios are conceivable for natural biofilms. The spread of genes by transducing bacteriophages in the aquatic environment has been shown in environmental containment chambers submerged on site both in the absence and presence of the natural microbial community (58). Virus-mediated gene transfer has also been shown on the phylloplane (61). It should be noted that bacteriophages can transfer not only chromosomal DNA but also plasmid DNA, and are therefore candidates for the spread of any foreign gene in the environment or in bioreactors. Native, lysogenized bacteriophages — phages which are replicated along with the host chromosome and are induced to become virulent by environmental conditions — were identified as important agents of horizontal gene dissemination in freshwater microbial populations (58). Even lytic

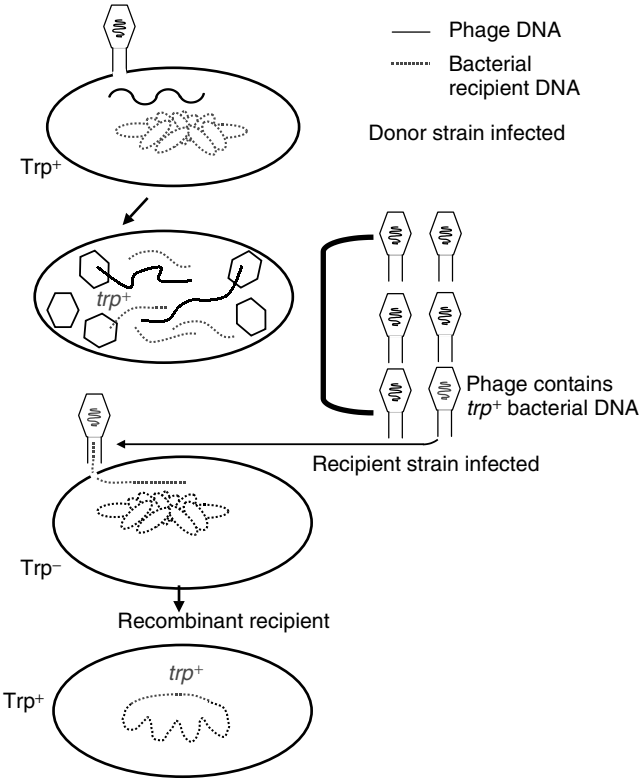

Figure 8. An example of generalized transduction. A phage infects a Trp^+ bacterium, and in the course of packaging DNA heads, the phage mistakenly packages some bacterial DNA containing the trp region instead of its own DNA into a head. In the next infection, this transducing phage infects the Trp^+ bacterial DNA instead of phage DNA into the Trp^- bacterium. If the incoming DNA recombines with the chromosome, a Trp^+ recombinant transductant may arise. Only one strand of the DNA is shown. *Source:* Redrawn after Ref. 11 with permission from the American Society for Microbiology, © 1997. See color insert.

phages establish a pseudolysogenic relationship with their bacterial hosts under low nutrient conditions (62). There are few reports of transduction in wastewater treatment facilities (63), and the importance of transduction as a means of gene transfer in biofilms in general remains to be established.

IN SITU FREQUENCIES OF GENE EXCHANGE

Transfer to Unknown Organisms

Until quite recently, gene transfer frequencies in biofilms have been evaluated exclusively by plating transconjugants, transformants, or transductants on selective agar media. Detection of transfer is thus dependent on the culturability of recipients under selective pressure. Obviously, such an approach ignores the vast potential of gene transfer to that part of the natural population that is not amenable to present cultivation techniques. It is estimated that only 0.1 to 10% of bacterial species in the environment can be readily cultured in the laboratory. The remainder has physiological requirements, which preclude their easy isolation in axenic culture. Furthermore, bacterial cells, which would normally grow under laboratory conditions, can enter the state known as *viable but nonculturable* (64).

The discovery of the GFP, which provides a label for living bacteria and can be used as a reporter molecule for the investigation of gene expression or protein localization (65), enabled the in situ microscopic detection of gene transfer events on a single cell level. This approach has been used to study conjugal gene transfer in situ in biofilms (17), activated sludge microcosms (66), and seawater bacteria filtered onto membranes (67). For activated sludge, transconjugants that had received the GFP-labeled RP4 plasmid were characterized microscopically by fluorescent in situ hybridization (FISH) with oligonucleotide probes for various subclasses of Proteobacteria as well as aeromonads and pseudomonads. This allowed the assignment of a phylogenetic affiliation of transconjugants by colocalization of fluorescent signals based on GFP and FISH without selective plating on solid media. The study revealed that more than 95% of transconjugants hybridized with the GAM42a probe, which targets bacteria belonging to the γ subclass of Proteobacteria, and using a more specific FISH probe, transconjugants were shown to belong predominantly to the genus *Aeromonas* (66). This information is important in so far as the plasmid RP4 is known to have a broad host range, yet in this experimental activated sludge system, its transfer was obviously limited to a well-defined group of organisms.

Quantitative Analysis of In Situ Gene Transfer

Recently, a quantitative method has been developed based on the concurrent use of GFP-labeled plasmids, automated confocal laser scanning microscopy (CLSM), and semiautomated quantitative image processing (68,69) to determine conjugation (70). and transformation (71) frequencies in biofilms. Using this technique, large volumes of biofilms can be scanned and analyzed in a systematic way. In addition, this approach delivers information concerning the localization and distribution of transformants and transconjugants within the biofilm (Fig. 9). Gene transfer frequencies detected in situ in biofilms using CLSM are higher than those quantified on selective agar media. For example, the conjugative transfer of the mobilizable (mob^+tra^-) plasmid pRK415, which belongs to the incompatibility group IncP and into which the gene *gfp* had been cloned, from *E. coli* to *Ralstonia metallidurans* in biofilms occurred at rates 1,000-fold higher than those determined using standard plating methods for the selection of transconjugants (70). It follows that the majority of cells that had received the plasmid were either compromised in their ability to divide on agar plates in the presence of selected pressure or did not pass the plasmid on to their progeny. The cells were not generally impaired in their ability to grow on agar because the total recipient cfu count on nonselective media approximated the total microscopic cell count. The quantitative determination of in situ horizontal gene exchange has also been applied to biofilms grown in flow cells (Fig. 10). This approach allows the careful control of environmental parameters such as the Reynolds number, *Re*, which is characterized by the ratio of inert forces, to frictional forces and describes the type of hydraulic

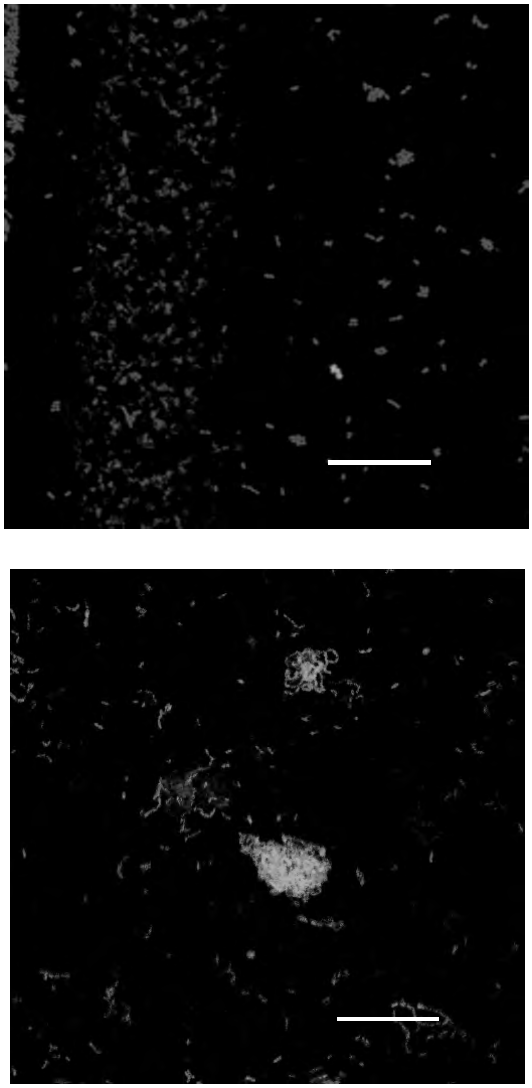

Figure 9. Transconjugant cells in a biofilm of *R. metallidurans* AE104 cultivated under nutrient-rich (**a**) and nutrient-poor (**b**) conditions. Recipient cells were grown as a confluent biofilm on microscope slides and exposed to high densities of donor and helper cells to allow transfer of the mob^+ plasmid, which carried the gene for the GFP. CLSM signals were collected consecutively and stored as gray scale images. AE104 cells were detected by FISH with a TRITC-labeled rRNA-directed oligonucleotide probe specific to the β-proteobacteria subgroup. With computer-assisted coloring, recipient AE104 cells were assigned the color red. Donor *E. coli* strain GM16 cells were detected based on the fluorescence emitted by GFP and are depicted in green. Transconjugants emitted both green light owing to GFP and red light owing to hybridization with the TRITC-labeled rRNA-directed oligonucleotide probe and are shown in yellow. Bar, 25 μm. *Source:* after Ref. 70;. reprinted with permission from the American Society for Microbiology, © 1998. See color insert.

conditions in a flow cell (72). Hence, gene transfer can be estimated in a defined hydrodynamic environment in the absence of a true measure of events as they occur in aqueous ecosystems.

The spatial structure or architecture of the biofilm plays a decisive role in gene transfer. While studying conjugation in flow cells, donor cells were shown to penetrate biofilms to varying depths depending on the distribution of microbial cell clusters and EPSs (73). The latter can act either as an obstacle preventing transport of cells or as an aid in facilitating cell-to-cell contact by the stabilization of donor cells. Recipient cell clusters of a certain size occurring deeper in the biofilm and close to the substratum (the glass surface upon which the biofilm was grown to enable microscopic visualization) supported the highest transfer frequencies. These recipient cell clusters could be divided into outer and inner groups using 3-D image analysis techniques. Interestingly, more transconjugant cells were detected in the inner portion of cell clusters (73). Taken together, these studies indicate considerable movement of donor cells inside biofilms and even within cell clusters.

Similarly, natural transformation has been quantified in situ in *Acinetobacter* sp. BD413 biofilms based on the expression of a variant GFP, the yellow fluorescent protein (YFP) (Fig. 11). It was shown that as little as 1 pg free plasmid DNA per milliliter resulted in detectable transformation (74). The plasmid DNA taken up had no known homology to any part of the host genome. Hence the plasmid was either recircularized via homologous recombination of two plasmid molecules or transcription and synthesis of YFP proceeded without the plasmid being present in a replicative form in the cell. As in the case of conjugation, in situ transformation frequencies are several orders of magnitude higher than those determined by plating transformants on selective media (74). Recent studies have also revealed that transformants become established deep inside biofilms. Even genes that exert an adverse effect on the biofilm, such as overexpression of certain proteins, may be taken up via transformation (74) and become established long enough to allow further transfer via conjugation to other bacterial species in which they have no negative effect. These results demonstrate that biofilms represent a habitat allowing the induction of competence in gram-negative bacterial species. The relevance of transformation in the environment is closely linked to the presence of biofilms.

CONCLUSION

Gene transfer in biofilms is an important mechanism of information exchange and adaptation of microbial communities. All three main routes of horizontal transfer, namely, conjugation (including retrotransfer), transformation, and transduction, have been demonstrated in laboratory-grown biofilms. Conjugation and transformation were also detected in the epilithic environment of rivers by introducing marker strains into the community and placing stones together so that inoculated areas may contact. The use of flow cells and CLSM in conjunction with fluorescently tagged plasmids has advanced our understanding of the dynamics, both spatial and temporal, of gene transfer by facilitating in situ investigations

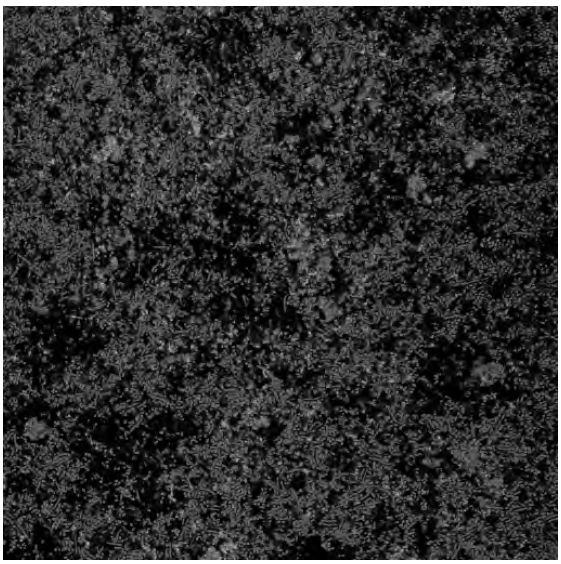

Figure 11. Transformant cells in an 18-hour biofilm of *Acinetobacter* sp. BD413 grown in a flow cell and exposed to 1 μg plasmid DNA/mL for 20 minutes. Cells were visualized with the general nucleic acid stain Syto 60 (Molecular Probes, Eugene, Oregon) and were detected with an LSM410 confocal laser scanning microscope (Zeiss, Jena, Germany). Transformants were detected by the emission of light owing to the GFP encoded by the plasmid, pGAR1. See color insert.

no longer solely reliant on the isolation of transconjugants, transformants, or transduced cells on selective growth media. Depending on the architecture of a biofilm and environmental factors such as nutrient supply, gene transfer may be limited to the top layer at the interface with the passing fluid, or it may occur deep within the biofilm. The very high frequencies of gene exchange reported in biofilms may be responsible for the dissemination of antibiotic resistance genes and the acquisition of multiple resistances by pathogenic strains. Cells that have received a plasmid may or may not divide in a biofilm. Vertical transfer after cell division must occur for the long-term establishment of genetic traits. Transformation in biofilms can account for the dispersal of DNA released by lysed cells. Plasmids thus transferred can be passed on to other species in the biofilm by conjugation. It is thus likely that conjugation is the most important route for the establishment of new genes. However, the importance of transduction in biofilms in the environment needs to be determined in view of the long underestimated relevance of viruses in planktonic populations.

The mineralization of organic molecules by microbes is essential for the carbon cycle to operate. The massive mobilization of compounds stored in natural resources or the introduction of xenobiotics into the biosphere produces unidirectional fluxes that result in the persistence of many chemicals in the biosphere, where they are a source of pollution. Molecular biology offers the tools to optimize the biodegradative capacities of microorganisms, accelerate the evolution of new metabolic activities, and construct totally new pathways through the assemblage of catabolic segments from different microbes. The number of genetically engineered microbes (GEMs) for potential use in biodegradation has increased significantly in the last few years and a number of catabolic modules for the specific evolution of new pathways are being constructed so that a number of new recombinant microorganisms will soon be available. The behavior and functioning of some of the already available recombinant microbes have been tested in microcosms in which the survival and fate of recombinant microbes in different niches under laboratory conditions have been found to be similar to those of unmodified parental strains. Recombinant DNA (rDNA), both on plasmids and on the host chromosome, is usually stably inherited by GEMs. The potential lateral transfer of rDNA from GEMs to other microbes is significantly diminished, although not totally inhibited, when rDNA is incorporated on the host chromosome.

KEY CONCEPTS

A large proportion of organic compounds of biological and chemical origin are ultimately mineralized (degraded to carbon dioxide, water, and other inorganic compounds), predominantly by microorganisms, as part of the continuous cycling of carbon between inorganic and organic states. The mineralization of a compound involves its structural alteration and the formation of metabolic intermediates that serve either as carbon skeletons for cellular constituents or as fuels for energy generation. Mineralization of organic compounds is a central feature of the carbon cycle and is a process critical to the maintenance of life on this planet.

Most naturally occurring molecules are easily mineralized, as are industrial chemicals with structures similar to organic compounds of biological origin. However, many xenobiotics (compounds that exhibit structural elements not found in natural ones) are not readily mineralized, and persist in the biosphere. This is because the structural elements of such compounds are chemically very stable, have novel substituents that are not generally found in organic molecules of biological origin, are toxic for microorganisms, or inhibit degradative enzymatic attack. Some organic compounds in nature undergo partial degradation; however, this is not necessarily beneficial: microbes may not gain energy for growth, and more recalcitrant toxic compounds or highly reactive products, which subsequently undergo chemical changes such as polymerization, may be formed.

Xenobiotics introduced in natural resources are not readily integrated into the natural nutrient cycles.

As a consequence of the progressive accumulation of pollutants in the biosphere, environments hostile to biological systems, that is, those polluted by aliphatic and aromatic hydrocarbons, chlorinated compounds, nitrotoluenes, dyes, explosives, organic solvents, and others, are appearing with increasing frequency (1).

Effective steps should be taken to protect environments from pollution. A variety of alternative treatments, including physical, chemical, and biological approaches, have been developed to reduce or eliminate contamination by hazardous compounds (1–3). Physical treatments comprise, among other methods, adsorption to activated carbon, filtration, and incineration. Chemical approaches involve solvent extraction or surfactant precipitation. These treatments are expensive, and may in some cases generate unwanted products. The biological approach, including continuous and batch treatments of liquid wastes, composting in situ and on-site soil treatments, and so on is usually cheaper and involves less risk to human health or the environment (3–8). The most promising approach is to optimize the biodegradative capacities of microorganisms, accelerate the evolution of new activities, and exploit them to eliminate these pollutants (3,8).

The introduction of some chemicals into the environment exerts selective pressure for the evolution of the corresponding catabolic activities. For example, the herbicide 2,4-dichlorophenoxyacetic acid, insecticides such as DDT and parathion, and explosives such as nitrate ester derivatives can be mineralized by single microbes or communities of microbes (7–15). However, other chemicals such as certain organic solvents, polychlorinated aromatic compounds, dioxins, and dibenzofurans are highly recalcitrant. In such cases, the evolution of new activities in the laboratory may be helpful because the frequency and types of genetic events needed (mutation, alteration of gene expression, gene dosage, gene transfer, and so on) may be carefully controlled under selective conditions (3,8,16–18). The experimental evolution of catabolic pathways offers considerable potential for accelerating the evolution of bacteria that are able to degrade toxic industrial chemicals, and this may be useful for reducing environmental pollution. Several strategies have been successfully applied to construct bacteria that are able to eliminate a wide range of organic solvents such as toluene derivatives, a number of chlorinated aromatic compounds arising from human industrial activities (chlorobenzoates, chlorosalicylates, and chlorophenols), and the more recalcitrant polychlorinated biphenyls (PCBs) and explosives such as 2,4,6-trinitrotoluene (TNT) (3,8,17–23).

Many of these bacteria belong to the genus *Pseudomonas*, a group of microorganisms that exhibit a wide range of metabolic activities against natural and xenobiotic compounds. The so-called fluorescent *Pseudomonas* group includes strains whose biochemical, physiological, and genetic characteristics have been well characterized (24,25). A number of genetic tools — wide host range cloning plasmids and cosmids, transposons and mini transposons, gene markers and probes, reverse genetics, and so on — have made it possible to design recombinant derivatives of this group of bacteria with increased biodegradative properties (26–31). Some of these constructions are summarized in the following chapter. Furthermore, some of these recombinant bacteria and their parental wild-type strains have been selectively introduced in polluted and nonpolluted environments, and their survival, performance, and ability to transfer recombinant DNA have been monitored.

HYBRID PATHWAYS FOR METABOLISM OF CHLOROORGANIC COMPOUNDS

Hybrid Pathways for Chlorobenzoates and Chlorotoluenes

Pseudomonas sp. B13 exhibits two ortho-cleavage pathways, one for the metabolism of benzoate and the other for the catabolism of *m*-chlorobenzoate (23). These pathways do not allow the mineralization of other chlorobenzoates or any alkylbenzoates (23,32). The chromosomal ortho-cleavage pathway for benzoate seems to be similar to other catabolic pathways for the metabolism of benzoate by Pseudomonads. The *m*-chlorobenzoate pathway is partially chromosome-encoded and partially plasmid-encoded. In this pathway, *m*-chlorobenzoate is first oxidized to *m*-chlorocatechol by chromosome-encoded genes; then *m*-chlorocatechol undergoes ring cleavage and chlorine elimination, a process involving four plasmid-encoded enzymes — catechol 1,2-dioxygenase, chloromuconate cycloisomerase, dienelactone hydrolase, and maleylacetate reductase. The products resulting from the action of the plasmid enzymes are further metabolized by chromosomally encoded enzymes. In *Pseudomonas* strains growing on *m*-chlorobenzoate, the plasmid-encoded genes involved in the degradation of this compound were duplicated; this duplication ensured an increase in protein dosage (33,34). *Pseudomonas* sp. B13 cannot grow on *p*-chlorobenzoate or mixtures of alkylbenzoates and halobenzoates. In contrast, *Pseudomonas* sp. FR1 (pFRC20P), a derivative of B13 that was constructed through the recruitment of genes from different microorganisms, is able to grow on *p*-chlorobenzoate and mixtures of alkylaromatics and chloroaromatics (17). Its construction involved chromosomal integration of the genes for the metabolism of *p*-chlorobenzoate and alkylbenzoates to *p*-chlorocatechol and alkylcatechols, respectively. The construct was completed by introducing a mobilizable plasmid (pFRC20P) carrying a key gene for the metabolism of alkyllactones. The genes encoding the TOL plasmid pWW0 toluate dioxygenase (*xylXYZ*) and the next enzyme in the pathway (a dehydrogenase encoded by *xylL*), together with the positive regulator *xylS*, were cloned into Tn5 and delivered into the host chromosome (Fig. 1). This allowed the recombinant bacteria to grow on *p*-chlorobenzoate and also allowed the metabolism of *p*-methylbenzoate to γ-methyl-lactone (Fig. 1). The resulting bacterium was called *Pseudomonas sp. FR1*. Plasmid pFRC20P carries the gene that encodes for an isomerase from *Alcaligenes* that allowed the conversion of γ-methyl-lactone into β-methyl-lactone (17) and subsequently allowed mineralization of the alkylbenzoate. Furthermore, this isolate grew and simultaneously assimilated mixtures of alkylbenzoates and halobenzoates.

Hybrid strains that mineralized *p*-chlorobenzoate (17,22), although able to transform 3,5-dichlorobenzoate,

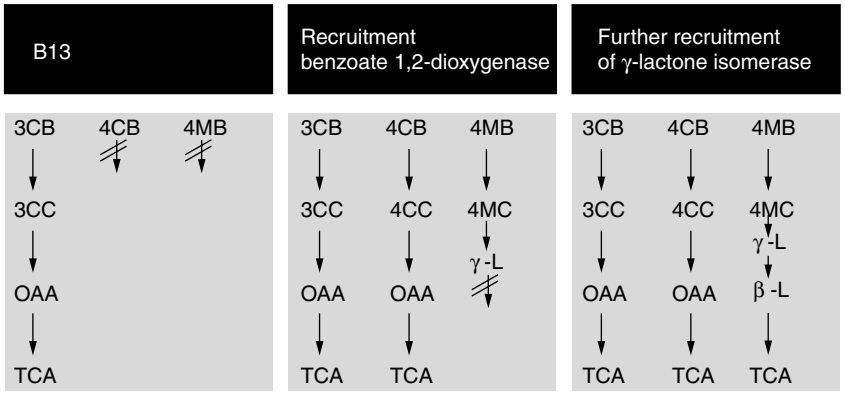

Figure 1. Expansion of the range of chloroaromatic compounds degraded by *Pseudomonas* sp. B13. Details of the pathway expansion strategies are as described in the text.

did not grow on this compound because the XylS regulator was not activatable by 3,5-dichlorobenzoate. By recruiting a XylS mutant regulator that is activated by this compound, a derivative mineralizing 3,5-dichlorobenzoate was constructed.

Recruitment into *Pseudomonas* sp. B13 of the upper pathway enzymes (xylene monooxygenase, together with benzyl alcohol dehydrogenase and benzaldehyde dehydrogenase) encoded by the TOL plasmid pWW0 (34–36) resulted in strains that are able to mineralize *m*-chlorotoluene (19,37,38).

Haro and de Lorenzo have investigated the degradation of *o*-chlorotoluene, a compound for which microbes with biodegradative activities have not been found. They took advantage of the relaxed substrate activity of toluene dioxygenase of *P. putida* F1, which functions as a monooxygenase with 2-chlorotoluene and converts this into *o*-chlorobenzyl alcohol (39). It was suggested that further metabolism of the latter to *o*-chlorobenzoate may be mediated by the TOL pathway benzyl alcohol dehydrogenase (XylB) and benzaldehyde dehydrogenase (XylC) (39). A gene cassette has been engineered so that the chromosomal *todABC* genes encoding toluene dioxygenase and the *xylBC* are expressed from the Pu promoter for the upper pathway of the TOL plasmid. This construct is now available for the transformation of *o*-chlorotoluene to *o*-chlorobenzoate (39). Once this module is transferred to an *o*-chlorobenzoate degrading strain, mineralization of *o*-chlorotoluene will be achieved.

Self-Inhibiting Metabolic Routes: The Case of Chlorobiphenyl Metabolism

A number of biphenyl-degrading microorganisms that have been isolated cometabolize a variety of polychlorinated biphenyls (PCBs) (39–44). The degradation of biphenyl and chlorinated analogs is initiated by dioxygenation at the 2,3-position. The 2,3-dihydro-2,3-dihydroxybiphenyl formed is dehydrogenated to 2,3-dihydroxybiphenyl, which then undergoes *meta* cleavage. Benzoates are produced by hydrolysis of the ring cleavage product. In most cases, biphenyl-degrading organisms are not able to mineralize the chlorobenzoates formed from chlorobiphenyls, although some strains cometabolize chlorobenzoates. An inhibitory effect of chlorobenzoates or their metabolic products has been observed in the *Pseudomonas testosteroni* strain B356, with *m*-chlorobenzoate being the most effective inhibitor (45). In the case of 3-chlorobiphenyl, the rapid formation of *m*-chlorocatechol from *m*-chlorobenzoate led to toxicity, manifested as a decrease in viable cells during substrate utilization (46). This toxicity was because of *meta* cleavage of *m*-chlorocatechol, which might produce a reactive acyl chloride intermediate. A similar mechanism for the interference of *m*-chlorocatechol with the utilization of biphenyl and monochlorobiphenyl is inactivation by *m*-chlorocatechol of 2,3-dihydroxybiphenyl dioxygenase, which is necessary for biphenyl metabolism. Two approaches have been tested to overcome chlorobenzoate-mediated inhibition of PCB degradation: the use of mixed cultures consisting of PCB and chlorobenzoate degraders and the in vivo and in vitro combination of PCB and chlorobenzoate pathways (46–51).

The *Burkholderia cepacia* strain JHR222 is a hybrid strain that was able to mineralize: 2-, 3-, and 4-chlorobiphenyl and *o*-, *m*-, *p*-chloro-, and 3,5-dichlorobenzoate, but not other isomers such as 2,3-, 2,5-, 2,6-, and 3,4-dichlorobenzoate. A problem related to the mineralization of complex mixtures of chlorobiphenyls by this strain is that certain dichlorobenzoates inhibited the metabolism of monochloro-substituted biphenyls (53). Further developments in this area are foreseen via the use of sequential anaerobic treatments to achieve dechlorination of PCBs and further aerobic metabolism of low chloro-substituted biphenyls (54).

A Hybrid Enzyme for Trichloroethylene Cometabolism

Trichloroethylene (TCE) has been recognized as one of the most significant environmental pollutants in soil and groundwater (1). This and related compounds persist in the environment and are suspected carcinogens. Wackett and Gibson (55) showed that toluene dioxygenase plays a role in the cometabolic elimination of TCE. Later, Suyama and coworkers (56) constructed a hybrid strain in which the *bphA1* gene coding for biphenyl dioxygenase was replaced by the *todC1* gene, which codes for toluene dioxygenase of *P. putida* F1 within the chromosomal biphenyl-catabolic *bph* gene cluster. This hybrid strain efficiently removed trichloroethylene and *cis* 1,2-dichloroethylene.

MODIFIED PATHWAYS FOR ALKYLAROMATICS

Expansion of the Catabolic Potential of the TOL Plasmid Catabolic Pathways for Metabolism of Alkylaromatics

Pseudomonas putida KT2440, harboring the self-transmissible TOL plasmid pWW0, grows on a variety of aromatic hydrocarbons used as solvents, including toluene, *m*- and *p*-xylene, and *m*-ethyltoluene (36). The lateral alkyl chain of these aromatics is oxidized to yield alkylbenzoates, which are further metabolized to Krebs cycle intermediates via catechol and alkylcatechols. In this strain, the metabolism of *p*-ethylbenzoate is blocked (21). By introducing a series of mutations in the TOL plasmid, the recombinant TOL plasmid pWW0-EB62 that allows the host microbe to grow on *p*-ethylbenzoate while maintaining its ability to grow on benzoate and *m*-methylbenzoate and *p*-methylbenzoate (21) was constructed. The strategy involved the isolation of several mutants, which are detailed later. XylSArg45Thr is a mutant protein that allows the induction of the meta-cleavage pathway in response to *p*-ethylbenzoate as an effector. When the mutant regulator was introduced in *Pseudomonas* bearing the TOL plasmid, *p*-ethylbenzoate was oxidized to *p*-ethylcatechol, which inactivated the wild-type *xylE*-encoded catechol 2,3-dioxygenase. Ramos and coworkers (21) then isolated a mutant *xylE* gene that encoded an enzyme resistant to inactivation by its substrate *p*-ethylcatechol. This mutant catechol, 2,3-dioxygenase, exhibited a single amino acid substitution (threonine 253 isoleucine) (57). The *xylS* and *xylE* mutations were recombined in the TOL plasmid pWW0-EB62 so that bacteria grew on *p*-ethylbenzoate as the sole C-source. This microbe has been extensively studied in microcosms (see following text).

de Lorenzo and coworkers (58) used the upper TOL operon of plasmid pWW0, together with its regulator *xylR*, to construct a cassette that would allow the bioconversion of toluene and a number of derivatives to the corresponding benzoates. This cassette can be transferred to microorganisms that use the housekeeping orthocleavage pathway of catechol for the metabolism of toluene and its derivatives.

Mineralization of Mixtures of Several Aromatics

The construction of a hybrid strain that is able to mineralize components of a benzene, toluene, and *p*-xylene mixture was achieved by redesigning two metabolic pathways of *P. putida* for toluene metabolism. Genetic and biochemical analyses of the *tod* and the *tol* pathways revealed that dihydrodiols formed from benzene, toluene, and *p*-xylene by toluene dioxygenase in the *tod* pathway could be channeled into the *tol* pathway by the action of *cis*-*p*-toluate-dihydrodiol dehydrogenase, leading to complete mineralization of a benzene, toluene, and *p*-xylene mixture (59). A hybrid strain was constructed by cloning the *todC1C2BA* gene encoding toluene dioxygenase on plasmid pRSF1010 and introducing the resulting plasmid into *P. putida* bearing the TOL plasmid pWW0. The hybrid strain, called *P. putida TB105*, was able to mineralize a benzene, toluene, and *p*-xylene mixture without accumulating any metabolic intermediates.

HYBRID PATHWAYS FOR NITROAROMATICS

Mineralization of Mononitrotoluenes

Apparently, the mononitrotoluene that can more easily be mineralized by microbes is *p*-nitrotoluene (60–62), because *o*-nitrotoluene and *m*-nitrotoluene are more recalcitrant, although a *Pseudomonas* strain that is able to metabolize *o*-nitrotoluene has been described (62). To date no microbe that is able to deal with *m*-nitrotoluene has been described. Two independent reports originally documented the mineralization of *p*-nitrotoluene by bacteria belonging to the genus *Pseudomonas* (10,60).

Nitrotoluenes may be regarded as structural analogs of toluenes and xylenes, the original substrates of the TOL plasmid-encoded pathway. In fact, the degradative pathway found in *p*-nitrotoluene-mineralizing microbes involves stepwise oxidation of the methyl substituent with *p*-nitrobenzoate as the intermediate (10,60). Further metabolism of *p*-nitrobenzoate occurred via *p*-hydroxylaminobenzoate, which was then transformed into protocatechuate, a central intermediate of the metabolism of aromatic compounds (61).

In contrast to *p*-nitrotoluene, *o*-nitrotoluene and *m*-nitrotoluene are more recalcitrant, and until recently only one *Pseudomonas* strain had been isolated because of its capability of metabolizing *o*-nitrotoluene (62). Delgado and coworkers (63) examined the ability of nitro-substituted compounds to serve as substrates for the TOL pathway enzymes toluene monooxygenase, benzyl alcohol dehydrogenase, and benzaldehyde dehydrogenase. All three enzymes were able to transform the substituted nitroaromatic substrates, when the nitro group was located at the meta or para position of the aromatic ring, revealing that enzymes of the TOL catabolic pathway can metabolize *m*-nitrotoluene and *p*-nitrotoluene to the corresponding *m*-nitrobenzoate and *p*-nitrobenzoate. The XylR regulator controls transcription of the genes of these enzymes from the Pu promoter. Its effector specificity is such that it recognized *o*-nitrotoluene and *p*-nitrotoluene as effectors, but was not activated by *m*-nitrotoluene (64). Therefore, the potential of the TOL upper pathway seems to be limited to the degradation of *p*-nitrotoluene as it is the only compound that acts as both effector and substrate. Transfer of the TOL upper pathway module to a *p*-nitrobenzoate-degrading *Pseudomonas* sp. strain resulted in the expansion of its catabolic potential to include *p*-nitrotoluene (65; Fig. 2).

A mutant XylR regulator that gained the ability to recognize *m*-nitrotoluene without losing its ability to recognize the other effectors was selected (64). This mutant regulator, together with the TOL upper catabolic pathway, provides the potential for the biotransformation of *m*-nitrotoluene to *m*-nitrobenzoate. This module can be transferred to a Pseudomonas strain that is able to mineralize *m*-nitrobenzoate (66). This was achieved after cloning the *xylR7* mutant allele and the upper genes enzymes into a mini Tn5. The mini Tn5 was transferred to strain JS51, and mineralization of *m*-nitrotoluene was achieved (67).

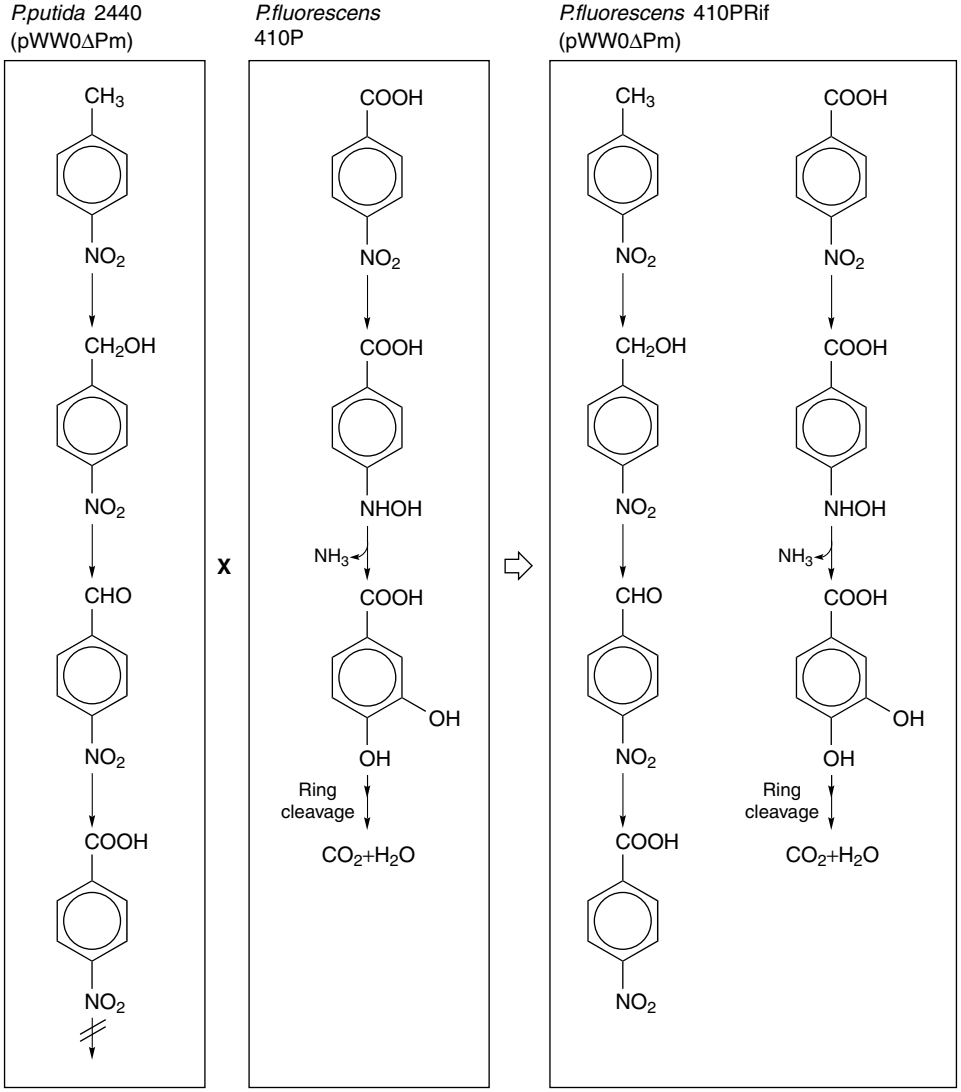

Figure 2. A catabolic pathway for the metabolism of 4-nitrotoluene. The hybrid pathway was as constructed by in vivo mating between strains with different catabolic potentials (35).

REMOVAL OF ORGANOMERCURIALS

Mercury (Hg) is a toxic metal that has been released into the environment in substantial quantities. Its toxicity results from the capacity of Hg(II) to bind sulfhydryl, thioether, and imidazole groups and thereby inactivate enzymes (68). Organic species of mercury (both alkyl and aromatic derivatives) accumulate in tissues of higher organisms, causing serious health problems (69).

The *merTPABD* genes of transposon Tn501, which encodes the enzymes involved in organomercury resistance (69), were cloned into a mini Tn5 that was used to insert the genes into the genome of *P. putida*. Transconjugants that constitutively expressed the *mer* genes (high resistance to phenylmercury) were selected (69). This allowed the engineered bacteria to cleave Hg from an organic moiety and reduce the Hg(II) released to Hg^0. These properties were also combined with benzene and toluene catabolism of several *Pseudomonas* strains, allowing the degradation of the aromatic moiety of the organomercurial as well as the detoxification of the metal component.

IMPROVED REMOVAL OF POLLUTANTS IN THE PLANT RHIZOSPHERE

The Bioremediation of sites polluted by compounds at very low concentrations may be favored by microbes that are able to grow in plant rhizospheres, in which the nutrient supplied by the plant may help to colonize soil sites that are poor in available substrates and ultimately enhance the elimination of pollutants (70–76). This process is known as *plant-assisted microbial bioremediation* or *rhizoremediation*. *Pseudomonas fluorescens* sp. F113 is an isolate from the sugar beet rhizosphere, which is an excellent root colonizer and shows potential for serving as an instrument of biological control (75). This microbe has been subjected to pathway expansion to include biphenyl and certain monochlorinated biphenyls (20). The *bph* genes

were cloned into a mini-Tn5 operon encoding resistance to a herbicide in the suicide plasmid pDDPCB (20) and then delivered into the host chromosome through this vector system. *Pseudomonas* sp. F113-PCB is a derivative that carries the *bphABCD* genes for the conversion of biphenyl into benzoate.

Plant compounds that induced biphenyl metabolism by bacteria have been identified. For example, *l*-carvone induced *Arthrobacter* sp. strain B1B to cometabolize Aroclor 1242 (a mixture of PCBs), resulting in significant degradation of 26 isomers in the mixture. Several compounds structurally related to *l*-carvone, including limonene, *p*-cymene, and isoprene, also induced cometabolism of PCBs by certain bacteria. These results suggest that in the plant rhizosphere gratuitous inducers may facilitate the activation of catabolic pathways and the removal of xenobiotic compounds.

In the plant rhizosphere, the metabolism of alkylbenzoates was stimulated so that degradation was enhanced and the remaining levels of these aromatics were lower than those found in soil without plants (76). A similar observation was seen for removal of TNT in the plant rhizosphere (A. Esteve-Núñez and J. L. Ramos, unpublished).

TRACKING GEMS IN MICROCOSMS AND BEHAVIOR OF RECOMBINANT MICROBES

Tools for Tracking GEMs in the Environment

Most of the recombinant bacteria constructed for biodegradation bear antibiotic-resistance markers. Although these markers are extremely useful in molecular genetics and microbial ecology, their use in uncontained applications is not very important (77). To avoid the use of antibiotic-resistance selection markers in GEMs designed for environmental applications, a series of nonantibiotic-resistance markers were developed. These markers include spontaneous resistance to phosphinothricin, bialaphos, heavy metal ions such as mercury, arsenate, or tellurite (28,29,77–79), and nutritional markers such as the genes that enable the organism to grow on lactose as the sole C-source (80). Some of these markers were introduced into the host microorganisms via mini-Tn5 derivatives (28).

Another approach, which may ultimately solve the problem of the presence of selectable markers, is the use of a selectable marker, that is, kanamycin resistance, flanked by two tandem *res* (resolution) sites of plasmid RP4, which can be provided as a cassette within a mini transposon (81). The *res* site is a short sequence that, once recognized by the resolvase of the ParA system, undergoes site-specific recombination that results in the deletion of the intervening DNA sequences (82). ParA can be provided in a suicide replicon.

An alternative is the use of genes such as *lux* and *luc*, which encode for light emission (83). This system now has been used to mark and track *Pseudomonas* strains that are able to colonize a number of plant roots (71,73).

An alternative to the introduction of a selectable marker in the target strain is to use tools that specifically recognize the target microbe. Monoclonal antibodies (mAbs) are powerful tools for tracking microorganisms because they can recognize epitopes on the surface of bacteria and thus serve as in situ identifiers. A series of mAbs were produced against whole cells of *Pseudomonas putida* KT2440 (84). One was shown to recognize the *O*-antigen of *P. putida* LPS. In the laboratory, this mAb specifically recognized the strain when grown in different culture media and at different growth stages. The mAb was used to track the strain after its release in a mesocosm established in Plussee Lake in northern Germany (85).

Another approach used in our laboratory has been to introduce new epitopes on bacterial surface proteins. For example, a mammalian coronavirus epitope (86) has been cloned into the OprL protein, a surface protein of *P. putida*, and is now being used as a reporter to track bacteria bearing rDNA (87).

The use of direct gene probes and PCR is a powerful approach to detect microorganisms without prior cultivation (88,89). For example, amplification of chromosomal genes from a highly specialized subpopulation of the total microbial community from the top layer sediment of the Elbe River in Germany made it possible to identify aerobic microbes that are able to degrade biphenyl (90).

Survival, Propagation, and Stability of GEMs in Their Target Ecosystems and Their Effects on Indigenous Microorganisms

A series of features that are crucial for the safe and effective functioning of some of the earlier recombinant and wild-type bacteria have been examined in soil microcosms with and without plants and in sewage microcosms. Microcosms offer a suitable approach to evaluate the survival and functioning of GEMs; however, it should be recalled that the samples are taken from nature and introduced into the laboratory. This imposes some limitations as a number of parameters are closely controlled, that is, incubation temperature, light/dark cycles, and so on. The survival of some of the recombinant microbes described earlier was assayed by introducing both parental and recombinant strains in the edaphic and the sewage water microcosms. These recombinant bacteria were designed to eliminate pollutants and were added to polluted soils and aquatic microcosms in relatively high numbers, for example, 10^6–10^8 colony forming units (CFU) per gram of soil or milliliter of sewage water.

Most studies have focused on the behavior of these microbes during the initial period after introduction into the microcosms, usually between four and eight weeks. It was generally observed that both the recombinant microbes and their parental strains were able to establish in soil, rhizosphere, and aquatic microcosms. In each ecosystem, the number of bacteria tended to reach the microcosm's carrying capacity, so that in microcosms rich in organic matter, the number of microbes was usually higher than that in microcosms poor in nutrients (72–74,88–96). Recombinant bacteria survived better than parental strains only when the former were introduced in soil or aquatic microcosms where up to 0.1% (wt/wt or wt/vol) pollutant had been added, that is, under conditions strongly favorable to the GEM. For example, the introduction of *P. putida* EEZ15 (pWW0-EB62) or *Pseudomonas* sp. FR1 (pFRC20) in soils supplemented with 0.1% (wt/wt) *p*-ethylbenzoate

and *p*-methylbenzoate allowed the strain to become established at at least one order of magnitude higher than in soils without the supplement (63,78,93). A similar finding was obtained when these bacteria were introduced into microcosms consisting of wastewater from a sewage treatment plant (91,92). Although survival of parental and recombinant bacteria approached 100% in short-term experiments, in the long term, a steady decline was observed in CFU per gram of soil until numbers in some cases fell below the detection limits (93).

Recombinant and parental bacteria survive in soils, and in certain cases, the total number of CFU increased. For example, when a low number (10^4 CFU per gram of soil) of *P. putida* (pWW0-EB62) was introduced in nonsterile soils, the strain multiplied to a density of 10^6–10^7 CFU per gram of soil (78). The stability of the genetic information introduced into *Pseudomonas* sp. FR1 (pFRC20P), *Pseudomonas* sp. F113-PCB, and *P. putida* EEZ15 (pWW0-EB62) has been studied (63,75,78). These strains can be considered genetically stable bacteria as the phenotype acquired through genetic manipulation was maintained under laboratory culture conditions in the absence of selective pressure. Furthermore, some natural properties of these strains that are not related to the recombinant phenotype, that is, biocontrol traits, growth rates, and pigment production, remained unaltered. The recombinant trait did not affect the competitive ability of the *Pseudomonas* sp. F113-PCB and *P. putida* strains in colonization assays in nonsterile soil microcosms on sugar beet, corn, tomato, and spinach-seedling roots (72–75). Furthermore, these strains have been shown to be stable in soil; 100% of the bacteria recovered after prolonged incubation in soil retained the ability to use the aromatic compounds that they were designed to deal with.

The effect of the introduction of wild-type or recombinant microbes into the indigenous microbiota has been studied by estimating the "total" number of culturable microbes in relatively rich medium (i.e., peptone agar) or by counting the indigenous population that is able to use a certain compound as the sole C-source, (i.e., *p*-hydroxyphenylacetic acid degraders), the denitrifying bacteria, or the "heterotrophic" population (74,89–95). Neither the wild-type nor the recombinant microbe affected indigenous microbiota, which suggests that natural environments have a certain buffering capacity against the introduced microbes.

The earlier cases suggest that the possible risks from the use of recombinant microbes in bioremediation are similar to those posed by the parental nonmodified strains. It also seems that the physicochemical and biological parameters of the microcosms affect the parental and recombinant microbes equally.

Functionality of Recombinant Microbes in Target Microcosms

The introduction of bacterial strains into the environment for in situ bioremediation will usually require that microorganisms be able to survive in high numbers and express the desired catabolic phenotype. For pollutants to be efficiently mineralized by natural and genetically modified microbes, the degrading microbe must not only become established in the polluted sites but also must express catabolic genes in response to the pollutant, even in the presence of other compounds. Soils, river sediments, and sewage treatment plants are complex environments where gene expression can be inhibited or stimulated. *Pseudomonas putida* harboring either the wild-type pWW0 or the recombinant TOL plasmid were able to mineralize ^{14}C-labelled substrates (*p*-methyl-^{14}C-benzoate) for at least a month (95,96). In soils, mineralization was monitored as the evolution of $^{14}CO_2$, whereas in aquatic microcosms the metabolism of alkylaromatics and chloroaromatics was monitored chromatographically by measuring the disappearance of the target chemical from the polluted site (92). It was shown that *Pseudomonas* sp. FR1 (pFRC20P) enhanced the rate of degradation of a mixture of *m*-chlorobenzoate and *p*-methylbenzoate that had been added to the water column of sediment cores made of intact-layered sediments from the Plussee Lake and the Rhine River (92).

Pseudomonas sp. FR1 bearing the *bph* genes inserted on the chromosome was able to remove up to 100 ppm of *p*-chlorobiphenyl per gram of sediment slurry in five days (20). In these assays, recombinant bacteria established at close to 10^8 CFU per gram of sediment.

Transfer of Recombinant DNA from *Pseudomonas* to Other Microorganisms

Gene transfer from recombinant microbes has been analyzed under optimum laboratory conditions and in soil and aquatic microcosms.

The genetic information introduced into *Pseudomonas* sp. F113-PCB was inserted into the host chromosome via a mini Tn5 lacking the transposase gene. In *Pseudomonas* sp. FR1 (pFRC20P), the information was located partially on the bacterial chromosome (Tn5:*xylXYZ*, *xylS*) and partially on a mobilizable broad host-range plasmid (pFRC20P). In *P. putida* (pWW0-EB62), the recombinant information was on a self-transmissible TOL plasmid. The recombinant DNA in these three strains was stably maintained under laboratory growth conditions and in bacteria introduced into soil and aquatic microcosms. In the laboratory, there was no transfer of the recombinant DNA from the chromosome of *Pseudomonas* sp. F113-PCB or *Pseudomonas* sp. FR1 (pFRC20P) to other *Pseudomonas* or to indigenous bacteria in soil and aquatic microcosms (63,75,91). In contrast, plasmid pFRC20P was transferred to other microbes, but only if a helper plasmid was supplied in the mating mixture (93). In these cases, transfer of the plasmid led to about 10^{-5} transconjugants per recipient. Transfer of the wild-type TOL plasmid or the recombinant pWW0-EB62 was restricted to microorganisms belonging to members of the pseudomonad rRNA group I (*P. putida*, *P. fluorescens*, *P. stutzeri*, and so on) and some enterobacteriaceae. In matings on plates, the rate of TOL transfer was on the order of 1 to 10^{-2} transconjugants per recipient, and the rate of intergeneric transfer ranged from 10^{-4} to 10^{-8} transconjugants per recipient (97,98).

In soils, the TOL plasmid was transferred from *P. putida* to other strains of *Pseudomonas* only at high cell densities (higher than 10^6 CFU/g soil). Transfer

was influenced by the type of soil used, the incubation temperature, the initial inoculum size, and the presence of chemicals that affected the survival of donor or recipient bacteria. Maximal transfer was observed in soils incubated at 15–17 °C, when the donor and recipient loads were about 10^8 CFU per gram of soil (97).

In conclusion, recombinant DNA can be transferred between microorganisms. Transfer is limited by the vector used to introduce the recombinant DNA into the host microbe and by the nature of the recipient microorganism. Chromosomal information is less likely to be transferred than is information on mobilizable plasmids. The latter is less likely to be transferred than recombinant DNA on self-transmissible plasmids.

Not all locations on the chromosome are similar in terms of expression, physical structure, or mobilization. This is particularly true in *Pseudomonas*. Ramos-González and coworkers (98) labeled the chromosome of *P. putida* randomly at 34 independent positions with the same marker, a mini-Tn5-Km. They found that the TOL plasmid was able to mobilize these insertions on the host chromosome at a rate between 10^{-4} and 10^{-8} transconjugants per recipient. Furthermore, mobilization of the host chromosome by the TOL plasmid occurred when the TOL plasmid and the marked chromosome were located in the two independent microbes, a phenomenon called *retrotransfer* (98–100). Retrotransfer involves the movement of a self-transmissible replicon to a recipient organism, the capture of DNA, and its return to the original donor (100). It follows that although chromosomal insertions are less likely to be mobilized than rDNA on plasmids, they can nonetheless be transferred potentially.

The deliberate release of GEMs in the environment raises a series of scientific and public concerns, and an active biological containment can provide a means to increase the predictability of the behavior and fate of recombinant microbes (101). Such biologically active containment systems have been shown to control the survival of GEMs and to inhibit lateral gene transfer (95,101,102) (see FIELD RELEASE OF GENETICALLY ENGINEERED MICROORGANISMS (GEM), this Encyclopedia).

CONCLUSION

Bringing about in vitro evolution of the catabolic pathways usually requires thorough knowledge of the biochemistry of the reactions involved in the degradation of a compound and of the genetics of the pathway. More specifically, intimate awareness of the organization of the genes that encode the enzymes and of the operation of the regulatory circuits that govern the activation of gene expression, including alteration of substrate and effector specificity by DNA shuffling (18,102,103), is required. These regulators can be useful for the design of new biosensors (104). The judicious combination of segments from different metabolic pathways in the appropriate bacteria can provide complete catabolic routes for recalcitrant xenobiotic compounds, and can circumvent certain problems related to substrate incompatibilities, and to the formation and accumulation of toxic intermediates. An example of this is the newly identified catechol 2,3-dioxygenase that is able to deal with chlorosubstituted substrates (105–107). This, in turn, can increase the catalytic potential and efficiency of microorganisms for the degradation of xenobiotics and can enhance their survival in environmental settings. Specifically designed pathways can also be introduced into microorganisms derived from contaminated sites of interest and hence, adapted to prevailing environmental conditions. As information accumulates on the genetic determinants of the characteristics that are important for treatment processes, such as tolerance or resistance to the toxic effects of solvents and other pollutants, surfactant production, and so on, our ability to generate more effective biocatalysts will increase (108–117). In recent years, a number of new catabolic pathways for toxic and recalcitrant compounds have been elucidated. These include pathways for the metabolism of dibenzodioxins and new pathways for chloroaromatics and polar and apolar nitroaromatics such as nitrobenzoates, monosubstituted, and polysubstituted nitrotoluenes (6,10,12,65,118–130). Equally important is the fact that many enzymes are extremely relaxed in their substrate specificity and are thus able to deal with multiple substrates. Some dioxygenases for one-ring aromatic compounds function also as monoxygenases and attack compounds with two or three aromatic rings and heterocycles (131–134). It is therefore expected that new catabolic pathways will be constructed on the basis of these catabolic modules, and as a consequence, the number of microbes able to mineralize halo-substituted and nitro-substituted aliphatic and aromatics, organic solvents, insecticides, and other xenobiotics should increase steadily.

Bioremediation research in simulated environments does not accurately represent real environmental conditions, and therefore, such experiments cannot test how prospective bioremediation schemes respond to the changes in the weather and to the movements of materials that may typify polluted sites. For these reasons, and to more fully address concerns regarding the safety and reliability of the approaches that are now being developed, carefully controlled field studies for bioremediation purposes need to be performed (see FIELD RELEASE OF GENETICALLY ENGINEERED MICROORGANISMS (GEM), this Encyclopedia).

Acknowledgments

The work, carried out in the authors' laboratories, was supported mainly by a biotechnology grant from the European Commission (QLK3-CT-2000-00170) and a grant from the Spanish CICYT (BIO2000-0964). We thank M. M. Fandila and C. Lorente for secretarial assistance.

GENETICALLY MODIFIED MICROORGANISMS (GMM) IN SOIL ENVIRONMENTS

LEO VAN OVERBEEK
DICK VAN ELSAS
Plant Research International B.V.
Wageningen, The Netherlands

The early 1970s witnessed a major breakthrough in molecular biology with the discovery of restriction enzymes. From that moment on, it has been possible to modify the genetic constitution of all organisms, and a new era in human history started. In the early years of genetic modification, the perspectives of these approaches were tremendous. It was, for instance, thought that it would not take long before one would be capable of modifying organisms in such a way that they could easily cleanup spills of waste or polluting materials or successfully control pathogens. Also, in

agricultural practice, expectations were high, for instance, considering the transfer of nitrogen fixation genes from bacterial hosts into plant genomes. Application of such plants would enable developing countries to decrease their expenditures on chemical fertilizers. Also, genetic modifications would make it possible, at least in theory, to reduce crop diseases, improve nutrient availability and, thus, drastically increase agricultural yields.

However, these expectations have been tempered ever since and have even led to an upheaval because of two reasons. Firstly, genetically modified organisms might not be as well adapted to their natural environments as their unmodified ancestors and thus perform poorly after release. Secondly, public concern was raised about the infringement on nature by genetic modification (often called genetic "manipulation" by persistent opponents to the application of these techniques). Maybe the first backlash was a result of the realization that genetically modified microorganisms (GMMs) would often indeed be outcompeted in their natural environments. In addition, the horizontal spread of recombinant genes was a second major concern because of the possible occurrence of unpredictable events due to lack of (ecological) knowledge about the effects of these new gene combinations on indigenous species.

However, it is currently well accepted that the application of GMMs to the environment needs a thorough understanding of the host strains carrying the genetic modification as well as the heterologous genes, with special emphasis on their regulating systems. Also, it is essential to gain an understanding of the spread and potential dormancy of modified bacterial cells in the environment, in order to assess the potential risks involved in their use in nature.

In this article, we focus on the requirements for the application of GMM strains in natural, unconstrained environments such as agricultural fields, and discuss approaches for tracking released GMM strains as well as limiting their spread by the construction of so called self-containing mechanisms.

CONSTRUCTION OF GMMs AND CONTAINMENT

For the construction of a genetically modified bacterial strain, developed to perform under field conditions, two considerations are important; (*1*) optimum survival and activity and (*2*) spatial and temporal containment. First, survival and activity of the introduced GMM often must be optimum; that is, metabolically active cells of the GMM strain should remain present in sufficient numbers for the required period of application (1). On the other hand, the strain must ideally remain restricted only to the location and period for which heterologous gene activity is desired (1). Both considerations may be contradictory when optimum survival is necessary on the one hand, while on the other hand the GMM has to ultimately be eliminated in order to prevent its persistence or escape from the site of application. However, sufficient survival as well as containment may be combined when different regulatory genes responding to intrinsic cellular or environmental signals are used. Regulatory genes necessary for controlling the heterologous genes inserted can be triggered under different conditions as genes necessary for containment of the GMM strain. In this section, special attention is given to the regulation of the gene inserts, both to improve survival and to contain the introduced strains with respect to time and location.

In general, GMM strains are ecologically less competent than their (unmodified) parent strains, as demonstrated by competition experiments in soil (2). Because of the expression of the heterologous gene, the cellular energy expenditure is increased, and hence GMM cells may be deprived faster of their energy sources. Therefore, uncontrolled expression of inserted genes can be harmful to the released GMM; controlled gene regulation at the appropriate time and site of application would be preferable. The use of regulatory genes specifically responding to cellular physiological status (e.g., exponential versus stationary phase) or specific environmental signals may help overcome cellular energy depletion. On the other hand, the signal used for beneficial gene expression can also be applied to regulate containment of gene expression via a "negative loop" construction (3). A repressor gene can be placed under the control of a promoter regulated by the environmental signal, whereas the intended containment gene is constructed downstream of a promoter/operator region controlled by the repressor protein (4).

The choice of different signals and their responding promoter sequences, with the aim to control heterologous gene expression, is an important first step. Subsequently, a screening of appropriate promoter sequences should be carried out and these promoter constructs should be used for further application. In this section, a study is included in which two different promoters of *Pseudomonas fluorescens* that respond to signals from the soil environment were characterized.

Promoter probe reporter systems are excellent tools for investigating the expression of genes involved in the response of bacteria to soil conditions. Plant-induced reporter gene expression has been determined with transcriptional fusions using reporter genes such as *lac*Z [ß-galactosidase] (5,6), *gus*A [ß-glucuronidase] (7,8), *lux* genes (light emitting genes from Vibrio fisheri) (9,10), *xyl*E (xylene degradative gene) (11), and *ina*Z (ice nucleation gene) (12). For microscopic detection of *in situ* induced reporter gene activity, specific fluorescence markers such as the green fluorescent protein (GFP) gene (*gfp*), which has been cloned from jellyfish (*Aequorea victoria*) (13), can be used. Using promoterless *gfp* as a promoter probe reporter, specifically induced expression can be observed by epifluorescence UV microscopy in which intracellular GFP will emit a green light.

Although testing of induction of reporter genes in situ is relatively unexplored, progress has been made recently. Bacterial strains with reporters inserted in genes that show expression upon exposure to stress conditions such as phosphorus limitation (14) have been studied *in vitro* and in soil, and the genes

identified were shown to function under soil conditions. Similarly, Kragelund and coworkers (15) showed the expression of N and C responsive genes under soil related conditions. Responsiveness to root exudates and carbon limitation was investigated in soil, soil supplemented with nutrients, and rhizosphere soil (16–18). Reporter gene expression upon carbon limitation was observed in unamended bulk soil, indicating that the carbon limitation induced promoter can be used as a regulatory element to control gene expression in GMM strains intended for application in soil (16). In situ root exudate-controlled reporter gene activity under natural conditions has been reported by Vande Broek and coworkers (8) and Brennerova and Crowley (9). Furthermore, *in situ* root colonization studies under gnotobiotic conditions have been performed with various different markers and bacterial species. For example, de Weger and coworkers (10) used naphthalene-inducible *lux*CDABE and constitutively induced *lux*CDABE and *lux*AB gene constructs for *in situ* root colonization studies with *P. fluorescens*. Reporter gene activity was detectable in the rhizosphere with the naphthalene-inducible *lux*CDABE and constitutively induced *lux*AB genes at a colonization level between 10^3 and 10^4 CFU/cm root.

Studies on the induction of reporter genes by soil or plant stimuli in natural soils are technically feasible (10,16–18). The promoter/reporter gene combinations can be used in the natural environment, for example, as biosensor systems or to determine the expression of genes of interest. Reporter gene expression was observed near wheat roots in microcosms as well as in the fields (16); the promoter identified proved to be an excellent regulatory gene of the expression of recombinant genes in a new generation of GMM constructs.

BIOTIC AND ABIOTIC FACTORS INFLUENCING BACTERIAL SURVIVAL IN SOIL

For decades, bacteria have been isolated from soil and characterized in the laboratory with the aim to study and improve their performance as biopesticides (19), biofertilizers (20,21), or bioremediation agents (22,23). Symbiotic nitrogen-fixing bacteria such as rhizobia (24), free-living nitrogen-fixing bacteria such as *Azospirillum* (25), as well as plant growth-promoting rhizobacterial (PGPR) gram-negative species such as *Pseudomonas* (26–28) and *Flavobacterium* (29) or gram-positive species such as the *Bacillus* species (28,30,31) are among the most frequently used soil inoculants. However, many species do not survive well in soil, either because they are not indigenous to soil or because they survive well only in specific soil types (25). It should be noted that, in addition to the specific intrinsic properties, such bacteria have often been selected on the basis of the fast growth of colonies or broth cultures under laboratory conditions and their suitability for genetic modification.

Much effort has been spent on the isolation and identification of ecologically adapted bacteria from specific sites in soil, such as the rhizosphere (32,33), under the assumption that these organisms possess traits that helped them adapt to the conditions prevailing at these sites. Copiotrophic gram-negative species such as those of the genus *Pseudomonas* (32,33) are abundant in the rhizosphere and have been suggested to be the best soil inoculants because of their fast growth and alleged optimum survival under prevailing conditions in the rhizosphere as well as their genetic accessibility. However, upon introduction, bacterial cells are often subjected to the harsh conditions present in the rhizosphere and bulk soils, which can limit their survival. How the bacteria cope with these conditions depends on their genetic makeup and their physiological condition at the time of introduction into the soil (34). For practical applications, bacterial cells should aptly colonize soil sites; optimum survival and activity is only ensured after successful occupation of such an ecological niche. It is clear that the site (i.e., rhizosphere or bulk soil) in which inoculant bacteria reside in soil greatly determines their physiological and metabolic status, which in turn determines the persistence and activity in soil.

Introduced Soil Populations

The main goals of field tests that have been conducted to date have been to monitor the fate of genetically marked bacteria as models for subsequent GMM releases with practical applications and to study the ecological effects of these inoculations (17,35–37). Most of these studies assessed the putative risks involved in the release of GMMs into soil by measuring parameters such as survival, spread, and gene transfer, but not the fundamental properties of the introduced population, such as its physiological status or its response to environmental stresses. The latter items are important as they determine the efficacy of the application.

Knowledge of the behavior and fate of indigenous soil bacteria upon their introduction into soil is of importance in all cases in which these bacteria are applied to practical purposes such as biological control or bioremediation. Survival of the introduced populations in soil has been studied for a wide range of organisms, and the generally observed progressive decline of bacterial numbers following introduction into soil has often hampered the effectiveness of bacterial inoculants [reviewed by Van Veen and coworkers (1)]. For instance, comparison of the population dynamics of fluorescent pseudomonas in different soils showed that all introduced populations declined to low numbers within time spans of several weeks to months. Overall linear decay rates varied from approximately log 0.2 to log 1.1 colony forming units (CFU) per 10 days, and depended on the strain and the soil used. Similar responses have been found in other introduced bacteria such as *Salmonella typhimurium* and *Klebsiella pneumoniae* (38) and *Flavobacterium* spp. and *Alcaligenes* spp. (29,33). Such responses might be characteristic of copiotrophic organisms exposed to soil conditions. Oligotrophic bacteria introduced into soil may also show progressive decrease in CFU numbers, albeit slower than copiotrophic bacteria (33,39). The slower decline of oligotrophic bacteria in bulk soil is possibly related to a better adaptation to the carbon-limited conditions of soil.

It is difficult to pinpoint a single dominating reason for the decline of introduced bacterial populations in

soil. However, introduced bacteria, particularly shortly after release, are likely to be affected by the same adverse soil conditions that affect indigenous bacteria, such as limitation of a range of nutrient sources. Upon introduction in soil, increasingly higher numbers of cells of an introduced *P. fluorescens* strain were detectable via specific immunofluorescence than via selective plating (28). This suggested a possible conversion of part of the introduced population into nonculturable forms that, however, might be still viable. Such viable but nonculturable (VBNC) cells were also found in other studies (40); recently it was found that their presence does not enhance the persistence of introduced *Pseudomonas* populations (41). The occurrence of nonculturable cells, in the indigenous as well as introduced bacterial populations, indicates that one or several major factors controlling the status of bacterial cells in soil are common to bacteria in soil. Moreover, given the relative immobility of bacterial cells in soil, the localization of introduced bacteria following their introduction is likely to affect their ultimate fate (42), that is, localization determines whether inoculant cells are successful in colonizing soil and developing a cellular form resistant to soil stress or whether they will die out.

PHYSIOLOGICAL ASPECTS THAT AFFECT THE FATE OF BACTERIA INTRODUCED INTO SOIL

The metabolic activity and physiological state of bacterial populations will greatly affect their fate and efficacy after introduction into soil. Moreover, it is important to determine whether GMM strains are impaired in this adaptation due to the presence or expression of heterologous genes, resulting in an increased metabolic load.

Different approaches have been taken to assess the metabolic and physiological conditions of cells in soil. Traditionally, the detection of specific strains in a natural environment has been based on CFU counts on selective plates or on immunofluorescence (IF) cell counts (43,44). Using both techniques in combination, information on the presence of nonculturable cells can be obtained (17). However, these approaches provide little information about the activity of inoculated cells in soil. To assess the risks involved in the release of GMMs in soil, it is important to determine whether such nonculturable cells are alive (viable) and metabolizing, alive but in a metabolically arrested state, or dead (45,46). To detect the presence of heterologous genes in bacterial cells in soil, including nonculturable ones, direct molecular detection techniques have been developed (47). Discrimination between viable and nonviable cells has often been performed using the direct viable count method (DVC, based on cell elongation by addition of nutrients in the presence of a cell division inhibiting compound) (48) or redox dyes such as 2-(*p*-iodophenyl)-3-(*p*-nitrophenyl)-5-phenyl tetrazolium chloride (INT) (49) or 5-cyano-2,2-ditolyl tetrazolium chloride (CTC) (50). The viable cell numbers, determined by either or both techniques, often appeared to be intermediate between the total (IF) cell and selective CFU counts in different habitats such as plant surfaces (51) and soil (52,53). However, it remains to be determined whether viable but nonculturable populations are responsive to environmental stimuli, or if they are metabolically arrested. At least in one study it was concluded that the viable but nonculturable state of introduced *P. fluorescens* cells does not represent a physiological stage in which cells are optimal adapted to the harsh conditions as present in soil (41).

Another criterion by which bacterial adaptation can be measured is their responsiveness to different, often stressful conditions that prevail in soil, such as carbon deprivation that limits growth (4). In general, bacterial growth-limiting conditions provoke cellular responses, leading to an increased, overall, generalized, resistance. For instance, *Escherichia coli* cells that were limited in their growth after depletion of carbon sources showed an enhanced resistance to stress conditions such as high temperature, osmotic stress, and the presence of oxidative or noxious compounds (54,55). A similar response was observed in a typical soil bacterium, *Pseudomonas putida*, and adaptation coincided with *de novo* synthesis of proteins upon growth limitation (56). Later, enhanced stress resistance was also demonstrated for *P. fluorescens* cells introduced into two texturally different soils (57). Although the rates of cell decline upon introduction of this strain in the two soils were different, the time spans needed for complete adaptation (1–5 days) were the same. This led to the conclusion that differences in survival time as a result of residence in different soil types are not related to differences in adaptation, but rather to other factors such as protection against predation. To address questions about bacterial responses that serve as signals for the onset of adaptation to soil, host cells carrying environmentally controlled reporter genes may help identify triggers to which these organisms will respond upon their release (16).

TRACKING GENETICALLY MODIFIED STRAINS IN SOIL ENVIRONMENTS

Sampling

Bacterial cells released into soil will not always remain at the site of application but may spread after their release. Such spread can be lateral (spurred by wind, rain, insects, or human activity) or vertical (induced by rain or burrowing worms). Also, cells may become nonculturable and die, whereas other cells become active and are mobilized. The relative density of introduced strains may thus fluctuate in soil. In order to obtain a reliable overview of the presence of released GMM strains in the field, it is necessary to use an appropriate sampling strategy (58).

Dispersal of a genetically modified *P. fluorescens* strain was monitored during a field release study in the Netherlands (17). From the ninth day onward, detectable GMM CFUs were observed just outside the inoculated plot, with a maximal distance of about 2 m. However, CFU numbers in soil never exceeded 10^3 per g of dry soil, and the released GMM strain outside the plot could no longer be detected after 3 months, whereas in the inoculated part in the plot, the introduced strain survived for more than one year. This example illustrates that the number and

location of the samples drawn should carefully be taken into account. Thus, the sampling strategy chosen will depend on: (*1*) the mode of introduction, (*2*) the time span after release, and (*3*) factors influencing the mobility of inoculant cells such as plant growth, soil water flow, and spread by wind, animals, or human treatments. Obviously, all considerations about the statistics of sampling play a role, as outlined by Van Elsas and Smalla (58).

The mode of application of (GMM) strains will determine the location where cells reside. Cells can be applied either directly to soil in suspension via injection or spraying, or indirectly by immobilization in carriers using coatings (seed coating or root dipping) or slow-release carriers (e.g., in alginate or κ-carrageenan beads) (59). Cells applied directly to soil will colonize the top soil layer, whereas immobilized cells tend to remain at the site of application. The way bacteria are introduced into the field (e.g., spraying versus application as immobilized cells) will influence the sampling strategy. Shortly after its release the effect of introduction is clearest, whereas, later, these effects may fade away because of dispersal in soil. Also, it should be taken into account that the introduced strain may spread heterogeneously over the field. To establish statistically significant differences between treatments related to the release of GMM strains, enhanced numbers of replicates will be needed to overcome increasing standard deviations.

Vertical movement of introduced bacterial cells in soils has been observed under controlled conditions (60–62) as well as in fields (63). Bacterial migration to deeper soil layers is mainly the result of water flow by heavy rainfall. However, in the same field experiment performed with a genetically modified *P. fluorescens* strain, vertical movement occurred without heavy precipitation (17). Supposedly, bacterial cells migrated in substantial numbers to deeper layers by other means, for example, through soil cracks or by activity of soil animals such as earthworms (64).

Plant growth is a major factor affecting the spread and activity of introduced bacterial cells. Bacterial growth near plant roots may result in increased ecological competence and thus competition with indigenous species residing near plant roots. Therefore, sampling of the rhizosphere of wild plant species near or in the test field is a prerequisite to determining the fate of the introduced GMM strain (65).

Methods for Sample Analysis

GMM strains in natural environments can be tracked with methods based on (*1*) their growth in selective media (cultivation-based methods), (*2*) intrinsic properties of the host (using antisera or probes targeting specific epitopes or nucleic acid sequences), and (*3*) the recombinant DNA (using probes or primers).

In most cases, GMM strains, when released into soils, are monitored over time using cultivation-based methods. Plating techniques are most convenient to use because of the selectable markers commonly present in GMM strains, as well as the possibility for quantification. Additionally, isolated colonies can be tested for phenotypic traits by carbon utilization testing [e.g., by using commercially available test systems such as API (Montalieu-Vercieu, France) or BIOLOG™ (Hayward, CA)] and molecular fingerprinting [e.g., by using Repetitive Extragenic Palindromic (REP)-sequences, Enterobacterial Repetitive Intergenic Consensus (ERIC-) or BOX-PCR] (66), and presence of the genetic insert can be tested by using molecular probes (47). However, bacterial growth is a prerequisite step for plate-counting methods and, thus, only the culturable fraction of the populations is assessed. Additional measurements by direct, cultivation-independent methods, such as selective cell counts, will be necessary to determine the total number of GMM cells present in soil. The nonculturable fraction can then be deduced by subtracting the CFU numbers from the cell numbers. The determination of the total GMM cell numbers can be accomplished by the use of fluorescent dyes conjugated to molecules targeted against host-specific properties such as epitopes (using antibodies) (44) or nucleic acids, generally 16S rRNA (using molecular probes) (67). Cells extracted from soil can be stained directly by using specific antibodies conjugated to a fluorescent dye such as fluorescein isothiocyanate (FITC) (immunofluorescent cell staining). However, when using molecular probes, cells must be fixed and permeabilized in order to allow entrance of the conjugated probes (whole-cell hybridization). Treated cells are visualized by their fluorescence under UV light (wavelength depends on the dye used) at about 1,000 times magnification. In both cases, the targeted molecules present in bacterial hosts (epitopes for antisera and nucleic acids for molecular probes) should be sufficiently available, even under conditions of cell starvation. Therefore, polyclonal antisera as well as probes directed against ribosomal 16S or 23S RNA are preferred, as the targets (multiple epitopes and ribosomal RNA) are expected to be most stable, albeit not constant.

The inserted genes in the released GMM strain can be detected independent of cell growth. For that purpose, DNA extracted from soil can be amplified by PCR using primers directed against the heterologous gene. Protocols for DNA recovery from soil are routinely applied in many research laboratories (68); they generally allow the detection of target molecules on the order of about 10^2 to 10^4 per g of soil. Quantification can be accomplished either by quantitative (Q)-PCR (quantification is based on the relationship between the number of target molecules initially present and the number of amplified products during several PCR cycles), competitive PCR (competition between amplification of target molecules and added target sequences) (69), and most probable number (MPN) PCR (end point dilution of target DNA followed by PCR). Moreover, PCR amplification in extracted and fixed cells (whole-cell PCR or *in situ* PCR) is a promising new tool for detection and quantification of released GMM strains (70).

The side-by-side use of a range of different techniques for tracking GMM strains in soil is recommended in all field releases. Only such a polyphasic approach allows the establishment of the possible occurrence of nonculturable cells, the number of cells that lost their heterologous DNA, as well as the occurrence of heterologous DNA without the presence of the original host cells. Concerning the last point, heterologous DNA may be present in soil as 'naked'

DNA (from lysed cells) or located in other hosts as a result of gene transfer (see later). Therefore, only a polyphasic detection strategy will allow an appropriate judgment of the presence and fate of GMM strains and their DNA in environmental samples.

ASSESSING THE EFFECTS OF GMMs ON POPULATIONS INDIGENOUS TO SOIL

Perhaps the most troublesome public concern about the release of GMM strains is the potential for concurrent undesirable effects on the indigenous microbial community upon introduction into the open field. Hence, most national governments currently require extensive data on such possible effects, prior to granting permission for field release of any GMM. Preceding every field release, a protocol must be set up that includes measurements of expected effects and, if possible, consequences that may not be directly related to the application. These considerations can either be directly related to an effect of the inserted (heterologous) gene on the native organisms or related to changes in the occupation of different (micro) habitats of natural species caused by the application of inoculant strains. Furthermore, an important potential consequence of the introduction of GMM strains into the environment is the transfer of recombinant DNA to indigenous species. The effects of GMM releases on natural populations can thus be considered by using two criteria; (*1*) an ecological and (*2*) a genetic criterion.

Ecological Effect of a GMM Release

In considering the impact of GMM releases, we deal only with the effects brought about by the novel genetic combination, thus disregarding effects that would have been caused by wild-type strains. Effects on natural populations can be expected from the expression of the inserted heterologous genes whose products are intended to target particular organisms, but which may, unintentionally, also affect nontarget, organisms. For instance, constructs consisting of genes whose products are aimed at a reduction of plant damage caused by soil-borne pathogens may also affect populations of nonpathogens. Examples are specific *Bacillus thuringiensis* crystal protein (*cry*) products targeted against larvae of dipteran insects (2) and genes encoding antifungal compounds from *P. fluorescens* such as phenazines (71). Both genes are not specific to just one particular pathogen, but can affect a broader range of organisms, although there is considerable specificity for limited insect groups among the various *cry* gene products.

Assessment of effects that cannot directly be rationalized from the function of the heterologous gene is more complicated. In fact, all possible targets should theoretically be included in the risk assessment protocol, which is a truly daunting task. Hence, we propose that, first, a reasonable assessment should be made as to which organisms might be possibly affected. Then, an appropriate technique that is capable of surveying the effects on all organisms of the selected groups must be chosen.

Recently, possible shifts in fungal community structures in field soil were studied upon release of a *P. putida* strain genetically modified by insertion of a gene responsible for the production of the antifungal compound phenazine-1-carboxylic acid, with the intention of a later application as a biocontrol agent (71). Fungal isolates were obtained from the rhizosphere of crop plants (*Triticum aestivum*) in different field plots treated with modified or parent strains and analyzed by Amplified Ribosomal DNA Restriction Analysis (ARDRA). A transient change in fungal community structure was observed in wheat rhizospheres from plots inoculated with either strains, and the effect on fungal populations in rhizosphere soil with the GMM strains was different from that containing the unmodified strain.

Exposure of soil microbial populations to different carbon sources in BIOLOG^{TM} microtiter plates is a commonly used approach to study differences or shifts in soil microbial compositions (72). Community Level Physiological Profiling (CLPP) using the 95 different carbon sources present in the Biolog microtiter plate (73) helped determine the effect of a soil-inoculated GMM strain on indigenous populations. As bacterial growth is not required, this approach can be considered as a measure of total activity of all bacterial population residing in the soil.

Studying microbial populations by molecular techniques excludes biases caused by growth steps prior to analysis, whereas large numbers of species can be investigated in a single profile. Nucleic acid extraction is a prerequisite, and methods for extraction and purification of DNA and RNA from soils are nowadays commonly available in many text books (68,74). In general, molecular fingerprinting of microbial communities is based on PCR amplification of hypervariable regions present on 16S rDNA genes using primers that target conserved regions directly adjacent to these (for a schematic overview, see Fig. 1). Ribosomal genes are "par excellence" suitable for molecular fingerprinting and different primers targeting 16S or 23S ribosomal genes have been developed. Analyses of the amplified products are performed by Temperature or Denaturing Gradient Gel Electrophoresis (TGGE and DGGE) (75) or Single Strand Conformational Polymorphism (SSCP) (65) (Table 1). Both methods have successfully been applied by different laboratories to study microbial community changes in different habitats. A fingerprint consisting of different bands, each representing individual organisms, reveals the complexity of the microbial populations in the environment, whereas, their activity can be determined by amplification from RNA (76). Individual bands can be sliced out from gels, cloned into vectors, and analyzed for DNA sequencing. Database comparisons of the sequences, for instance, by BLAST searches on the Internet, helps establish the potential affiliation of the selected bands.

Schwieger and Tebbe (65) described a field release study in which molecular fingerprinting of microbial communities was applied. Two *Sinorhizobium meliloti* strains chromosomally tagged with the luciferase gene (inserted for convenient recovery; one strain was mutated in a gene responsible for DNA repair after damage, i.e., *rec*A) were introduced into field plots planted with alfalfa (*Medicago sativa*, the natural host for *S. meliloti*). Three months after

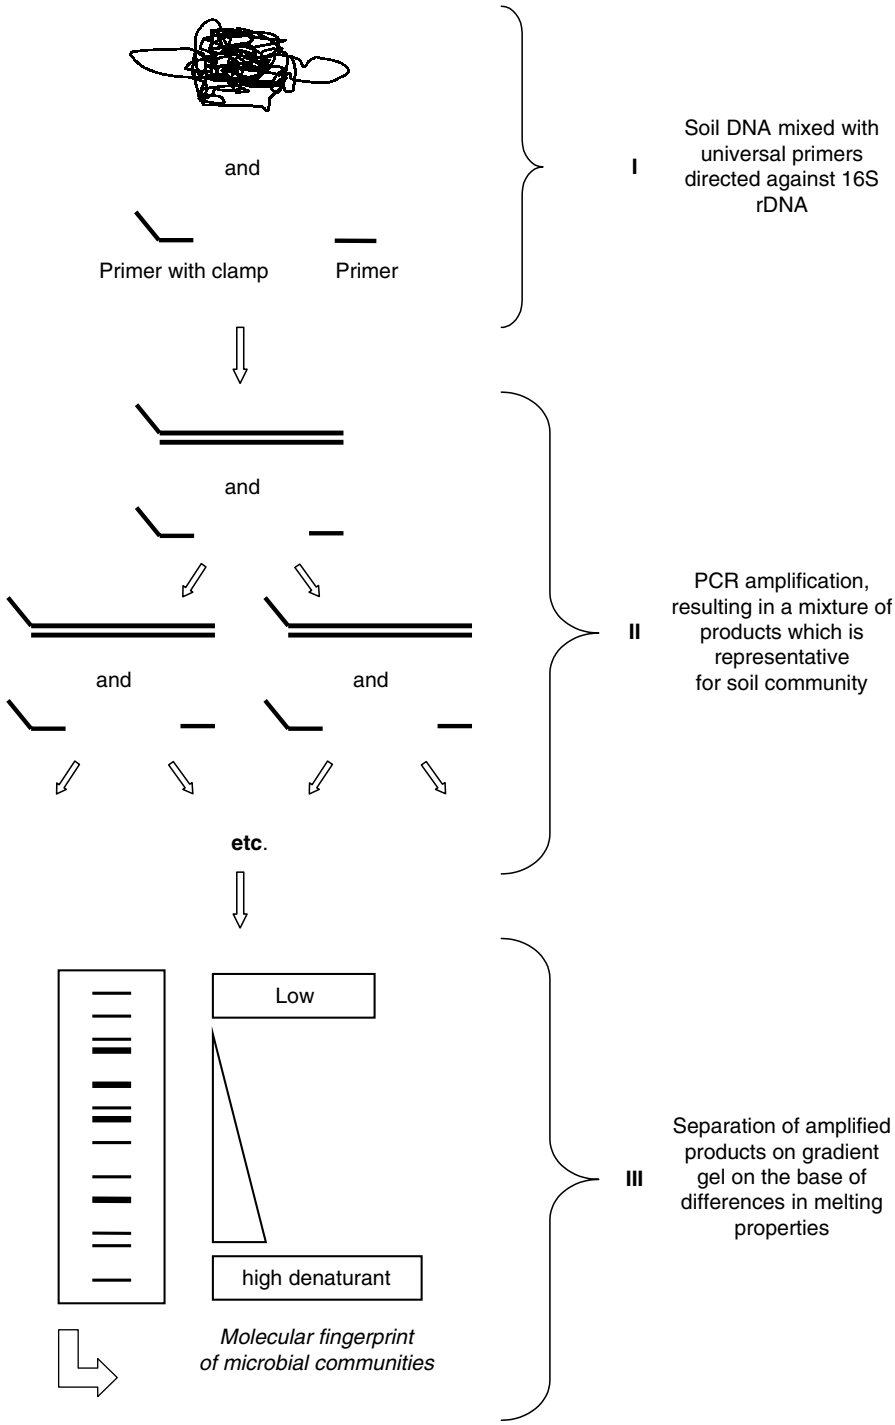

Figure 1. Schematic representation of the procedure for DNA fingerprinting of soil habitats. Molecular analysis of soil communities is independent of preceding culturing and consists of the following steps: (*1*) extraction of soil DNA, (*2*) PCR amplification of 16S ribosomal DNA using a primer set with GC clamp (necessary for analysis of the products on denaturing gradient gel), and (*3*) separation of the PCR products on a gradient gel.

introduction of both populations, the community structures near the alfalfa roots were clearly affected by the release, as demonstrated via SSCP. The dominant *Pseudomonas* population was reduced in the rhizosphere of alfalfa plants treated with the modified strains. However, the rhizosphere community structure near a weed commonly observed in the field plots (*Chenopodium album*) was not affected by the introduced strains.

Although the data obtained by molecular fingerprinting of inoculated soils show a great deal of detail, a major drawback of the method is the use of highly conserved ribosomal primers. Only the most dominant species (over 0.1% of the total) can be visualized on gel. Therefore, development of primers for selected groups of organisms, including prokaryotes and archeal and fungal species, are in progress. Such systems would allow the in-depth study of specific groups of organisms.

In conclusion, the development of molecular techniques, either or not in combination with classic techniques such as culturing or enrichment steps, allows the study

of changes in natural populations as a result of the introduction of GMM strains. So far, different effects on natural populations caused either by the introduced strain or by expression of the inserted gene(s) have been shown (17,35–37,65,71). None of the effects shown are thought to pose a threat to ecosystem functioning. It is prudent to allow the testing of a wealth of novel microbial gene products on a case-by-case basis, building on the experience of no apparent risk gained so far.

Genetic Impact of GMM Releases

Transfer of genetic inserts from released GMM strains into ecologically competent species that reside in soil may have consequences for the persistence and expression of these genes in the environment. Therefore, special care has to be taken during construction of GMM strains with respect to the possibility of transfer of heterologous genes to natural species. Most commonly, genes are inserted into the chromosome either by genetic crossing-over using DNA sequences homologous to the target site for insertion or by transposon mutagenesis. The advantage of chromosomally inserted constructs is: (*1*) the inserts are present in the cells as single copies, (*2*) the mutants are genetically stable, and (*3*) transfer is limited and only possible via interactions with mobilizing elements such as plasmids, conjugative transposons, insertion elements, and/or phages. Such elements would first have to enter the inoculant cell from the natural microflora, a low-frequency occurrence in soil (95). A drawback of chromosomal insertion, however, may be the low copy number of the heterologous genes, possibly resulting in restrictions on expression. Therefore, nonmobilizable plasmids carrying these constructs are favored in some occasions.

Movement of genes between organisms in soil is possible via the prokaryotic gene transfer mechanisms: transduction, transformation, and conjugation. Transduction, a phage-mediated DNA transfer, has been only incidentally described for soil environments but it cannot be ignored that it plays an important role in the movement of genes between bacterial species. Transformation, the transfer of extracellular DNA by competent bacterial cells, and mobilization, for example, plasmid-mediated transfer of DNA, are better known processes in soil environments. Transformation between introduced strains in natural soils has been conclusively demonstrated by Lee and Stotzky (96). Nielsen and coworkers (97) extended this work, showing that cells of the transformable bacterium *Acinetobacter* sp. BD413 can become naturally competent in soil and

then effectively capture available DNA (97). However, most information about bacterial gene transfer in soils has been obtained for conjugation using self-transmissible plasmids such as RP4 and pIPO2 and mobilizable plasmids (IncP and IncQ plasmids) such as RSF1010 and pIE723 (98–100). Although transmissible plasmids are not recommended for use in GMMs intended for release, these studies have conclusively demonstrated that gene transfer does take place in natural soils. The use of mobilizable but non–self-transmissible plasmids (IncQ plasmids) may be a safer option, although the isolation of a cryptic mobilizable and self-transmissible plasmid from soil (100) may imply that IncQ plasmids can be transferred into indigenous soil bacteria by retromobilization. As indicated, chromosomally inserted genes are transferable to other species via excision and insertion into incoming plasmids or conjugative transposons from the natural microflora, although the incidence of such an occurrence is likely to be very small.

In general, gene transfer is an unwelcome event when releasing GMMs to the environment. However, transfer of heterologous genes to indigenous species may sometimes be very advantageous as it may result in stable integration of these genes into species that are well adapted to the habitat and are, thus, ecologically more competent than the inoculant (host) strain. This strategy has been applied under contained conditions in bioreactors, in which the xenobiotic compounds 3-chlorobenzoate (101) and 3-chloro-aniline (102) were degraded. Introduced GMM strains carrying the respective catabolic genes on mobilizable plasmids were transferred to indigenous strains and the transconjugants that appeared were successful in the degradation of noxious compounds. Although, up to now, this application is restricted to bioreactors, it may be extended to soils, in particular, in the degradation of xenobiotics in contaminated soils.

PROSPECTS FOR THE USE OF ENVIRONMENTALLY-INDUCED PROMOTERS IN SOIL

Environmentally controlled promoter regions can certainly be applied to regulate the expression of biological control (control of plant diseases) or biological containment (containment of GMMs) of genes in soil inoculant strains. To achieve this goal, the reporter gene that enables the detection of the regulatory regions should be replaced by an appropriate biocontrol or biocontainment gene [using a negative loop (3)]. Suitable candidates for the construction of environmentally regulated biocontrol agents are bacterial genes involved in the synthesis of antifungal antibiotics, such as phenazine-1-carboxylic acid (103,104), and 2,4-diacetylphloroglucinol (105) from fluorescent *Pseudomonas* spp. or genes toxic to soilborne insect larvae, such as the *B. thuringiensis cry*IVB gene (106). Genes of rhizosphere bacteria involved in antagonism toward plant-pathogenic fungi are of special interest and may be used as targets for cloning experiments. When these genes are brought under the control of a rhizosphere-induced promoter, the timing and extent of gene expression can be controlled depending on the promoter of choice. This new strategy in the utilization of GMMs as biocontrol agents is promising because it can enhance and concentrate the beneficial action of the control agent to the site and time that it is most needed, for example, at the onset or peak of pathogen activity. However, in addition to the production of antibiotics (1), bacterial antagonism toward phytopathogenic microorganisms in the rhizosphere may also be affected by competition for nutrients (107), or it can be based on a combination of both actions (108).

Genes proposed for biological containment are the *E. coli gef*/*hok* (host killing) and *rel*F genes (109) and the *Serratia marcescens nuc* (nuclease) gene (110). Overexpression of *gef*, *hok*, and *rel*F genes causes a collapse of the membrane potential, whereas *nuc* gene expression results in intracellular degradation of DNA. The result of both actions is severe damage to the host cell, resulting in cell death. These genes can be brought under the control of a carbon starvation inducible promoter or a rhizosphere induced promoter region connected to the "negative loop" construction, as discussed before. Induction of the host killing genes by carbon limitation in bulk soil can result in cell death, thus confining the active GMM cells to the rhizosphere, which is the site where expression of biocontrol genes is desired. Thus, a GMM strain can be constructed that expresses its biocontrol gene in the rhizosphere whereas, after escape from this site, expression of the biocontrol gene is switched off and the host strain will be killed by expression of the biocontainment gene.

CONCLUSION

The success of the application of GMM strains in soil environments depends on the selection of the bacterial host that should be ecologically competent in the selected habitat. Survival of the inoculant strain can be optimized by using appropriate carrier materials, whereas its activity can be regulated by selection of appropriate regulatory sequences used for the control of expression of the heterologous gene(s). From a biotechnological point of view, there are no limitations in the optimization of suitable inoculants. However, more information is needed about the adaptation and survival of released GMMs, upon introduction into the target environment. Up to now, we lack fundamental knowledge of a full understanding of the adaptational processes with respect to the metabolic activity and dormancy of inoculant cells (111) (for overview, see Fig. 2). Unraveling these mechanisms will potentially allow an interference in the cellular properties and, thus, optimize survival under selected conditions.

Restricting GMM strains to the site of application may decrease the putative risks involved in the release of these inoculants into the environment. The development of optimized modes of introduction, aimed to restrict released GMM strains to specific sites, as well as the tools necessary to track these strains and to determine fate, activity, and effect on natural microflora, is needed on a case-by-case basis. Techniques for impact assessments now make it possible to pinpoint drastic effects on microbial fluctuations, but more development is necessary to enable detection of subtle changes in microbial community structure upon releases of GMMs into the environment.

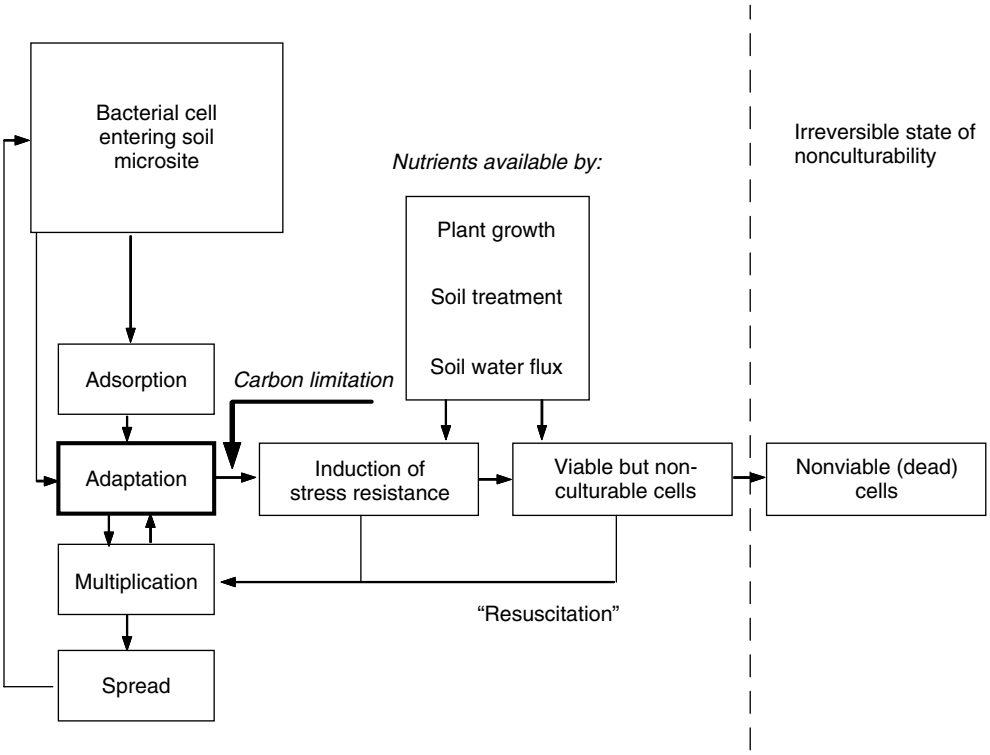

Figure 2. Concept of the sequence of events following the introduction of bacterial cells into soil and the specific factors influencing the physiological status of bacterial cells in soil. (Data taken from L. S. van Overbeek, in Responses of Bacterial Inoculants to Soil Conditions, Ph.D. Thesis, Leiden, The Netherlands, 1998.)

Nevertheless, mankind should not lose its feeling of optimism about the great potential offered by the prospect of GMM releases in bioremediation and biocontrol. Compared with the prospects available only 10 years ago, major steps forward have been taken. It is very feasible that genetically modified biocontrol strains will replace chemical pesticides, or be used in an integrated fashion, to control soil-borne diseases in some of the key crop plants that feed the world.

GENOMICS, ENVIRONMENTAL

KAREN E. NELSON
IAN T. PAULSEN
JOHN F. HEIDELBERG
CLAIRE M. FRASER
The Institute for Genomic Research
Rockville, Maryland

In 1995, the complete research of genome sequence of the first free-living organism, *Haemophilus influenzae* (1), was completed. This accomplishment opened the door to the genomic era in microbiology. From this point, until recently, material on 28 microbial research genomes including *Archaea, Eubacteria*, and *Saccharomyces cerevisiae* have been published and are available (*http://www.tigr.org/tdb/mdb/mdb.html*) (Fig. 1). Several hundred additional microbial genomes are expected

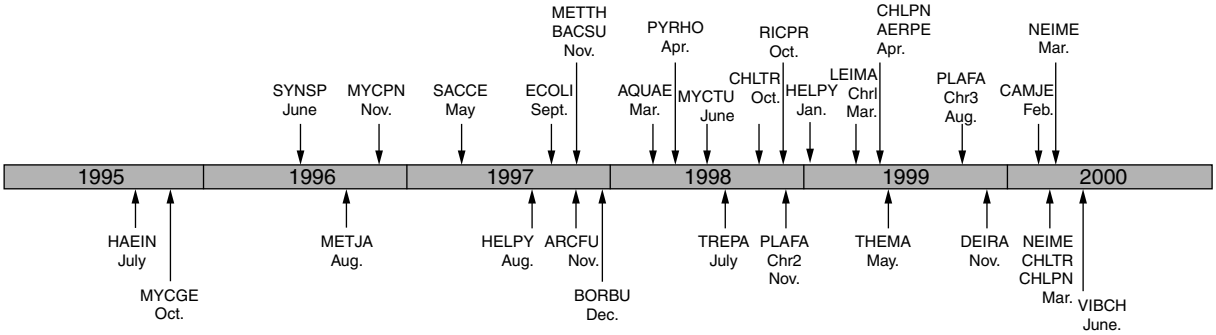

Figure 1. Sequencing timeline of complete microbial genomes. The arrows indicate the dates of publication for each of the completed genomes. The organism abbreviations are as follows: HAEIN, *Haemophilus influenzae*; MYCGE, *Mycoplasma genitalium*; SYNSP, *Synechocystis* PCC6803; METJA, *Methanococcus jannaschii*; MYCPN, *Mycoplasma pneumoniae*; SACCE, *Saccharomyces cerevisiae*; HELPY, *Helicobacter pylori*; ECOLI, *Escherichia coli*; METTH, *Methanobacterium thermoautotrophicum*; BACSU, *Bacillus subtilis*; ARCFU, *Archaeoglobus fulgidus*; BORBU, *Borrelia burgdorferii*; AQUAE, *Aquifex aeolicus*; PYRHO, *Pyrococcus horikoshii*; MYCTU, *Mycobacterium tuberculosis*; TREPA, *Treponema pallidum*; CHLTR, *Chlamydia trachomatis*; RICPR, *Rickettsia prowazekii*; PLAFA, *Plasmodium falciparum*; LEIMA, *Leishmania major*; CHLPN, *Chlamydia pneumoniae*; AERPE, *Aeropyrum pernix*; THEMA, *Thermotoga maritima*; DEIRA, *Deinococcus radiodurans*; CAMJE, *Campylobacter jejuni*; NEIMA, *Neisseria menigiditis*; VICHO, *Vibrio cholerae*. See color insert.

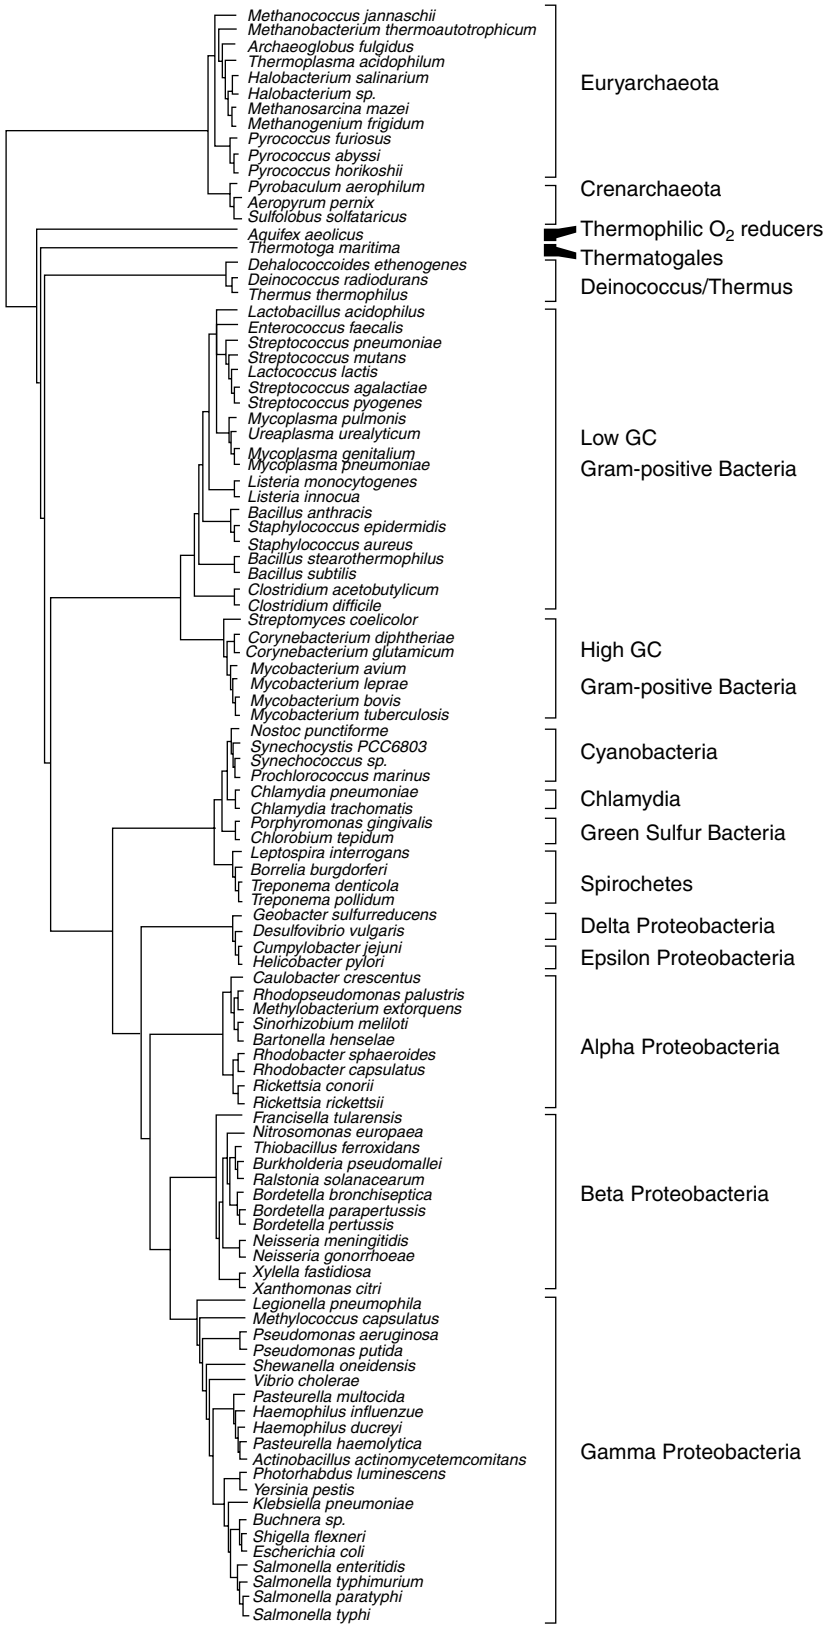

Figure 2. Phylogenetic tree based on 16S-rRNA sequences for each of the prokaryotic organisms whose complete genome sequence has been published (highlighted in green) and other organisms for which genome sequencing projects are underway (*http://www.tigr.org/tdb/mdb/mdb.html*). The major prokaryotic phylogenetic groupings are indicated to the right of the tree. The *archaea* are indicated in red and the *eubacteria* are indicated in blue. The phylogenetic tree was derived from sequences from the Ribosomal Database project (RDP) (*http://www.cme.msu.edu/RDP/html/index.html*) using Phylip (52) for tree construction. In some instances where the rRNA sequence of the particular strain was not available, the rRNA of a close relative was substituted. See color insert.

to be completed in the next 5 to 10 years. Additionally, chromosomes and genomes from eukaryotic model systems such as *Caenorhabditis elegans, Drosophila melanogaster*, and *Arabidopsis thaliana* have been published (2–4).

The current range of genome-sequencing projects includes representatives from all three domains of life. These genome projects provide good coverage of most of the major groupings within the *archaea* and *eubacteria*, as can be seen from a 16S-rRNA phylogenetic tree (Fig. 2). There is a relative concentration of sequencing projects on well-studied groups such as the γ-Proteobacteria and the low (GC) gram-positive bacteria. Other groupings such as the crenarchaeota are underrepresented. Another way to consider the type of microorganism being sequenced is by their ecological role. Considered in this manner, pathogenic organisms and organisms from extreme environments are well represented in current genome sequencing efforts. However, organisms of agricultural significance and difficult to culture organisms are currently relatively poorly represented. With the growing rate of genome sequencing, it is anticipated that these deficiencies will only be temporary.

The diversity in the representative organisms allows for comparative studies of individual organisms, as well as for comparative studies of genome composition, and gene organization within and across the domains. Insight has also been gained into how genes are acquired and shared between organisms (5,6), and the ability of bacteria to change their genome composition rapidly by capturing and maintaining mega plasmids (6,7). The later events have been suggested to increase the competitive nature of *Vibrio cholerae* in the aquatic ecosystem, which may be responsible for the dominance of this genus in such environments.

With each newly sequenced, annotated, and publicly released genome there is typically increased research activity surrounding the organism, and the genome data has resulted in some major achievements for the field of environmental microbiology. Examples of unusual bacteria with completed genome sequences that will continue to allow significant advances for microbial ecology include the only known aerobic hyperthermophilic archaeon, *Aeropyrum pernix* (8), the hyperthermophilic bacteria *Thermotoga maritima* (5) and *Aquifex aeolicus* (9), and the radiation-resistant bacterium *Deinococcus radiodurans* (7).

In these early days of genomics, a major challenge to the scientific community is both keeping up to date with the remarkable amount of genomic data being released, digesting away the "wheat from the chafe" for study, and determining how to best apply these data to science. This chapter will review the current status of the field of microbial genomics, discuss hypotheses being addressed in environmental microbiology by the use of genomic data, and give an overview of where the field is going.

MICROBIAL GENOME SEQUENCING AND ANNOTATION

For the complete sequencing of microbial genomes, the most efficient and cost-effective strategy has proven to be the random shotgun sequencing method (Fig. 3; 10). This approach has successfully been used to completely sequence microorganisms with varying genomic characteristics including variations in genome size (560 kb–6.2 Mb), base composition (19%–67% G + C), presence of various repeat elements, insertion sequence (IS) elements, and multiple chromosomal molecules and plasmids (6,7,11,12). In the random shotgun method, total DNA of the organism of choice is isolated, randomly sheared, size selected, cloned into a plasmid, and the ends of the clones are sequenced to give a predetermined level of coverage that represents the entire genome.

The theory for shotgun sequencing follows from the Lander-Waterman application of the equation for the Poisson distribution (13). On the basis of the Lander-Waterman model, and assuming an average sequence read length of 500 base pairs (bp) for a 2.0 Mbp genome, it would be necessary to sequence approximately 32,000 sequencing reactions to obtain eight-fold sequence coverage of the genome (Table 1). This approach, with an ideal library of

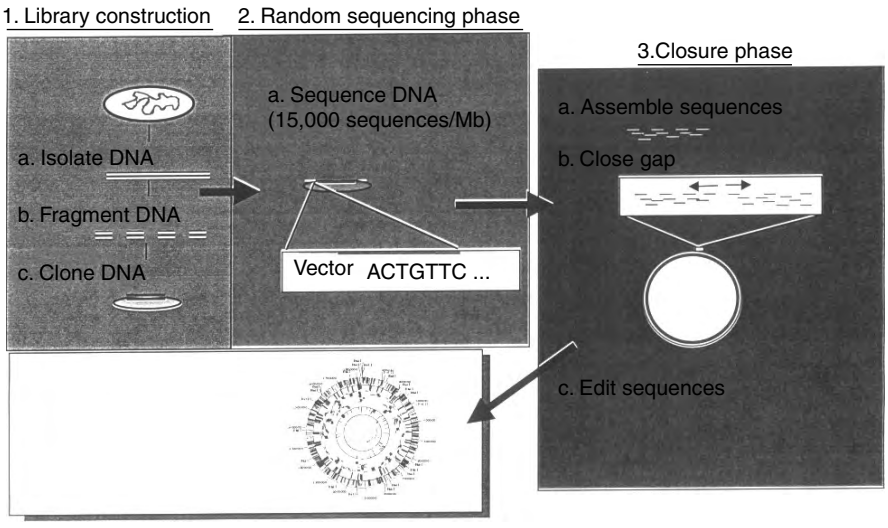

Figure 3. Strategy for random shotgun sequencing of microbial genomes. The first phase involves construction of small and large insert libraries with DNA from the organism of interest. The second phase involves the sequencing of random clones from the libraries to a predetermined level of coverage. The third phase involves assembling the random sequences into contiguous segments and subsequent gap closure. Finally, the completed sequence is annotated and published. See color insert.

Table 1. Computer Simulation of Random Sequencing where the Genome Size is 2.0 Mbp and Assuming an Average Sequence Read Length of 500 bp

Clones (n)	% Unsequenced	bp Unsequenced	Gaps	Av.Gap Length (bp)	Fold Coverage
5,000	28.65	573,010	1,433	400	1.25
10,000	8.20	164,170	821	200	2.5
15,000	2.35	47,035	353	133	3.75
20,000	0.67	13,476	135	100	5.0
25,000	0.19	3,861	48	80	6.25
30,000	0.06	1,106	17	67	7.5
32,000	0.03	671	11	63	8.0

random inserts and random clone selection, should result in approximately 11 gaps (regions of the genome with no sequence coverage) with a total length of about 700 bp of unsequenced DNA after the sequencing reactions have been assembled (Table 1). Note that in practice, more gaps are likely to occur because of repeat areas, secondary structures, and unclonable regions in the genome.

The successful construction of random libraries, with few no-insert and chimeric clones, is the most critical step for the generation of good representation of the entire genome during the random-sequencing phase. Once a sufficient number of sequences are generated, the sequences are retrieved to be assembled into contigs. Current systems for managing microbial sequencing projects are designed to automate data flow as much as possible, thereby reducing user error. These databases store and correlate information collected during the entire sequencing operation from library construction and template preparation to final analysis of the sequence.

After assembling the contigs, any remaining unsequenced regions of the DNA are closed by a combination of methods. Contigs that are linked by forward and reverse pairs become groups, and these clone-linked contigs can usually be closed by sequencing off a spanning clone, or by sequencing a polymerase chain reaction (PCR) product generated from primers designed at the ends of the contigs. Gaps for which there is no linking information are termed *physical gaps*, and are ordered by multiplex or combinatorial PCR (14), or optical maps. Spanning clones from large insert libraries that point off the ends of these contigs can also be used as linking information. These gaps are closed by sequencing the PCR products generated from the large insert clones, or from chromosomal DNA. Direct walking on bacterial DNA can also be used to close these gaps. All repetitive sequence regions including IS elements, ribosomal RNA (rRNA) regions or transposons are confirmed by walking spanning clones across the repetitive regions.

Completion of the sequencing phase does not represent the end of the project. Bioinformatic analysis of the completed genome is essential for interpreting and understanding the sequence data. This involves identification of all the genes and other features (tRNA, rRNA, repeated sequences, etc.) in the genome and subsequent analyses of these features. Gene prediction programs using Hidden Markov models (HMMs) or Interpolated Markov models (e.g., GLIMMER (15)), have proven effective at identifying microbial genes in an automated fashion. Biological names and functions are assigned where possible; assignments are being made by a combination of computer programs and human annotation/curation. Functional predictions are based both on traditional methods such as BLAST or FASTA searches against sequence databases, as well as approaches based on homologous families of proteins, such as HMMs, Pfams and COGs (16,17). In addition to the identification of all open reading frames (ORFs), annotation also involves the identification of intergenic regions, and novel features on the genome including nucleotide biases, origins of replication, and putative regions of horizontal gene transfer, repeat structures, insertion elements, and plasmids. More detailed analyses of the genomic sequence can allow for a reconstruction or complete description of the biology of the organism. See for example a recent reconstruction of the physiology and transport abilities of *V. cholerae* (Fig. 4).

A major problem encountered with the dissemination of genome data is cascading gene nomenclature error also known as transitive catastrophe error. This occurs when an overly ambitious gene name and biological function is assigned to an ORF with no experimental evidence. This incorrect gene assignment can then in turn be passed onto the next genome during annotation, and so on. This type of transitive error can be reduced in several ways; the first is by careful and consistent reannotation of genomes and consulting new computational models and phylogenomic methods for gene naming. It is critical that future ORF assignments take into account this potential problem.

THE ENVIRONMENTAL APPLICATIONS OF GENOMICS

In mid-2000, there are 28 published complete microbial genomes. These include those from five *Archaea* and 22 *Eubacteria* and yeast (see *http://www.tigr.org/tdb/mdb/mdb.html*; Figs. 1 and 2). Currently, sequencing efforts exist worldwide for at least 90 additional microbial genomes. This availability of genomic data from a diverse assemblage of organisms allows scientists to address numerous specific hypotheses. However, and perhaps more importantly, these data increase the ability to consider the larger picture of the mechanisms and regulation involved with a microorganism and how it interacts with its environment. Also, in combination with functional genomics, the genome sequence and annotation information allows for better modeling of an organism's global response to changes in its ecosystem. As a result,

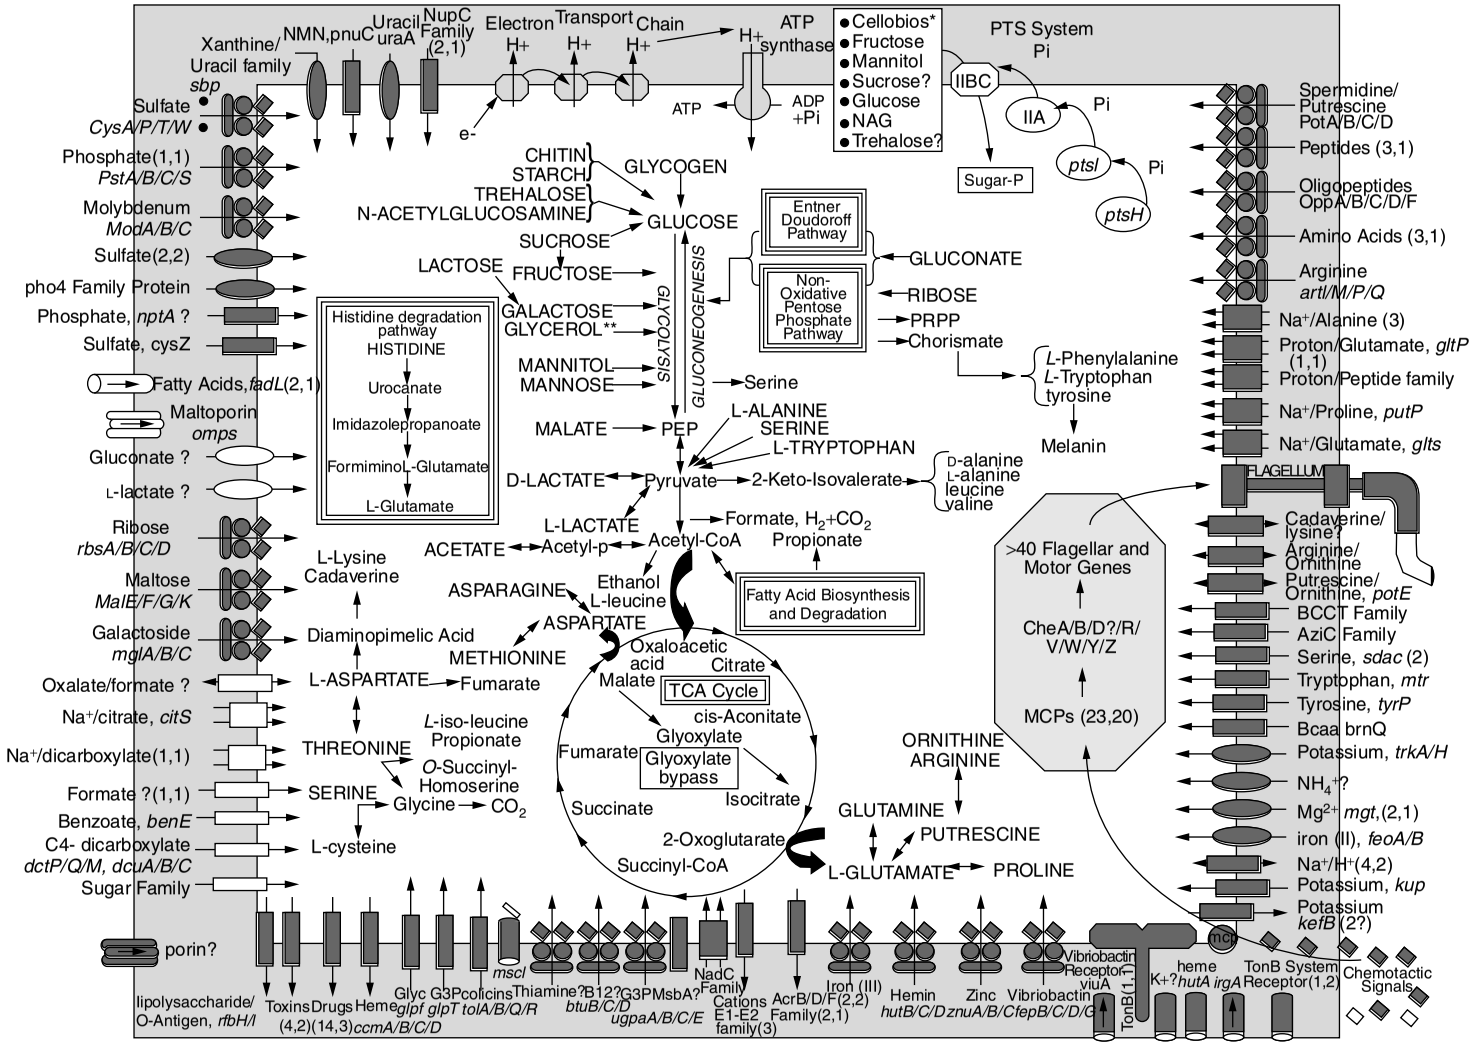

Figure 4. (*Continued*)

Table 2. Current and Past Genome-Sequencing Projects for Environmentally Significant Organisms

Archaea	Size (Mbp)	Completion	Significance*
Aeropyrum pernix	1.67	1999	Aerobic hyperthermophile, biotech.
Archaeoglobus fulgidus	2.18	1997	Hyperthermophile, sulfate reducer, oil well problem, biotech.
Halobacterium sp.	2.50	—	Halophile, biotech.
Halobacterium salinarium	4.00	—	Halophile, biotech.
Methanococcus jannaschii	1.66	1996	Hyperthermophile, methanogen, biogas production, biotech.
Methanococcus maripaludis	?	—	Mesophile, methanogen, biogas production, biotech.
M. thermoautotrophicum	1.75	1997	Hyperthermophile, methanogen, waste digestion, biotech.
Methanogenium frigidum	?	—	Psychrophile, methanogen.
Methanosarcinia mazei	2.80	1999	Hyperthermophile, methylotroph, biogas production, biotech.
Pyrobaculum aerophilum	2.22	2000	Hyperthermophile, sewage digestion, biogas production, biotech.
Pyrococcus abyssi	1.80	1999	Hyperthermophile, biotech.
Pyrococcus horikoshii	1.80	1998	Hyperthermophile, biotech.
Pyrococcus furiosus	2.10	—	Hyperthermophile, biotech.
Sulfolobus solfataricus	3.05	—	Hyperthermophile, sulfur-reducer, biotech.
Thermoplasma acidophilum	1.70	—	Thermophile, sulfur-oxidizer, biotech.
Bacteria			
Aquifex aeolicus	1.50	1998	Hyperthermophile, biotech, evolution, chemolithoautotroph.
Bacillus halodurans	4.25	1999	Alkaliphilic, deep-sea adaptations, industrial applications.
Bacillus subtilis	4.20	1997	Industrial applications.
B. stearothermophilus	?	—	Extracellular xylanases.
Caulobacter crescentus	3.80	2000	Cell cycle regulation.
Chlorobium tepidum	2.10	2000	Photosynthetic, evolutionary implications.
Clostridium acetobutylicum	4.10	—	Solvent production.
Clostridium thermocellum	?	—	Degradation of plant polysaccharides.
C. glutamicum	3.10	—	Amino acid biosynthesis.
Deinococcus radiodurans	3.20	1999	Radiation resistance, environmental clean up.
D. ethenogenes	1.50	2000	Tetrachloroethene degradation.
Desulfovibrio vulgaris	1.70	2000	Microbial transformation of sulfites.
Geobacter sulfurreducens	2.50	2000	Iron reduction.
Nitrosomas europaea	2.20	—	Nitrite removal.
Photorhabdus luminescens	5.50	2000	Biological insecticides.
Pseudomonas putida	6.20	2000	Pollution control, bioremediation.
Rhodobacter capsulatus	3.70	2000	Photosynthetic.
Rhodobacter sphaeroides	4.34	—	Photosynthetic.
Shewanella oneidensis	4.50	2000	Metal reduction.
Streptomyces coelicolor	8.00	2000	Makes 66% of all natural antibiotics.
Synechocystis sp.	3.57	1996	Photosynthetic.
Thermotoga maritima	1.86	1999	Hyperthermophile, evolution, bioremediation, biotech.
Thermus thermophilus	1.82	2000	Thermophile, biotech.
Thiobacillus ferrooxidans	2.90	2000	Iron reduction.

Note: Hyperthermophiles grow at or above 90 °C. Psychrophiles grow below 18 °C. Abbreviations: *B. stearothermophilus, Bacillus stearothermophilus; C. glutamicum, Corynebacterium glutamicum; D. ethenogenes, Dehalococcoides ethenogenes; M. thermoautotrophicum, Methanobacterium thermoautotrophicum*.

Figure 4. (*continued*) Reconstruction of transport and metabolism of *V. cholerae* on the basis of the annotated genome sequence. Pathways for energy production and the metabolism of organic compounds, acids and aldehydes are shown. Transporters are grouped by substrate specificity: cations (green), anions (red), carbohydrates (yellow), nucleosides, purines, and pyrimidines (purple), amino acids/peptides/amines (dark blue), and other (light blue). Question marks associated with transporters indicate a putative gene, uncertainty in substrate specificity, or direction of transport. Permeases are represented as ovals, ABC transporters are shown as composite figures of ovals, diamonds, and circles, porins are represented as three ovals, the large-conductance mechanosensitive channel is shown as a gated cylinder, other cylinders represent outer membrane transporters or receptors; all other transporters are drawn as rectangles. Export or import of solutes is designated by the direction of the arrow through the transporter. If a precise substrate could not be determined for a transporter, no gene name was assigned and a more general common name reflecting the type of substrate being transported was used. Gene location on the two chromosomes, for both transporters and metabolic steps, is indicated by arrow color: all genes located on the large chromosome (black), all genes located on the small chromosome (blue), all genes needed for the complete pathway on one chromosome, but a duplicate copy of one or more genes on the other chromosome** (purple), required genes on both chromosomes (red), complete pathway on both chromosomes (green). Gene numbers on the two chromosomes are in parenthesis and follow the color scheme for gene location. Substrates underlined and capitalized can be used as energy sources. Abbreviations: PRPP, phosphoribosyl-pyrophosphate; PEP, phosphoenolpyruvate; PTS, phosphoenolpyruvate-dependant phosphotransferase system; ATP, adenosine triphosphate; ADP, adenosine diphosphate; MCP, methyl-accepting chemotaxis protein; NAG, N-acetylglucosamine; G3P, glycerol-3-phosphate; glyc, glycerol; NMN, nicotinamide mononucleotide. *Because *V. cholerae* does not use cellobiose, we expect this PTS system to be involved in chitobiose transport. **Complete pathways, except for glycerol, are found on the large chromosome. See color insert.

genomic data mining is likely to become one of the most powerful molecular tools available. The following sections look at various aspects of environmental biology and describe some of the relevant genome-sequencing projects that are expected to impact on these areas (Table 2).

UNDERSTANDING PHYLOGENY AND EVOLUTION

Horizontal Gene Transfer and Acquired Genes

Initial analyses of genomic data across the sequenced microorganisms suggest that single universal phylogenetic trees (e.g., Fig. 2) may not be the best way to depict relationships among organisms (18). Instead a net-like pattern that reflects the frequency and significance of horizontal lateral gene transfer has been proposed (18). Complete genome sequences of a number of environmental and pathogenic microorganisms, including closely related *Pyrococcus* sp. and *Chlamydia* sp. have shown significant differences in genome structure, organization, and composition (19,20). A very recent example of lateral gene transfer has been shown from the genome sequences of the two hyperthermophilic archaea *Pyrococcus furiosus* and *Thermococcus litoralis* (21). Both organisms share a 16-kb region on their genomes that contains only 173 nucleotide differences from one to the other; the 16-kb insert in *P. furiosus* is flanked by insertion elements with inverted and direct repeats. These transposable elements were proposed to be the mechanism for the exchange of this 16-kb segment between these two archaea (21).

Analysis of the *T. maritima* genome sequence suggested that almost one quarter of the genome was acquired by lateral gene transfer with the thermophilic archaea. There was also extensive conservation of gene order between *T. maritima* and the archaeon that it shared the highest level of similarity with (5). These acquired genes probably convey some selective advantage to these thermophiles, or alternatively may not be detrimental to the organism and have subsequently ameliorated into the genome. Lawrence and Ochman (22) have attempted to calculate time frames for lateral gene transfer in *Escherichia coli*. They have concluded that subsequent to the divergence of *E. coli* and *Salmonella* (100 million years ago), 10% of the *E. coli* genome was acquired in more than 200 events of lateral gene transfer. Their data also suggest that a significant percentage of *E. coli* might have been acquired recently, at an average rate of 16 kb per million years (22).

Clearly, the comparisons of various genome sequences in parallel with new methods for analyzing this data, has and will continue to provide fundamental insight into evolution. This is particularly significant for the archaea that inhabit the extremes of temperature and anaerobic conditions for life.

Captured Megaplasmids

Another mechanism for an environmental bacterium to rapidly change its overall genomic content is by capturing a megaplasmid and all the associated genes. Required genes can be moved from the chromosome to the megaplasmid, thus making the captured megaplasmid essential for the survival of the cell, and thereby stabilizing this new replicon. This model was proposed for the small chromosome of *V. cholerae* (6). In this case, the genome sequence analysis suggests that the smaller replicon was captured by an ancestral *Vibrio* subsequent to travelling through a broad range of hosts. The capture of this megaplasmid, which presumably contained genes that gave the ancestral *Vibrio* a competitive advantage in its ecosystem, resulted in it being stabilized by the transfer of essential genes to this replicon.

In addition to containing genes that make the cell more competitive, second chromosomes (and megaplasmids) may increase survivability and speed recovery from hostile environmental conditions. Such situations have been suggested from analysis of the small chromosomes from *D. radiodurans* and *V. cholerae*. For *D. radiodurans*, it appears that the small chromosome may have genes involved in de novo synthesis and importing precursors (7). For *V. cholerae*, the small chromosome has been suggested to help cells survive in biofilms and as a suggested model to help explain the VBNC (viable but nonculturable) state.

BIOREMEDIATION

Hope for Mixed Waste Sites Exposed to Radiation

The potential remediation of radioactive waste sites has driven much of the focus on the recently sequenced *D. radiodurans* as a model organism. *D. radiodurans* is the most radiation-resistant organism known, capable of surviving exposure to ionizing radiation doses of 15,000 Gy. The completed *D. radiodurans* genome sequence, however, gave little insight into the extreme ionizing radiation resistance of this organism. In addition to the earlier-mentioned radiation resistance, the bacterium reduces Fe(III)-nitrilotriacetic acid coupled to the oxidation of lactate to CO_2 (carbon dioxide) and acetate. *Deinococcus radiodurans* can also reduce uranium and technetium in the presence of humic acids or synthetic electron shuttle agents (23).

Mutant strains of *D. radiodurans* expressing the cloned mercury resistance gene (merA) from *E. coli* have recently been developed (24). These mutant strains reduce Hg(mercury) (II) to volatile elemental mercury, which is less toxic. The strains also grow in the presence of both radiation and ionic mercury at concentrations well above those found in radioactive waste sites. Recombinant *D. radiodurans* expressing toluene dioxygenase have also been constructed (25), the recombinant bacterium able to oxidize toluene, chlorobenzene, 3,4-dichloro-1-butene, and indole. The bacterium is capable of producing the toluene dioxygenase in a highly irradiating environment. The above studies support the potential use and practical applications of engineered *D. radiodurans* for bioremediation of mixed wastes exposed to radiation.

A Better Understanding of Metal Oxidation/Reduction

Shewanella oneidensis is a model organism for a comprehensive understanding of bioremediation of metal-contaminated sites. This bacterium grows both aerobically and anaerobically, acting as a metal reducer in its anaerobic phase. Iron oxides are specific substrates, so

competition for the electron acceptor is minimal and in a stratified aquatic environment, reduced iron will diffuse upward into the overlying oxic zone and be oxidized, and then return to the anoxic zone through gravity, thus acting as a "pump" for oxidizing equivalents.

Geobacter sulfurreducens is a dissimilatory metal-reducing microorganism and sulfur-reducing microorganism isolated from surface sediments (26). This bacterium grows in a defined medium with acetate as an electron donor and ferric PPi, ferric oxyhydroxide, ferric citrate, elemental sulfur, Co(cobalt) (III)-EDTA (ethylenediaminetetraacetic acid), fumarate, or malate as the sole electron acceptor. It also couples the oxidation of hydrogen to the reduction of Fe(iron) (III). The genome sequence will undoubtedly increase our understanding of the mechanisms that this organism utilizes to reduce metals and give insight into other novel pathways that it may have.

Biodegradation of Halogenated Aliphatic Compounds, PCBs, and Ground Water Pollutants

Many sites of environmental concern contain groundwater contaminated with nonaqueous phase liquids, dry cleaning, and degreasing solvents. Tetrachloroethene, for example, is a groundwater contaminant often persisting in subsurface environments. It is recalcitrant under aerobic conditions and is not readily susceptible to oxidation. *Dehalococcoides ethenogenes* strain 195, which is currently being sequenced, is the only organism so far isolated that dechlorinates tetrachloroethene all the way down to ethylene (27,28). This bacterium is therefore capable of degrading dry-cleaning, and degreasing solvents that pollute ground waters.

Nylon-6 is another man-made polymer used in the manufacture of car tires, fabrics and automobile parts (29). The unreacted monomer used in its synthesis (epsilon-caprolactam) can be found in wastewater generated during production of nylon-6. Epsilon-caprolactam can, however, be degraded by *Pseudomonas aeruginosa* (MCM B-407), an organism that was first isolated from activated sludge used to treat waste from a factory producing nylon-6. Other *P. aeruginosa* strains have demonstrated abilities to degrade 2,4,6-Trinitrotoluene (TNT) (30) that can accumulate in the environment as a result of the manufacture of explosives. *P. aeruginosa* strains that can utilize gasoline as the sole carbon source have been isolated from gasoline-contaminated aquifers (31). *Pseudomonas putida* can mineralize numerous organic wastes and pollutants including many ring-based compounds. Chromate, a widespread environmental contaminant can be converted to the insoluble and less toxic Cr(III) by the novel chromate reductase from *P. putida*. The genome sequence is expected to reveal additional previously uncharacterized pathways for the degradation of environmental contaminants.

In wastewater systems, the microbial removal of ammonia commences with ammonia oxidation to nitrite, and the resulting nitrate being reduced to molecular nitrogen. The individual steps are carried out by nitrifying and denitrifying bacteria, respectively. *Nitrosomonas europaea* has been shown to efficiently remove nitrogen from various wastewaters. An additional benefit is that this organism can conduct ammonia-stimulated aerobic transformation of halogenated aliphatic compounds including dichloromethane, dibromomethane, trichloromethane, bromoethane, ethylene dibromide, vinyl chloride, trichloroethylene, and 1,2,3-trichloropropane (32).

INDUSTRIAL APPLICATIONS

New Enzymes for Degradation of Refractory Carbohydrates

The complex plant polymers cellulose and xylan are recalcitrant to degradation, but a diversity of organisms and enzymes have been identified, which are capable of degrading these polymers that are based on glucose and xylose, respectively. The recently completed *T. maritima* is known to have an extensive ability to degrade both simple and complex plant polymers. On the basis of the genome sequence, numerous other proteins likely involved in plant polymer degradation were identified. Similarly, *Clostridium thermocellum* contains a cellulosome, a large multienzyme complex that allows for adherence to plant surfaces and initiates plant cell wall degradation. The complete sequence will no doubt reveal other mechanisms associated with the efficient degradation of plant cell walls by aerobic bacteria. *Bacillus stearothermophilus* produces an extracellular xylanase that is thermostable and alkaline tolerant that can bleach pulp optimally at pH 9 and 65 °C. This enzyme has successfully been used in large-scale biobleaching mill trials.

Chitin is a carbohydrate polymer that consists of alternating β-1, 4-linked *N*-acetylglucosamine residues. Estimates are that more than 10^{11} metric tons of chitin are produced annually (33), making chitin the second most abundant organic compound in nature. *Vibrio cholerae* is an autochthonous aquatic organism that can grow with chitin serving as the sole carbon and nitrogen source. *Bacillus halodurans* is an alkaliphilic bacterium that produces keratin-decomposing enzymes, which devolve keratinous proteins including hair, nail, and feathers.

Natural Production of Solvents, Drugs, and Insecticides

Clostridial acetone-butanol fermentation by *Clostridium acetobutylicum* is one of the largest biotechnological processes known, and there is a significant potential for the use of cheap agricultural wastes as novel substrates. Many continuous culture methods have been successfully established that would allow for various substrates to be used to generate solvents produced by microorganisms.

Streptomycetes are used to produce the majority of antibiotics applied in human and veterinary medicine and agriculture. They also have an interesting mycelial, sporulating life cycle, which involves complex regulation of gene expression in space and time. The genetic control of antibiotic and enzyme production is both temporally and causally related to the morphological differentiation (34). The Sanger Centre (*http://www.sanger.ac.uk/*) is currently sequencing the model streptomycete *Streptomyces coelicolor* A3 (2). Elucidation of the *S. coelicolor* sequence should help clarify the complex genetic and metabolic

regulation of antibiotic production. Comparative genomic analyses of the streptomycetes may assist in genome engineering of *Streptomyces* sp. to make polyketide antibiotics more efficiently and to create novel secondary metabolites.

Novel biological insecticides have been cloned from *Photorhabdus luminescens*, a gram-negative bacterium belonging to the *Enterobacteriaceae*. This bacterium is mutualistic with certain nematodes and can kill the insect by a combination of toxin action and direct infection (35). Initial studies have highlighted that this bacterium can be used to produce insecticides, and present an alternative mechanism to concerns arising from the use of transgenic crops that express toxin genes from *Bacillus thuringiensis*.

Improving Oil Well Productivity

Archaeoglobus fulgidus (36) is a sulfate reducer that has been associated with the contamination of oil wells. The organism serves as a model for understanding corrosion and the souring of hydrocarbon reserves. Inhibition of certain essential biochemical pathways can disrupt its normal metabolism, and therefore limit its detrimental effects in the environment. The genome sequence revealed numerous pathways, which could serve as candidates for initial inhibitory studies.

UNDERSTANDING ENVIRONMENTAL PATHOGENESIS

Several environmental bacteria have also acquired the capacity to cause serious human disease. Notable bacteria that have had their genome sequenced that fall into this category include *V. cholerae* and *P. aeruginosa*. The genome sequence of these environmental pathogens allows for a more complete understanding of how environmental bacteria emerge to become significant human pathogens. For example, although *V. cholerae* is the etiological agent of cholera, it is also an autochthonous aquatic organism. This bacterium seems to have achieved its human pathogenicity in several different mechanisms. These include the chromosomal integration of a filamentous phage (CTXϕ) containing the cholera toxin genes, and other recently acquired regions of DNA (the VPI or vibrio pathogenicity island). Both of these reside on the large chromosome and have a trinucleotide composition that is significantly different from the rest of the *V. cholerae* genome. Also, the small chromosome (apparently a captured megaplasmid) contains an integron island to allow additional gene capture and several of the ORFs in this region maybe important to pathogenicity (e.g., drug resistance genes and virulence factors).

Additionally, genome analysis offers evidence to evaluate genes implicated in human pathogenicity. The maltose-sensitive hemagluttinin (MSHA) was originally implicated in intestinal colonization; however, recently several investigators have reported that MSHA is not required for intestinal colonization, but instead is important in biofilm formation. Therefore, MSHA maybe more important in the "environmental fitness" of *V. cholerae* rather than pathogenic potential. Interestingly, this gene cluster does not appear to be recently acquired (i.e., there are no integrase, transposase, or phage homologs that might suggest an origin other than *V. cholerae*), and the trinucleotide composition is similar to the rest of the chromosome. These genome analysis tools lend evidence to these genes being with *V. cholerae* longer than the other pathogenicity genes, and thereby suggest their greater importance in the environmental aspects of this bacterium rather than the pathogenic.

AS ENVIRONMENTAL MODEL SYSTEMS

Although the many applications from the genomics sequence are evident, the environmental organism also acts as a model organism for understanding how many systems function. For example, *Caulobacter crescentus* currently being sequenced at The Institute for Genomic Research (TIGR), stands out as a model organism for increasing our understanding of life cycles that include an asymmetric cell division and an obligate cell differentiation. With each cell division, a motile but replication-inert swarmer cell and a sessile replication-competent stalked cell are generated. Although the stalked cell immediately reinitiates DNA replication and cell division, the swarmer cell remains motile and chemotactically active for a period of the cell cycle before it differentiates into a stalked cell. Motility is lost by ejecting the flagellum, a stalk is synthesized, and the swarmer eventually initiates chromosome replication and cell division. Development phases in this bacterium appear to be controlled in part by localized cues that control morphological changes and cell cycle progression (37). Additionally, Caulobacters are biofilm-forming members of the natural flora of soil and aquatic environments, which exhibit several characteristics that make them attractive for development of high surface area microbial bioreactors or biosensors. Other microorganisms recently or currently being sequenced, which stand to give insight into particular metabolic processes include *Bacillus subtilis*: a model system for understanding sporulation, *Chlorobium tepidum*: for understanding the origin of photosynthesis; *Desulfovibrio vulgaris*: for understanding sulfate respiration; and *Methanobacterium thermoautotrophicum*: for understanding methane production and single carbon metabolism.

WHAT THE FUTURE HOLDS IN STORE

Functional Genomics

The elucidation of complete genome sequences has led to the development of new fields of research in the area of functional genomics. The term *functional genomics* is widely used but somewhat ill defined. One possible definition is that functional genomics uses high-throughput or large-scale approaches that investigate the roles of large numbers of genes or proteins in a systematic fashion rather than more traditional approaches that investigate the role of a single gene or protein. This definition includes areas such as microarray expression analysis, large-scale gene knockouts and high throughput phenotypic screening, structural genomics and proteomics.

DNA array technology, more colloquially known as *gene chips*, can be used to measure expression patterns

of thousands of genes in parallel. This technology involves the immobilization of large numbers of PCR fragments or oligonucleotides, typically corresponding to all of the genes from a particular organism, onto a support matrix (glass slide, nylon membrane, or silica chip). This can then be probed with fluorescently labeled mRNA isolated from cells grown under different conditions to examine gene expression or with DNA from different strains or isolates to look at environmental variability. The use of arrays reduces a dependence on extensive biochemical analyses to identify the functions of unknown genes. Although comparisons of genome sequences allows for a prediction of enzyme activity, arrays can provide a more reliable identification of genes associated with particular pathways. By increasing our understanding of gene function, arrays ultimately allow for new and more accurate classification schemes.

A complementary approach to that of microarray expression are proteomic studies using two-dimensional gel electrophoresis to examine protein production and localization. Traditional two-dimensional gel electrophoresis methods used Edman degradation methods of peptide sequencing for identification of protein spots on gels. A more sensitive and automated approach, MALDI TOF (Matrix Assisted Desorption/Ionization-Time of Flight) Mass Spectrometry, enables high throughput screening of protein samples derived from two-dimensional gel electrophoresis (38). Using such an approach it starts to become practical to undertake whole proteome analysis studies for completely sequenced microbial organisms.

Complete genome sequences also enable large-scale gene knockout studies either through use of saturation transposon mutagenesis and identification of the transposon insert sites by sequencing, or by making targeted gene knockouts (39,40). The construction of such knockouts enables the presumptive identification of essential genes, and enables the generation of large banks of gene mutants, whose phenotypes can be examined using high throughput screening processes such as Biolog plates (41). One example of a large-scale gene knockout study was the transposon mutagenesis of *Mycoplasma genitalium* and *Mycoplasma pneumoniae*, to identify nonessential genes under laboratory growth conditions (40). As *M. genitalium* has the smallest known microbial genome with only 480 protein-encoding genes, this approach indicated that only approximately 265 to 330 of these genes were essential for growth under the conditions examined, thus providing an estimate of the minimal genome required for life.

The area of structural genomics deals with high throughput protein structure determination, involving gene overexpression, protein purification, and subsequent structural determination using X-ray crystallography or NMR (nuclear magnetic resonance) spectroscopy (42). This approach works on the assumption of being able to deduce information on the function of unknown proteins based on their structure. Current structural genomic projects are focussing on determining the structures of representative members of different protein families whose members are not predicted to conform to any currently known structures with the aim of identifying all of the possible protein folds in nature. Currently, such studies are only in preliminary or formative phases, and this approach is problematic for membrane proteins that are typically recalcitrant to crystallization and frequently too large for NMR-based approaches.

GENOMIC ENGINEERING

The ability to release genetically modified microorganisms for environmental remediation is still under debate. However, numerous examples of successfully engineered microorganisms exist and will continue to increase as we elucidate new pathways from completely sequenced or newly identified organisms. The genetically engineered *E. coli* cells manipulated to express mercury transport systems (43) effectively accumulated the toxin and were thought to have excellent properties for bioremediation of mercury-contaminated environments. The gene for toluene dioxygenase has recently been inserted into the chromosome of *D. radiodurans* (25), and the recombinant bacterium degrades toluene and other organic compounds in high-radiation environments. A synthetic acetone operon derived from *C. acetobutylicum* genes was constructed and introduced into *E. coli*. Ace4 was expressed in *E. coli* and demonstrated the ability to use clostridial genes in nonclostridial hosts for solvent production.

Improvements in our ability to engineer microorganisms to synthesize molecules, to have desired biodegradative pathways, and to increase and optimize enzyme activity will continue to reveal the potential applications from genomics for environmental microbiology.

BIOINFORMATICS APPLICATIONS

Databases

As more genomes are discovered, the amount of data being generated is enormous. To make reasonable use of this data, researchers should be able to easily compare data among these organisms. To do this, databases that can be openly accessed by the research community and that can be easily queried must be available. A variety of second generation biological databases have been developed, which address particular demands resulting from the mountain of genomic data. An increasingly important feature of databases such as the Omnione and Ecocyc is that they incorporate detailed manual curation of the data in addition to sophisticated automated analysis. Examples of such bioinformatic databases are described later.

TIGR's comprehensive microbial resource (CMR) (*http://www.tigr.org/*) enables intergenomic and intragenomic comparisons of microbial genomes. The CMR contains a variety of tools for querying the Omnione database, which incorporates the detailed curated genome dataset from each of TIGR's microbial genome projects as well as the original annotation and further automated annotation by TIGR for all of the non-TIGR microbial genome-sequencing projects. Thus, the CMR allows comparison between genomes based on role categories, protein families, best matches, and other criteria, and enables complex queries based on a variety of features.

Interpro (*http://www.ebi.ac.uk/interpro/*) presents an integrated database based on SwissProt, TrEMBL, Pfam, PRINTS, and PROSITE, and thus includes data on proteins, protein families, and domains/motifs, thereby proving useful for proteome analyses of completed genomes and for predicting protein structure and function.

The Ecocyc database (*http://ecocyc.PangeaSystems.com/ecocyc/*) is an *E. coli*–specific database that combines functional and bioinformatic information describing the metabolic pathways, signal transduction, membrane transport, and gene regulation of *E. coli* (44). Each of the proteins and enzymes in *E. coli* is annotated in detail, including references to the original literature. Thus, Ecocyc acts both as an online review article and a qualitative model of the *E. coli* biochemical machinery. The Pathway Tools graphical user interface provides a wide variety of query operations and visualization tools. The related MetaCyc database is a more generalized metabolic-pathway database that describes pathways and enzymes of many different organisms (44). Other metabolic databases include WIT (*http://wit.mcs.anl.gov/WIT2*) (45) and KEGG (*http://kegg.genome.ad.jp/kegg/*) (46). Such metabolic databases are valuable in metabolic reconstruction of pathways in newly sequenced genomes.

Orthologs are genes in different organisms that evolved from a common ancestral gene by speciation, and paralogs are homologous genes that are diverged by gene duplication (47) and hence may have diverged in function. Accurate functional predictions of protein function are increasingly dependent on methods that take into account assignment of orthologs and paralogs within families of homologous proteins. Phylogenetic approaches are particularly valuable for determining orthology. Other family-based approaches for identifying orthologs and paralogs include the COG database (*http://www.ncbi.nlm.nih.gov/COG*) (17) and Pfam database (*http://www.sanger.ac.uk/Software/Pfam/*) of protein family sequence alignments and Hidden Markov models (16).

COMPARATIVE GENOMICS

Comparison of the Transport Capabilities of Microorganisms

The availability of complete genome data enables systematic genomewide comparisons to provide insight into the overall physiology of each organism. Comparison of 76 families of cytoplasmic membrane transport systems in each completely sequenced microbial genome (48–50) provides one example of such a comparative genomic approach. The overall numbers of membrane transporters was found to vary over 15-fold between organisms, but was generally proportional to the genome size of the organism. The transport bioenergetics matched the overall mode of energy generation in each organism. For example, organisms such as the mycoplasmas and spirochetes, which lack a TCA cycle and an electron transfer chain and hence can only generate a proton motive force by substrate-level phosphorylation, were highly dependent on ATP-dependent rather than proton-dependent transporters, whereas the converse was true of more metabolically versatile organisms such as *E. coli*.

The overall transport substrate specificities were found to correlate with the organisms lifestyles, that is, with the concentration and diversity of nutrients in their particular ecological niche. For instance, organisms from deep marine environments were found to possess only a limited array of transporters for organic nutrients but a preponderance of transporters for inorganic cations and anions, which presumably reflects the availability of these substrates in this environment. Similarly, intracellular parasites, such as the chlamydias and *Rickettsia prowazekii*, have an extensive set of transporters for amino acids and nucleotides, but little ability to transport free sugars, which almost certainly reflects the relative accessibility of these compounds in an intracellular environment.

Thus comparative analysis of transporters appears to provide insights into both the physiology of the organism and the environment in which it dwells. It is anticipated that such comparative genomic studies will become increasingly pertinent as complete genome data becomes available for representative organisms from different phylogenetic lineages and different lifestyles or environments.

Unknowns and Conserved Hypotheticals

It is important to note that for each completed genome sequence project, an average of 40 to 50% of the ORFs in the genome is either shared with other organisms but has not been previously characterized (conserved hypothetical), or is completely unknown (unique) (Table 3). One major challenge remains in the elucidation of these unknowns and conserved hypotheticals. Hopefully the use of microarrays, in combination with proteomic studies and other functional genomic approaches (see earlier) will accelerate the rate at which we can begin to characterize these ORFs. Undoubtedly, many of these unknown genes will prove to have interesting or important functions relevant to environmental microbiology.

EXPLORING MICROBIAL DIVERSITY ON EARTH

Nonculturable Microorganisms and Genomic Potential

One of the most exciting future steps for genomics is the analysis of the huge population of uncultured microorganisms. To date, studies on unculturable bacteria have been primarily limited to phylogenetic analysis based on 16S-rRNA sequence and enumeration of specific 16S-rRNA containing cells. These methods have greatly increased our knowledge of the phylogenetic diversity of many ecosystems, but they do not allow accurate determination of the functional niche these microorganisms occupy. On the basis of 16S-rRNA sequence, the only way that biogeochemical function can be assigned to an uncharacterized organism is by relatedness to cultured bacteria. However, environmental genomics confers the ability to examine both the biogeochemical capabilities of uncultured bacteria (genomic potential) and what specific genes and metabolic pathways are being

Table 3. Comparison of Total Number of Predicted Open Reading Frames (ORFs), ORFs of Unknown Function, and ORFS Unique to Each Organism for Each of the Completed Genomes

Organism	ORFS	Unknowns	Uniques
Aeropyrum pernix K1	2694	523(19%)	1538(57%)

expressed in response to changes in the environment (functional genomics, see earlier).

To determine the genomic potential of an environment, the DNA from the environment is isolated, cloned into large (100 Kbp) bacterial artificial chromosomes (BAC), and these BACs are sequenced to closure. These BACs can then be annotated similarly to an entire microbial genome (i.e., genes found and roles assigned, RNAs found, etc.). Although this does not necessarily give the genome of any single uncultured bacterium, the gene content of the BACs can give an idea of what important biogeochemical processes may be going on in an environment. From end-sequencing and annotation of 450 BACs derived from Monterey Bay surface water DNA extraction, several interesting results can be seen (DeLong and Heidelberg, in preparation). Most of the Monterey Bay BACs have greatest amino acid sequence similarity to *R. prowazekii*, and α-Proteobacteria, the same group that comprises the greatest percentage of the 16S-rRNA sequences in this ecosystem (Fig. 5). Also, by comparing the functional roles of genes identified from the Monterey Bay BAC sequences to the complete gene complement of *V. cholerae*, it can be seen that the representative set of BACs tend to have a greater percentage of genes involved in amino acid biosynthesis, purines, pyrimidines, nucleosides, and nucleotides, and protein synthesis (likely a result of smaller genome size), whereas *V. cholerae* has a greater percentage involved in transport and binding, regulatory functions, and cellular processes proteins, possibly because *V. cholerae* needs to be competitive in a greater diversity of environments that the microorganisms inhabiting the Monterey Bay surface water (Fig. 6). Such methodologies may also prove valuable commercially because of the large potential for new gene discovery. This also has the advantage of providing a mechanism for expressing genes from unculturable organisms in alternative hosts such as *E. coli*.

Use of Subtractive Hybridization Methods to Identify Differences Among Environmental Strains

Despite the indisputable value associated with whole genome sequencing, it is often cost-prohibitive to obtain sequence data for multiple strains of the same microbe, or for related species. Alternatively, gene diversity and genome plasticity can be examined in related microbes through the use of suppressive subtractive hybridization. Suppressive subtractive hybridization was developed by CLONTECH and kits have been optimized for use with genomic DNA and cDNA. For genomic differences, genomic DNA from the strain of interest (tester) and the strain to subtract with (driver) is fully digested using a frequent cutter. The fragments that are obtained average between 250 and 2,000 bp. Following a series of reactions, complexes of unique DNA's containing different adaptors at either end allow for logarithmic amplification. A nested PCR is run using a small amount of the primary PCR product as template, to give a final product that is highly enriched for unique DNA's. Unique regions can be further characterized to identify the unique metabolic characteristics of individual strains or species. This method has been used to identify unique regions in the closely related species of *Helicobacter pylori* (51) and *P. putida*. The differences are likely a reflection of the environmental niche that individual

species occupy. Having at least one completely sequenced genome of the organisms of choice is invaluable to the successful interpretation of the data generated from this procedure.

CONCLUSION

Complete genome sequences have increased abilities to address biological questions. The field of genomics

continues to expand, and each new sequence gives insights into genome organization, gene regulation, gene content, novel genes, and gene families, and the many biochemical pathways that reside in these organisms. Although many unknown and conserved hypothetical proteins remain to be characterized, techniques for meeting these challenges are being continuously developed. Sequence information and functional genomic studies continue to lead the identification of enzymes with unique properties, physiological adaptations, evolution of genes and gene families, polypeptide structure–function relations, and metabolic regulation. The development of new and improved activities in these organisms will be possible using current gene technology.

GEOCHEMICAL AND GEOLOGICAL SIGNIFICANCE OF SUBSURFACE MICROBIOLOGY

TULLIS ONSTOTT
Princeton University
Princeton, New Jersey

The concentration and isotopic composition of the inorganic ions and gases dissolved in groundwater and the mineralogy, organic geochemistry, and isotopic chemistry of the associated rock strata can be used to delineate the impact of microbial processes on (*1*) the geochemistry of groundwater, (*2*) the diagenesis of sediments, and (*3*) the cycling of elements at redox gradients in the subsurface. This article deals with the current state of knowledge with regard to the isotopic and mineralogical signatures of microbiological activity reported in the laboratory and compares them with those identified in the subsurface.

The discussion will focus on deep terrestrial environments where resident microbial populations must rely on endogenous energy sources rather than those replenished by transport from the surface. Microbial populations in this case are insensitive to 10-kyr changes in the surface climate and vegetation. Their activity, instead, relies on their ability to access energy from more recalcitrant organic substrates or reduced inorganic mineral surfaces.

These surfaces may quickly become depleted of bioavailable nutrients and/or coated with the by-products of microbial and geochemical reactions. As a result, the overall activity of "deep"-subsurface microbial communities will reflect changes in fluid flow and mineral precipitation induced by long-term volcanic or tectonic episodes (1) or changes in sea level. In the deep subsurface, the anaerobic microbial processes that are occurring today may also be very similar to those that dominated the earth's surface in the Archean. Clues to the formation of isotopic signals or inorganic "biomarkers" in Archean rocks may exist in modern, subsurface microbial ecosystems.

BACKGROUND

The extent to which microbial communities affect subsurface geochemistry was first explored in the 1920s, when a geologist at the University of Chicago, Edson Bastin, examined the source of hydrogen sulfide and bicarbonate in water from deeply buried oil fields in Illinois. In an experiment reported in Science in 1926 (2) Edson Bastin and Frank Greer, a microbiologist also from the University of Chicago, cultured sulfate-reducing bacteria (SRB) from groundwater samples collected from oil fields at depths of 150 to 600 m. Their results suggested that microorganisms were responsible for the in situ reduction of sulfate to sulfide. See Geochemical Aspects of Subsurface Microbiology, Esotopic Fractionation, Subsurface Microbiology

The presence of microorganisms in groundwater is not surprising because bacteria are dependent on diffusion, through water, of substrates to and products from cells for metabolism and growth. Groundwater sampled from wells typically originates from the most transmissive zones of the aquifer, and these zones usually have sufficient pore spaces and higher nutrient fluxes to support microbial populations. For this reason, groundwater, almost regardless of the environment, invariably harbors bacteria at densities between 10^3 and 10^6 cells per milliliter, and evidence of their activity is present in the concentrations and isotopic values of the dissolved inorganic or organic species and gases. The isolation and analysis of the microorganisms whose physiology is consistent with the inferred in situ geochemical process (3–5) also provides evidence that the microorganisms are active in that environment. Deep terrestrial environments through which water is readily transmitted are more favorable habitats for microbial populations than are regions where pore spaces or fractures are small or nonconductive (6,7).

In contrast to groundwater, a relative paucity of microorganisms occurs in the consolidated, indurated rock of the deep terrestrial subsurface. Many of the samples examined till date have had microbial biomass levels below limits of detection. Although evidence of microorganisms existing in these environments is strong, for many rock samples, microorganisms were not detected by either molecular or enrichment approaches. Progress in the detection in rock cores of diagenetic mineral phases produced by modern, subsurface microorganisms has been slow because of the low biomass of deep subsurface samples with some notable exceptions (8).

MICROBIAL FLUID INTERACTIONS

Microbially Catalyzed Oxidation-Reduction Reactions

Microorganisms have evolved or adapted to occupy essentially any niche where energy can be obtained from oxidation-reduction reactions involving organic and inorganic aqueous species, as long as those reactions have a favorable ΔG. The ability of microorganisms to survive or even thrive in environments in which energy is theoretically available is influenced by temperature, low abiotic reaction rates, and available pore space.

Deep subsurface environments inhabited by microorganisms can essentially be considered 'aphotic' systems. Photosynthesis plays only an indirect role in subsurface microbial metabolism, providing reduced organic compounds by burial and metamorphism that can be metabolized by heterotrophs. Microbial generation of energy in deep subsurface environments, therefore, is derived from biochemical reactions involving the oxidation of reduced compounds and the subsequent transfer of electrons to an adjacent oxidized compound of the following elements: Hydrogen, nitrogen, oxygen, sulfur, manganese, and iron.

From a thermodynamic perspective, the oxidation of organic carbon to carbon dioxide using O_2, NO_3^-, MnO_2, FeOOH, or SO_4^{2-} as oxidants or electron acceptors is exothermic, though kinetically frustrated. The ΔG for the oxidation of organic carbon also diminishes in order from O_2 to SO_4^{2-}, indicating that the oxidation of organic carbon should occur sequentially, beginning with the reduction of O_2, the most thermodynamically favored reaction, in descending order through methane-fermentation. From microbial and geochemical standpoints, the bioavailability of the electron acceptor, the reactive transport of the products, and the reaction kinetics will influence the sequence and the extent of these reactions. At macroscopic scales in systems in which microorganisms are active, such as a sediment–water interface or along an aquifer flow path, the sequential utilization of the oxidants as electron acceptors can be readily observed.

One of the principal reductants in sedimentary depositional environments is organic matter; this also holds true for many subsurface environments. Dissolved or colloidal organic matter is probably the only significant source of reductant in shallow (<50 m) aquifers, whereas sediment-associated (detrital) organic matter of terrestrial or marine origin and soluble hydrocarbons are a major source of reductant in deeply buried sediments.

In addition to organic carbon, reduced inorganic species, for example, Fe^{2+}, Mn^{2+}, S^{2-}, NH_4^+, CH_4, or H_2, can also provide reducing power for microbial metabolism. These reactions are particularly favorable when coupled to a strong oxidant such as oxygen, but some microorganisms can gain energy from oxidation of some reduced inorganic species coupled to weaker oxidants (such as nitrate or even carbon dioxide). Microorganisms that can derive energy from the oxidation of inorganic compounds for metabolism and for growth are termed

chemolithotrophs or *chemolithoautotrophs*, respectively. Reduced inorganic species may be the dominant source of energy for microorganisms in some deep terrestrial subsurface environments, particularly those dominated by hard rocks such as basalt (9) or granite (8) in which organic carbon is scarce or absent.

For confined aquifers where the DIC is not equilibrating with soil carbon dioxide (referred to as a *closed* system for carbon cycling), the DIC represents a balance between subsurface microbial and inorganic processes. These processes include: (*1*) the flux of soil carbon dioxide from the recharge zone, (*2*) the depletion of carbon dioxide during dissolution of calcite and dolomite, (*3*) the liberation of carbon dioxide during calcite or siderite precipitation, (*4*) the microbial oxidation or fermentation of either dissolved organic matter (DOM) or sedimentary organic matter (SOM), (*5*) the disproportionation of acetate during methanogenesis (10), (*6*) the depletion of carbon dioxide during methanogenesis by carbon dioxide reduction, (*7*) oxidation of methane (i.e., methanotrophy, 11,12) (*8*) the fixation of carbon dioxide in the microbial biomass, and (*9*) the thermal disproportionation of acetate. For deep subsurface environments at temperatures greater than 100 °C, the abundance of DIC may reflect metastable equilibrium reactions among DIC, carbonate, feldspar, and clay, and is inversely proportional to the Ca^{2+} concentration (13–15). In this case, as the temperature and depth increase, the pH will decrease, pCO_2 will increase, and both will be insensitive to microbial activity.

Similarly, subsurface organic acid concentrations represent the balance between production by either microbial fermentation or acetogenesis and by hydrous pyrolysis of kerogen (Carothers, 1978 #658) or petroleum (Helgeson, 1993 #551), consumption by microbial respiration (16), and, at higher temperatures, metastable equilibrium with DIC (15).

Dissolved oxygen generally diminishes with distance along the flow path in shallow aquifers as a result of aerobic bacterial respiration (either heterotrophic or chemolithoautotrophic). Dissolved nitrogen varies in concentrations and is composed of numerous species. Dissolved NO_3^- tends to decline with distance along the flow path in shallow aquifers as a result of NO_3^- reduction to N_2 by bacterial activity, producing a wide variety of intermediate products, such as NO_2^-, NO, N_2O, or NH_4^+. In deep subsurface environments, the dominant nitrogen species is either N_2 or NH_4^+, the latter produced by deamination of organic matter or perhaps from other abiotic reactions. Sinks for NH_4^+ are oxidation to NO_3^- by ammonia-oxidizing bacteria or fixation of NH_4^+ in the microbial biomass.

Dissolved Fe(II) reflects the production of Fe(II) by reduction of Fe(III)-bearing mineral phases by iron-reducing bacteria or by dissolved sulfide. Sinks for Fe(II) include the sorption of Fe(II) to mineral surfaces, the precipitation of Fe(II) bearing minerals such as green rust, vivianite, FeS, $FeCO_3$, and Fe_3O_4, and the oxidation of Fe(II) to Fe(III) oxide phases abiotically or by iron-oxidizing chemolithoautotrophic bacteria using either O_2 or NO_3^- as an electron acceptor.

Groundwater SO_4^{2-} concentrations typically reflect a balance between SO_4^{2-} production by gypsum dissolution, biotic or abiotic pyrite, or sulfide oxidation and bacterial SO_4^{2-} reduction and barite precipitation. Dissolved HS^- or S^{2-} concentrations reflect a balance between production by bacterial SO_4^{2-} reduction and FeS precipitation, S fixation into the microbial biomass and, possibly, sulfur or thiosulfate disproportionation reactions. Intermediate sulfur species, such as S_2O_3 and SO_3^- tend to be ephemeral in groundwater systems.

Because the enzymatic electron acceptor processes have varying affinities to hydrogen, the concentration of hydrogen can reflect the dominant electron-acceptor reaction (17). In subsurface environments that are electron-donor limited, the hydrogen concentration appears to be thermodynamically controlled by the principal, terminal electron-acceptor reaction so as to maintain a constant ΔG (18) under varying temperatures and pH. The segregation of the dominant electron-acceptor processes along the flow paths of many aquifers also reflects this competition for acetate and hydrogen (19). In deeper, hydrocarbon-bearing, sedimentary formations at temperatures of 100 to 150 °C, hydrogen concentrations may primarily reflect abiotic, irreversible, hydrolytic disproportionation, hydrolysis of light paraffins, and metastable equilibrium among organic acids (20). The groundwater hydrogen concentrations reflect the production of hydrogen by water disproportionation reactions (9,21), pore water radiolysis (22), or microbial fermentation of organic matter, and the microbial consumption of hydrogen linked to various terminal electron-accepting processes (17).

Finally, in natural gas reservoirs, the concentration of dissolved hydrogen, methane, and organic acids will be controlled by DIC concentration, the partitioning factor between the aqueous and gas phase and the total pressure (23).

Geochemical Evidence of Subsurface Microbial Activity: Case Studies

Hydrogeologists and geochemists have commonly observed systematic decreases in the E_h of groundwater as it migrates from elevated recharge areas to low lying discharge areas under conditions of confined flow, and have attributed the changes to microbial metabolic processes (24). The spatial scale for the transition from one redox zone to the other in aquifers may extend over kilometers in contrast to the centimeters typical for modern sediments. The redox status of the groundwater at any specific geographic position will represent the integrated effect of a heterogeneous mixture of redox couples varying over scales from centimeters to millimeters. Finally, accurate knowledge of groundwater flow path and detailed delineation of the redox gradients are far more difficult to obtain in the deep subsurface than in most surface sediments, because of the spatial heterogeneity of redox properties in combination with aquifer inaccessibility and limitations associated with sampling water from wells.

E_h declines along the groundwater flow path for the Middendorf formation of the Atlantic coastal plain, southeastern United States (25). Redox zonation has also been

delineated by changes in the concentrations of chemical species involved in redox reactions, such as sulfate, and when linked to the microbially catalyzed oxidation of organic carbon to carbon dioxide in the extensive Madison aquifer of Montana, Wyoming, and South Dakota (26). Observations reporting similar zonation of redox processes have been reported for other regional groundwater systems including the Fox Hills-Basal Hell Creek aquifer of North Dakota and South Dakota (27), but not the chalk aquifers of the United Kingdom (28) (including the Lincolnshire Limestone).

One of the first studies that closely linked microbial analyses of sediment core samples to carbon dioxide increases in groundwater of deeply buried coastal plain sediments of the eastern United States was conducted by Chapelle and coworkers (29). In this study, the presence of bacterial cells, including methanogens and sulfate-reducing bacteria, was unequivocally identified in deep sediment cores, indicating that the source of carbon dioxide was microbial oxidation of organic matter (possibly sedimentary lignite). Later work by Murphy and coworkers (25) identified geochemical changes along a groundwater flow path in the Middendorf aquifer of South Carolina that were consistent with the physiology of microorganisms cultured from Middendorf core samples, including aerobic chemoheterotrophs and iron-reducing and sulfate-reducing bacteria. They suggested that lignite inclusions in the aquifer sediments were the principal source of organic carbon for microbial fermentation and respiratory processes. Redox processes within the Middendorf were heterogeneous and probably linked to lignite distribution in the sediments. Subsequent research confirmed the presence of active bacteria in core samples by measuring the oxidation of ^{14}C-labeled glucose or acetate (30), incorporation of ^{14}C-labeled acetate into lipids and ^{3}H-thymidine into DNA of bacterial cells (7). Jones and coworkers (31) found that some subsurface sediment slurries accumulated acetate in the absence of amendment with any organic compounds, indicating the presence of endogenous fermentable carbon compounds. Later, McMahon and Chapelle (16) identified that microbial fermentation of organic matter was occurring in fine-grained aquitard sediments, and was probably responsible for driving bacterial respiration in adjacent course-grained aquifers. McMahon and Chapelle (32) also demonstrated the biological generation of carbon dioxide from endogenous carbon in ACP sediments incubated with O_2 ,NO_3^-, or SO_4^{2-} as the electron acceptor, providing additional evidence of sedimentary organic carbon as the principal electron donor driving microbial metabolism in deeply buried Atlantic coastal plain sediments.

In oil-rich environments, microbial degradation of petroleum manifests itself by the progressive depletion of n-alkanes, followed by branched alkanes and alkyl aromatics, leaving a residue enriched with napthlenes and polynuclear aromatic hydrocarbons, resins, and asphaltenes (33). These features have been reported for subsurface petroleum reservoirs with maximum formation temperatures of 88 °C, and are normally associated with aerobic (oxygen respiring) conditions (33). More recently, however, anaerobic oxidation of n-alkanes and alkylbenzenes to carbon dioxide has been reported for mesophilic and thermophilic SO_4^{2-} reducing bacteria (34,35). Hyperthermophilic SO_4^{2-}-reducing archaea and thermophilic SO_4^{2-} reducing bacteria have been reported from oil fields worldwide (36–39) to depths as great as three kilometers beneath the seafloor. Such cultures were shown to grow at temperatures as high as 102 °C (36).

In deep igneous rock environments where solid phase–associated organic carbon is sparse (40,41), low E_h (< -200 mV) groundwater is typical with relatively high concentrations of Fe(II) and HS^- (40,42). Interestingly, dissolved hydrogen concentrations as high as 60 μM in the Columbia River basalt aquifer of south-central Washington and 70 μM in the granite aquifer of southeastern Sweden have been reported (9). Hydrogen has also been found to comprise up to 30% of the natural gas discharged freely from deep subsurface fractures (43). These values are several orders of magnitude greater than the sediments in which microbial fermentation is occurring (17) and the origin of the hydrogen remains controversial. Many of the bacteria that reside in these environments can grow autotrophically with hydrogen as the sole electron donor and carbon dioxide as the carbon source, including acetogenic bacteria and autotrophic methanogens (9). The acetogenes represent a potential dissolved carbon source for heterotrophic bacteria. Alternatively, the CH_4 and C_{2+} compounds found in these environments may originate from hydrous pyrolysis organic matter disseminated nearby or the degassing of the underlying mantle. Recently, abiogenic Fischer-Tropsch synthesis has been proposed as a source mechanism for CH_4 and C_{2+} compounds from the subsurface of the plutonic rock-hosted aquifers of the Canadian and Fennoscandian Precambrian shields on the basis of their δ^{13}C and δD values (44,45).

To determine the extent to which a subsurface relies on indigenous energy sources requires estimates of the rates of various microbial respiration processes and the flux of electron donors and acceptors from the surface. In modern depositional settings where microbial activity measurements are based on geochemical and radiolabeled substrate, incubations are compatible with each other and with the rate of sediment burial. Geochemical estimates of microbial respiration rates within aquifers are on the order of nmoles $L^{-1}yr^{-1}$, which are a factor of 10^3 less than those derived from modern lakes or marine sediments (46,47). Microbial activity measurements derived from laboratory incubations with radiolabeled substrates using homogenized sediment from the same aquifer (46) yield rates that are 10^6 times more than those derived from geochemical mass balance, and are unrealistically high. Geochemical estimates, however, have relied on assumptions of mass balance that are difficult to establish in deeply seated aquifers. Stable isotope analyses partly alleviate the need for this assumption and can provide more reliable estimate of in situ microbial respiration rates.

The Impact of Subsurface Microbial Activity on Isotopic Composition

Elements commonly involved in biological redox reactions contain more than one isotope and the reaction rate

varies slightly with the atomic weight. Reactions that break bonds preferentially break those between the lighter isotopes of an element, ^{12}C versus ^{13}C, for example. This is true regardless of whether the reaction is biologically driven or in thermodynamic equilibrium, but the degree of preference for the lighter isotope differs between the enzymatically driven microbial reactions and thermodynamic equilibrium between products and reactants.

The degree to which the kinetic (first-order) reaction rate for one isotope, k_1, is greater than that of another, k_2, for the same element is reflected in the value of ε, where

$$\varepsilon = [k_1/k_2 - 1] \times 10^3 \quad (1)$$

Determinations of the ε values for electron donor/acceptor reactions of different bacterial strains have been mostly based on batch experiments where the product of the reaction cannot equilibrate with the reactant. The isotopic compositions of the reactant and/or the product, expressed as δ values, are determined for multiple experiments terminated at varying degrees of F, the fraction of reactant remaining. Under these conditions, which are defined as isotopically "closed" conditions in Table 1, ε is derived from either of the following Rayleigh distillation relationships,

$$\varepsilon = [\delta_{rf} - \delta_{ri}]/\ln(F) \quad (2)$$

$$\varepsilon = [\delta_{ri} - \delta_{pf}]/[F \times \ln(F)/(1-F)] \quad (3)$$

where δ_{rf} and δ_{ri} are the final and initial isotopic compositions of the reactant and δ_{pf} is the final isotopic composition of the product and δ is defined as,

$$\delta = [(R_{sample} - R_{standard})/R_{standard}] \times 10^3 \quad (4)$$

where R_{sample} and $R_{standard}$ are the isotopic ratios of the sample and a standard. Isotopic determination of both the reactant and product phases provides two independent measurements of ε. If these two measurements are not in agreement, then a significant portion of the reactant is being converted to some other phase, such as fixation in a growing biomass, or partial equilibration between the reactant and product is occurring.

In some instances isotopic fractionation experiments are performed under steady state conditions, defined as isotopically "open" conditions in Table 1, in which the reactant and product concentrations are kept constant during the course of the experiment. In this case, the value of ε is given simply by,

$$\varepsilon = \delta_p - \delta_r \quad (5)$$

The kinetic fractionation values are quite distinct from equilibrium fractionation values (Table 1) given by,

$$\delta = 10^{13} \times \ln(R_{product}/R_{reatant}) = \delta_p - \delta_r \quad (6)$$

where $R_{product}$ and $R_{reactant}$ are the isotopic ratios of the product and reactant. Typically, these quantities are determined at high temperatures where reaction rates are enhanced. To compare the δ values with the ε values derived from the lower temperature microbial experiments, Δ values are extrapolated using the following relationship,

$$\Delta = a(10^6/T_K^2) + b(10^3/T_K) + c \quad (7)$$

where a, b, and c are experimentally derived constants (81).

To illustrate the differences between Δ and ε, consider the SO_4^{2-}-reduction reaction. Sulfate and dissolved hydrogen will react to form S^{2-} at 300 °C relatively quickly, and the reaction is reversible (87). The lighter ^{32}S preferentially composes the S^{2-} at equilibrium; whereas the ^{34}S tends to remain in the residual sulfate. The $\delta^{34}S$ of the S^{2-}, δ_{pf}, and SO_4^{2-}, δ_{rf}, depends on the initial $\delta^{34}S$ of the SO_4^{2-}, δ_{ri}, and the fractional amount of reaction progress and the $\Delta_{S^{2-}-SO_4^{2-}}$, δ, according to the following relationships,

$$\delta_{rf} = \delta_{ri} + \Delta \times (F - 1) \quad (8)$$

$$\delta_{pf} = \delta_{ri} + \Delta \times (F) \quad (9)$$

where $\delta S^{2-} - SO_4^{2-} = -20‰$ at 300 °C (or −73‰ at 25 °C, Table 1). If pyrite (or greigite) is produced or the reaction is performed by SRB at low temperatures, however, then the reversibility of the reaction is eliminated and a Rayleigh distillation enrichment in the residual SO_4^{2-} results. A plot of the $\delta^{34}SO_4^{2-}$ as a function of InF typically yields linear relationships. In the case in which SO_4^{2-} is continuously fed to a culture of SRB (steady state experiment or "open" system in Table 1), the $\delta^{34}SO_4^{2-}$ and $\delta^{34}S^{2-}$ are given by the expressions. Because S^{2-} is isotopically lighter than the SO_4^{2-} by 20‰, the more sulfur that is S^{2-}, the more enriched in ^{34}S the S^{2-} and SO_4^{2-} become, but the $\delta^{34}S$ of the total S still has to match that of the inlet SO_4^{2-}.

In groundwater, the $\delta^{34}S$ of the source SO_4^{2-} may not be known, in which case it is derived from the aforementioned mass balance relationship by assuming a value for Δ and by using the measured concentrations of S^{2-} and SO_4^{2-} (i.e., F) and values of $\delta^{34}SO_4^{2-}$ and $\delta^{34}S^{2-}$ (26). For groundwater in which the S^{2-} concentrations are too low for accurate determination of either S^{2-} or $\delta^{34}S^{2-}$, the amount of SO_4^{2-} reduction, F, is obtained by inferring the $\delta^{34}S$ of the source SO_4^{2-} (e.g., modern marine systems) or deriving it from sediment measurements, by assuming the $\Delta_{S^{2-}-SO_4^{2-}}$ and by measuring the $\delta^{34}S$ of the SO_4^{2-} (47). The isotopic geochemical estimates of microbial SO_4^{2-}-reduction, therefore, are dependent on which mass balance law is selected, Rayleigh distillation versus steady state mass balance, and on the value of $\delta_{S^{2-}-SO_4^{2-}}$ or $\varepsilon_{S^{2-}-SO_4^{2-}}$.

Rayleigh Versus "Open" System Isotope Behavior

Plots of $\delta^{34}S$ of SO_4^{2-} for bacterial cultures and for marine sediments conform to Rayleigh distillation trends,

Note: $\varepsilon_{p-s} = \delta_p - \delta_s$ and $\varepsilon_{b-s} = \delta_b - \delta_s$, where p = product, s = substrate, b = biomass, $\delta = [(R_p - R_{\text{standard}})/R_{\text{standard}}] \times 10^3$, R is the isotopic ratio and $\delta_{p-s} = a(10^6/T_k^2) + b(10^3/T_k) + c$.n.a. = not analyzed.

*Bold letters in chemical formula specify the specific molecular site for which the isotopic fractionation was determined.

**See discussion in text. The $\delta^{18}O$ of SO_4^{2-} was found to depend on the $\delta^{18}O$ of H_2O.

***See discussion in text. The δD of H_2, CH_4 and the cells were found to depend on the δD of H_2O.

but those for aquifers typically do not. In subsurface environments, the definition of Rayleigh or "closed" systems versus "open" isotopic systems depends on the exchange rate of the fractionated substrate between an elemental volume of water and its surroundings relative to the rate of microbial SO_4^{2-}-reduction. Following Jorgensen (88), the degree of isotopic "openness" for SO_4^{2-} reduction is determined by the following steady state relationship,

$$\begin{aligned} SO_4^{2-}\text{-reduction rate} = {} & \text{pore water diffusion supply rate} \\ & + \text{groundwater advection} \\ & \text{supply rate} \end{aligned} \quad (10)$$

If the diffusion term dominates, the system is considered "open," whereas if the groundwater advection term dominates, then the system is "closed." Instead of having one pair of equations defining the biogeochemical mass balance, we have two pairs, one for each isotope of sulfur, ^{32}S:

$$\partial[^{32}SO_4^{2-}]/\partial t = D^{32}SO_4^{2-}\partial^2[^{32}SO_4^{2-}]/\partial x^2 + V\partial[^{32}SO_4^{2-}]/\partial x - R^{32}SO_4^{2-}(x) \quad (11)$$

where

$$R^{32}SO_4^{2-}(x) = [^{32}SO_4^{2-}]/[SO_4^{2-}] \times (1 + 0.5 \times \varepsilon^{32}_{SO_4^{2-}-S^{2-}}/10^3) \times R(x) \quad (12)$$

and

$$\partial[^{32}HS^-]/\partial t = D^{32}HS^-\partial^2[^{32}HS^-]/\partial x^2 + V\partial[^{32}HS^-]/\partial x + R^{32}SO_4^{2-}(x) \quad (13)$$

An identical set of relationships exist for ^{34}S.

In depositional environments, plots of $\delta^{34}S$ versus $^{32}SO_4^{2-}$ mimic Rayleigh fractionation trends, but because of their partially "open" system behavior (88), the $\varepsilon_{S^{2-}-SO_4^{2-}}$ is less than that in "closed" systems and depends on the rate of SO_4^{2-} reduction. Because microbial SO_4^{2-} reduction preferentially depletes the SO_4^{2-} of ^{32}S, the diffusive flux of $^{32}SO_4^{2-}$ is greater than that of $^{34}SO_4^{2-}$ toward the zone of SO_4^{2-} reduction, although $D^{32}SO_4^{2-}$ is indistinguishable from $D^{34}SO_4^{2-}$. Simultaneously, the diffusive counterflux of $^{32}S^{2-}$ is greater than that of $^{34}S^{2-}$ away from the SO_4^{2-} reduction zone. With increasing

burial depth, the SO_4^{2-} reduction rate decreases, the sulfur isotope system becomes more "closed',' and the $\varepsilon_{S^{2-}-SO_4^{2-}}$ increases, but the Rayleigh enrichment trend is still observed.

In the low porosity, low permeability environment typical of the deep subsurface, dissolved electron donor/acceptor fluxes are largely controlled by diffusive rather than advective transport of the spatial scale directly relevant to microbial activity. The length scales, L, for observed redox or activity gradients in aquifer microsites (25,89) are on the order of millimeters. Soluble substrates will diffuse toward the pore that contains the bacteria, because of the microbiologically induced concentration gradient. The same argument can be made for nonmotile cells metabolizing in liquid or solid media (90). The mass-transfer to the cell's surface is governed by the expression:

$$\partial C/\partial t = D\{\partial^2 C/\partial r^2 + 2/r\partial C/\partial r\} \quad (14)$$

where c is the concentration of the soluble chemical substrate and D is its diffusivity. The transient solution to this equation assuming constant bulk-phase, C_0, and cell surface, C_1, concentrations is:

$$C - C_0/C_1 - C_0 = R/r \text{ erfc } \{(r - R)/2\text{vDt}\} \quad (15)$$

where R is the radius of the cell assuming a spherical shape. The steady state solution is given by Crank (1975):

$$\text{C} = \text{R/r } \text{C}_0/\text{C}_1 + \text{C}_0 \quad (16)$$

The net substrate flux, in units of atoms per cell-time, is equal to:

$$\Phi = 4\pi\ \text{r}^2\text{J} = -\text{D}\partial\text{C}/\partial\text{r} = 4\pi\ \text{D}(\text{C}_1 - \text{C}_0)\text{R} \quad (17)$$

The substrate diffusion rate within the pore in which the cell resides is governed in some cases by the Stokes-Einstein relationship,

$$\text{D} = \text{k}_\text{B}\text{T}/6\pi\mu\text{R}_\text{o} \quad (18)$$

where k_B is Boltzman's constant, μ is the media viscosity, and R_o is the substrate radius. However, in deep subsurface environments, which are undersaturated, natural gas deposits, for example, diffusion of gaseous substrates are modeled by the Chapman-Enskog theory (91):

$$\text{D} = \{0.00186\text{T}^{3/2}\text{v}(1/\text{M}_1 + 1/\text{M}_2)\}/\{\text{p}\sigma_{12}^2\Omega\} \quad (19)$$

where T is temperature °K, p is the pressure in atmospheres, M_1 and M_2 represent the molecular weight of the diffusing substrate and the average molecular weight of the gas medium, and σ_{12}^2 and Ω are molecular properties derived from viscosity.

The substrate diffusion rate toward the pore, D_{eff}, will be somewhat more restricted by porosity, θ, and toruosity, τ(91),

$$\text{D}_\text{eff} = \theta\text{D}/\tau^2 \quad (20)$$

and by viscous drag as modeled by the Rankin relationship (91),

$$\text{D}_\text{eff} = \text{D}\{1 + 9/8\lambda \ln(\lambda) - 1.54\lambda\} \quad (21)$$

where λ is $2\text{R}_\text{o}/\text{d}$ and d is the pore diameter.

Microbial Isotopic Fractionation

Expressions 1 through 20 can be used to constrain the rates of microbial activity if the total isotopic fractionation factor, ε, is known for the specific redox reaction. ε can vary, however, as a function of reaction rate. This relationship has been established for SO_4^{2-} reduction. The total isotopic fractionation, $\varepsilon_{S^{2-}-SO_4^{2-}}$, associated with the reaction sequence for SRB is the sum of several enzymatic steps, each with a distinct ε_i, linked in series to produce a net $\varepsilon = \sum_i \varepsilon_i$. By examining *D. desulfuricans* cells for various growth rates, temperatures, electron donors, and for cell-free enzyme extracts, Kemp and Thode (69) deduced that dissimilatory SO_4^{2-} reduction proceeds by three reactions linked in series: (*1*) SO_4^{2-} diffusion through the membrane and reaction with ATP sulfurylase to adenosine-phosphosulfate, (*2*) conversion of SO_4^{2-} to SO_3^{2-} and production of adenosinemonophosphate, and (*3*) reduction of SO_3^{2-} to S^{2-}. The ε value for the first step is only 1 to 3‰, whereas those of the second and third reactions are both approximately −20 to −25‰ (72). The total $\varepsilon_{SO_4^{2-}-S^{2-}}$ value depends on the reaction rates and concentrations for each step. When SO_4^{2-} concentrations are greater than 10^{-3} M, the $\varepsilon_{S^{2-}-SO_4^{2-}}$ varies inversely as a function of reduction rates from a maximum of −45‰for less than 10^{-17} moles/cell-hr to a minimum of −6‰for greater than 5×10^{-16} moles/cell-hr for organic electron donors (Fig. 1; 92). When hydrogen is the electron donor, the $\varepsilon_{S^{2-}-SO_4^{2-}}$ varies from −10 to −20% and may exhibit a slight positive correlation with reduction rates. At SO_4^{2-} concentrations less than 10^{-3} M, the $\varepsilon_{S^{2-}-SO_4^{2-}}$ decreases, approaching 3‰as diffusion of SO_4^{2-} into the cell becomes the rate-limiting step (93). The $\varepsilon_{S^{2-}-SO_4^{2-}}$ was the same, −14‰, for *Desulfofotomaculum nigrificans* cultures grown at 55 °C as that for *Desulfofotomaculum salexigens* grown at 35 °C (73). Unlike the $\Delta_{S^{2-}-SO_4^{2-}}$ values for equilibrium systems, the $\varepsilon_{S^{2-}-SO_4^{2-}}$ does not inversely correlate with temperature.

A parallel assimilation reaction competes for intracellular S^{2-} and can significantly perturb the isotopic composition of S^{2-} during the log-growth phase, because the S isotopic fractionation during assimilation, $\varepsilon_{biomass-SO_4^{2-}}$, is −2.4‰ (70). *Clostridium* growing on SO_3^{2-} (67) produces S^{2-}, which is isotopically enriched instead of depleted. The effect of biomass incorporation would be to reduce the $\varepsilon_{S^{2-}-SO_4^{2-}}$.

For Other Microbial Reactions

Microbial reduction of O_2, NO_3^-, and CO_2 produce large isotopic fractionation trends in $\delta^{18}O$, $\delta^{15}N$, and $\delta^{13}C$ of the residual electron acceptor (Table 1). In the case of aerobic respiring bacteria, the $\varepsilon_{HCO_3^- - O_2}$ is −18% for pure cultures (Table 1). Isotopic enrichment of residual NO_3^- during bacterial reduction in steady-state laboratory cultures (62)

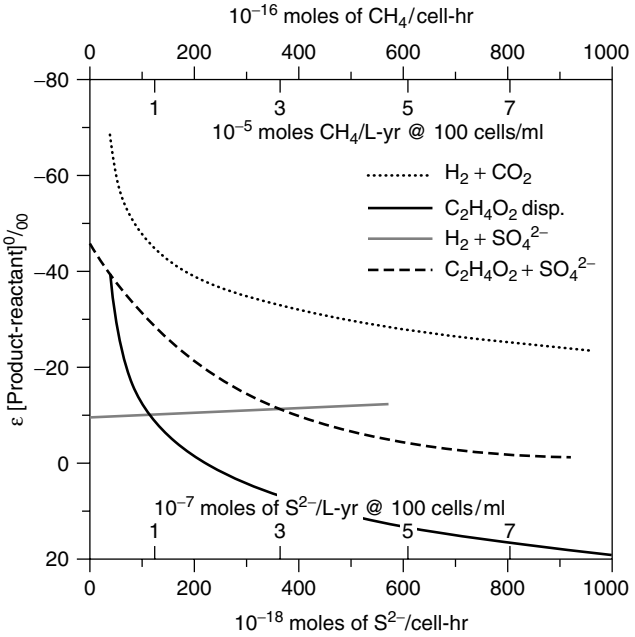

Figure 1. The $\varepsilon_{product-reactant}$ in parts per trillion versus reaction rate for four reactions: (*1*) $4H_2 + CO_2 = CH_4 + 2H_2O$ (gray dashed)(56); (*2*) $CH_3COOH = CH_4 + CO_2$ (solid black)(56); (*3*) $4H_2 + SO_4^{2-} = HS^- + 3H_2O + OH^-$ (solid gray)(92); (*4*) $CH_3COOH + SO_4^{2-} = HS^- + 2CO_2 + H_2O + OH^-$ (black dashed)(92); reaction rate units are in moles of product per cell-hr and in moles of product per L-yr assuming 100 cells/ml.

yields an $\varepsilon_{NO_3^- - N_2}$ of 28.6%. This represents the maximum fractionation because $\varepsilon_{NO_3^- - N_2}$ decreases with increasing denitrification rates. When NO_2^- concentrations become limiting (<2.5 mM), the $\varepsilon_{NO_3^- - N_2}$ is less.

The greatest isotopic enrichment occurs during reduction of carbon dioxide via methanogenesis. Batch laboratory experiments conform to Rayliegh distillation trends and yield $\varepsilon_{CH_4-CO_2}$ values ranging from −25 to −59% (Table 1). Zyakun (94) reported $\varepsilon_{CH_4-CO_2}$ values as high as −80% and decreasing to −10% as CH_4 production rates increased from 10^{-15} to 10^{-12} moles per cell-hr (Fig. 1). The enrichment of residual carbon dioxide by acetogens is equally as great as in methanogens with $\varepsilon_{C_2H_4O_2-CO_2}$ values ranging from −40 to −59% (Table 1). As in the case of SO_4^{2-} and NO_3^- reduction, when carbon dioxide is less than a critical value concentration, the $\varepsilon_{CH_4-CO_2}$ decreases (94), but this critical value is probably well below the inorganic carbon concentrations that typify the deep subsurface.

The $\delta^{18}O$ of the residual SO_4^{2-}, NO_3^- and CO_2 are also enriched during bacterial reduction. The time required for oxygen in water and carbon dioxide to reach thermodynamic equilibrium is essentially instantaneous, however, on the timescale of microbial respiration in laboratory incubations, and so no effect is observed. The time required for the oxygen in water and SO_4^{2-} to equilibrate, however, is on the order of thousands of years (75). During the SO_4^{2-} reduction process, however, the oxygen of the SO_4^{2-} bound to the enzyme complex can isotopically equilibrate with that of water far more rapidly than isolated SO_4^{2-} (74,95). As a consequence, the more enriched the $\delta^{34}SO_4^{2-}$ of residual SO_4^{2-}, the closer to equilibrium the $\delta^{18}O$ of the SO_4^{2-} is with water (95). Because the $\varepsilon_{S^{2-}-SO_4^{2-}}$ is larger when the reduction rate is lower, the slower the SO_4^{2-} reduction rate, the closer to equilibrium the $\delta^{18}O$ of the SO_4^{2-} becomes with water (95). Unlike SO_4^{2-} reduction, the oxygen in the NO_3^- reduction process does not appear to isotopically equilibrate with the oxygen in water. Böttcher and coworkers (96) reported isotopic enrichment in the oxygen of the residual NO_3^- consistent with Rayleigh fractionation with an $\varepsilon_{NO_3^- - H_2O}$ of −8.0‰.

Oxidation of CH_4, NH_3^+, H_2, and HS^- yields enrichment trends in the $\delta^{13}C$, $\delta^{15}N$, δD, and $\delta^{34}S$ of these electron donors. Batch experiments on methanotrophs follow Rayleigh distillation trends (97) and yield $\varepsilon_{CO_2-CH_4}$ of −5 to −31‰ (53,54,56,94). The cause of the variability in the $\varepsilon_{CH_4-CO_2}$ has not been established, but Zyakun (94) reported that the $\varepsilon_{CO_2-CH_4}$ decreased from 30‰to −10‰ when CH_4 became limiting. The effect of the competing assimilation reaction can also be significant as methanotrophs can fix up to 50% of the carbon from CH_4 and the fractionation associated with assimilation of the carbon can be as high as −30‰ and −11‰ for particulate MMO and soluble MMO, respectively (55). The carbon isotopic fractionation has been found to be associated primarily with the first step of methanotrophy, the conversion of CH_4 to CH_3OH. The subsequent conversion of CH_3OH to cell biomass yielded $\varepsilon_{biomass-CH_3OH}$ values of −3.0 to −10‰ (55). The isotopic enrichment of the *D* in the residual CH_4 is more profound with $\varepsilon_{H_2O-CH_4}$ as high as 325‰ (54). Similar enrichment factors for carbon and hydrogen are observed in anaerobic CH_4 oxidation experiments, but neither the specific mechanisms nor the active microbial communities are known (11).

The $\delta^{15}N$ of the residual NH_3 becomes heavier upon progressive oxidation by nitrifying bacteria yielding $\varepsilon_{NH_3-N_2O}$ of −65‰ (60). The concomitant enrichment of the δD of the residual NH_3 is probably equally as great as observed for CH_4 during methanotrophy, but has not been reported.

During oxidation of hydrogen by methanogens the δD of hydrogen, CH_4 and the cells were found to correlate with the δD of the water and not with the rate of hydrogen consumption (79,80). The δD values of the hydrogen were close to those predicted by equilibrium fractionation, whereas the δD values of the CH_4 were still far removed from complete isotopic equilibration with water. The H isotopic exchange rates between water vapor and hydrogen and methane (98) are rapid relative to the geologic timescale, but they are too slow to account for these laboratory effects. Balabane and coworkers (79) proposed that the enzymatic reduction of carbon dioxide to produce methane involved an intracellular water-reduction step in the pathway. This would imply that not all of the H in the CH_4 is derived from extracellular, dissolved hydrogen. Whether this is true for other microbial reactions in which hydrogen is the electron donor is not known. This partial isotopic equilibration of the H in CH_4 with that of water makes the δD_{CH4} formed by carbon dioxide reduction heavier (−150 to −250‰ SMOW) than that formed during

aceticlastic methanogenesis (−250 to −400‰ SMOW), in which some of the H originates from the methyl group within the acetate (99).

Kaplan and Rittenburg (58) reported $\varepsilon_{HS^- - SO_4^{2-}}$ of −20‰ for the oxidation of HS^- to SO_4^{2-} by pure cultures of *Thiobacillus concretivorus*. Bacterially mediated oxidation of base metal sulfides produces SO_4^{2-} with $\varepsilon_{S^{2-} - SO_4^{2-}}$ of −2 to −5.5‰ (100). The oxidation or reduction of solid-phase S^0, however, produces no measurable fractionation of the $\delta^{34}S$ (Table 1).

Oxidation of C_{2+} organic compounds to carbon dioxide generally results in a respired carbon dioxide that is isotopically lighter by 3 to 12‰ (Table 1), with the exception of hydrocarbons for which little fractionation has been observed. During fermentation reactions, the $\delta^{13}C$ of acetate, on the other hand, may be either isotopically enriched or depleted in ^{13}C with respect to the organic substrate depending on the proportion of carbon oxidized to carbon dioxide. Aceticlastic methanogenesis enriches the ^{13}C of the residual acetate with an $\varepsilon_{CH_4 - C_2H_4O_2}$ of −21‰ (Table 1), but this fractionation value may also depend on the reaction rate (94). At high reaction rates (Fig. 1), the $\delta^{13}C$ of methane becomes heavier than that of the source acetate, whereas the $\delta^{13}C$ of carbon dioxide becomes lighter.

Subsurface Isotope System Behavior: Case Studies

To deconvolve the multiple sources and sinks for carbon and SO_4^{2-}, geochemical estimates of the microbial carbon dioxide production and SO_4^{2-}-reduction rates in aquifers have used stable isotope analyses of the DIC, the SO_4^{2-}, and S^{2-} (25,26,101). Isotopic analyses of other electron acceptors, such as O_2 and NO_3^-, have been used to delineate biogeochemical processes in marine environments, but their application to subsurface environments has been limited to contaminated shallow aquifers (96).

In the Cubero sandstone of northwestern New Mexico, enrichment in the ^{34}S of the groundwater SO_4^{2-} is related to the activity of SRB (6,102), and the overall trend approaches a Rayleigh distillation trend with an $\varepsilon_{S^{2-} - SO_4^{2-}}$ of −5‰. On the basis of the measured temperature, porosity, and the average pore diameter determined from Hg porosimetry, the D_{eff} for SO_4^{2-} using Equations (18) and (21) was approximately 6×10^{-6} cm^2/s. Microautoradiography of the Cubero sandstone revealed that SO_4^{2-} reduction was concentrated in microsites with radii of several millimeters (89). Radiotracer measurements also indicated that the minimum SO_4^{2-} concentration that promoted SO_4^{2-} reduction was less than 6×10^{-5} M and the groundwater SO_4^{2-} concentration in the Cubero sandstone was 8×10^{-4} M (6). These measurements suggest that the concentration gradient surrounding a SO_4^{2-} reducing microsite is approximately 10^2 M/m^2 and that the diffusive SO_4^{2-} flux would be 5×10^{-10} moles/m^2-s using Equation (17). The groundwater velocity in the Cubero sandstone estimated from ^{14}C model ages and hydrogeological modeling is 0.2 m/y (102). This yields an advective flux of 5×10^{-9} moles/m^2-s, and according to Equation (10) the isotopic system is predominantly "open" at the pore scale. This suggests that the observed $\varepsilon_{S^{2-} - SO_4^{2-}}$ will be less than the actual $\varepsilon_{S^{2-} - SO_4^{2-}}$ at the microsite. Furthermore, the $\varepsilon_{S^{2-} - SO_4^{2-}}$ will vary as a function of the size and distribution of microsites. For the horizontal scale greater than 100 m sampled at Cerro Negro studies, diffusive mixing is insignificant compared with advective transport, and isotopic variations should behave according to a Rayleigh distillation trend, unless pore scale S cycling or groundwater mixing from multiple reservoirs is occurring.

The $\varepsilon_{S^{2-} - SO_4^{2-}}$ at a microsite in the Cerro Negro aquifer should be small because the concentrations often fall below the 10^{-3} M level (102). For the case of the Cubero Sandstone at Cerro Negro, the substrate flux expression, SO_4^{2-} concentrations and diffusivity used in the preceding text indicate that the SO_4^{2-} flux to a cell that is 0.5 μm in diameter is approximately 10^8 atoms per cells. The limited isotopic fractionation implies that the SO_4^{2-} flux is the rate-limiting step and that most of the intracellular SO_4^{2-} is being converted to S^{2-}. Such a conversion rate would correspond to 10^{-8} moles per cell-yr of S^{2-}. On the basis of data presented by Walvoord and coworkers (102), the SO_4^{2-} reduction rate along the flow path over a time interval of 20,000 years is approximately 10^{-6} moles per L-yr. These two rate estimates are compatible only if about 10^2 cells/L of metabolically active SRB exist in the Cubero Sandstone. MPNs from microbial enrichments, however, suggest much higher cell densities (6). Sulfur isotope data on the dissolved sulfide is required to determine whether the low $\varepsilon_{S^{2-} - SO_4^{2-}}$ implied by the sulfate data is representative and that additional sulfate is not being supplied to the groundwater by gypsum dissolution.

For the Madison aquifer in which isotope data exist for both sulfate and sulfide, the data are too complex to be represented by a simple Rayleigh distillation trend. Plummer and coworkers (26) suggested that microbial SO_4^{2-} reduction is occurring in the Madison aquifer at depths of 2.2 km and temperatures of 87 °C, based on the S isotopic differences between SO_4^{2-} and HS^-. The isotopic enrichment of the residual SO_4^{2-} implies an $\varepsilon_{S^{2-} - SO_4^{2-}}$ of less than −7‰; whereas the $\delta_{S^{2-} - SO_4^{2-}}$ reported ranges from −20 to −38‰ (26). With such fractionation values, the isotopic enrichment of the residual SO_4^{2-} would be very large if additional SO_4^{2-} was not being supplied by the dissolution of gypsum. Measurement of the $\Delta_{S^{2-} - SO_4^{2-}}$ is, therefore, critical to determining both the rate of microbial SO_4^{2-} reduction and the source of the sulfate. The observed $\Delta_{S^{2-} - SO_4^{2-}}$ values correspond to laboratory reduction rates ranging from 10 to 100 × 10^{-18} moles/cell-hr (Fig. 1). The population density of SRB in the Madison aquifer is approximately 100 MPN/mL (103). Combination of these two estimates yield a net SO_4^{2-} reduction rate of 10^{-7} to 10^{-8} moles/L-yr, which is comparable to the SO_4^{2-}-reduction rate estimated by geochemical modeling.

In principle, the actual $\varepsilon_{S^{2-} SO_4^{2-}}$ values observed in enrichments of SRB from an aquifer under varying SO_4^{2-}-reduction rates could be compared with the observed $\Delta_{S^{2-} SO_4^{2-}}$ values to model the rate of in situ microbial SO_4^{2-}-reduction rate. Comparisons of the SO_4^{2-}-reduction rates determined by $^{35}SO_4^{2-}$ radiotracer experiments with the rates derived by stable isotope modeling, however, are very limited (89). The published values of $\Delta_{S^{2-} - SO_4^{2-}}$ for aquifers range from −9 to −65‰ and appear to be

an inverse function of temperature (26), similar to that observed for high-temperature equilibrium systems. If SO_4^{2-} reduction is controlled by microbial activity, the inverse relationship between $\delta_{S^{2-}-SO_4^{2-}}$ and temperature observed by Plummer and coworkers (26) and Figure 1 imply that the specific SO_4^{2-}-reduction activity increases with depth or with temperature.

Some $\Delta_{S^{2-}-SO_4^{2-}}$ values, such as those reported for the Floridian aquifer (104), are too large to simply attribute to low SO_4^{2-}-reduction rates based on current laboratory observations. Disproportionation of an intermediate product of sulfide oxidation, thiosulfate, can increase $\Delta_{S^{2-}-SO_4^{2-}}$ values, because the isotopic difference between oxidized and reduced sulfur constituents of thiosulfate are such that the resulting sulfate is enriched with respect to ^{34}S and the sulfide is depleted in ^{34}S (105). Although this mechanism has been proposed to explain the extreme isotopic differences between solid-phase sulfide and sulfate, Wortmann and coworkers (106) have recently reported $\Delta_{S^{2-}-SO_4^{2-}}$ values of up to 70‰ for deep coastal marine sediments. Disproportionation reaction of thiosulfate can be used by facultative anaerobes, for example, *Shewanella putrefaciens* (107) and SRB's (108) facilitating the rapid turnover of thiosulfate in anoxic depositional settings. The spatial juxtaposition of a relatively permeable and microaerobic sandy aquifer and an organic and sulfide-rich clay aquitard could also provide the requisite components for indigenous sulfur cycling by sulfide oxidation using oxygen or Fe(III) as an oxidant, thiosulfate disproportionation, SO_4^{2-} reduction, and the fractionation of sulfur isotopes. If such environments occur in the subsurface, they could provide a potent source of chemical energy for subsurface microbial ecosystems.

Unlike the sulfur system, the $\Delta_{CH_4-CO_2}$ observed in natural environments is frequently consistent with the $\varepsilon_{CH_4-CO_2}$ observed in laboratory cultures. Jenden and Kaplan (109) documented the $\delta^{13}C$ of carbon dioxide and methane in deep-sea sediments from 28 to 336 meters below the sediment-water interface. The $\delta^{13}C$ of the diminishing carbon dioxide conformed to a Rayliegh relationship with a $\varepsilon_{CH_4-CO_2}$ that decreased from −84‰to −63‰ with increasing depth. The methane production rate must be extremely high in these organic-rich sediments for the carbon dioxide-reduction rate to exceed the rate of carbon dioxide production by anaerobic oxidation of organic matter, acetate dissimilation, and thermal decarboxylation. In sandstone aquifers of the Gulf Coast, Carothers and Kharaka (110) reported evidence for aceticlastic methanogenesis at temperatures as high as 80 °C, on the basis of the $\delta^{13}C$ of DIC.

A much lower abundance of organic carbon characterizes the CRB aquifer where Stevens and McKinley (9) reported evidence for in situ microbial carbon dioxide reduction to methane. In this case, the deeper the water, the lower the DIC and the heavier the $\delta^{13}C$ of carbon dioxide. The data followed a Rayleigh distillation relationship in which the $\varepsilon_{CH_4-CO_2}$ was −60‰. Because groundwater ages in the CRB are younger than 35,000 years, the methane-production rate is greater than approximately 10^{-8} moles/L-year. The specific rate derived from $\varepsilon_{CH_4-CO_2}$ and Figure 1 is 5×10^{-15} moles CH_4/cell-hr. These two rate estimates are compatible only if three metabolizing methanogens are present per milliliter of water. The microbial enumeration of the groundwater samples suggested larger population densities, up to 10^4 cells/mL (9). The use of $\varepsilon_{CH_4-CO_2}$ and Zyakun's (94) results as a measure of in situ respiration, if reliable, implies that either the groundwater ages are much younger or that methane cycling is occurring by methanotrophy. Isotopic analyses of both CH_4 and DIC for the CRB aquifer are required in order to verify that the $\varepsilon_{CH_4-CO_2}$ derived from the DIC is representative.

The fixation of carbon dioxide into microbial biomass will increase $\delta^{13}C$ of the residual carbon dioxide. The $\varepsilon_{cell-CO_2}$, however, varies from −3 to −36 (Table 1) making it difficult to incorporate into geochemical models. In the case of carbon dioxide methanogenesis, the increase $\delta^{13}C$ of the residual carbon dioxide is more likely to be caused by catabolic versus anabolic conversion of the carbon dioxide.

MICROBIAL–MINERAL INTERACTIONS

With increasing depth or distance along a flow path, groundwater tends to become supersaturated with respect to carbonates, sulfides, or sulfates, silica, and clay (26,32,102). Although the formation of these phases is thermodynamically favored, abiotic precipitation may be kinetically inhibited. In this case, subsurface microbial participation in these solid/liquid reactions could play a significant role in diagenesis. Microbially mediated changes in the isotopic composition of the DIC and HS^- are usually reflected in the isotopic composition of precipitated carbonates and iron sulfides, but whether the mineral type or form is also specific to biotic precipitation processes, as is the case for aragonite precipitation in marine systems, has not been determined.

In vitro experiments indicate that a variety of extracellular iron sulfides (111) and dolomite (112,113) are formed during microbial SO_4^{2-} reduction. Bacterial Fe(III)-reduction experiments have yielded extracellular formation of siderite (114), magnetite (4,115), vivianite (because of phosphate in the growth media), and green rust (116) (because of chlorine in the growth media). Slobodkin and Wiegel (117) demonstrated that extracellular magnetite and siderite could be produced by Fe(III)-reducing and hydrogen-oxidizing bacteria growing at temperatures as high as 87 °C. Bacteria have also been implicated in the direct or indirect nucleation and precipitation of silica and various carbonate and sulfate minerals in the laboratory (118,119) and in natural surface and aqueous environments (120–124). These studies indicate that the types of minerals, their crystal symmetry, size, and morphologies are a complex function of biotic and abiotic factors including solution and cell surface chemical properties such as pH, Eh, ion composition, temperature, and type of microbial metabolism.

Because many of these experiments are performed under artificial conditions in the laboratory, it is difficult to determine the extent to which microbial–mineral precipitation reactions occur in the subsurface relative to abiotic processes. It is also unclear whether all

microbial biominerals are distinguishable from those produced as a result of abiotic reactions, but recently Thomas-Keprta and coworkers (125) used a combination of morphological, textural, and compositional properties to distinguish magnetite formed by magnetotactic bacteria from other forms of biotic and abiotic magnetite and applied this approach to the analyses of magnetite from Martian meteorites. Experiments using subsurface bacteria, media with compositions similar to groundwater and seed mineral or rock substrates, are becoming more common (126). Dong and coworkers (127) demonstrated that a subsurface bacterial strain, *S. putrefaciens* CN32, could reduce the Fe(III) in fine-grained magnetite. Kostka and coworkers (128) reported bacterial reduction of Fe(III) within smectite and later determined that this process had a dramatic effect on the chemical properties of the clay (129). Both phases are more recalcitrant and representative of deep subsurface environments than amorphous or microcrystalline forms of Fe(III). Detailed investigation of bacterial dissolution and precipitation of minerals under subsurface environmental conditions, however, is still in its infancy.

An alternative approach to examining subsurface bacterial mineralization is to study recently contaminated aquifers where microbial activities are elevated above background levels by the pollutant. In a hydrocarbon-contaminated sandy aquifer, Bennet and coworkers (130) found, by using submersed in situ mineral microcosms, that groundwater-inhabiting bacteria enhanced the weathering of silicates and the precipitation of clay minerals. Because contaminants impose geochemical conditions within aquifers that are distinct from those that prevailed throughout the aquifers' geological history, diagenetic phases formed during the contamination history are often distinguishable from those precipitated over geologic time. Tobin and coworkers (131) used this approach to detect traces of pore-filling ferroan calcite in a TCE-contaminated basaltic aquifer, where a normally aerobic environment had been replaced by anaerobic conditions, resulting in Fe(III) reduction.

Pore or fracture-filling diagenetic minerals, therefore, may provide constraints on the type and magnitude of subsurface microbial activity. Diagenetic carbonate and sulfide assemblages are particularly informative, because the relative contributions of microbial Mn(IV), Fe(III), and SO_4^{2-} reduction and methanogenesis can be delineated by determining the iron and maganese content, the $\delta^{13}C$ of the carbonate, the abundance, and $\delta^{34}S$ of the sulfide, and by calculating the mass balance as constrained by the redox equations (123). High positive values of $\delta^{13}C$ (ca. 10 to 20‰ PDB for the carbonate reflect methanogenesis by carbon dioxide reduction. Inferences with respect to aceticlastic methanogenesis are undermined by the potential variation in the $\varepsilon_{CO_2-C_2H_2O_2}$ with activity (Fig. 1) and the potential variation in the $\delta^{13}C$ of the acetate. Intermediate negative values of $\delta^{13}C$ (ca. −15 to −30‰ PDB) for carbonate reflect the combined effects of fermentation and microbial oxidation of formate or acetate coupled to microbial Mn(IV), Fe(III), and SO_4^{2-} reduction. Finally, very light $\delta^{13}C$ values in carbonate (ca. < -35‰ PDB) are indicative of methanotrophy (8,132).

Measurement of ^{13}C values in carbonate has been successfully used to model the organic oxidation and inorganic mineralization in low-temperature, near-surface marine sediments (133–135), and the formation of carbonate concretions in shallow nonmarine settings (123,136) where microbial processes dominate most redox reactions. Mineralogical evidence of low level, deep subsurface, and microbial activity can be inferred by determining whether diagenetic cement was formed at depth or near a surface or shallow subsurface sediment-water interface in the remote past. Several approaches exist for deriving the age of diagenetic carbonate/sulfide formation, relative to a rock unit's geologic history. The active precipitation of diagenetic carbonate in an aquifer can be verified by comparing the $\delta^{18}O$ and trace metal concentration, $^{87}Sr/^{86}Sr$, of the carbonate to that of the groundwater for the present-day formation temperature (137). The timing of pore-filling carbonate formation can also be related to a basin's burial history by measuring the detrital porosity, because differential burial compaction of partly cemented sediments produces a heterogeneous porosity distribution. If the burial and thermal histories of a rock unit are known, determining the temperature of diagenetic carbonate formation can constrain its age. The $\delta^{18}O$ can be used to surmise the temperature of carbonate precipitation, if the $\delta^{18}O$ of the paleogroundwater can be constrained. Analyses of primary aqueous fluid inclusions in the carbonate not only can establish the formation temperature, but analyses of secondary inclusions can determine whether the temperature of the rock has exceeded approximately 120 °C, which is the generally accepted upper limit for microbial life (138). Finally, in carbonate that contains hydrocarbon inclusions and/or is associated with sulfide, U(IV) can substitute for Ca(II) (139). Consequently, the secondary carbonate formed in anoxic environments is amenable to radiometric dating by either the U-series disequilibrium method, as in the case of the 500 kyr Devil's Hole vein calcite (140), or the U-Pb approach, as in the case of secondary calcite in Paleozoic limestone (141,142).

McMahon and Chapelle (32) related the diagenetic mineral assemblages present in a 50 to 80 m deep confined aquifer to microbial activity. The volumetric abundance, isotopic composition of calcite and pyrite cement, and the distribution of secondary porosity of 70 Ma. marine ACP sediments were used to derive the rates of microbial fermentation and SO_4^{2-} reduction. The sparry calcite tended to have light ^{18}O and ^{13}C signatures, characteristic of precipitation in present-day meteoric water, whereas the micritic calcite preserved a marine origin. When averaged over 70 myr, the volumetric abundances yielded rates for carbon dioxide production and SO_4^{2-} reduction of 10^{-6} and 10^{-8} moles $L^{-1}yr^{-1}$ rates, respectively. These estimates are similar to those derived from present-day pore water fluxes of acetate and SO_4^{2-} from the clays into the sandy aquifer (32). Furthermore, the cement and secondary porosity was concentrated near the interfaces between the clay aquitards and sandy aquifers, consistent with observations that present-day fermentation in the clay layers supplies organic acids to the sandy layers, where they are oxidized by SO_4^{2-}-respiring bacteria.

Because the small pore sizes in the clays restrict access of bacteria to organic matter and because the organic matter that is accessible is consumed and/or becomes more recalcitrant with continued biodegradation, the subsurface microbial respiration rate should decrease with time. Consequently, much of the cement may have formed early in the ACP burial history and respiration rates derived from the diagenetic cements only provide maximum estimates of the present-day subsurface microbial activity.

Evidence of the involvement of subsurface and hyperthermophilic SO_4^{2-}-reducing archaea in the formation of diagenetic carbonate has been reported for a North Sea chalk oil reservoir (143). These investigators reported the presence of biodegraded hydrocarbon inclusions within fracture-filling calcite comprised of light $\delta^{13}C$ values, associated with pyrite depleted in ^{34}S. The aqueous inclusion data and $\delta^{18}O$ of the carbonate indicate that the biodegraded oil was trapped at temperatures between 95 and 130 °C, sometime during the late Miocene to the present. These results suggest that hyperthermophilic SO_4^{2-}-reducing bacteria have been active in the subsurface for an extended period.

Grossman (144) documented sulfur cycling in a shallow subsurface environment using a combination of microbial assays and stable sulfur isotope analyses. In this case, however, the sulfur isotopic signature of the solid-phase sulfide in the aquifer sediments clearly indicated that it had not formed because of the modern sulfur cycling.

Analyses of many carbonate concretions in sandstone, which can attain diameters of several meters, indicate they grew at depths sufficient to prevent the diffusive transport of solute from the sediment-water interface and precipitate from meteoric groundwater (123,145). Textural features preserved in some of these carbonates suggest bacterial involvement in the precipitation process (146), and may reflect subsurface microbial activity.

Reduction halos are centimeter-sized, bleached, carbonate-cemented spheroids, with heavy metal and/or organic-rich cores that typically occur in terrestrial red beds, but are also reported in igneous rocks (22). Hoffman (22) has hypothesized that many reduction halos form as a result of microbial reduction of Fe(III) minerals in the host rock and precipitation of reduced metals in the core of the reduction halo. This supposition is based in part on Th-Pb ages of 100 Ma for reduction halos in Permian red beds, indicating a formation depth of at least 1,000 m (147), fluid inclusion homogenization temperatures of 40 to 70 °C, suggesting formation at depth, and sulfur isotope composition of sulfide in the core that suggest significant fractionation.

CONCLUSION

Microbial populations in the deep subsurface are generally characterized as being present at relatively low-population densities, heterogeneously distributed, and having very low metabolic activities. Their activity is constrained primarily by the availability of energy sources, pore space, and water. They obtain energy for growth and maintenance from oxidation of sediment or rock associated organic matter (heterotrophy), or from reduced inorganic compounds such as H_2, CH_4, or S^{2-} (lithoautotrophy). These metabolic reactions include, for example, oxidation of organic matter to carbon dioxide, reduction of Fe(III), to Fe(II) Mn(IV) oxides to Mn(II), and SO_4^{2-} to S^{2-}. Although their metabolic rates are glacial, they persist over eons and thus impart major changes in the geochemistry of the aqueous and solid phases of the subsurface. These changes are most easily recognized by progressive decreases in the $p\varepsilon$ of groundwater as it moves from the point of recharge to distal points in a confined aquifer. Microbial processes are also evident in groundwater and diagenetic minerals from the isotopic composition of elements such as carbon and sulfur that are fractionated during enzymatic catalysis.

In spite of recent advances in our scientific understanding of the microbiology of the deep terrestrial subsurface and of the biogeochemical processes microorganisms catalyze in this environment, many unanswered questions remain. Although evidence mounts that lithoautotrophic microbial communities may be common in the deep subsurface, we know little about their distribution and ecology or the origin of their primary energy source(s). There has been considerable speculation, but little actual scientific evidence that such microbial communities may support subsurface heterotrophic communities and that the entire ecosystem may make significant contributions to carbonaceous deposits in the earth's crust. Future scientific investigations should focus on addressing these questions, by applying developing technologies for deep drilling and sampling, by using conventional and molecular analyses for characterizing microbial communities and the enzymes they express, and by adapting isotope geochemistry to constrain in situ rates of respiration, growth, and mineralization. Exploration of the present-day deep subsurface ecosystem may provide insights to unraveling the surface biogeochemistry of the Archaen and guide the search for extraterrestrial life in our solar system.

GIARDIA: BASIC BIOLOGY, GENETICS AND EPIDEMIOLOGY

JACQUELINE A. UPCROFT
PETER UPCROFT
Queensland Institute of Medical Research
Brisbane, Australia

Giardia duodenalis, also known as *G. lamblia* and *G. intestinalis*, is the most commonly detected flagellated protozoa in the intestinal tract (1). The parasite is regarded as zoonotic by the World Health Organization (WHO), although there is evidence that host range can be restricted (2,3), and there is a lack of evidence for the extent of zoonosis (4) such that animal reservoirs of human outbreaks have not been unequivocally identified, although several likely sources have been reported (5,6). It has been estimated that 280 million people are infected each year with *Giardia*, with the incidence very high in children in developing countries, decreased to 2 to 7% in some industrialized nations (1,7), and varying significantly with locale (8,9). More recently, the WHO has estimated that three billion people live in unsewered environments in developing countries. In these people, the rates of giardiasis approach 30%, suggesting closer to one billion cases of giardiasis at any one time and contributing to 2.5 million deaths annually from diarrheal diseases (10).

HISTORY

Giardia duodenalis was the first protozoan parasite of man to be discovered when in 1681 the Dutch lens maker, Antonie van Leeuwenhoek, observed the parasite in his own stools using a simple self-constructed microscope (11,12). Van Leeuwenhoek's chronic diarrhea, which he described as "a looseness of bowels.... So I went to stool some twice, thrice, or four times a day... especially when I took hot smoke beef that was a bit fat, or bacon..." is an old complaint. Giardia cysts having been found in fossilized human feces several thousands of years old (13). His clear description of what he saw, "...very prettily moving animalcules..." and "...although they made rapid movement with their feet... they made but slow progress" is likely to be the first description of Giardia. In 1859, Vilem Lambl, from whom Giardia obtained one of its names, rediscovered the parasite in children's stools, but it was not until the twentieth century that convincing evidence was presented that the clinical syndrome of persistent diarrhea, colicky abdominal pain, abdominal distension, a feeling of bloating often associated with nausea, vomiting, and loss of appetite were attributed to Giardia parasites (12).

BIOLOGY

Organisms of the genus *Giardia* belong to the class Zoomastigophorea (zooflagellates), order Diplomonadida (cells with bilateral symmetry) and family Hexamitidae (6–8 flagella), and representatives of the genus have been reported to inhabit the intestinal tract of a wide variety of vertebrate hosts. The soft-bodied trophozoite, the feeding stage of the parasite, attaches to the small intestinal epithelium of its host by means of a large ventral disk. It reproduces by binary fission until, in some cases, the gut lining is completely covered with parasites. The trophozoite, 11 to 16 μm in length, is pear shaped, flattened like a leaf, with two nuclei dorsal to the ventral disk, four pairs of flagella, and complex microtubular structures including a claw hammer–shaped median body (Fig. 1) (14). A flange that overhangs the disk is also a distinguishing feature of *G. duodenalis* (15). Most of the information regarding Giardia biology and giardiasis, the disease, is derived from studies of the trophozoite stage.

The parasite has a simple life cycle (Fig. 2). Passage of the trophozoite through the gut induces encystation, whereby the binucleate trophozoite becomes a binucleate cyst and subsequently the nuclei undergo division within the cyst to form a quadrinucleate cyst (14,16). Only the cyst will survive in the environment and stomach acid, allowing it to reinfect another host. In fact it is the stomach acid that initiates excystation and which is completed in the small intestine (16,17). The cyst is responsible for transmission directly via the fecal/oral route or via fecal contamination of food and water. It is this form of the parasite that concerns water treatment authorities.

No sexual stage has yet been observed in the life cycle of *Giardia*. However, other organisms such as the ciliates have very complex mating systems, so presently we cannot fully discount the sexuality of *Giardia*. The observed

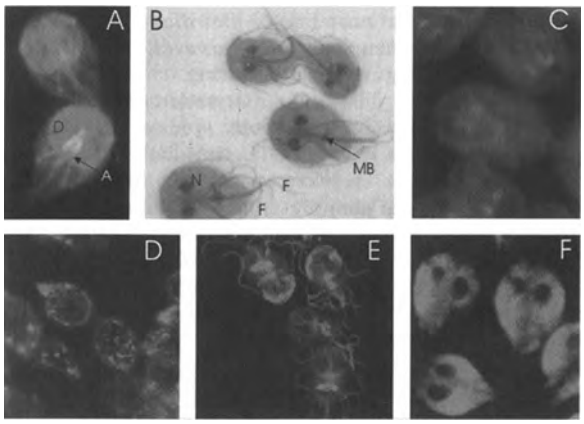

Figure 1. (**a**) Immunofluorescence of Giardia trophozoites reacted with mouse polyclonal sera raised against proteins of around 32 kDa (including giardins) extracted from a polyacrylamide gel. The disk and axonemes are clearly visible. (**b**) Giemsa-stained trophozoites showing nuclei, median body, and flagella, but not the disk. One trophozoite is undergoing division, which is almost complete. (**c**) Trophozoites stained with Hoechst showing nuclear staining. (**d**) Live trophozoites (hence, some are not in the focal plane) exposed to the fluorescent drug quinacrine overnight. The drug is apparently accumulated in dorsal vesicles. (**e**) Trophozoites reacted with a fluorescein-labeled antitubulin antibody. All of the microtubule bearing structures are visible; disk, flagella, and median body. (**f**) IFA of trophozoites reacted with a monoclonal antibody against a Giardia cytosolic protein. Trophozoites are 12–15 μM × 6–8 μM (15).

Figure 2. Life cycle of *Giardia*. Trophozoites colonize the small intestine, particularly the duodenum and jejunum. When trophozoites move through the digestive tract, encystation commences, the nuclei divide, and the protective cyst wall is synthesized. Cysts are passed in the feces and the length of time of viability depends on environmental conditions. A new host is infected via fecal/oral, food-borne, waterborne, or sexual transmission. Ingested cysts excyst under the influence of stomach acid and recolonize the gut.

polyploidy and aneuploidy (18), however, is consistent with the lack of regular meiotic pairing.

Much of the following information described in this article was obtained from studies on *Giardia* parasites grown in vitro (19). The invaluable techniques of excysting cysts in vitro, passaging cysts through a rodent model to amplify trophozoite numbers prior to committing them to continuous culture (20) and the medium with which to sustain trophozoites in culture (19) represent vital contributions to our understanding of this organism.

Speciation

Morphology-Based. Apart from *G. duodenalis*, which infects mammals, several other species belonging to this genus have been described. On the basis of the shape of the median body and body size and form, Filice (21) proposed that the bewildering list of *Giardia* species, generally named after their host species, be reduced to just three, *G. duodenalis*, *G. muris* (confined to rodents), and *G. agilis* (found in reptiles). More recently, two additional species have been proposed — *G. ardeae*, found in blue herons (22) and *G. psittaci*, first reported in budgerigars (23). The distinguishing features of *G. ardeae* are claimed to be a rudimentary caudal flagellum and a distinctly different chromosome profile to the *duodenalis* species (22). An incomplete ventral lateral flange and a rough, deeply pitted dorsal surface appears to be characteristic of the *G. psittaci* trophozoite (23).

Sequence- and Isozyme-Based. Although the above mentioned proposals are morphologically satisfying, molecular biology and biochemical studies point to further divisions in the *duodenalis* group. Analysis of many isolates established in culture in several laboratories around the world have revealed at least two demes, assemblages, or subspecies within the *G. duodenalis* sp. on the basis of differences in the rDNA repeat unit (24–26), differences in isoenzyme electrophoretic mobility patterns (27–28), sequence variation in housekeeping enzymes (29–30), surface antigen variability (31), DNA fingerprinting (24), and electrophoretic karyotype or chromosome profiles (6,24,32–35).

Over many years, many isolates obtained from children admitted to the Royal Children's Hospital in Brisbane with chronic gastrointestinal problems have been analyzed. Forty-one isolates collected over 12 years were divided on the basis of rDNA, electrophoretic karyotypes, and restriction fragment length polymorphism into two distinct demes (33). Since this study was completed, a third group has been defined by an isolate obtained from a calf (34), but more recently, an isolate of *G. duodenalis* was established in culture from a bird which died of an overwhelming infection of the parasite (36). The latter isolate, which chronically infects mice, mimicking the failure-to-thrive syndrome seen in children, is by all criteria a human isolate. This exemplifies the lack of practical significance of current *duodenalis* systematics. There are presently no reliable genetic markers or classification systems to distinguish pathogenic, drug-resistant, or potentially zoonotic strains derived from either clinical or environmental samples, apart from the extensive molecular biology data accumulated to date.

Giardia's Place in the Animal Kingdom

Evolution. *Giardia* shares many characteristics with both eukaryote and anaerobic prokaryote. It is on the basis of primitive characteristics that Sogin and coworkers (37) and Cavalier-Smith (38) proposed that the Metamonada, which includes the diplomonad *Giardia*, are primitive and "that they represent a surviving relic of a very early stage in eukaryotic evolution before the three organelles mitochondria, peroxisomes, and dictyosomes evolved" (39). However, malate dehydrogenase (40), valyl-tRNA (41), cpn60 and triose phosphate isomerase (42), which are classically of eubacterial origin, are present in *Giardia,* suggesting that the *Giardia* ancestor may have carried a symbiont related to those that went on to generate mitochondria. To complicate matters further, horizontal gene transfer is now believed to have had a major impact on species diversity and evolution (43), and consequently it is unlikely to be definitively resolved

whether *Giardia* ever carried, transiently or otherwise, a symbiont. An alternative and more parsimonious interpretation is that similar cell fusions generated the first eukaryotes, and *Giardia* retained predominantly the anaerobic gene repertoire, whereas others pursued the aerobic, mitochondrial evolutionary route (44).

Cell Structure. The highly developed cytoskeleton and membrane-bound nuclei (two) of Giardia trophozoites are clearly eukaryotic. Microtubules are typical features of eukaryotes and *Giardia* has several types of microtubule structures; the ventral disc, the flagella and axonemes, funis, and the median body (15) (Fig. 1). The ventral disc is the most distinctive structure of the trophozoites. It is composed of a single layer of uniformly spaced coiled microtubules adjacent to the ventral plasma membrane (15). Microribbons extend from the microtubules into the cytoplasm and are cross-bridged by electron-dense structures connecting adjacent microribbons (45). Novel *Giardia* proteins, the giardins, a heterogeneous group of some 23 proteins, are major components of the cross-bridges and the microribbons, but their organization in these structures is not well understood (45). Giardins are confined to the ventral disk, and the flagella and axonemes are the typical $9 + 2$ microtubules common to most eukaryotes (15). The median body, which is a separate and compact bundle of microtubules lying across the top of the funis (15,46) is not always present and has no defined function. However, it has been suggested that median body tubules, which are associated with giardins and the median body-specific protein, nucleate giardin core assembly (47). It is not surprising, considering this highly developed cytoskeleton, that the anthelmintic drugs, the benzimidazoles, specifically albendazole, are potent antigiardials. The benzimidazoles are known to interact with tubulin, preventing microtubule polymerisation or dissociating mature microtubules in helminths (48). They are not, however, effective against mammals. Conversely, colchicine, which binds to mammalian tubulin (48), does not affect *Giardia*. Consistent with the helminth data, albendazole appears to act via disruption of the Giardia cytoskeleton (49) and albendazole-resistant parasites induced under laboratory conditions have an altered cytoskeleton with enlarged median body (50). Together with the microtubular structures, *Giardia* has a collection of microtubule-associated proteins including those mentioned above — actin, median body protein, a head-stalk protein with homology to motor proteins, and dynein as would be expected for a highly motile, flagellated eukaryote (18).

Giardia cysts are elliptical and range in size from 6 to 10 μm. The thick cyst wall has an outer filamentous portion, which apparently forms from successive layers of cyst wall materials (51), and an inner membranous portion. It is tightly associated with the surface of the organism. In the periphery of the cyst cytoplasm, an extensive network of vacuoles and tubules exists just beneath the cell membrane (15). The cytoplasm of the cyst contains an apparently disorganized array of all of the highly ordered structures seen in the trophozoite (15). On excystation, the cyst ruptures at the pole opposite the nuclei and the tetranucleate organism within the cyst is liberated apparently with assistance from the flagella. Several minutes after excystation, the organism undergoes cytokinesis (division) and the typical morphology of the trophozoite is evident (15).

Trophozoite Metabolism. *Giardia* is amitochondrial and microaerotolerant (52). Its glycolytic and fermentative metabolism generates ATP by substrate level phosphorylation (53). The key ATP-generating step following the glycolytic pathway, the decarboxylation of the oxoacid, pyruvate, is executed by the anaerobic bacterial homolog pyruvate:ferredoxin oxidoreductase (PFOR) (54,55, Genbank L27221). In aerobic organisms, the mitochondrial multienzyme complex pyruvate dehydrogenase (PDH) performs this function (56). PFOR uses ferredoxin as an electron acceptor, whereas PDH uses NAD^+ and four cofactors. Acetyl CoA, a product of the decarboxylation reaction can in turn be used to generate ATP. But anaerobes, including the microaerophiles and microaerotolerant organisms, have many alternative energy producing pathways including alternative oxoacid oxidoreductase (54,57,58) and amino acid catabolism (59).

Cyst Formation. In suckling mice the jejunum is a major site of encystation and one suggestion is that primary bile salts trigger encystation (60). An alternative proposal relates to the inability of Giardia trophozoites to synthesize cholesterol de novo (61). The absorption of lipids in humans occurs almost completely in the jejunum, so trophozoites travelling through the intestine will encounter a lipid-free environment that initiates encystation (62).

Once initiated, encystation proceeds with the synthesis, processing, and transport of unique cyst wall constituents and their assembly into a protective cyst wall. Genes encoding two of these components, *CWP1* and *CWP2*, predict acidic and leucine-rich proteins, respectively, targeted to the secretory pathway by amino-terminal signal peptides. Both proteins share many features including induction kinetics, sequence similarity, and colocalization in encystation-specific vesicles (62).

Giardia Genome. *Giardia* trophozoites have two apparently identical, transcriptionally active nuclei. Unlike the bacterial nature of its metabolism, Giardia chromosomes are eukaryotic; linear and capped with typical telomere repeats $(TAGGG)_n$ (63). Each nucleus carries several copies of 5 to 8 chromosomes ranging in size from approximately 1 to 7 Mb. There are also a number of variable "minor" or "accessory" chromosomes (in representation), which are partial duplications of most or all of the major chromosomes and are associated with drug resistance (44). The relatively small size and the ease with which the chromosomes, once stripped of their proteins, can enter and migrate through an agarose gel matrix has allowed detailed study of the Giardia genome (44).

Giardia is not clearly diploid or haploid. Apart from its two nuclei and partial duplications, many chromosomes are present in greater copy number than others and chromosome representation varies from isolate to isolate.

Giardia is therefore polyploid and aneuploid but has survived successfully as an asexual organism. It has also been proposed that polyploidy may be the asexual means to replace and repair defective genes and mutations in three-way genetic crosses (44).

GIARDIASIS: THE DISEASE

Epidemiology

Giardia ranks in the list of "top ten" human parasites. It is more prevalent, with more severe symptoms, in children than adults (64). *Giardia* infections are common in institutions, particularly day care centers, where infected children may be asymptomatic. Giardia infection rates typically range from 100% of children infected at some stage during their first three years in rural Guatemala (65), to 2 to 6% of children under 11 in suburban Brisbane, Queensland, who were infected at the time of study (66). A recently reported longitudinal study of well-nourished children, four years and under, in day care centers in Havana indicated that 9% of children appeared to be predisposed to Giardia infections (they were always infected), 51% were never infected, and the remainder were infected once or twice (67). Reinfection after cure is very common, with one study among the Australian Aboriginal population reporting a 37% prevalence of *Giardia* infection before treatment, 12% soon after, and 28% within a month of treatment (68). Giardiasis is the most common cause of chronic diarrhea in travellers (7,69–70), with travel to St. Petersburg notoriously associated with the disease and cyst-contaminated food and water well documented sources (65,71).

Symptoms

The incubation period for giardiasis is one to two weeks duration after ingestion of viable cysts, following which various grades of symptoms including nausea, stomach cramps, diarrhea, and vomiting ensue. The acute stage can last from 3 to 4 days, but can persist for much longer. In children, a failure-to-thrive syndrome may occur (7), and in the developing world giardiasis is an important cause of morbidity. Persistent infection and diarrhea may occur in immunocompromized individuals, for example, IgA deficiency, but is less obvious in cases of acquired immunodeficiency syndrome (HIV/AIDS) (5,7,65). In a study of 200 patients with diarrhoea in a two-week window in a drought rehabilitation camp in Korem, Ethiopia, 98% of apyrexial patients carrying trophozoites of *Giardia* or *Entamoeba* had dysentery (72).

Infestation by the organism causes decreased small intestinal brush border surface area, microvillus and villus atrophy, enterocyte immaturity, disaccharidase and luminal enzyme deficiencies, and malabsorption of electrolytes, a multifactorial pathogenesis which is not well understood (73). A number of other symptoms have been associated with giardiasis (5), but these have not been routinely or consistently found. Similarly, granulomatous hepatitis and cholangitis have been associated with chronic diarrhoea attributed to giardiasis (74). A more recent survey of 25 patients with giardiasis and raised liver enzymes demonstrated return to normal function after antiparasite therapy (75). This may be consistent with poor fatty acid uptake and steatorrhoea in giardiasis (7); previous anecdotal observations may therefore have a stronger foundation, but vary with patient (e.g., immunological status), parasite burden, or strain.

Mechanisms of Pathogenicity

It is not known why symptoms range from a carrier state to failure-to-thrive syndrome although a Giardia gene was recently reported, which has 57% homology with the sarafotoxins, which cause stomach cramps, nausea, diarrhoea, and vomiting (76). It has long been postulated that toxins were the reason for symptoms, but the Giardia toxin homolog was the first solid data. It is only present in some isolates, and subject to the silencing of telomeric position effects, where expression of the toxin-like protein can also be induced to very high levels (77). The gene is a member of a family of genes that vary via a cassette-like mechanism (44,78), and is not present in all isolates (77). Such complex expression patterns of genes encoding diverse toxin and cell-signaling molecules may explain the variability in symptoms.

An alternative mechanism of conferring virulence appears to be via a *Giardia* plasmid. Such a plasmid was harbored by parasites obtained from a child admitted to hospital with hematemesis, and who had lost sufficient blood to warrant a transfusion. Endoscopy, biopsy, and extensive workup failed to find any aetiologic agent other than *Giardia* (18). In microbiological terms, the presence of a plasmid is usually associated with drug resistance or increased virulence, conferring upon the host cell the ability to adapt to a more hostile environment. However, the metabolic burden of carrying such elements is not conducive to their continued maintenance in the entire population unless the prevailing conditions require their presence. In fact, the *Giardia* plasmid decreases in copy number upon serial in vitro culture. This is suggestive that the plasmid conferred an advantage only on the parasite in vivo. The plasmid has since been identified in some other isolates.

A number of reports have documented a range of pathogenicity among Giardia isolates. These included a report of three isolates which differed in their ability to cause functional mucosal damage (79); only one of nine strains that was able to infect adult mice of a particular mouse strain (80), and *G. duodenalis* isolated from a bird that died together with its cage mates from an overwhelming infection of the parasite. This highly pathogenic strain established chronic infections in mice that were associated with weight-gain impairment. Before the description of this strain in 1997 (36), it was believed that avian species of *Giardia* could not be transmitted to mammals. Mice infected with the avian strain carry about a fourfold higher parasite load compared to other strains tested, and this may be responsible in part for the severe symptoms. Other molecules from the avian isolate associated with cytotoxicity are currently under investigation.

Table 1. Antigiardial Drugs: Doses and Side Effects

Drug	Recommended Dose	Side Effects
Metronidazole (Flagyl)	250 mg (adults) or 5 mg/kg (children) thrice daily, 10 d	Nausea, malaise, headache, dizziness
Tinidazole (Fasigyn)	2 g single dose or, 150 mg twice daily, 7 d	Nausea, fatigue, malaise, headache
Furazolidone (Furoxone)	100 mg (adults) four times daily, 10 d; 2–3 mg/kg (children) thrice daily, 7–10 d	Nausea, malaise, headache, hemolysis in G-6-PD[a] deficiency
Quinacrine (Atebrine or Mepacrine)	100 mg thrice daily, 7 d	Nausea, malaise, headache, hemolysis in G-6-PD[a] deficiency, neurotoxicity (including psychosis)
Albendazole (Zantel)	200 mg twice daily, 7 d	
Dual therapy (treatment failures)	500 mg thrice daily, 10 d metronidazole + 400 mg twice daily, 7 d albendazole	

[a] G-6-PD, glucose-6-phosphate dehydrogenase

Persistence of giardiasis in patients with nodular lymphoid hyperplasia almost certainly reflects inability to mount a secretory IgA-response against *G. duodenalis*. Other antibody deficiency syndromes that also predispose individuals to severe and prolonged giardiasis are further evidence for the immune involvement in parasite clearance (81). Under normal circumstances, in immunocompetent individuals, it is likely that IgA-coated trophozoites are unable to adhere to the intestinal epithelium and expulsion of the parasite is mediated by peristalsis (81). Children with a severe T-cell deficiency and $CD4^+$-deficient AIDS patients are not more susceptible to giardiasis than immunocompetent individuals, and thus the role of cell-mediated immunity to *Giardia* in humans is uncertain (82).

Finally, symptoms are also very subjective, and similar symptoms may be disregarded by one community but considered important by another.

Diagnosis

Diagnosis of giardiasis currently depends on microscopic identification of the parasite either as the cyst in stools or as the trophozoite in the small intestine. Trophozoites can be occasionally seen in stools of patients with diarrhea. Because cysts are not continuously excreted, it is recommended that three successive samples are examined (64). Some chronically infected patients who continually test negative for cysts may require duodenal biopsies and juice sample for microscopic and histological examination and for mucosal enzyme assessment (64). Other methods including commercially available enzyme-linked immunosorbent assay kits that, detect among other proteins, CWP1 (83,84), and PCR detection of DNA from Giardia cysts (85) are viable alternatives for diagnosis.

Chemotherapy

Current treatment for giardiasis includes tinidazole, metronidazole, furazolidone, and quinacrine with success rates less than 90%, followed by albendazole (along with paromomycin) with success rates of 10 to 95% (5,86–89) [Table 1 (52,64–65,86–87,93,100)].

Quinacrine was the first effective antigiardial (90) until it was supplanted by the nitroimidazole, metronidazole (91). It is a substituted acridine and was introduced as an antimalarial in the mid-1930s. Quinacrine is not recommended in Australia because of side effects, although it is still used in Europe and has been used effectively in cases of nitroimidazole treatment failure (92).

Metronidazole is regarded as the drug of choice, with the derivative tinidazole being an alternative, except in the United States where it is not available (93). Single high-dose regimens, or three, five, and seven-day regimes with lower doses have variously been recommended (Table 1) with the single, high doses of metronidazole or tinidazole being an advantage for compliance. Clinical resistance prevalence levels as high as 20% have been reported (7,94), with recurrence rates as high as 90% (95). There is a large range in susceptibility of strains to metronidazole, and resistant organisms have been isolated from patients refractory to the drug (7,52,91,96–98). Metronidazole is activated to its toxic nitroso and other radicals in *Giardia* via PFOR/ferredoxin reduction, and consistent with this mechanism of action of metronidazole, both PFOR and ferredoxin levels are downregulated in metronidazole-resistant *Giardia* (52,54,91,99).

The nitrofuran, furazolidone, where available, is recommended for children because of its availability as a suspension (93). Like metronidazole there is a range of susceptibilities of strains to furazolidone, and the development of resistance has been demonstrated in patients (97).

Albendazole was first introduced in 1982 as an anthelmintic. The first published (and successful) report of albendazole against *Giardia* was in 1986 with other benzimadazoles also being tested prior to 1990, and having mixed success (93). The first large-scale human study was in Bangladesh where the average efficacy of albendazole was 62 to 95% compared with 97% for metronidazole (100). Higher levels of efficacy with albendazole require multiple doses. Albendazole is proving very useful as an alternative,

or in combination, particularly in cases of metronidazole treatment failure (Table 1). Consistent with binding of albendazole to tubulin as its mechanism of action, albendazole-resistant *Giardia* have altered cytoskeletons with particularly enlarged median bodies (50,52).

Animal Models of Giardiasis

The ability of axenically cultured *G. duodenalis* to infect and complete its life cycle in suckling mice is well documented (101). The model has been used to assess the pathogenicity of strains by monitoring villous atrophy and associated deficiencies (102–103), drug susceptibilities in vivo (104), and to establish cultures in vitro (24). In most cases the infections spontaneously resolve after about three weeks (101). Gerbil and suckling-rat models are also used for giardiasis, the former has the advantage of using adult animals (105). However, specific pathogen-free (SPF) gerbil colonies are not as readily available as SPF mice, and in Australia gerbils are not available.

CONTROL AND IMPLICATIONS OF ENVIRONMENTAL CYST CONTAMINATION

Giardia duodenalis continues to be the most frequently identified etiologic agent in waterborne diseases outbreaks in the United States (1). Of all 22 outbreaks of waterborne disease, both chemical and microbial in origin in the United States between 1995 and 1996, giardiasis involved the largest number of cases in an outbreak with 1,449 ill people (106). In all other cold climates, where cysts remain viable for many weeks in water at 8 °C (107) (viability decreases rapidly with increased temperature), waterborne outbreaks have been attributed to *Giardia* (65,71). However, in Australia, where only sparsely populated regions are likely to have reservoir and recreational water this cold, despite some anecdotal evidence, no proven case of waterborne outbreaks has been documented. Wherever outbreaks have been investigated, fecal-oral transmission was the most likely route of infection (108). Nevertheless, waterborne contamination with *Giardia* cysts is an issue for all travelers and backpackers in cold and mountain climates worldwide, and drinking raw water should be avoided in these areas.

Water Purification and Detection of Cysts

The most efficient method of disinfecting water contaminated with *Giardia* cysts is by boiling, whereby cysts are immediately killed (107). Steam cleaning of animal enclosures is effective. For large bodies of water, chlorination is of some use, but coagulation and filtration are recommended in addition to disinfection (71,107). A variety of disinfection methods have been described, including ultraviolet radiation and chemical agents such as chlorine, iodine, and ozone (107,109). Optimal filtration of water through diatomaceous earth or sand can effect a 99.9% (3-log) reduction in *Giardia* cyst numbers (110).

The U.S. EPA requires that public water systems associated with surface water be treated to comply with at least a 3-log reduction of cysts or cyst viability (111) and an action level of 3 to 5 *Giardia* cysts per 100 L based on monitoring outbreaks has been proposed (112).

During the 1998 Sydney water contamination events, as many as 4,000 cysts per 100 L were detected in the eastern central business district water supply at one sampling (113). In comparison, a Canadian study reported a maximum of 2,000 in raw water in a longitudinal study of 86 sites in British Columbia (114).

In order to detect cysts in water they must be concentrated. This can be carried out using wound fiberglass depth filter cartridges (Diamond filters) (115), membrane and particulate filter methods, or using yarn wound cartridge filters (116). Detection of cysts after concentration employs essentially the same methods as used for diagnosis using fluorescent anticyst monoclonal antibodies (114), although the whole process may be automated using flow cytometry in water-treatment plants (117).

The severity of an outbreak will depend on a number of factors including viability and numbers of cysts, although as few as 10 can establish an infection (16), and previous exposure and herd immunity of the infected population (118).

Source of Cyst Contamination — Zoonosis

The role of animals in the transmission of giardiasis to humans is unclear, but there is considerable evidence that some *Giardia* found in humans is the same as that found in some animal species (6). In a Canadian waterborne outbreak, electrophoretic karyotyping of Giardia isolates from a giardiasis epidemic correlated with the karyotype obtained from a beaver believed to be responsible (6), and one carefully executed study reported that a human volunteer infected with Giardia cysts of animal origin shed cysts and developed symptoms consistent with giardiasis (119). The establishment of avian *G. duodenalis* in culture and chronic infection of mice with this isolate suggests that birds, previously thought not to be associated with Giardia contamination of watersheds, are indeed a potential source of contamination (3). On the other hand, it appears that *Giardia* from dogs is unlikely to be involved in transmission to humans (120). A further issue to be considered is that cyst-shedding in young animals is significantly greater than in older animals (121), and thus watersheds are likely to be heavily contaminated with animal Giardia cysts during spring (122,123). This may be controlled if young animals are located outside major water-catchment areas.

Whether contaminating cysts are infectious to humans has only been looked at carefully where beavers have been implicated (6). However, it is important to identify the source of a contamination where drinking water supplies are concerned, to stem an outbreak or prevent future similar problems. In some cases, associated coliform contamination data may indicate the likely host source of contamination, thus human fecal contamination may have arisen from sewage contamination, but Giardia cyst contamination has been reported in the absence of bacterial contamination (71). Ideally, stock and humans should not have access to water- catchment areas, but this is not always possible.

Viability of Contaminating Cysts

The contamination of Sydney's water supply in 1998 with Giardia cysts and Cryptosporidium oocysts (113) at levels more than 10 times higher than those of 13 oocysts per 100 L measured during the infamous Milwaukee outbreak (124) was not accompanied by an increase in giardiasis or cryptosporidiosis. In spite of the lack of clinical cases, boiled water alerts were posted for the entire city. This costly exercise may have been entirely avoided if the viability of the organisms had been assessed. Although this may not be an easy task, several stains have been used to measure cyst viability. SYTO-9 and Live/Dead BacLight available from Molecular Probes (Eugene, OR, U.S.A.), for example, are effective in distinguishing dead and viable cysts and staining correlates with animal infectivity (109). Live cysts fluoresce dark green and nonviable cysts light green to orange-yellow when stained with Live/Dead BacLight. Other stains including eosin (107), and propidium iodide (114), together with DAPI (125), have been successful. PCR is claimed to be useful assaying viability (115), and the neonatal mouse model (104), gerbils (126) or severe combined immunodeficient (SCID) mice (114) can be infected with cysts, although the results of viability would not be known for several days following animal infection — until either the animals begin shedding cysts or sufficient trophozoites have colonized the animal's small intestine to be detected after gut dissection.

Well-established methods for excystation in vitro have also been used to assess cyst viability (127). These involve exposure of the cysts to hydrochloric acid, salts, cysteine, and sodium bicarbonate followed by incubation and exposure to excystation medium containing trypsin. Reported excystation rates determined microscopically have been as high as 90%, but depend on the source and age of the cyst preparation (127).

FUTURE CONSIDERATIONS

Human *Giardia* infections are unlikely to be ever eradicated, and thus, chemotherapy and other methods of control of the disease will always be required. The drugs available cannot be replaced in the short term, so every effort should be made to ensure their long-term efficacy. The search for new drugs will inevitably continue, and successful drugs may well be based on inhibition or inactivation of *Giardia*-specific molecules. Such molecules will continue to be exposed by future research efforts such as those involving genome projects (128), but may also involve combinatorial chemistry (129).

GIARDIA: DETECTION AND OCCURRENCE OF IN THE ENVIRONMENT

PAUL A. ROCHELLE
Metropolitan Water District of Southern California
La Verne, California

Giardia duodenalis is a protozoan parasite that causes symptoms ranging from mild diarrhea, flatulence, abdominal cramps, and epigastric tenderness to steatorrhea and full-blown maladsorption syndrome in individuals who become infected. Asymptomatic infections also occur. Giardiasis is one of the most commonly reported enteric diseases, and according to some sources *G. duodenalis* is the most frequently isolated intestinal pathogen in humans. Estimates of the annual incidence of giardiasis in the United States range from 260,000 to 2.5 million cases and the overall incidence of *Giardia* carriage may be as high as 2% (1,2). The organism can be transmitted via person-to-person contact and food (3) but the waterborne route is considered by many to be the main source of giardiasis. It has been estimated that up to 60% of all *Giardia* infections are caused by drinking contaminated water (4). However, other authors stated that waterborne transmission is the least common of the regular routes of infection with person-to-person contact accounting for the majority of cases (5). *Giardia* cysts are very common in environmental waters and *G. duodenalis* has historically been the most frequently identified cause of waterborne disease outbreaks (6). The organism is also frequently a cause of diarrheal illness among children in day care centers and backpackers who drink untreated river water.

Table 1. Reported Animal Hosts of *Giardia duodenalis*

Alpaca	Cockatoo	Guinea pig	Pig
Baboon	Cow	Hare	Raccoon
Bear	Coyote	Horse	Rat
Beaver	Dog	Human	Rhesus monkey
Cat	Elk	Moose	Sheep
Chimpanzee	Gerbil	Mule deer	Slow loris
Chinchilla	Goat	Muskrat	Water vole

The highest rate of giardiasis occurs among children below 5 years and the overall incidence peaks during late summer and early autumn (2). *Giardia lamblia* was originally considered to be a human-specific pathogen but it is now recognized by most authorities to be the same species as that found in many other mammals, *G. duodenalis*. The organism has also been called *G. intestinalis* by some authors with claims that this name has a precedence in standard nomenclature (7). Therefore, *G. duodenalis*, *G. lamblia*, and *G. intestinalis* are synonymous. Historically the taxonomy of *Giardia* spp. has been somewhat confused with many host-specific species being named. In a 1952 paper, morphological criteria were used to define three species types: *G. duodenalis* from mammals; *G. muris*, which infects rodents, birds, and reptiles; and *G. agilis*, which infects amphibians (8). A species more recently isolated from the intestine of a gray heron was named *G. ardeae* (9) and *G. psittaci* from budgerigars has also been described. Some isolates from cats, dogs, and rats have been named *G. cati*, *G. canii*, and *G. simoni*, respectively, but the wide host range of *G. duodenalis* (Table 1) and the demonstration of its occurrence in all of these animals raises questions about the use of species designations based on animal hosts. The focus of this review will be *G. duodenalis* since it is the species known to infect humans. However, many studies of *Giardia* in the environment do not use species-specific detection methods, so much of the data on occurrence in natural environments and prevalence in animals is on "*Giardia*" rather than on specifically *G. duodenalis*.

BIOLOGY AND GENETICS

Giardia duodenalis is a single-celled, multinuclear, amitochondrial, anaerobic (but aerotolerant), flagellated protozoan. It has a simple life cycle involving an infective cyst and a vegetative trophozoite (Fig. 1). Following ingestion of a cyst by a suitable host animal, excystation in the small intestine leads to the formation of two trophozoites. The trophozoites replicate by binary fission resulting in giardiasis in the host. Most cases of giardiasis respond well to treatment, with metranidazole (Flagyl) being the most commonly prescribed drug. Albendazole and mebendazole are also effective. Some of the trophozoites encyst, resulting in the formation of new cysts that are excreted in the feces. The mechanism of encystation is not fully understood, but it has been suggested that trophozoites are triggered to encyst by a decrease in host cholesterol concentration as they move down the intestine (10). The cyst is relatively resistant

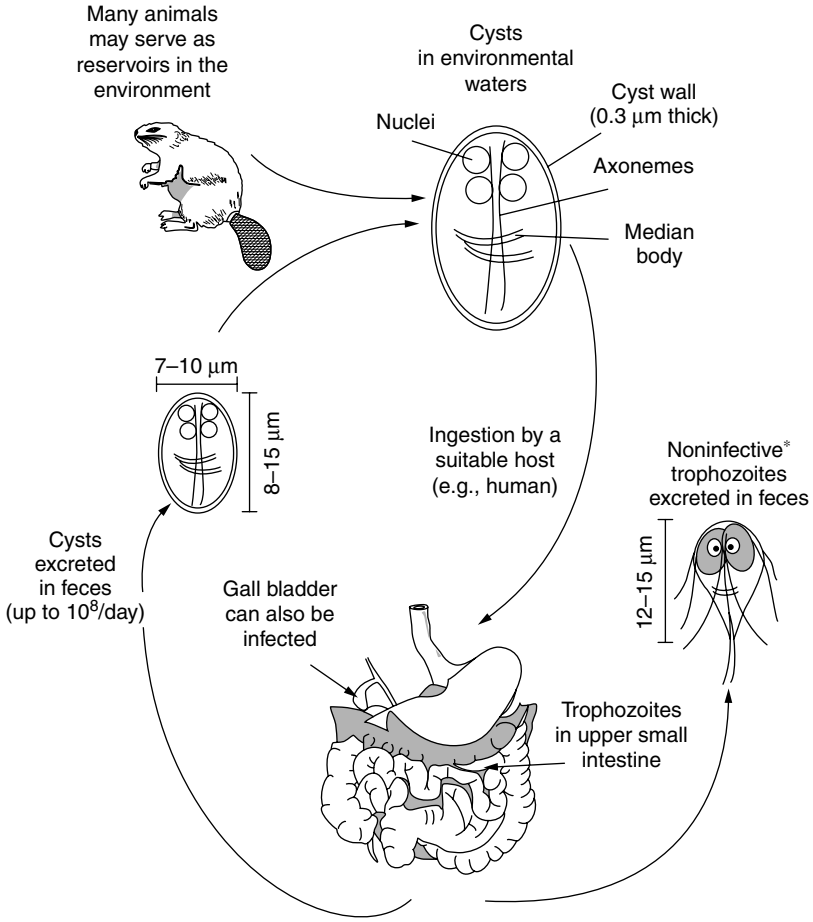

Figure 1. Diagrammatic representation of the life cycle of *G. duodenalis*. Following ingestion of cysts the incubation period is usually one week to the onset of illness. Without treatment, in otherwise healthy individuals, the average duration of illness is approximately six weeks. *, Trophozoites have been shown to initiate infection experimentally (38) but cysts are by far the most common cause of infection. Trophozoites do not survive well outside of the host organism.

to physical and chemical stresses and is the form found in the environment. Cysts are ovoid and measure 8 to 15 μm by 7 to 10 μm. The internal structures of the cyst include 2 to 4 nuclei, 2 to 4 median bodies, and axonemes of the flagella. The newly formed cysts have two nuclei but the older ones that are excreted usually have four. The median bodies are *Giardia*-specific structures that may be functionally related to the ventral disk, which acts as a suction cup in attachment of the trophozoite stage to the intestine (11). These internal structures can be observed by light microscopy using Nomarski differential interference contrast optics but the nuclei are more easily visualized by staining with nonspecific fluorescent compounds such as 4′,6-diamidino-2-phenylindole (DAPI) and epifluorescence microscopy. Other internal structures such as lysosomal vacuoles, ribosomal granules, and fragments of the ventral disk are generally only visible by electron microscopy. A variety of bacterial and virus-like endosymbionts are also present (11). The number of chromosomes and overall genome size is unresolved.

Phylogenetic analysis of the small subunit rRNA gene places *Giardia* as a very early branch of eukaryotes with no close relatives yet identified (Fig. 2a). It is considered to be one of the most primitive extant eukaryotes. The small subunit (SSU) rRNA gene of *G. duodenalis* is only approximately 1,450 bp compared with at least 1,750 bp for most other eukaryotes. It has long been recognized that there is a high level of genetic heterogeneity between isolates of *G. duodenalis* (Fig. 2b). Using both phenotypic and genetic criteria, it has been established that most isolates recovered from humans and many other mammal species can be classified into two primary groups. Just as there is still confusion over naming the *duodenalis* species, there are also naming inconsistencies within the species. The names of the two groups of isolates differ according to continent, but they appear to be synonymous. Group 1/2 isolates (North American name) are generally called the Polish group in Europe and Assemblage A in Australia. They have been detected in humans, livestock, cats, dogs, beavers, guinea pigs, and slow loris (12). The North American Group 3 is referred to as the Belgian group and Assemblage B in Europe and Australia, respectively, and have also been recovered from a wide range of animals including humans, chinchillas, dogs, beavers, and rats. The genetic distance between these two groups is much greater than the distance separating many species of higher organisms. Recent analysis has demonstrated that each of the two groups can be further subdivided. Within Group 1/2, one cluster contains isolates from humans and other animals. Isolates in a second cluster have so far only been recovered from humans (12). In addition, it has been reported that some isolates from dogs, cats, livestock (alpaca, cattle, goats, sheep, pigs),

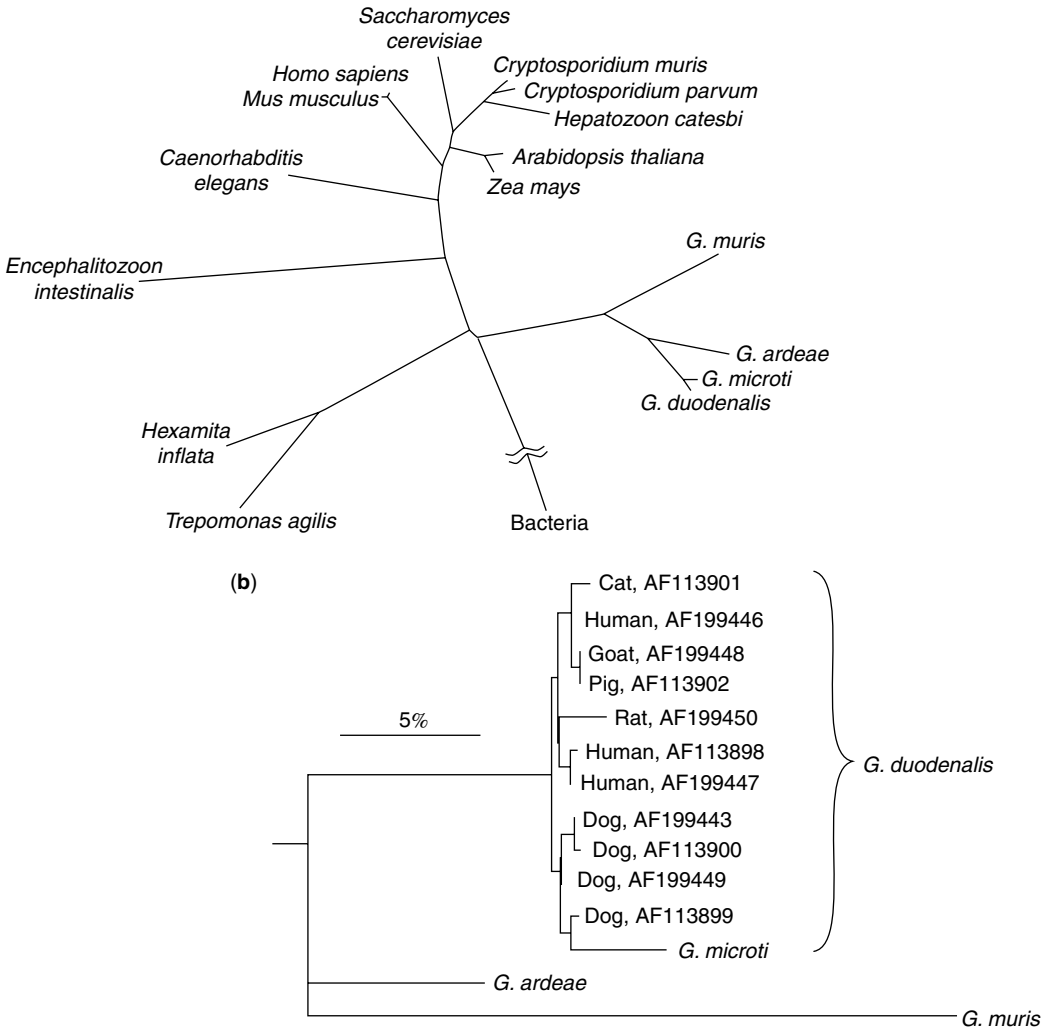

Figure 2. Phylogenetic analysis of a portion of the *G.duodenalis* small subunit rRNA gene in relationship to other major groups of eukaryotic organisms (**a**) and within the species *G. duodenalis* (**b**). The analyses in A and B were based on 780 and 424 aligned bases, respectively, and the dendrograms were constructed using the PHYLIP package of programs (Phylogeny Inference Package, ver. 3.57c). All sequences were obtained from the GenBank; the alphanumeric codes for each organism in B are GenBank accession numbers.

rats, and muskrats form separate lineages distinct from Groups 1/2 and 3. These various lineages have been called Assemblage C (dog isolates), D (dog), E (hoofed livestock), F (cat), and G (rats) (7). As has occurred recently with *Cryptosporidium parvum*, the taxonomy of *Giardia*, and specifically *G. duodenalis*, is undergoing revision. A novel livestock genotype within Group 1/2 was reported to have an exclusive association with cloven-hoofed animals (13). In addition, a group of morphologically distinct isolates from water voles and muskrats identified as *G. microti* (14) falls within the *G. duodenalis* group, as found in an analysis of the SSU rRNA gene. Genetic variation within the *G. duodenalis* group differs depending on the gene used for analysis. In a comparison of four genes, the greatest interisolate variation was displayed by the triose phosphate isomerase gene, whereas a gene encoding an elongation factor demonstrated the least variation (7). The heterogeneity seen within the species *G. duodenalis* suggests that although multiple synonymous names have been used historically, new species names may eventually be assigned to the various distinct clusters. There is currently very little information regarding the relative risk to human health posed by the various genotypes of *G. duodenalis* or whether some types are more dominant in the environment than others. However, it is likely that genotypes with restricted animal hosts will be less common in environmental water samples.

DETECTION METHODS FOR *GIARDIA* CYSTS IN WATER

Although *Giardia* is biologically and genetically very different from *Cryptosporidium* (Fig. 2a), both organisms are pathogenic protozoa and so there is a general tendency, at least within the water industry, to think of the two

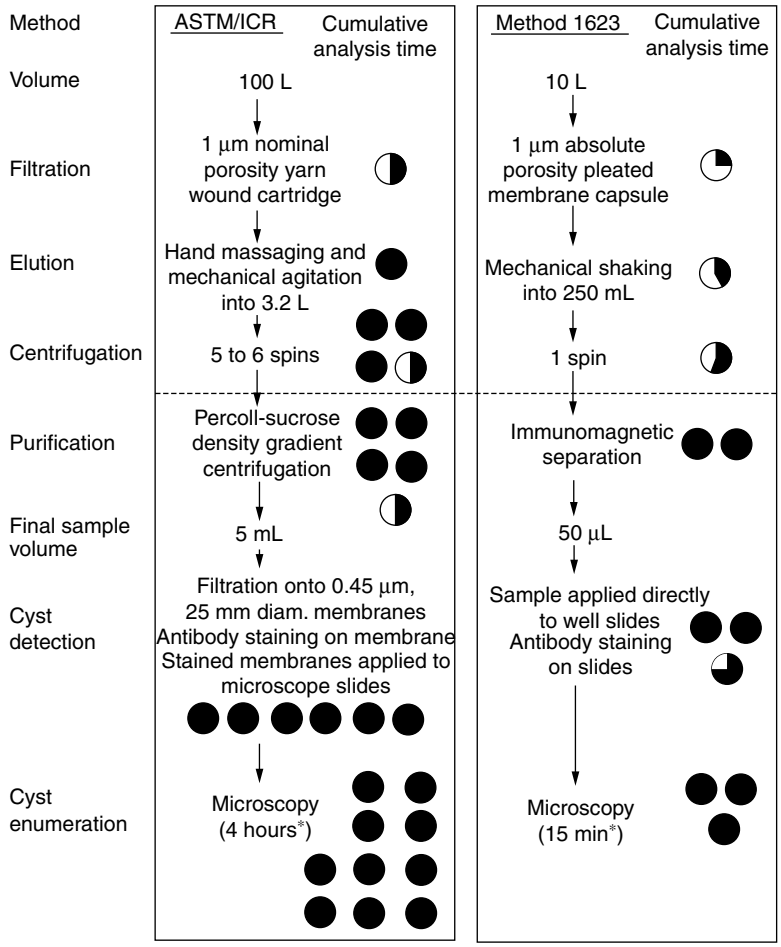

Figure 3. Comparison of ASTM/ICR and Method 1623 procedures for recovery and detection of *Giardia* cysts in water. These methods were developed for the concurrent recovery and detection of *Giardia* cysts and *Cryptosporidium* oocysts. *, Approximate microscopy time to analyze the equivalent of a 10-L sample. DNA-based detection methods can be substituted at any position below the dashed line.

organisms together. Consequently, methods have been developed for detecting both organisms simultaneously in environmental samples and the majority of environmental surveys have assessed the occurrence of both organisms.

Microscopy-Based Methods

The only methods currently approved by the United States Environmental Protection Agency (U.S. EPA) for detecting *Giardia* cysts (and Cryptosporidium oocysts) in water are based on recovery of cysts by filtration, steps to concentrate and purify the cysts, and finally detection by an immunofluorescence microscopy assay (Fig. 3). Until recently, the most widely used method was that described in a proposed standard detection procedure (15) later modified for incorporation into the U.S. EPA Information Collection Rule (ICR; 16). This method requires filtration of large volumes of water (up to 600 L for source water and more than 1,000 L for treated drinking water) through yarn wound cartridge filters. Samples are usually collected on site using a gasoline-powered vacuum pump. Filters are cut open and the fibers teased apart, and cysts are removed from the filter by a combination of manual and mechanical agitation. Cysts are concentrated and purified from the eluate by multiple centrifugation steps including Percoll-sucrose density centrifugation (specific gravity of 1.1). Cysts are stained using an indirect method with a primary unlabeled anti-Giardia antibody followed by a secondary fluorescein-labeled antiprimary antibody. Cysts are detected by fluorescence microscopy (excitation wavelength 450–490 nm, emission 525 nm) based on the color (apple green) and intensity of fluorescence, size, and shape of fluorescent objects. Cysts presumptively identified by immunofluorescence assay (IFA) are supposed to be confirmed using differential interference contrast optics to identify internal structures such as the nuclei, axonemes, and median bodies.

Studies with seeded samples have demonstrated that this method can grossly underestimate the numbers of *Giardia* cysts (and *Cryptosporidium* oocysts) in environmental water samples because of poor recovery efficiencies. Recovery efficiencies can vary greatly between laboratories and between analysts within a laboratory. Both false-positives and false-negatives are quite common. An evaluation of 12 commercial laboratories offering *Giardia* and *Cryptosporidium* detection services reported an average recovery efficiency of only 9% (range = 0 to 140%) and a high rate (36%) of false-negatives (17) although a standardized methodology was not used in the study, possibly leading to poor performance. Average cyst recovery efficiencies of 57%, 63%, and 80% were reported for just the centrifugation and Percoll-sucrose flotation steps for each of three analysts, with varying levels of experience, in the same laboratory (18).

Because of the low and variable recovery efficiencies of the ASTM/ICR method, a number of investigators have evaluated the various steps of the procedure to determine sources of loss and variation and to develop method improvements or alternatives. LeChevallier and coworkers (19) reported losses of 1 to 17% of 7-μm-diameter particles during filtration through a variety of 1-μm nominal porosity yarn-wound filters and although they recommended cotton filters, there were no significant differences between recoveries with cotton, rayon, or nylon filter materials. These authors also recommended increasing centrifugation RCF to 7,000 to 10,000 X g and increasing the specific gravity of Percoll-sucrose gradients to 1.15 to improve recovery efficiencies. Using an optimized procedure, they reported average recovery efficiencies of $50 \pm 14\%$ ($n = 6$) for samples seeded with 96,400 cysts. Nieminski and coworkers (20) reported a 12% recovery of cysts for the ASTM method compared to the 49% for an alternative recovery procedure involving filtration through 293-mm-diameter, 2-μm porosity flat polycarbonate membranes and purification by centrifugation through a two-step Percoll-Percoll gradient (specific gravity 1.09/1.05). However, high cyst losses occurred during the density gradient flotation steps of both methods. Modifications to the cyst elution procedure following filtration (essentially involving more vigorous agitation) and elimination of the density gradient centrifugation step resulted in recovery efficiencies of 60 to 80% for water samples with turbidities of 0.6 to 160 NTU (21). In this latter study, a portable battery-powered filtration device that had the capacity for introducing defined cyst spikes during sample collection for more accurate and representative determination of recovery efficiencies was used.

Typically the volume of the sample concentrate resulting from filtration, elution, and centrifugation of greater then or equal to 100 L of some water can be in excess of 5 mL, depending on sample turbidity. Since the volume of concentrate that can be applied to the 25-mm-diameter membrane prior to antibody staining ranges from 100 μL to 1 mL, depending on sample turbidity, a total of 5 to 50 membrane filters or more would need to be examined microscopically to analyze the entire sample. However, the labor costs involved in such analyses frequently requires that less than the entire sample is analyzed. In a study of backcountry waters in the Adirondack mountains, analyses were frequently limited to less than 3% of the original sample volume (22). This "subsampling" of water concentrates does not present problems so long as cysts are homogeneously distributed throughout the sample concentrate. However, in reality, the coefficients of variation (CV) for subsamples of environmental water concentrates ranged from 23 to 200% (22). Unless the entire original sample was analyzed using multiple slides, the reported cyst concentrations could have varied by as much as nine-fold.

Recognition of the limitations of the ASTM/ICR procedure led to the development of a new method (Method 1623, Fig. 3) for detecting *Giardia* cysts (and *Cryptosporidium* oocysts) in water (23). This method involves filtration of 10-L volumes of water through a 1-μm absolute porosity capsule filter, recovery of cysts by agitation in a laureth-12 based elution buffer, concentration by centrifugation, and purification of cysts by immunomagnetic separation (IMS). The resulting concentrate (50 μL) is relatively free of contaminating organisms and debris and is applied directly to a well-slide for direct fluorescent staining. Interlaboratory evaluations of this method demonstrated average *Giardia* cyst recovery efficiencies of 9.9 to 76.7% with a CV of 8.4 to 69.1% for reagent water samples seeded with 129 cysts (24). Seeded surface water samples resulted in mean recovery efficiencies of 8.9 to 73% and CVs of 7.1 to 130.4%.

Although Method 1623 has been validated using Envirochek filtration capsules (Pall Gelman) and one particular IMS kit (Dynal), alternative filtration, IMS, and fluorescent antibody staining kits can be used provided that equivalency with the approved method can be demonstrated. Alternative filtration procedures may include flat membrane disk filters, vortex flow filtration, and different types of capsule filters. Continuous centrifugation is a potential alternative to filtration. In the United Kingdom, the current routine method for sample collection uses a filter composed of compressed foam disks (Genera Technologies). Cysts (and oocysts) are eluted by repeated decompression/compression of the foam in a detergent-based solution. This method has recently been approved by the U.S.EPA for use with Method 1623. *Giardia* and *Cryptosporidium*-specific IMS kits are available from a few suppliers (Dynal, Clearwater Diagnostics) and "homemade" kits can be put together using commercially available antibodies and paramagnetic beads from various suppliers. Fluorescently labeled antibodies are also available from many suppliers (Meridian Diagnostics, Waterborne, Cel Labs). However, all alternative recovery and detection methods should be developed and evaluated within a framework that allows robust statistical analysis of results and comparison with approved, standardized methods.

Method 1623 only allows analysis of 10 L of water compared with the ASTM/ICR method, which allows 100 L or greater. With volumes above 10 L, cyst recovery efficiencies may decrease due to inefficient removal of cysts from the filter matrix. Therefore, a simple analysis would suggest that routine recovery efficiencies would have to be at least five times higher with Method 1623 compared to the ASTM/ICR procedure for the method to demonstrate equivalent sensitivity. However, a great advantage of Method 1623 is that because of the IMS purification step, the entire sample can be analyzed on a single microscope slide. Subsampling is frequently necessary with ASTM/ICR-generated concentrate, resulting in much less than the original 100 L being analyzed. Also, the rate of sample processing is much higher with Method 1623, allowing for multiple samples to be collected either temporally or spatially, thus increasing the effective volume sampled. In addition, a modification of Method 1623 using alternative capsule filters is currently being evaluated for large volume (>100 L) samples.

The advantage of microscopy-based assays is the ability to easily enumerate cysts. However, the accuracy of enumeration depends not only on the recovery efficiency of the various methods used but also on the quality

of the antibodies used for final detection. Variations in antibody specificity, avidity, and fluorescence intensity can affect enumeration accuracy. False-positives are often due to binding of the antibody or autofluorescence by non-*Giardia* organisms. Some algal cells are approximately the same size as *Giardia* cysts and may be mistakenly enumerated if they have green fluorescence. If cysts are not lost in the concentration and purification procedures, false-negatives may still be recorded if the background fluorescence and debris mask the fluorescing cysts. These problems are far less serious with Method 1623 because the additional antibody-based procedure of IMS removes most (but not all) of the background debris and nonspecific organisms. However, acknowledged problems with the specificity of fluorescent antibodies provided the impetus for the development of molecular-based detection assays.

Molecular Detection Methods

DNA-based methods are often mistakenly referred to as an alternative to the ASTM/ICR procedure for detection of protozoa in water. In fact, DNA-based methods are only an alternative to the final antibody-based detection step (IFA) of these methods. Cysts still have to be recovered and concentrated from water using filtration and centrifugation steps such as those used in the ASTM/ICR and Method 1623 procedures. DNA can be extracted at any of the procedural steps below the dotted line in Figure 3. There are numerous published methods for extracting DNA from environmental samples including water concentrates obtained with the ASTM/ICR procedure. The advantage of molecular detection techniques based on DNA extracted from such concentrates is that once extracted, the "total community" DNA can be used for detection of multiple pathogens, not just a single organism such as *Giardia*. However, the disadvantage is that DNA extracted from crude environmental samples such as water concentrates often contains coextracted materials, which are inhibitory to subsequent molecular detection methods such as the polymerase chain reaction (PCR). Consequently, DNA extraction after cyst purification by density gradient centrifugation or IMS may be preferable. However, such purification steps are semi- to very selective, and so narrow the range of organisms that can be targeted.

The first application of nucleic acid–based technology for the detection of *Giardia* in water was a radioactively labeled 265-bp probe that hybridized to a region of the small subunit rRNA gene (25). The reported sensitivity was 1 to 5 cysts in 1 mL of environmental water concentrate and there was complete agreement between the probe assay and IFA. However, the increased specificity and sensitivity possible with PCR led to the abandonment of unamplified hybridization assays. A variety of PCR primer pairs have been developed for *Giardia*, some of which are genus-specific, whereas others are specific to just *G. duodenalis* (Table 2). While some of these primers were developed for genotyping *Giardia* cysts recovered from environmental and fecal samples, others have been used for direct detection in environmental

water concentrates. Generally, DNA has been extracted following centrifugation of filtration eluants. Mahbubani and coworkers (27) developed two sets of primers targeting a giardin gene, one genus-specific pair and a second pair amplifying a 218-bp fragment from just *G. duodenalis*. The giardins are *Giardia*-specific proteins located only in the ventral disk and at least 23 distinct giardin proteins have been identified (11). A single cyst (recovered using a micromanipulator) was detected with both primer pairs under ideal conditions. Detection sensitivities in seeded Ohio river water samples were less than 1 cyst/mL for 100-mL samples. PCR did not detect 10^5 cysts seeded into concentrates of 400-L samples. However, a sensitivity of 3 cysts/mL in highly turbid water samples was achieved with the giardin genus-specific primers if cysts were first purified by immunomagnetic separation (31).

Primers targeting a heat shock protein (HSP) gene successfully detected a single cyst seeded into an amplification reaction (28) and a comparison of giardin and HSP primers demonstrated maximum sensitivities of 1 to 10 purified cysts per amplification reaction and 5 to 10 cysts/100 L for cysts seeded into environmental water concentrates of greater than 600-L samples (32). Also, these authors reported the successful detection by PCR of *Giardia* in two unspiked water samples containing less than 1.3 and 7 cysts/100 L (cyst concentrations determined by IFA). Unfortunately, PCR-based detection assays for water samples have not been evaluated in a thorough manner and there has been little effort to standardize methods. Water samples still have to be concentrated before DNA extraction and PCR, and these methods also concentrate inhibitory compounds. In a comparison of six DNA extraction and purification methods, including hexadecyltrimethylammonium bromide (CTAB) precipitation, Chelex-100 and Sephadex resins, and activated charcoal, the authors reported that the inhibitory effects of coextracted humic substances on PCR amplification of *Giardia* DNA in environmental water samples could not be completely eliminated (33). Increasing $MgCl_2$ concentrations in the amplification reaction and diluting the DNA alleviated some of the inhibition but dilution reduces detection sensitivity and so is not really a suitable solution to inhibition.

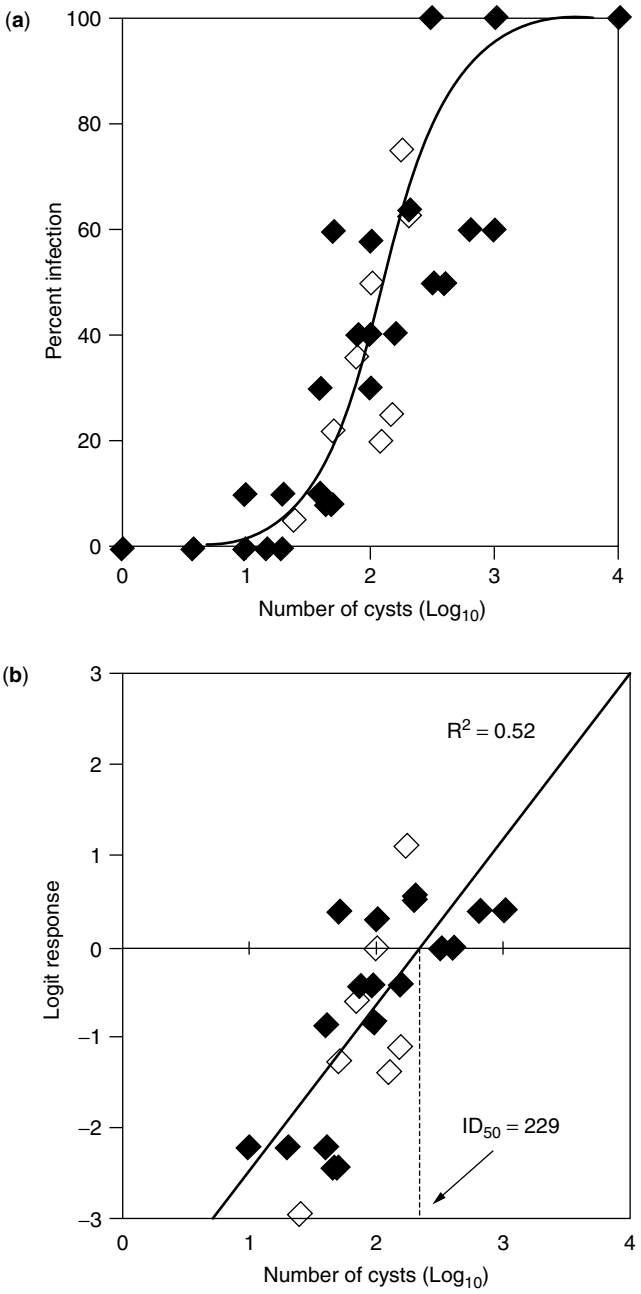

Figure 4. Dose response curve for *G. duodenalis* in artificially infected gerbils. Data was compiled from various publications (30,35–37). Open symbols indicate the values for cysts that were recovered from environmental water samples (30). Data was plotted as the percentage of animals that became infected at each dose of cysts (**a**) and as the logit response (**b**), which linearizes the dose response curve.

METHODS FOR ASSESSING VIABILITY

The most informative method for determining viability of parasites is an in vivo infectivity assay, with the gerbil being the animal of choice for *G. duodenalis*. Such methods address not only viability but also the capacity of the parasite to initiate an infection. Human volunteer studies have been conducted indicating that the minimum infectious dose is 10 cysts or less (34) but such studies are not practical for routine purposes and so they are rarely performed. Some authors have reported establishing infections in gerbils with isolates recovered from water while others have been unsuccessful. A compilation of data from published reports gives an ID_{50} of 229 for various isolates of *G. duodenalis* in gerbils (Fig. 4). The ID_{50} for *G. muris* in CD-1 mice has been reported as 36 cysts (38) and 100% infectivity in gerbils has been reported with only five *G. duodenalis* cysts (5). However, animal infectivity is a highly specialized technique limited to a few laboratories. Consequently, alternative methods of determining viability have been developed. *Giardia duodenalis* infections have been established by inoculating trophozoites onto Caco-2 cell cultures (39) but the methods

have not been applied widely. There have been no reports of initiating infection in cell culture with cysts directly. *Giardia duodenalis* trophozoites can be cultured in axenic media typically containing bovine serum, bile salts, casein digest, yeast extract, ascorbic acid, and cysteine (11). For application to environmental samples, which contain the cyst form of the organism, both cell culture and axenic culture would require in vitro stimulation of excystation as a prerequisite. In vitro excystation methods have been developed (40) and could be used as a measure of viability but they require purified cysts and lack the sensitivity and robustness necessary for use with environmental samples.

All of the viability methods described in the preceding text involve observing the actual biological functioning of *Giardia*. While these methods may give the most accurate assessment of viability, they are not practical for routine purposes. Therefore, viability surrogates that detect indications of viability but not direct biological functions have been developed. A variety of staining techniques have been developed, which allow microscopic determination of cyst viability. A combination of the fluorescent dyes fluorescein diacetate (FDA) and propidium iodide (PI) was originally used, but more recently, FDA has been replaced by DAPI (41). The assay is based on inclusion of DAPI and exclusion of PI by viable cells and staining of dead cells by both compounds. Thiriat and coworkers (42) used the method to demonstrate that up to 21% of cysts in human stool samples were viable but a maximum of 3% and less than 1% were viable in primary sewage sludge and digested sludge, respectively. However, stain-based viability assays can be inconsistent, difficult to interpret, and give variable results in different laboratories. DAPI/PI staining was included in the initial stages of developing Method 1623 but was dropped before publication of the final method. Alternative vital dyes including hexidium, SYTO-9, and SYTO-59 were all reported to provide good discrimination between live and dead *G. muris* cysts (43).

Molecular methods for assessing viability generally rely on the presence of naturally labile RNA in live cells and its absence in dead ones. RT-PCR-based detection of mRNA transcribed from the giardin gene was used to distinguish between viable and dead cysts, but positive amplification depended on the method of inactivation (44). Primers targeting the giardin gene were also used by Kaucner and Stinear (45) to detect viable cysts in river water, treated sewage discharge, and finished drinking water. The RT-PCR method detected viable *Giardia* cysts in 69% of samples ($n = 29$) compared to 24% using IFA with DAPI and PI staining. The reported sensitivity of an RT-PCR assay targeting a *G. duodenalis* heat shock protein gene mRNA transcript was 10 viable cysts in a 100-μL amplification reaction (28) but other authors have reported inconsistent viability determination using these primers (45). Dead cysts were not detected by this assay but its performance with environmental water samples was not evaluated. However, difficulties obtaining reproducible RT-PCR results, the presence of inhibitors in environmental samples, and questions on the stability of some forms of RNA have resulted in this technique being used only in a limited fashion.

PREVALENCE IN ANIMALS

Giardia duodenalis (or *G. duodenalis*-like organisms) have been detected in many animals (Table 1) and domestic or companion animals are often implicated as the source of human *Giardia* infections. The mean prevalence of *Giardia*-positive animal fecal samples (assumed to be dog feces) in seven public parks in Scotland was 11% ($n = 100$; 46). In New Zealand, cysts were detected in the feces of 24% of possums ($n = 76$), 42% of rats ($n = 19$), 31% of mice ($n = 46$), 33% of hedgehogs ($n = 6$), 1 of 3 ferrets, 20% of rabbits ($n = 5$), 35% of blackbirds ($n = 20$), 50% of thrushes ($n = 14$), 15% of sparrows ($n = 104$), and 60% of chaffinches ($n = 10$; 47). The cysts detected in birds may not have been *G. duodenalis* since some birds appear to carry distinct host-adapted species (*G. ardeae* in herons and *G. psittaci* in budgerigars). However, an extremely virulent isolate confirmed as *G. duodenalis* was recently isolated from a sulfur-crested cockatoo (48). Acute giardiasis resulted in the death of the cockatoo and several other caged birds and led to severe infection in experimentally inoculated mice. *Giardia* cysts have also been identified in fecal droppings of migratory geese (49). Consequently, contrary to earlier assumptions, birds need to be considered as potential sources of *Giardia* contamination in water. Atwill and coworkers (50) concluded that given their propensity for activity in riparian areas and the detection of *Giardia* cysts in 7.6% ($n = 221$) of the animals studied, feral pigs should be considered as a potential source of surface water contamination. Farming activities also serve as potential sources of contamination. A broad survey of farm animals across Canada detected cysts in 29% of cattle ($n = 104$), 38% of sheep ($n = 89$), 9% of pigs ($n = 236$), and 20% ($n = 35$) of horses (51). Among dairy calves 2 to 10 weeks of age in Western Canada and Western Australia, 57% ($n = 28$) and 58% ($n = 36$), respectively, were positive for *Giardia* with geometric mean cyst concentrations of 839 to 3,475/g of feces (52).

OCCURRENCE IN THE ENVIRONMENT

Considering the widespread prevalence of *Giardia* in both domesticated and wild animals, it is not surprising that cysts are found to be very common in natural bodies of water. Numerous surveys have reported prevalence figures for *Giardia* cysts ranging from 9 to 100% in surface waters (lakes, rivers, and streams), with concentrations as high as 16,666 per 100 L (Table 3). Surveys by Rose and coworkers (53) and LeChevallier and coworkers (54) demonstrated that higher cyst numbers were associated with source waters that were polluted by industrial or sewage effluents. However, it has also been reported that there was no difference in cyst prevalence between pristine and unprotected source waters (5). Pristine watersheds can of course have large populations of wild animals, which may contribute significant quantities of cysts to the water. A survey of 22 remote pristine raw water samples in Yukon, Canada, reported 32% positive for *Giardia* (65). Six percent of groundwater samples were

also positive, with up to 120 cysts/100 L (62). *Giardia* cysts also appear to be very common in treated drinking water, with 4.6 to 77% of samples testing positive (Table 4). Cyst concentrations in these samples ranged from 7.7 to 107 per 100 L, with an average maximum of 33 cysts/100 L for the surveys included in Table 4. Most of the occurrence data in these surveys was based on the ASTM/ICR methodology described earlier, so the actual incidence and concentrations of cysts in the environment are probably higher than has been reported. It is likely that most of the cysts detected in the surveys of treated drinking water were either dead or damaged due to a combination of environmental stresses and treatment processes. However, cysts can survive for prolonged periods in surface water, depending on the temperature of the water and other conditions. Outbreaks do occur, indicating that some cysts retain their infectivity. For example, cysts recovered from 2.2% ($n = 223$) of untreated source waters established infections in gerbils (30). These samples were collected during an outbreak of giardiasis, with an attack rate of 30% in a population of 1,000. Wallis and coworkers (30) also reported that 7.6% of treated drinking water samples ($n = 79$) resulted in positive infection. Most of these samples were collected from a single treated water supply but no outbreak of giardiasis was reported in the community served by the supply. In a second study, covering much of British Columbia, 45% of cyst-positive raw water samples ($n = 91$) inoculated into gerbils were infectious (60). This study also detected infectious cysts in 10% of treated drinking water samples ($n = 42$). On the basis of a two-year cyst survey of two rural communities drinking chlorinated surface water and an IgM seropositivity of 7%, the authors suggested that there was a low level of endemic waterborne transmission in the communities. Using microscopically observed morphological criteria as a measure of viability, it was reported that 12.8 to 14.6% of cysts detected in various surface waters were viable (54,63) but most cysts detected in treated drinking water were dead (67).

[f]Water collected in cisterns.
[g]Information not available in original report.

It is generally accepted that cysts enter surface waters on a periodic basis, but there is little information on the travel characteristics or distribution of cysts once they are in the water. Weekly sampling of a river at three times on each sampling day for a period of two months demonstrated that cysts were homogeneously distributed with an approximate concentration of 700 to 1,000 cysts per 100 L (18).

Cyst concentrations in surface waters increase during wet weather, particularly in areas with dry summers where the first rains of the wet season wash many months of accumulated animal feces into watersheds. During watershed sampling in Southern California, 45% of wet season samples ($n = 31$) were *Giardia*-positive compared with 15% ($n = 72$) during the dry season. The maximum cyst concentration of 16,666/100 L was obtained with a first-flush sample immediately following a rainstorm (55). Similarly, an extensive survey of surface waters in Wisconsin detected cysts in 47.5% of winter samples compared with 25 to 28.8% in other seasons (56). However, other authors have reported no seasonal variation in cyst occurrence or concentration (60).

Specific PCR primers are not yet available for all of the distinct genotypes of *G. duodenalis*, so it is not known whether isolates in water represent all genetic lineages. However, both the main genetic lineages of *G. duodenalis* (Groups 1/2 and 3) have been recovered from water, with no apparent difference in geographical distribution (30).

OUTBREAKS OF GIARDIASIS

The first outbreak of giardiasis in the United States, which was indisputably linked to drinking water by detection of infectious *Giardia* cysts in the water supply during the outbreak, occurred in New York state in 1974–1975, with 350 confirmed cases (69). Since this time there have been many waterborne outbreaks in many states of the United States and in many countries around the world. In many of these outbreaks involving small community systems, the number of infected individuals was low. However, in some incidents, more than 700 people have become sick. From 1971 to 1985, 92 waterborne disease outbreaks were attributed to *Giardia*, with a total of approximately 24,000 infected individuals, and between 1976 and 1994, *Giardia* was the most frequently identified etiologic agent in outbreaks caused by drinking water (70). During 1993 and 1994, *G. duodenalis* was the causative agent in 9 out of the 39 (23%) waterborne disease outbreaks in the United States, where the etiological agent was identified (70). These outbreaks were associated with both surface water ($n = 3$) and groundwater ($n = 2$) intended for drinking and two of these were linked to unfiltered, chlorinated drinking water. Four outbreaks were associated with recreational activity (swimming in pools, rivers, and lakes). One of the largest waterborne outbreaks of giardiasis with 1,400 confirmed cases (and an estimate of at least 3,000 cases) was caused by an overflow of sewage into the drinking water system at a Swedish ski resort (71). There were four waterborne outbreaks in the United States, totaling 159 confirmed cases during 1997–1998, all associated with drinking unfiltered surface water or untreated groundwater (72). During one of these outbreaks with 50 confirmed cases, tap water samples were found to contain up to 200 cysts/100 L.

Considering the widespread occurrence of *Giardia* in animals, tracing the source of contamination in outbreak situations is difficult. However, beavers have frequently been referenced as a potential source. Karyotype analysis by pulse-field gel electrophoresis demonstrated that an infected beaver found at a drinking water intake had an identical profile to human isolates recovered during an outbreak of giardiasis in Creston, British Columbia, thus implicating the beaver as the original source of contamination (73). In another study of isolates recovered during an outbreak of giardiasis, 20 *Giardia*-positive water samples were collected (cyst status determined by IFA) but DNA extracted from the samples was not successfully amplified by primers targeting the triose phosphate isomerase genes (74). However, restriction enzyme digest patterns following PCR were identical to DNA extracted from beaver fecal samples and human isolates collected during the outbreak, again implicating the beaver. In some areas of Colorado, cysts were detected in up to 45% of beavers and 100% of muskrats, with some animals shedding 1×10^8 cysts per day (5).

Cyst Removal During Water and Wastewater Treatment

Giardia cysts can survive in river water for prolonged periods, depending on water temperature. Their sedimentation velocities are low (1.4 μm/sec) so they will remain suspended in the water column unless attached to larger particles (75). They are relatively resistant to disinfection so correctly operating filtration systems are essential for removal of cysts from drinking water. The majority of waterborne outbreaks have been attributed to drinking unfiltered water or failures of filtration during treatment of surface waters. The predicted chlorine CT (contact time × concentration) value for 99.99% inactivation of cysts is approximately 245 for temperatures of 0.5

Table 5. Distribution of *Giardia* Cysts During Sewage Treatment

Sample Type	Prevalence (%)	n^a	Cyst Conc.[b]	Reference
Raw sewage	73	164	88,000	30
	100	43	26 to 3,022	65
	100	42	1,100 to 52,500[c]	78
	100	121	21 to 9,760[d]	78
	100	–	25,000	79
	100	29	130 to 7,900	80
Combined sewer	100	5	37.5 to 1,140	57
overflows	100	11	90 to 2,830	61
Effluent from sewage	83	24	1 to 461	57
treatment plant	96	28	5 to 940	78
	86[e]	35	2 to 310	80
	82[f]	33	4 to 130	80
	100	5	2 to 3,511	65
	92.5[g]	40	0 to 3	79
	67[h]	6	–	45

to 5 °C (5), and an ozone CT of 4.2 was required for 99.99% inactivation of *G. duodenalis* cysts (35).

Although apparently ubiquitous in surface waters, a large proportion of *Giardia* cysts are effectively removed by proper operating of drinking water treatment plants. Studies of a full-scale treatment plant demonstrated an average of 99.88% removal of cysts (76). In addition, the configuration of treatment plant filters (sand, anthracite/sand, deep anthracite/sand) did not affect cyst removal efficiencies, with 99.5 to >99.99% removal occurring regardless of filtration media (77). States and coworkers (57) reported that 63% of raw surface waters were cyst-positive, with an average concentration of 34 cysts/100 L, but no positive treatment plant effluents were detected. Nevertheless, *Giardia* is frequently detected in treated drinking water (Table 4).

The data in Table 5 demonstrate that *Giardia* cysts are detected in an average of 95.5% of raw sewage samples, 88% of samples following secondary sewage treatment, and far less frequently in final effluents. Inoculation of 22% of samples recovered from raw sewage ($n = 135$) resulted in infection in gerbils (30). In general, sewage treatment reduces the concentration of cysts by 90 to 99.99%. In one study it was demonstrated that the majority of wastewater treatment plant effluents contained cysts but cyst concentrations were reduced by at least 99.8% (79). With this removal efficiency, effluents contained an estimated average of 60 cysts/L but 97% of these cysts were determined to be dead based on morphology and staining with propidium iodide. Thiriat and coworkers (42) used vital dyes to demonstrate that only 3% of cysts in primary sewage sludge and less than 1% of cysts in digested sludge were viable. However, because cyst concentrations can be very high in raw sewage, treated effluents may still contribute significant cyst loads to receiving waters. On the basis of the reported occurrence and removal data, a 100 million gallons per day sewage treatment plant may be introducing 5×10^8 potentially viable cysts per day into receiving waters.

CONCLUSION

Giardia duodenalis is ubiquitous in aquatic environments and has a high prevalence in a broad diversity of animals. It is globally distributed and is the most frequently isolated intestinal pathogen in humans. The organism has multiple potential routes of transmission including consumption of water, recreational use of water, food, and contact with animals, but the true significance of zoonotic transmission has not yet been determined. Although giardiasis is not considered a fatal disease and it is not as devastating on a worldwide scale as diseases such as malaria, there are very large health and economic burdens resulting from widespread infection by the parasite. Consequently, giardiasis continues to represent a significant threat to public health. Continued efforts to improve recovery and detection methods for environmental samples and further molecular characterization of isolates will help elucidate the epidemiology of the disease and may lead to the development of tools that can be used to definitively identify the sources of contamination in environmental waters.

GRANULAR ACTIVATED CARBON, BACTERIOLOGY OF

ANNE K. CAMPER
Montana State University
Bozeman, Montana

The goal of drinking water treatment has always been to provide microbiologically safe water to the consumer. To accomplish this, especially when surface water is being treated, gravity filters containing sand and/or anthracite are typically used to remove particulate matter. When filtration is followed by disinfection, pathogens should be removed and the microbial load of the water reduced to an acceptable level. As water quality regulations have become more restrictive, granular activated carbon (GAC) has been used to a greater extent as a filter medium because of its ability to adsorb regulated synthetic organic carbon compounds, materials that contribute to taste and odor in finished water, and organic matter that leads to the formation of disinfection by-products. GAC is known to become colonized with bacteria, and this trend has been exploited in treatment by using the organisms on biologically active carbon (BAC) to metabolize a fraction of the organic carbon found in the water. However, there has been concern that indicator organisms and bacteria of public health interests may colonize and proliferate on GAC and BAC filters. For these bacteria to be found in finished water they must successfully colonize and compete with the indigenous organisms (or be retained in large numbers), be released from the filter and penetrate the disinfection barrier. This review describes these issues and the beneficial aspects of BAC filtration in water treatment.

PROPERTIES OF GAC

Granular activated carbon (GAC) has the beneficial property of adsorbing compounds from water. Consequently, its use in drinking water treatment has increased substantially over the past few decades due in large measure to increasingly stringent regulations on finished water quality. Of rising importance are regulations related to the requirement to remove organic compounds involved in the formation of disinfection by-products. GAC can also adsorb gasoline constituents, pesticides, and other regulated synthetic organic compounds. The aesthetic properties of potable water can also be improved because GAC can remove a variety of organic compounds that cause tastes, odors, and color.

The adsorptive properties of GAC are related in part to its surface area. GAC particles are characterized by very high surface area ranging from a few hundred to 1,500 m^2/g, most of which is provided by their porous nature (1). Pore size distributions are in the range of $1–10^4$ Å, with most pores being smaller than the average bacterium ($1–2$ μm or $1–2 \times 10^4$ Å in length). Although the majority of the pores is small, the porosity of GAC appears to be an important factor that enhances the ability for bacteria to colonize GAC particles in water treatment systems.

GAC can also react with oxidizing disinfectants such as free chlorine (1,2), combined chlorine (3) and chlorine dioxide (4). This property may also be important in providing a hospitable environment for bacteria attached to GAC in filters subjected to chlorinated backwash water.

COLONIZATION OF GAC

Virtually any surface immersed in water will eventually become colonized with microorganisms, and granular activated carbon is no exception. Indirect evidence for colonization was noted by treatment system operators who observed that microbial counts emanating from GAC filters frequently exceeded those found in the influent. This was also observed in early pilot scale work with a GAC filter, and the increase in counts was attributed to the growth and subsequent release of the organisms from biofilms on the filter media into the effluent water (6). This phenomenon has led to the belief in some industries that GAC columns act as "bug farms" and are therefore undesirable in the treatment train (7). Biological activity on activated carbon in the drinking water industry was initially investigated in the 1970s (8–10), with a subsequent flurry of research on the properties of GAC that make it conducive to bacterial colonization.

One such property is the strong affinity between GAC and bacterial cells. In experiments where the initial attachment of *Escherichia coli* to fresh powdered activated carbon was followed, nearly 100% of the initially suspended bacteria attached within 30 minutes (11). In similar experiments, approximately 90% attachment was seen for *Klebsiella oxytoca* (12) and *E. coli*, (13) on fresh GAC. Rollinger and Dott (14) demonstrated nearly 100% attachment of *E. coli*, *Klebsiella pneumoniae*, *Streptococcus faecalis*, and *Pseudomonas aeruginosa* within six hours, whereas *Pseudomonas putida* required four days.

Another property that may enhance bacterial colonization is the adsorption of organics in the pores of the carbon. These organics may then act as a growth substrate for the attached bacteria. Davies and McFeters (12) reported that the growth rate of attached *Klebsiella oxytoca* was 10 times higher than suspended cells in a low nutrient medium containing glutamate as the carbon source. The GAC had been exposed to the glutamate before colonization by the bacteria. The attached organisms were also more active, as determined by tritiated thymidine and uridine uptake. Compared with the suspended cells, the attached bacteria did not exhibit a reduction in cell size, that is typical for organisms entering into a starvation

state. Others have noted that organic carbon adsorbed on GAC can desorb, be transported out of the micropores, and then be degraded by bacteria attached to GAC (15,16). This mechanism may enhance the attachment of bacteria and subsequent growth of biofilms on carbon particles.

Regardless of the mechanisms, it is common knowledge that bacteria populate GAC in water-treatment systems. The actual numbers will vary depending on location, time of year, and the enumeration technique used. At one location, Parsons (17) found values ranging from 1.5×10^4 to 1.8×10^8 colony-forming units (CFU) per gram wet weight. The high end of this range was comparable to the average value of 3.6×10^8 CFU/g wet weight carbon at a New Jersey pilot plant (18). In another pilot system, culturable cell counts varied from 3×10^5 to 6×10^7 per gram (dry weight) of carbon (6). These same authors used ATP to estimate cell concentrations, and obtained levels of 5 to 490 ng ATP per gram dry weight of GAC. Using C^{14} glucose uptake to assess biomass concentrations on carbon, Prevost et al. (19) reported a range of approximately 15 μg C/cm^3 to 7.5 μg C/cm^3, depending on the location within the filter. If the biomass is assessed using a phospholipid assay, concentrations varied in an experimental carbon filter system from 500 to 20 nmols lipid-P/g (20).

Scanning electron microscopy images of GAC particles from drinking water filters have shown that the surfaces are colonized by a diverse suite of morphological types, including filaments, rods, cocci, fungi, and protozoans (21–23). A recently taken image of a particle from a laboratory biologically active carbon column is shown in Figure 1. These organisms are often associated with the macropores and cracks on the surface of the carbon (13) where they are most likely protected from the mechanical effects of shear and scraping from backwashing of the filters. Images of these particles also indicated that the organisms had produced extracellular polymeric substances (EPS, see Fig. 2), suggesting that the organisms were actively attaching and growing on the surfaces.

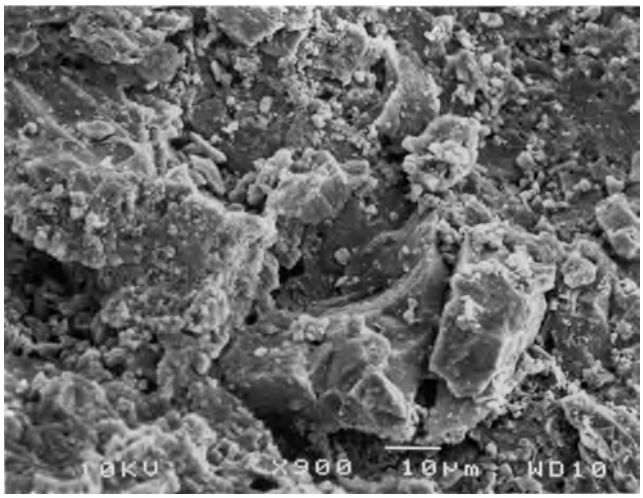

Figure 1. Scanning electron micrograph of microorganisms and detritus associated with the surface of granular activated carbon.

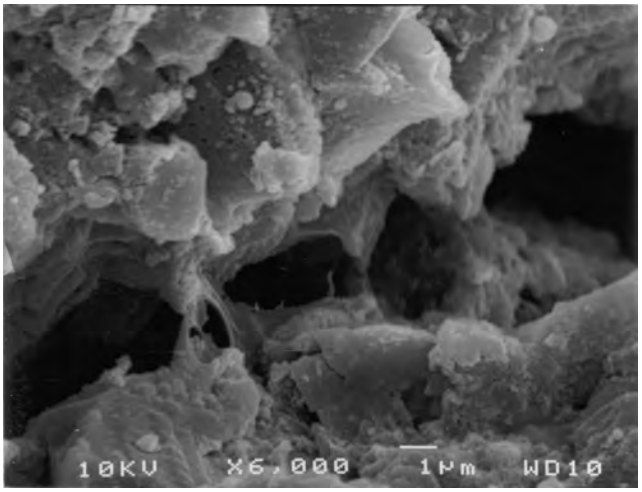

Figure 2. Scanning electron micrograph illustrating the presence of extracellular polymeric substances (EPS) in the crack of a granular activated carbon particle.

The bacteria colonizing and proliferating on the surface of GAC are likely to be nonpathogenic heterotrophs and autotrophs because the carbon and energy sources present in water support the growth of these types of organisms. Bacteria typically identified in GAC filters and their effluents are common soil and water organisms. Using culturing techniques and metabolic characteristics for classification, researchers have identified *Achromobacter*, *Arthrobacter*, *Alcaligenes*, *Acinetobacter*, *Bacillus*, *Flavobacterium*, *Micrococcus*, *Corynebacterium*, *Pseudomonas*, and *Moraxella* (14,17,22,24). At one plant, members of the genera *Pseudomonas*, *Acinetobacter*, *Bacillus*, and *Corynebacterium* were found on the filter media, with effluent heterotrophic plate counts ranging from 0 to 600 CFU/ml (25). Wilcox and associates (6) detected *Achromobacter*, *Acinetobacter*, *Aeromonas*, *Alcaligenes*, *Bacillus*, *Chromobacterium*, *Corynebacterium*, *Micrococcus*, *Microcyclus*, *Paracoccus*, and *Pseudomonas* in water and on GAC particles from a pilot facility. At other locations, *Acinetobacter*, *Alcaligenes*, *Bacillus*, *Pseudomonas*, *Micrococcus*, *Flavobacterium*, *Aeromonas*, *Achromobacter*, *Chromobacterium*, *Corynebacterium*, *Arthrobacter*, *Caulobacter*, *Nitrosomonas*, *Nitrobacter*, and actinomycetes were isolated from GAC filter media (26,27). Using fatty acid analysis for bacterial identification, Norton and LeChevallier (28) found 19 gram-negative and 5 gram-positive genera in biofilms on GAC. Gram-negative bacteria predominated, with the highest number of isolates belonging to the genera *Acidovorax*, *Hydrogenophaga*, *Pseudomonas*, *Xanthomonas*, and *Sphingomonas*. The majority of these isolates matched the organisms identified in the filter effluent.

It is also possible for coliforms to grow on GAC filter media. The proliferation and subsequent release of these organisms may cause a violation of the total coliform rule (TCR), even though there is no immediate fecal contamination. The TCR uses the presence of coliforms to indicate the potential presence of enteric bacterial pathogens in drinking water. Requirements state that

fewer than 5% of water samples collected on a monthly basis from the distribution system can be positive for total coliforms. The potential for positive tests resulting from detached biofilm coliforms is obviously of great concern to utility operators. There are several cases where coliforms (*Escherichia*, *Enterobacter*, *Klebsiella*, *Citrobacter*, *Serratia*, *Hafnia*, *Aeromonas*) have been found in filter effluent when they were absent in the influent water (6,24,29,30,31), suggesting that the organisms were accumulating and replicating in the filter. This is supported by the observation that coliforms such as *Citrobacter freundii*, *Enterobacter cloacae*, *Klebsiella pneumoniae*, and *Escherichia coli* have been detected in filter media samples (13,32). The growth of coliforms in filter media may also contribute to the observations of Bucklin and coworkers (33) who reported elevated coliform levels in filter effluent the first few hours after backwash. It is important to note that coliforms are not typically isolated from GAC filters, even if detailed analyses are performed (14,22,28), indicating that colonization may be a site-specific issue.

BIOLOGICAL FILTRATION

Biological filtration uses filter media, usually GAC, which has been optimized for the growth of indigenous heterotrophic bacteria that degrade the available fraction of organic carbon in the water. The filter media used in the process is termed biologically active carbon (BAC). Benefits of biological filtration include improved total organic carbon (TOC) removal and reduced disinfectant demand (35–38), improved aesthetic properties (38), and the potential for reducing microbial growth in distribution systems (39).

The process was first implemented in western European countries nearly 20 years ago (10,40,41). In the most traditional form, conventional treatment including filtration to remove particles takes place upstream from the biological filters, and ozonation is often included in the treatment train. The downstream biological filters are operated with exhausted carbon, that is, the chemisorptive capacity of the GAC has been exceeded. The surfaces of the filter media act as a support for microbial attachment and growth, resulting in a biofilm adapted to using the organic matter found in that particular water. TOC removals in these filters range from 5 to 75% (42). Conversion of organic carbon to biomass can eventually lead to a complex ecosystem containing higher life forms such as oligochetes and rotifers (43). Controlling the amount of biomass by periodic backwashing is necessary so that these organisms are not released into the filtered water (44).

One of the first observations in the full-scale use of biological filtration was that the type of filter media had an influence on the net removal of organic carbon from the water. For instance, although rapid sand filters do have the capacity to biologically remove carbon (45–48), GAC filters have superior performance [(49); comparison between DeWaters and DiGiano, (50) and Hozalski and coworkers, (51)]. LeChevallier and coworkers (49) demonstrated that there were 37 times more bacteria per unit surface area on GAC than sand, and that the TOC removal rates were 51% (vs) 26%. Greater biomass levels on GAC (vs) anthracite were also correlated with better organic carbon removals (52). Although correlations between biomass and filter performance were established in the above cases, Urfer and coworkers (53) contend that as long as the biomass level exceeds a minimum concentration, cell numbers do not limit filter performance. The ability to retain this biomass may be material-related, however, because GAC can remove potentially inhibitory compounds (8), sequester organic molecules for growth (12,54) and may protect bacteria from removal by abrasion because of its microporous structure. Another practical advantage of GAC over other media is that the attached microbial population is less prone to shock from changes in water quality, down time, or accidental application of disinfectant (55,56).

Ozonation before biological filtration is often practiced because it frequently improves the biological removal of the smaller molecular weight organic compounds created during oxidation of the natural organic matter (46,57). Preozonation can also result in increased biomass within the filters, most likely because of a higher concentration of usable organic matter (53,58). This effect is not universal, however, because there are cases where ozone does not enhance the metabolism of the organic carbon (59). It has also been observed that populations developing in biological filters fed ozonated water are different from those given nonozonated water. Microbial communities established on nonozonated water used a wider variety of carbon sources at all depths in the filters. In contrast, there was a greater segregation in substrate utilization specificity with depth in filters that were exposed to ozonated water (60).

Because ozonation tends to produce a variety of easily utilized organic compounds, microbial communities in biological filters generally exhibit greater activity at the top of the filters (58,61). The stratification is due to the rapid utilization of the easily degradable organic matter in the top of the filter, with the subsequent dependence on degradation of more recalcitrant compounds as depth and hydraulic residence time increases. This activity may be characterized by both a decrease in the number of carbon substrates used and a change in population with increasing filter depth as determined using phospholipid fatty acid profiles. In the same experimental system, arbitrarily primed PCR sequencing also identified a higher diversity of organisms in the tops of the filters (60). The biomass profile through a filter has been described as first order, and if the filter is sufficiently deep, a portion of it will not be contributing to the biological removal of organic carbon constituents (61).

The potential for a wide range of metabolic functions of the microbial communities in biological filters is further exemplified by the multiplicity of compounds that can be removed from the water. Micropollutants such as phenol can be metabolized when fed simultaneously with ozonated natural organic matter (50). This effect also occurs in simulated wastewater situations, where a biofilm on GAC degraded a mixture of phenols, *N*-heterocyclic compounds and aromatic amines (62). It is also possible to reduce bromate to bromide in biological filters, providing

that the competitive effects of nitrate and oxygen as alternative electron acceptors are controlled (63).

THE PERSISTENCE OF PATHOGENS AND INDICATOR ORGANISMS ON GAC

There has been apprehension expressed by the drinking water industry over the potential proliferation and/or concentration of organisms of public health concern on granular and biologically active carbon filters. As noted earlier, coliforms can become a component of the microflora on filter media. Because biological filtration encourages the growth of bacteria on the filters, it is important to know whether indicator organism and pathogen growth would be enhanced along with the general heterotrophic population.

To address this concern, the potential for coliforms to persist on laboratory columns with virgin GAC, GAC that had been in operation in a filter for a few months, and biologically activated carbon (BAC) from a full-scale plant, was evaluated. The columns were challenged with a suite of five coliforms that had been originally isolated from drinking water distribution systems. The release of the coliforms was tracked by enumerating the organisms in the column effluent. The loss of coliforms in the water for fresh GAC was 0.12 to 0.16 log/day and 0.12 to 0.25 log/day for BAC. The coliforms were detected in the column effluent for approximately one month, although up to 100 mL was filtered to obtain a positive result. Overall, the loss rate from the biologically active carbon was the most rapid of the three media tested. At the end of the experiments, carbon samples were processed and the numbers of coliforms per gram dry mass GAC were determined. Levels were highest on the fresh GAC, intermediate for the precolonized GAC and lowest for the BAC. Conversely, the BAC had the highest concentration of heterotrophic bacteria (38). These results suggest that there is competitive exclusion of the coliform bacteria on the BAC and that the presence of initially attached heterotrophs may decrease the potential for the long-term persistence of undesirable organisms.

In studies performed using BAC filters inoculated with *Pseudomonas aeruginosa*, *P. putida* and *Escherichia coli*, Rollinger and Dott (14) showed that all of these organisms were eliminated from the column between ten and sixteen days. In the same experiments, fresh GAC was colonized with *E. coli*, *K. pneumoniae*, *S. faecalis*, *P. aeruginosa* and *P. putida*. The two pseudomonads and *E. coli* colonized the filter media, whereas the other two organisms were eliminated. These data suggested that perhaps antagonistic compounds were produced by the autochthonous bacteria in the BAC, but less than 1% of the tested strains inhibited the test organisms. Even though the mechanism was not discovered, the observation that colonized BAC reduces the potential for long-term persistence of organisms of public health was confirmed in this study.

The potential growth of coliforms on filter media is of regulatory concern, but has little direct public health significance. However, because coliforms can colonize and persist on GAC filters, there has been the concern that various pathogens may act in a similar manner. The drinking water industry is interested in the survival on GAC and BAC filters of both opportunistic (causing disease only in the immunocompromised individual) and primary pathogens (causing disease in the entire population providing that the infective dose is sufficiently large).

A review of opportunistic pathogens in drinking water has been prepared by Geldreich (64). This review lists a wide variety of organisms that are known to be components of the general heterotrophic population. As such, the presence of these bacteria in drinking water treatment and distribution systems can be expected. Two examples are *Klebsiella* spp. and *Aeromonas* spp. Both of these organisms are capable of expressing virulence factors for human infections that are not waterborne (65–67), and both have been found in granular activated carbon filters (13,68). Others that belong to this group are the *Mycobacterium avium* complex (MAC) and *Legionella* spp. Both are known to grow in biofilms in distribution systems (28,69–73), but there have been no documented reports of their presence in filter media.

In contrast to the opportunistic pathogens, the primary pathogens are not natural components of environmental systems; they are more likely to be found in the gastrointestinal system of a warm-blooded host. To colonize and persist on filter media, these pathogens must be able to successfully compete with the heterotrophic bacterial populations. As with the coliform bacteria, competition with the existing microflora may be a key parameter in preventing proliferation of these bacteria. In a study where the ability of primary pathogens to persist on granular activated carbon was assessed, three enteric pathogens (*Yersinia enterocolitica*, *Salmonella typhimurium*, enterotoxigenic *Escherichia coli*) were added to: (*1*) fresh GAC as pure cultures, (*2*) fresh GAC in the presence of unsterilized river water containing naturally occurring bacteria, and (*3*) GAC previously colonized with river water bacteria (74). Using cultural methods, the greatest level of persistence of the pathogens was on the fresh GAC with sterile river water. Survival decreased when the natural organisms were present, and was the lowest on the previously colonized GAC. Pathogens could be detected in the column effluent by culturing for more than 20 to 24 days when introduced to fresh GAC but were eliminated between 8 and 14 days if the support medium was precolonized GAC. The rate of elimination on the precolonized GAC was 0.11 to 0.7 log per day. Other laboratory studies (14) with several pathogens on GAC reported similar results. The pathogens persisted when introduced to sterile GAC and fed sterile water, but were eliminated from the medium when they were subsequently challenged by autochthonous bacteria in tap water. These data demonstrated that colonized GAC was likely to be beneficial in preventing the proliferation of pathogens.

In the earlier experiments, detection of the pathogens was limited to culturing techniques, which are known to underestimate the numbers of organisms present. Subsequent work has used cultural media combined with direct microscopy and polymerase chain reaction (PCR) methods to follow the fate of bacterial pathogens (*E. coli* O157 : H7 and *S. typhimurium*) in laboratory biologically

active filter media columns. Suspensions of the pathogens were circulated through the columns for 24 hours followed by a continuous flow of dechlorinated tap water with and without relevant concentrations of ozonation by-products. The ozone by-products (aldehydes, etc.) were supplied to determine whether the potential for pathogen survival increased if more degradable low molecular weight compounds were present in the water. Column effluent was sampled routinely, and filter media cores were taken at the end of the experiment. Semi-quantitative PCR showed that there was a 90% reduction in pathogens in the recycled column inoculum before initiation of the tap water feed. These results were mirrored by fluorescent antibody direct counts for *E. coli* O157 : H7. One may assume the reduction is due to attachment to the filter media, because the control system (batch system, no exposure to filter media) showed no decrease in cell numbers over the same period. When throughflow was resumed, no culturable pathogens were detected, and PCR and direct counts using fluorescent antibodies indicated a decline of cells in effluents over the 2.5-week duration of the experiment. After this time, filter media were directly examined for the presence of pathogens. PCR amplification from DNA extracted from the filter media were positive for both *S. typhimurium* and *E. coli* O157 : H7 in one replicate experiment and only for *E. coli* O157 : H7 in the second run, although the signal intensity was quite low. Columns that were supplied additional organic carbon in the form of ozonation by-products did not have enhanced pathogen bacterial persistence or proliferation (68).

RELEASE OF BACTERIA AND COLONIZED PARTICLES FROM GAC FILTERS

As water passes through GAC filters, particularly those that are optimized for biological activity, a significant number of bacteria can be released. The increase in the numbers of organisms from filter influent to effluent can be two orders of magnitude (75). These organisms may be released as single cells, aggregates, or attached to filter media particles (filter fines) that escape through the underdrain of the filters.

In field studies, Camper and coworkers (76) collected released filter fines from GAC filters by passing water from the underdrain during an entire filter run through a gauze filter in a 47 mm Swinnex. The average volume sampled was 18,600 liters. The number of released carbon fines in 201 samples was determined using image analysis. Recognizing that small fines may not have been efficiently retained in the gauze, the average number of particles in a sample was 2,333 ranging in size from 1.0 to $3.5 \times 10^3 \mu m$ in diameter. The bacteria were desorbed from the surface (24) and the number of heterotrophs and coliforms determined by plate count. The results indicated that 17% of the filter runs released carbon fines that contained coliform bacteria, and 28% of these coliforms exhibited the fecal biotype. It should be noted, however, that none of these utilities experienced elevated coliform numbers in their distribution systems. In a similar study, Stewart and coworkers (77) used a modified Swinnex with a polycarbonate filter to trap carbon particles released from a pilot GAC filter. An average of 36 particles per liter were detected with sizes ranging from 2 to greater than 40 micrometers. Using the homogenization technique it was determined that 200 to 7,000 viable bacteria could be recovered from 1,000 particles. Numbers of coliforms were low, with one reported fecal coliform isolated from the released filter fines.

The type of filter media and filter operations may influence the release of colonized filter particles. In a comparison between bacterial counts on released particles from biologically activated sand, anthracite, and biologically activated carbon, the BAC particles contained significantly higher numbers of heterotrophs (49). When the release of particles from full-scale anthracite and sand filters was evaluated (76), particle counts were similar to those from GAC filters. In the same study, where particles released from GAC filters throughout a filter run were enumerated, higher filtration rates, deeper GAC filter beds, and higher applied water turbidity resulted in higher particle release. The age of the carbon was not an important factor. In a similar study, Stringfellow and coworkers (78) demonstrated that the number of particles released from sand or GAC contactors were similar. They also observed that these particles were frequently colonized by heterotrophs, although no coliforms were detected.

Amirtharajah and Westein (79) showed that an elevated number of particles were released both immediately before backwash and shortly after the filter was put back in operation if proper filter-to-waste procedures were not followed. It is probable that colonized filter fines or detached bacteria were also released during these two times, as illustrated by an elevated number of coliforms detected in the filtrate immediately after backwash (33). More recently, Moran and coworkers (80) showed that there can be breakthrough of turbidity due to detachment of particles from deep laboratory filters at the end of a filter run, and these particle sizes were comparable to the range associated with *Cryptosporidium* oocysts.

DISINFECTION OF ATTACHED BACTERIA

The release of bacteria from GAC filters, especially those attached to carbon particles, is important because cells in aggregates or attached to filter media are less susceptible to disinfection than single cells (13,17,24,77). The level of protection appears to be dependent on the size of the fine (78), with bacteria associated with larger particles less susceptible to disinfection than those attached to particles of approximately the same size as the bacterium. The lack of disinfection efficacy against particle-associated bacteria may be the result of biofilm formation on the surfaces. It has been demonstrated that biofilms in general are far less susceptible to disinfectants than single suspended cells (81). In the case where oxidizing disinfectants are used, the phenomenon has been explained as a reaction-diffusion issue. The oxidizing partially disinfectant is consumed in the outer layers of the biofilm, resulting in levels insufficient to kill cells at the base of the biofilm (82,83). However, this phenomenon is inadequate

to explain the apparent lack of disinfection efficacy against very thin biofilms seen on GAC particles. Work by Srinivasan and coworkers (84) showed that thin biofilms were resistant to monochloramine, and suggest that physiological changes in these cells is responsible for the decreased sensitivity.

Regardless of the mechanism, the magnitude of this reduced sensitivity has been demonstrated in many experiments. LeChevallier and coworkers (13) showed that GAC-associated bacteria were not affected by exposure to 2-mg/L free chlorine for one hour. In similar experiments, free chlorine or monochloramine at concentrations of 1.5 mg/L for a 40-minute exposure time did not decrease the plate counts of GAC attached cells (77). Camper and coworkers (24) treated filter fines from operating GAC filters with 2-mg/L free chlorine for 30 minutes, and still recovered culturable cells from the GAC particles. In experiments where free chlorine and monochloramine were compared, monochloramine provided better log reduction of GAC attached cells only if the concentrations of both disinfectants exceeded 2 mg/L (38).

Even though particle-associated bacteria have been shown to be less susceptible to disinfectants, the quality of water produced by GAC filters has not been shown to be compromised. In a study where GAC pilot system effluent samples containing coliforms in the range of <1 to 300 CFU/100 ml were exposed to 2.5-mg/L free chlorine for 30 minutes, no coliforms were detected in 62 of 64 samples. For the two positive samples, the maximum detected number was 7/100 ml. In the same study, heterotrophic plate counts were reduced from an average of 58 CFU/ml to $<1-4$/ml (85). Similarly, the efficacy of disinfection downstream from biological filters in reducing microbial loads in finished water has been documented in both research and utility settings (35,36,38,47,49,55).

IMPLICATIONS FOR DISTRIBUTION SYSTEMS

It is known that heterotrophic bacteria carried by particles can penetrate the disinfection barrier, attach to the pipe surface, grow, and develop into a biofilm; this becomes critical if pathogens are involved (86,87). With the evidence mentioned earlier that particle associated bacteria are less susceptible to disinfection in mind, utilities have concerns about the possible transport of organisms on filter fines through the disinfection barrier to the distribution system and subsequent regrowth of undesirable bacteria.
