In streams, like other aquatic environments, protozoa are viewed as a major contributor to bacterial mortality and serve as a link to higher trophic levels (11). However, much more information is available about the microbial loop in marine systems and freshwater lakes (106–108). In these other ecosystems, the role of protozoa as a link between bacteria and higher trophic levels is more clearly illustrated (106) compared with streams. In the food web of streams, protozoan biomass that is derived from bacterial consumption is available for consumption by animals. This process acts to increase the size of the available carbon resources allowing a greater opportunity for carbon transfer to higher trophic levels; for example, few macroinvertebrates can effectively feed on bacterial-sized particles (3).

Protozoans are a major source of bacterial mortality and this role has been investigated in streams primarily through the use of fluorescently labeled bacteria (FLB; 109). In the Ogeechee River of Georgia (U.S.A.), an average of 15.6% of the water column was cleared of bacteria by protozoans per day (110). Protozoans were then consumed by filter-feeding macroinvertebrates (111). Estimates from the Butron River (Spain) suggested that flagellates grazed 43 to 65% of bacterial production in the water column depending on the season (112). Ciliates had higher consumption rates than flagellates but because ciliates typically have much lower abundances in rivers, they were less significant sources of bacterial mortality (113).

Benthic bacteria are also heavily grazed by protozoans (114). In White Clay Creek (Pennsylvania), protozoans grazed about 80% of benthic bacterial annual production. Ciliate grazing rates were considerably higher than flagellate grazing rates (46 to 176% higher) but ciliates were less abundant (9.1×10^3 versus 1.3×10^6 cm^{-2}) and the investigators concluded the flagellates were the most significant grazers (114).

Protozoa are commonly enumerated based on microscopic examination of live samples or after staining of preserved samples with DAPI or primulin (Table 1). The most abundant types are small flagellates and ciliates; generally ciliates are much less common than flagellates (43,110,112). Few studies have examined spatiotemporal changes in protozoan number, but in one such study, the number of planktonic protozoa in the Ogeechee River did vary greatly among sites (43). Benthic protozoan number also varies among locations in a stream; Schmid-Araya (115) found that the number of ciliates and flagellates was highest in the hyporheos compared with the surface of the benthos. Total numbers of benthic protozoa range from less than 1 to 68×10^5 cm^{-2} (75,115–117).

Identification of protozoa is typically based on morphological appearances but identification of stream protozoa (especially the small and abundant flagellates) is quite difficult (118). The size of the organisms coupled with a lack of distinguishing features and changes in appearance induced by exposure to preservatives, suggests that as for bacteria, molecular-based methods may be needed for identification. Techniques used for bacteria, such as in situ hybridization with fluorescently labeled probes, can be used to identify and enumerate protozoa (118). However, this approach has to be applied yet with much frequency in any environment.

Like algae (as discussed in a subsequent section), the presence or absence of certain protozoan taxa or changes in community composition may be a useful indicator of

ecosystem health (119). Biological indicators and indices are widely used to evaluate the ecological "health" of different streams and are often based on examination of fish and invertebrate communities. Protozoa could also potentially be used in such indices because they are widespread, diverse, and responsive to environmental changes (119).

Some pathogenic protozoa, most notably *Giardia* and *Cryptosporidium*, can occur in streams as the result of human activities (Table 2). In the same way as bacteria that are introduced into streams in feces, many protozoan parasites do not reproduce in streams but have a negative impact on water quality (22). *Giardia lamblia* is perhaps the most common cause of waterborne disease in the United States; this organism can enter streams in the feces of wildlife independent of human activities. *Cryptosporidium parvum* is another major concern; oocysts of this organism can enter water from human and domestic animal feces. Protozoan pathogens are particularly problematic because unlike bacterial pathogens and indicators, there are few simple established methods for detection and enumeration (77).

FUNGI

Fungi are a major contributor to the decomposition of leaf litter or, more generally, particulate organic carbon (POC). The most important and well-studied component of the stream fungal community are the Hyphomycota (3,120). Other nonfungal eukaryotes, like the Oomycota, potentially are important but are not well studied.

In streams, the hyphomycetes decompose POC through the production of extracellular enzymes (3,121). These enzymes are maintained in the biofilms and intermingle with extracellular enzymes produced by bacteria and algae. The biofilm enhances the retention of these enzymes and facilitates overall enzyme activity and degradation of POC (especially complex, recalcitrant compounds such as lignocellulose). The activity of these enzymes has been measured in a variety of studies.

Seven classes of extracellular enzymes have commonly been measured in streams (122–126). The enzyme classes examined include those capable of hydrolyzing: (*1*) organic phosphates (phosphatase), (*2*) organic sulfates (sulfatase), (*3*) carbohydrates (chitobiase, glucosidases, xylosidase), (*4*) cellulose (endo- and exocellulase, cellobiase) (*5*) proteins (protease, peptidase), (*6*) lipids (lipase and esterase), and (*7*) lignin (phenol oxidase and peroxidase). Enzyme activity is commonly determined by measuring the concentration of label hydrolyzed from a representative substrate. Substrates are typically linked to either a fluorochromic label, 4-methylumbelliferyl, or a colorimetric label, paranitrophenol, and enzyme activity is measured.

Enzyme activity is positively correlated with several environmental factors. Biofilms generally have greater activity than the water column (127) and, among particles, higher activity is associated with high surface area to volume ratios (121,122). Relationships between activity and microbial biomass and productivity (123), phytoplankton abundance (124), and water quality (125) have also been reported. Enzyme activities appear to be unrelated to cell number (124,128).

Fungi in leaf biofilms are consumed along with the leaves by leaf-eating invertebrates (or shredders). The fungi (and other microorganisms) contribute directly to the nutrition of the invertebrates and also act to make the leaf more digestible (120). Thus, microbial conditioning of leaves acts to make leaves more palatable and increases their nutritional value (129). Different fungal species differ in their ability to make leaves more palatable and this is reflected in the feeding preferences of the invertebrates (130). Also, different types of macroinvertebrates differ in their use of fungi on leaves; for some (such as the isopod, *Asellus*) fungi themselves provide an important food source, whereas for others (such as the amphipod, *Gammarus*) the action of the fungi in making the leaves more palatable is more significant (131).

Fungi can also provide another benefit to leaf-shredding invertebrates: extracellular enzymes consumed by the invertebrates may remain functional in their gut (129,132). Because aquatic insects do not generally exhibit much cellulase activity, acquisition of enzymes from fungi may help in leaf digestion (3).

The composition of the fungal community in streams has been determined to some degree but direct quantification of population sizes has not been accomplished. This is because of the mycelium-style bodies of the fungi; definition and delineation of individuals is difficult and hyphae may persist that do not contain cytoplasm (34). Thus, typically, conidia are recovered, identified based on their morphology, and enumerated. In one such study, Chauvet (133) discovered that the species composition of the hyphomycetes community differed among streams perhaps based on differences in environmental conditions. In addition, there is a documented succession of changes in species composition on leaves (134).

Community level studies of fungi have focused largely on the examination of extracellular enzymes. However, in the past few years it has become possible to measure fungal biomass and production (Table 1). To estimate biomass, the amount of ergosterol, a membrane sterol unique to fungi, can be determined (135). Similarly, fungal production can be estimated by amending samples with radiolabeled acetate and subsequent detection of the label in ergosterol. In one such study, Suberkropp (136) found that the annual production of fungi on decomposing leaves in a stream was 34 $g\,m^{-2}$. Using this same method, Weyers and Suberkropp (137) showed that fungal production exceeded bacterial production on leaves and that fungal production varied among streams.

ALGAE

Algae are abundant in streams where light is not limiting (3). Typically, they are found in biofilms or periphyton and thus are intermingled with a variety of other microorganisms. Periphyton is often described based on the nature of substrata on which it is formed; for example, epiphyton is on plants, epilithon is on rocks, epipelon is on soft sediments, and epixylon is on wood. (See also PERIPHYTON, this Encyclopedia.)

Diatoms are typically the most diverse algae in streams; cyanobacteria, green and red algae are also abundant (3). The contributions of these various taxa to the community biomass varies among streams. In addition, certain groups of species seem to frequently co-occur and can be placed into named assemblages that are characteristic of particular conditions (138). In addition, to these larger scale differences, periphyton is distributed in a patchy manner at a given location.

Perhaps the most common approach for examining algal abundance is to determine the amount of chlorophyll in a sample and use this to estimate total algal biomass (Table 1; 3). Many algae are amenable to identification based on morphology; for diatoms, in particular, the features of the silica tests are quite useful taxonomically. One difficulty encountered in the study of algal abundance in streams are the problems associated with collecting quantitative samples and removing algae from surfaces. For these reasons, some studies employ artificial substrates, such as ceramic tiles or glass slides, which are placed in the streams and recovered after algal colonization.

Factors that influence the amount and type of periphyton include light, temperature, flow rate, substrate type, water chemistry, and herbivory (3). Many studies have been conducted concerning the role of these factors in determining algal biomass, production, and community composition but no clear generalities have emerged. Some studies have focused on the effects of disturbance, namely, flooding, on standing stocks of periphyton and have determined that frequency of floods and the extent to which they cause movement of the sediments are important (139). Other studies have shown that the presence of grazers (including the number and type) is important (140) but that the effects of grazers are somewhat inconsistent among different studies (141). Nutrient limitation (142) and light limitation (143) can also be important. Overall, a multitude of factors can influence algal ecology in streams and it is likely that the role of these factors depends on environmental conditions and features of the algal community (144).

As a result of the great diversity in the diatom component of the algal community, some studies have suggested that examination of diatom assemblages may be useful in understanding the "health" or "quality" of a stream (145). Diatoms of different species differ in their responses to stream conditions and thus examination of the composition of the diatom assemblage can be used to calculate indicators of biotic integrity.

CONCLUSION

Microorganisms are important in streams for several reasons: they play a central role in the food web, contribute greatly to the nitrogen and carbon cycles, and some are human pathogens that have detrimental effects on water quality. Benthic biofilms play a major role in microbial ecology of streams because they allow organisms to maintain their position in the flowing water and facilitate concentration of dissolved organic carbon and nutrients from the overlying water. Because streams tend to be detritus-based, bacteria and fungi play central roles in the food web. Bacteria are the primary utilizers of the DOC, whereas fungi play a major part in the degradation of POC through the use of extracellular enzymes. The action of these microorganisms makes the carbon and energy in the detrital pool available to higher trophic levels. In the case of bacteria, this connection to other trophic levels is accomplished by protozoa, which are major sources of bacterial mortality in streams.

STRESS RESPONSE IN ARCHAEA

Alberto J. L. Macario
Everly Conway de Macario
Wadsworth Center, New York State Department of Health
The University at Albany (SUNY)
Albany, New York

Salient aspects of the stress response in archaea are covered in this article. The stress response, also called heat-shock response, in the other prokaryotes, the bacteria is treated in the entry Stress Response in Bacteria: Heat Shock, this Encyclopedia. In that entry, basic concepts are introduced and explained. Consequently, they will not be repeated here but frequent reference to the Stress Response in Bacteria: Heat Shock, entry will be made to complement this entry and enhance its understanding.

Several reviews are available in print and electronically on various aspects of the archaeal stress genes, proteins, molecular chaperones, chaperonins, and related topics such as implications for general biology, medicine, environmental microbiology, and biotechnology/industry. These publications will be quoted as often as is convenient to provide the reader with the opportunity to expand on what is presented in condensed and simplified fashion in this article. In these reference publications, there is extensive bibliography covering original work, microreviews, and general articles, which the reader may also consult for experimental details, hard data, hypotheses, and predictions. The aim of this article is to provide an overview of the field — so hopefully the reader will become acquainted with the basics — highlighting areas that are still unexplored and exciting roads that the curious mind might follow in the pursuit of new knowledge.

TERMINOLOGY

Most of the terminology used in discussing stress response and related topics has been clarified in the entry Stress Response in Bacteria: Heat Shock. However, there are specific terms that apply more often to archaea than to other organisms and require explanation here. Organisms grow at various temperatures within a range that is characteristic for each species/strain, but grow faster and better at a certain temperature within that range, and this temperature is called the *optimum temperature for growth* (OTG). Organisms can be classified, considering the OTG, into several groups: psychrophiles, psychrotolerants, mesophiles, thermophiles, and extreme thermophiles or hyperthermophiles, with OTG (in degrees centigrade or C for Celsius) of 15 or less, 20 to 30, 35 to 40, 50 to 70, and 80 or higher, respectively (1). Temperatures higher and lower than the optimum may cause cell stress, which would be more marked as the difference with the optimum increases, up to the point at which there will be no stress response but cell paralysis followed by death. Another parameter to consider is the duration of the exposure to the stressful temperature, the longer the exposure and the higher the heat-shocking temperature the greater the impact on the cell, which will result in a more pronounced stress response or in death, as mentioned earlier. The same applies to any other stressor, such as environmental salt concentration, pH, barometric pressure, and so on.

It follows from the classification of organisms based on the OTG that a temperature that is optimum for a species may be stressful for another. Thus, while describing stress caused by heat shock one refers to a particular organism and a defined set of conditions pertinent to that organism and considering primarily its OTG. The same principle applies to stress caused by stressors other than heat shock (see list of stressors in the entry Stress Response in Bacteria: Heat Shock).

THE THREE DOMAINS OF LIFE

A significant revolution within biology was started by the discovery of the archaea, formerly named archaebacteria (2). These organisms were first distinguished from other prokaryotes, the bacteria, by comparative analysis of 16S rRNA sequences (2), antigenic fingerprinting (3) and cell-wall chemistry (4). The proposal was made to classify all living cells into three main evolutionary lines of descent or phylogenetic domains, Bacteria, Archaea, and Eucarya (5–7). Although this classification has been disputed and may not be perfect, it has been and still is useful to understand the diversity of life. It has been taken into account in this article, and as it will become apparent to the reader, the classification does indeed help organize knowledge on the stress response and antistress molecules and mechanisms. Stress genes and proteins can be grouped into "bacterial" and "archaeal" sets considering their similarity in sequence and other properties, such as the promoters and transcription patterns in the case of the genes. However, instances of a "bacterial" gene existing in an archaeal genome complicate the evolutionary schemes inferred from comparative analyses of sequences (8); one must invoke lateral (horizontal) gene transfer as a probable mechanism that would explain the presence of a "foreign" gene in an archaeon. A case in point is the stress, molecular chaperone gene *hsp70(dnaK)* (9), as it is explained in the following section. Despite some of the arguments and observations against the subdivision of all life into the three domains mentioned earlier, it is clear that archaea can be distinguished from bacteria by some important features such as the basal transcription and translation machineries, and the DNA repair mechanism (10–16). These machineries and mechanism in archaea are more similar to those operating in eukaryotic cells than to those of bacteria. Pertinent to this article, also some components of the chaperoning systems in archaea are more similar to their counterparts in eucarya than they are to the bacterial homologs (17). This is illustrated by the chaperonins that belong to the group II in archaea and also in eucarya, whereas bacterial chaperonins are different and belong to group I. As more and more genomes are sequenced, the "contamination" of archaeal genomes with bacterial genes grows in magnitude, and the separation between the two domains becomes increasingly fuzzier. This state of affairs, which is reflected in the data presented in some of the tables of this article, must be borne in mind by the reader. It is likely that in the not too distant future many of the today's clear-cut differences among the three domains will no longer be evident. Consequently, it is expected that while going over this article the reader will see new territories for exploration, discover critical questions that still need an answer, and think of experiments to perform for obtaining the answers and of theories for explaining what is now obscure.

THE BEGINNINGS

Initial studies of the stress response in archaea were done in the classical fashion with the means available at the time: mid-1980s and early 1990s (18). Archaeal cells were submitted to heat stress, that is, they were heat-shocked by abruptly rising the temperature of the culture several degrees above the OTG. The cells were kept at the elevated temperature for variable periods from about 10 minutes to

Table 1. Examples of Heat-Shock Response in Archaeal Species: Main Features[a]

Organism		Heat Shock		Heat-Shock Proteins (Hsp)		
Archaeal Group *Species*	OTG (°C)[b]	Temp.(°C)[c]	Duration (min)	Number[d]	MM Range (kDa)[e]	Hsp70
Extreme halophiles

Strain ES4	77–99	102	120	1	98	No

[a]Reproduced from E. Conway de Macario and A. J. L. Macario, *Trends Biotechnol.* **12**, 512–518 (1994), in which additional information may be found, with permission from the copyright owner; [b]OTG, optimum temperature for growth; [c]Heat-shocking temperature; [d]Number of protein bands determined by one-dimensional sodium-dodecyl sulfate-polyacrylmide gel electrophoresis followed by autoradiography (*H. volcanii*, *M. voltae*, *S. acidocaldarius*, and *S. shibatae*) or densitometry (*P. occultum* and strain ES4); [e]MM, molecular mass estimated from migration distance in the gel by comparison with a standard ladder made of proteins with known masses; [f]*hsp70(dnaK)* genes have been demonstrated more recently in this and other species of this group by direct cloning of the gene, or by genome sequencing (see also Table 2(I)); [g]Absence of the *hsp70(dnaK)* gene has been confirmed in every extreme thermophilic archaeon whose genomic sequence has been determined up to this time; see examples in Table 2 (II); [h]Described as an ATPase complex with two polypeptides of 56 and 59 kDa (19).

about 4 hours, and subsequently lysed to examine protein patterns. These were compared to those of lysates from nonstressed cells. A sample of the reported data is shown in Table 1.

Several features emerge from examining the data. One of them is the tendency by the investigators to apply the stressor for long periods by comparison with similar experiments performed with bacteria (see the entry STRESS RESPONSE IN BACTERIA: HEAT SHOCK). This trend might be because of a requirement of archaeal species, at least some of them, for a longer exposure to stressors as compared with bacteria for mounting a detectable stress response.

Another noteworthy feature is that, contrary to the typical bacterial response to heat shock that is manifested by an increase in many proteins, some archaeal species show an increase in just one protein.

Last but not least, these early experiments already indicated that the Hsp70(DnaK) molecular chaperone is not present in some archaeal species. This is an important topic that will be treated in some detail in a subsequent section.

GENE CLONING

In the late 1980s, efforts were made in a few laboratories to clone the genes producing some of the Hsp observed in archaea responding to stressors. In 1991, the gene encoding the chaperonin subunit TF55 was cloned from the thermophile *Sulfolobus shibatae*, and sequenced (20). The deduced protein was found to be the homolog of the eukaryotic molecule t-complex polypeptide-1 (TCP-1), and was subsequently established to be the same type of molecule as that of a component of an ATPase complex found earlier in the cytoplasm of the hyperthermophile *Pyrodictium occultum* (19). Afterward it was also established that TCP-1 is the typical chaperonin of the eukaryotic cytosol; subsequent studies have advanced considerably our knowledge of the chaperonin family in the three domains of life (see section The Chaperonins).

Also in 1991, the occurrence of the *hsp70(dnaK)* gene in an organism of the domain Archaea was demonstrated for the first time by cloning and sequencing (21). At the time, this finding seemed simply to confirm the general belief that the *hsp70(dnaK)* gene is highly conserved and universally distributed — it is present in every bacterial and eukaryotic species tested, therefore, it seemed only natural that the gene will also exist in archaea without exceptions. However, the discovery of the gene in an archaeon acquired a new dimension when it was observed that some archaeal species do not have it. As mentioned in the preceding text (see Table 1), early studies had indicated that the product of the gene, the molecular chaperone Hsp70(DnaK), did not show up in the protein patterns detected in heat-shocked cells, in contrast to the rule in bacteria and eukaryotes, in which an increase in Hsp70(DnaK) is observed in response to heat shock (18). The search for the *hsp70(dnaK)* gene among archaea using indirect means such as blottings (Northern, Southern, Western) and protein pattern determination by electrophoresis produced negative results in several instances — suggesting absence of the gene — but the results could not be considered definitive. This had to wait until the genomes of archaeal organisms were sequenced, and the situation is now quite clear, as explained later.

DISCONTINUOUS DISTRIBUTION OF THE *hsp70(dnaK)* GENE WITHIN THE DOMAIN ARCHAEA

One of the major conceptual revisions within the field of stress and antistress mechanisms was fueled in the last five years or so by the cumulative evidence demonstrating the discontinuous occurrence of the *hsp70(dnaK)* gene among archaea (9,18,22). In contrast, the gene has been found in bacteria and eukaryotes with no exception. This is one example showing a difference between the Archaea and the other two domains of life. A sample of the data is displayed in Table 2. The situation pertinent to one

of the archaeal groups, the methanogens, is depicted in Table 2(I). Different lineages of methanogens either have or do not have the gene. Interestingly, among the species that do not have the gene are the hyperthermophilic methanogens. Table 2(II) presents information on the other two archaeal groups, the extreme halophiles and the hyperthermophiles. All the extreme halophiles studied thus far have the gene but none of the hyperthermophiles do. Remarkably, all the hyperthermophilic bacterial species examined do have the gene, as illustrated in Table 2(III). Thus, one may conclude that the lack of the *hsp70(dnaK)* gene is a trait present only in archaea and is more generalized among hyperthermophiles. Also noteworthy, is the absence of the genes encoding the other two components of the molecular chaperone machine (see pertinent section in the following text), the proteins Hsp40(DnaJ) and GrpE, whenever the *hsp70(dnaK)* gene is missing (9). The three genes seemed to have evolved together, as a group.

STRESS PROTEINS IN ARCHAEA

A comprehensive list of stress proteins is available in the entry Stress Response in Bacteria: Heat Shock, this Encyclopedia. Examples of stress proteins and molecular chaperones in archaea are provided in Table 3. Bacterial equivalents are also shown for comparison. Once again, differences between these two prokaryotic groups are apparent. However, some archaeal proteins resemble more the homologs from bacteria than those from eucarya, for example, the components of the molecular chaperone machine (17,21,23–25). In contrast, other archaeal proteins are closer to the eukaryotic than to the bacterial homologs, for instance, the chaperonins ((17,26–28); and see following section). Another important group encompasses comparatively small molecules, the small heat-shock proteins also known as sHsp (17). These are currently being studied and their role in protein folding and refolding, and in the stress response is being assessed.

THE MOLECULAR CHAPERONE MACHINE

This machine is made of three major components, Hsp70(DnaK), Hsp40(DnaJ), and GrpE or nucleotide exchange factor and, depending on the circumstances, it also includes one or more cochaperones (28–31). The three main proteins associate and interact while performing the tasks of assisting nascent polypeptides to fold correctly or partially denatured proteins to refold, and newly made proteins to translocate to the cell's locale where they reside and function, for example, the periplasmic space in prokaryotes and the organelles in eukaryotes.

As discussed in a preceding section, a number of archaeal species do not have the machine whereas others do. A sample of the latter is displayed in Table 4. It is apparent that the organisms possessing the machine are mesophiles or moderately thermophilic; no hyperthermophilic species that has the machine has been found yet.

The functions and mechanism of action of the machine have been extensively studied in bacteria, particularly in *Escherichia coli* (29–31), and also in eukaryotes (32–34), but very little is known about the archaeal counterpart (17). One may assume that the machine works in archaea under the same circumstances and by the same mechanisms known for bacteria, but this inference would be unwarranted. Although the components of the machine are very similar in sequence to the homologs from bacteria, particularly gram-positives, such as *Bacillus subtilis* and others (17,21,23–25), and one may even hypothesize they were received during evolution from bacteria by lateral gene transfer (9,22), they may not follow the same rules that dictate the behavior of the bacterial machine. In the archaeal cell, the intracellular milieu is different as compared with that of bacteria and, most importantly, the genes are within a DNA with promoter regions different from those of bacteria (10,14–16,35). Thus, at least the mechanisms controlling the production of the machine components must be expected to be different in archaea by comparison with bacteria. This is suggested by the transcription patterns of the *hsp70(dnaK)*, *hsp40(dnaJ)*, and *grpE* genes in the only archaeal species studied up to this time, *M. mazeii* (36,37). In this organism, the genes are clustered together like in several gram-positive bacteria (35), but are not transcribed as a unit or operon, as they are in bacteria (see entry Stress Response in Bacteria: Heat Shock). In *M. mazeii* the genes are transcribed separately, each from its own promoter, and consequently the transcripts are monocistronic. In contrast, the genes function as an operon in bacteria and the transcript is polycistronic. These data indicate that the regulatory mechanisms in archaea differ from those of bacteria and, therefore, one might expect that the biochemical interactions of the chaperone machine components among themselves, and with the substrate and ATP are also somewhat unique for archaea. This idea is also encouraged by the realization that the cochaperones present in archaea are not the same as those found in bacteria (see section on Cochaperones). In any case, this is an extremely interesting topic that deserves investigation.

THE CHAPERONINS

Bacteria and archaea differ in their stock of chaperonins: the former have the bacterial or group I and archaea have the eucaryal or group II molecules (17). The typical example of group I chaperonin is GroEL, an Hsp of the Hsp60 family, Tables 3 and 5 (see also entry Stress Response in Bacteria: Heat Shock in this Encyclopedia). Group II chaperonins, exemplified by the TF55 molecule characterized a decade ago, are the homologs of the eukaryotic cytosolic chaperonin TCP-1 (see Section The Beginnings, in the preceding text; 38). The structural features, biochemistry, evolution, and functions of archaeal and eukaryotic chaperonins have been extensively investigated and reviewed (19,26,27,39–43). Suffice to say here that depending on the species, archaea possess one, two, or three different chaperonins or subunits of the chaperonin complex, sometimes called thermosome. The subunits associate to form homo- or hetero-oligomeric rings, which in turn associate with each other to build a cylindrical

body with a central cavity. The latter is called the folding chamber because it is where polypeptides are folded into a functional shape. Interaction of the chaperonin complex with the chaperone machine in eukaryotes and in bacteria is under active investigation. In bacteria, GroEL also forms polymers, rings, and a cylinder with a cavity whose lid is provided by GroES (41,44,45). In some instances it has been proposed that the molecular chaperone machine "presents" the nascent polypeptide in a "foldable" state to the GroEL complex and promotes its entry into the folding chamber from which the protein emerges with a functional shape (29). If the folding process was unfinished, then the partially folded polypeptide reenters the cylinder's cavity for a second round of assisted folding. These cycles continue until a fully folded protein emerges. An ATP cycle accompanies these folding steps which has been studied in bacteria and in archaea in relation to subunit and ring interactions, and in relation to allosteric changes in the conformation of the multiring complex (40,45).

A crucial question that remains unanswered is whether the molecular chaperone machine of archaeal species that have it interacts with the group II chaperonin complex that coexists in the same cell (9,17). This is an important theme not only within the field of archaea but also for the entire field of protein folding that deserves investigation, and archaea, such as *M. mazeii*, which has the chaperone machine and the group II chaperonins, offer unique experimental models for this investigation.

THE COCHAPERONES

Recent studies have revealed that the chaperoning of nascent polypeptides can occur cotranslationally, that is, as the amino acid chain is being assembled on the ribosome (29), and that it involves ribosome-associated chaperones (28). These are named cochaperones or chaperone cofactors, as are other molecules that interact with the three major components of the chaperone machine, as explained in a preceding section, Table 5. A bacterial cochaperone is the trigger factor (TF), and eucaryal cochaperones are BAG-1, Hop, Hip, and NAC, all described in detail in a recent publication, which contains extensive referencing to the original work (28).

A search for genes that would encode cochaperones in fully sequenced genomes from five archaeal species with various OTG, including one species possessing the molecular chaperone machine, did not reveal any clear, highly conserved example of such genes (28). However, it must be said that the search provided some evidence favoring the existence of archaeal representatives of the eucaryal Hop and alpha-NAC subunit, a point that deserves further investigation.

PREFOLDIN

Prefoldin was found in the cytosol of eukaryotic cells and is composed of six subunits (46,47). The subunits associate in a multimeric complex, GimC, which assists protein folding. In archaeal genomes, a similar system has been found, but it includes only two genes that encode only two different subunits, alpha and beta. The archaeal alpha subunit would be the equivalent of the eukaryotic subunits Gim2 and Gim5, whereas beta would be the homolog of the eukaryotic Gim 1, 3, 4, and 6 subunits.

The molecules from *Methanobacterium thermoautotrophicum*, named MtGimC alpha and beta subunits, were studied experimentally (48,49). The archaeal complex is a heterohexamer (two alpha and four beta subunits) with a total mass of 87 kDa. The functions of the archaeal prefoldin and its role in the stress response have not yet been fully elucidated. The genes are not stress inducible, which raises questions about whether prefoldin does belong in the category of stress proteins, although it certainly seems to act as a chaperone. If this were the case, prefoldin would be one example of molecular chaperone that is not a stress protein. Future experiments ought to aim at answering the questions of whether prefoldin interacts with the molecular chaperone machine and/or with the chaperonins in the process of assisting protein folding and refolding in vivo, and whether prefoldin plays a role in cell survival in the face of stress and in cell recovery after stress. Other topics that deserve investigation are the mechanism of action of archaeal prefoldin, and preferred intracellular substrates under physiological conditions and during the stress response.

OTHER STRESS PROTEINS AND ANTISTRESS MECHANISMS IN ARCHAEA

Archaeal organisms are widespread in nature and occupy a diversity of ecosystems from the mild (i.e., suitable to human and many other warm-blooded animals) to the extreme: very cold or hot, very acid or alkaline, high barometric pressure, and so on. One, therefore, expects that archaea have evolved an array of molecules, and mechanisms to cope with these, sometimes unusual by human standards, environments that constitute their habitats. Also, a number of different stressors have been used experimentally to study the stress response in archaea,

Table 5. Examples of Molecular Chaperones and Chaperonins in the Three Phylogenetic Domains[a]

Bacteria	Archaea	Eucarya[b]
GroEL (Hsp60)	No[c]	mt, chl: Hsp60 (Rubisco subunit-binding protein); ct, ER: No
GroES (Hsp10)	No	mt, chl: Yes; ct, ER: No
No	TF55; thermosome subunits	ct: TRiC (CCT; TCP-1) subunits; mt, chl, ER: No

a sample of which is shown in Table 6. The archaeal antistress mechanisms are indeed varied and comprise the genes and molecules described in the preceding section, and others, which are briefly discussed later.

Small Heat-Shock Proteins and Nonproteinic Antistress Molecules. In addition to the better known components of the molecular chaperone machine and the chaperonins, there are other proteins and nonproteinic compounds that play a role in protein folding and protection from the consequences of stress, and in the stress response, which also deserve attention. A comprehensive list of stress proteins is provided in the entry Stress Response in Bacteria: Heat Shock, this Encyclopedia, and some of them are listed in Table 3 (small Hsp). These have recently been reviewed and an extensive bibliography is available in the review articles (17,50).

Antioxidants. Oxygen is necessary for life to many aerobic organisms, including humans. However, it can give rise to toxic radicals that the cell must eliminate or neutralize, otherwise they will damage many molecules especially lipids, proteins, and DNA. The antioxidant defense system is constituted of superoxide dismutases (SOD) that scavenge toxic oxygen derivatives and thus it is considered part of the cell's armament against oxidative stress. SODs have recently been found in archaea but their precise role and evolution have not yet been elucidated (51).

Built-in Protein Stability. Those archaeal species with OTG above 50 °C, particularly the hyperthermophiles with OTG around or above 80 °C, present a challenge to common knowledge about protein stability, which is mostly grounded on the study of enzymes and other proteins from mesophilic organisms. It is well known that heating denatures many proteins, and one wonders how the enzymes and other molecules in extreme thermophiles manage to maintain a functional shape. Several studies have looked into this problem, and the conclusions are somewhat surprising (52,53). No specific structural feature has been identified that would be distinctive of proteins from hyperthermophilic archaea and that would per se endow them with extra stability in the face of high temperature (52). Different proteins have evolved different strategies for stability but they all resort to the same weak electrostatic forces and hydrophobic interactions among the same 20 amino acids that are found in the proteins from mesophilic organisms. Other observations indicate that the surface of hyperthermophilic proteins have a larger proportion of solvent-accessible charged residues paralleled by decrease of polar (noncharged) amino acids (54), and these proteins have more salt bridges than the mesophilic molecules (55).

Resistance to Changes in the Environmental Salt. Cells exposed to a change in external salt concentration mount short- and long-term responses (56). Osmoregulation and osmoadaptation mechanisms are set in motion. Water moves in or out of the cell in the direction dictated by the salt gradient. Organic solutes (osmolytes) accumulate inside the cell either by uptake from the surrounding medium or by de novo synthesis. Archaea have unique osmolytes that contribute to stabilize intracellular proteins in the face of altered osmolarity, and do not interfere with other cellular functions. These osmolytes along with the synthesis of chaperonins and molecular chaperones seem to cooperate in the stress responses elicited by hypo- and hyperosmotic shocks. However, more information is needed to reveal all the mechanisms involved in these responses.

Cell Membrane. Many archaeal species inhabit extreme environments, very cold or hot, very acid or alkaline, or very salty. Many hyperthermophiles are also extreme acidophiles and live at very low pH as compared with the pH that is optimum for human cells. These extremophiles have unique membrane-spanning tetraether lipids (57). A compromise must be reached by the molecules of the extremophiles between the rigidity necessary to withstand potent stressors and the flexibility needed to perform functional intramolecular and intermolelcular interactions. Archaea offer a uniquely rich set of organisms and molecules for studying how the latter manage to perform their physiological functions, very much like those of mesophilic homologs, but under very different conditions of pH, temperature, and salinity.

THE PROTEASOME AND PROTEOLYSIS

The proteasome is a proteolytic multisubunit assembly that occurs in the cytosol and nucleus of eukaryotic cells, and in the prokaryotes gram-positive actinomycetes and archaea (58,59).

Proteolysis, its role in maintaining the intracellular protein balance together with the chaperoning systems, and its participation in the stress response and its regulation in bacteria have been explained in the entry Stress Response in Bacteria: Heat Shock, this Encyclopedia. Moreover, the archaeal proteasome has been discussed in detail in a recent publication (58).

Proteases such as FtsH (HflB), Lon, ClpAP, ClpXP, HslUV (ClpYQ), and proteasome complexes are energy dependent and their participation in the stress response is suggested by the fact that when they are inhibited, or are present at low levels in the cell, the stress response is deficient. Furthermore, the genes coding for some of these proteolytic enzymes (e.g., subunits of the proteasome, Lon, ClpXP, FtsH, and HslUV) are stress inducible.

The amino acid sequences of these proteases are not conserved, and therefore are not very similar to one another, but they all form multimeric complexes and ring structures with a central cavity, like the chaperonin complex discussed in a preceding section. The central chamber is the place where degradation of polypeptides occurs after they have gained access into the central cavity through narrow windows. The size of these windows allows the passage of thin structures, which suggests that only denatured polypeptides can enter the proteolytic chamber.

The archaeal 20S proteasome, like its bacterial equivalent, has a simple composition by comparison with the eukaryotic homolog, including only two to four different subunits — in contrast the eukaryotic 20S proteasome is made of 14 different subunits.

There are also proteasome-associate AAA ATPases (ATPases associated with various cellular activities) that cooperate to unfold misfolded polypeptides and to dissolve aggregates of proteins and thus allow their introduction into the proteolytic chamber of the proteasome. In addition, there is an archaeal proteasome-activating nucleotidase (PAN) that, as its name suggests, activates the proteasome and promotes proteolysis. All these molecules are currently under investigation to determine their role in vitro and, most importantly, in vivo, in normal cellular physiology, in the cell's response to stress, and in recovery after stress.

MULTICELLULAR STRUCTURES

Some archaeal species undergo morphological conversions and form multicellular structures (60). *Methanosarcina* species are the most remarkable in this regard, and *M. mazeii* has been studied in some detail. This species forms three main morphotypes: single cell, packet, and lamina in laboratory cultures (61), which differ not only in macro- and microscopic anatomies, but also in composition (62). The argument can be made that these morphotypes are part of a life cycle that reflects a differentiation-development process that might be set in motion by environmental changes and stress (28). The three morphotypes also occur in complex ecosystems, such as methanogenic bioreactors (63,64), as illustrated in Figure 1. The single cell morphotype consists of cells (3 to 5 micrometer in diameter) separated from one another that grow in suspension in liquid medium. They are fragile and sensitive to different stressors: mechanical shearing, pressure, chemicals, temperature, and antibiotics. In contrast, the packet morphotype is considerably resistant to all these stressors. A packet

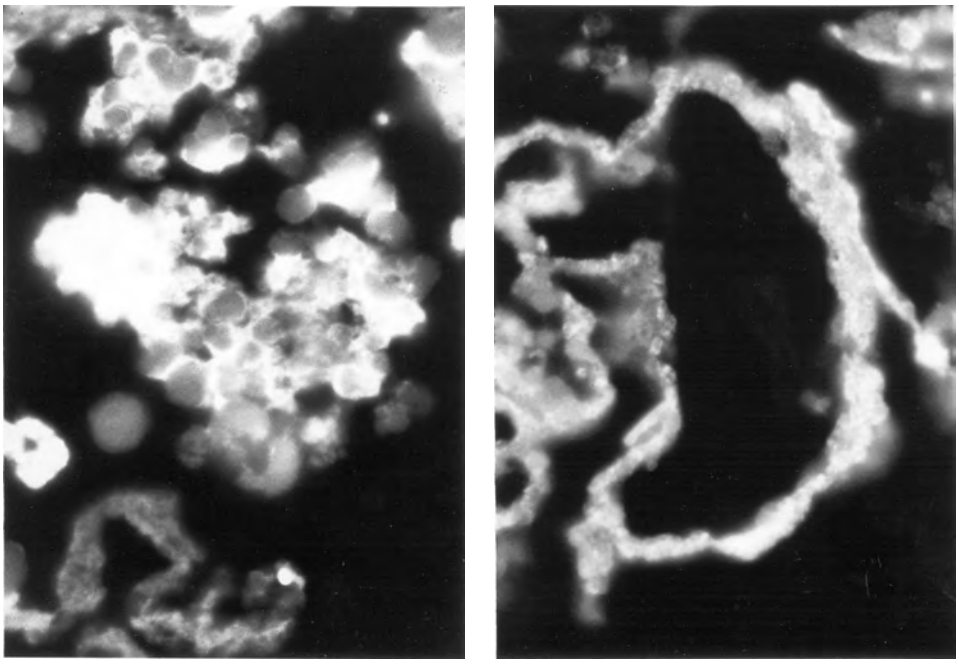

Figure 1. Microscopic view of two thin histological sections of a granular consortium from a methanogenic bioreactor showing *Methanosarcina* packets (left) and lamina (right); the latter has been torn apart from the body of the granule by the sectioning blade. The lamina folds onto itself, sometimes several times, and forms cylindroids that appear in sagital sections, such as the one shown on the right, as an irregular ring or more or less concentric rings, respectively. In this preparation, the packets and lamina are bright with fluorescence because the sections were submitted to a method, indirect immunofluorescence, which uses a calibrated antibody probe of predetermined specificity spectrum and specifically stains *Methanosarcina* cells. Scale: 1 cm = 11.2 micrometers for both, left and right panels. Reproduced from J. E. Schmidt, A. J. L. Macario, B. K. Ahring, and E. Conway de Macario, *Appl. Environ. Microbiol.* **58**, 862–868 (1992) (65), with permission from the copyright owner.

is formed by many cells held together by intercellular connective material, which also surrounds the whole structure, Figure 1, left panel. The latter is globular in shape, and can reach large sizes with diameters measurable in millimeters rather than in micrometers. The third main morphotype of *M. mazeii* is also a multicellular structure, but in contrast to the packet, which is spheroidal, it is flat, see Figure 1, right panel. Its thickness rarely surpasses three cell diameters, that is, the flat structure is typically a cell monolayer. Because of its shape, this morphotype is called lamina. It grows in suspension — it does not stick to the bottom or the walls of the culture vessel — and reaches several centimeters in every horizontal direction. Lamina is more resistant to stressors than single cells but not as nearly as resistant than the packets.

It may be hypothesized that formation of multicellular structures by bacteria, archaea, or eukaryotes is, at least in part, an antistress mechanism, and that the capacity to form such structures conferred evolutionary advantage to primitive organisms (28). Likewise, today's organisms may be able to resist stressors more efficiently by forming multicellular structures. Experimental observations with *M. mazeii* suggest the following chain of events: a stressor impacts on single cells, these mount a stress response including the synthesis and extrusion of the substance that will form the intercellular connective material, and as the cells multiply they remain together enmeshed in that material. Cells continue to thrive and multiply inside the newly-formed multicellular structure protected from the environment and its potentially stressful changes.

FUTURE PROSPECTS

A number of aspects of the stress response in archaea deserve study either because they are not yet as well understood as their bacterial and eucaryal counterparts, or because they do not have a known equivalent in the other two life domains and are interesting for this very reason. Some of the topics open for investigation have been mentioned in the course of this article. Others pertain, for example, to the potential applications of the knowledge gained studying the archaeal stress response and antistress mechanisms in areas at first sight unrelated to these organisms, for example, medicine (66). It must be borne in mind that archaeal organisms might be suitable experimental models to study specific aspects of cell and molecular biology that are directly pertinent to eukaryotic biology, including human's. A case in point is represented by the basal transcription factors and the transcription-initiation mechanism, which involve molecules very reminiscent of the eukaryotic counterparts (12). In this regard, it is also important to realize that very little is known on the control and regulation of the stress genes in archaea. Regulatory factors, pertinent regulatory DNA sites, and DNA-factor(s) and factor–factor interactions have not yet been elucidated. Recent work in *M. mazeii* showed that stress-gene promoters induce conformational changes on a promoter-binding transcription-initiation factor, the TATA-binding protein or TBP (67). These changes were not induced by a promoter for a nonstress gene, and were different for each promoter tested, that is, those for *hsp70(dnaK)*, *hsp40(dnaJ)*, and *grpE*. It may be speculated that the TBP conformational changes are a mechanism for differential gene expression. Each gene's level of induction would be determined by the type and magnitude of the TBP conformational change. Similarly, the mechanism would be involved in determining the levels of induction required by the prevailing environmental conditions, physiological or stressful, and thus regulate the transition from basal to stress-induced transcription.

Furthermore, it is safe to say that the entire complement of chaperones, chaperonins, and cochaperones of archaeal cells has not yet been unveiled. New members of these families of molecules are still being discovered in bacteria (68) and in eukaryotes (69,70), and one can predict that many more will be discovered not only in these organisms but also in archaea. The time is ripe to search for archaeal homologs of eukaryotic, and possibly also bacterial, stress and chaperoning molecules and systems, and to discover new ones, unique to archaea. Studies on these topics in archaea will certainly shed light on similar phenomena that might also occur in eukaryotes, and will provide the means for developing strategies and tools to manipulate stress genes and their products. One may envisage in the near future the engineering of cells that are highly resistant to stressors of importance in environmental microbiology and related biotechnology industries.

STRESS RESPONSE IN BACTERIA

A. Matin
Stanford University School of Medicine
Stanford, California

Stress is a fact of life in nature. Bacteria and other microbes inhabiting the natural environments are constantly subjected to deleterious and fluctuating conditions that can be harmful. The pH may shift abruptly to dangerous levels, and so can a host of other conditions, namely, temperature, salinity, osmotic pressure, oxygen, reactive oxygen species concentration, and the nutrient supply. The specter of starvation is nearly always present (1). Oceans are estimated to have 0.8-mg carbon/L, most of which is

nonavailable for bacterial growth, and in freshwater the concentration of individual carbon compounds can be as low as 6 to 10 μg/L. In soils also nutrients are scarce because most of its 0.8 to 2% carbon is recalcitrant humus. For the disease-causing bacteria too life is a constant struggle. To establish infection in a mouse, the pathogen *Salmonella typhimurium*, for example, must first survive passage through in the stomach, where the average pH over a 24-hour period is as low as 1.5. It is then eaten up by the host macrophages, in which it encounters not only the pH stress but is also attacked by reactive oxygen species, and suffers nutrient deprivation. A bacterium's challenge is thus to be ever on guard to prevent damage to its vital components that stresses might cause. This challenge is met in two fundamental ways: first, by increasing the ability to neutralize stress in the face of that stress; and second, to increase the ability to repair the damage that the stress might cause. Because the damage that different stresses inflict has common ingredients, the second response often results in elevated general resistance, that is, what does not kill makes a bacterium stronger overall.

Both the ability to escape stresses and to resist them is achieved by the synthesis of a special class of proteins termed the stress proteins, which in turn is attained by the activation under stress of complex regulatory mechanisms involving transcriptional, translational, and posttranslational control. At the onset of starvation, for example, a large number of proteins are synthesized, which fall in different temporal classes: early, in-between, and late (Fig. 1; 2). Our understanding of the

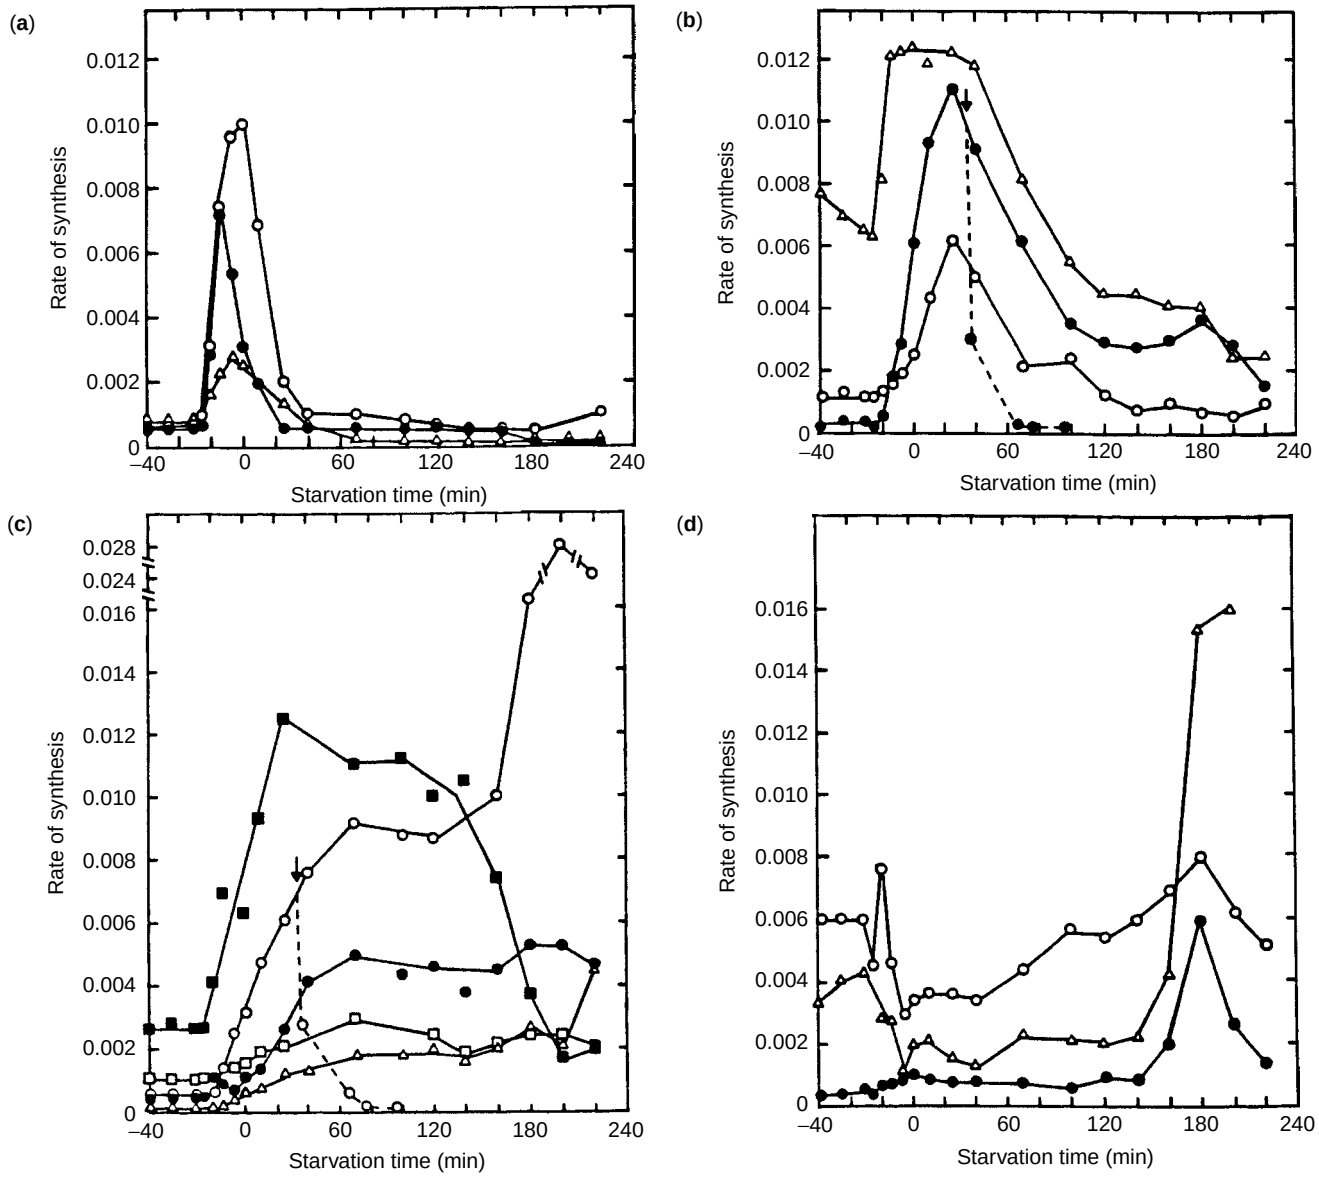

Figure 1. Rate of synthesis of selected polypeptides in *E. coli* entering starvation due to glucose exhaustion. Dashed lines show rate of synthesis of certain polypeptides after readdition of glucose (indicated by the arrow). A similar temporal pattern was observed upon succinate starvation. Figure 2. SoxRS regulation of the genes involved in defense against the $O^{\cdot -}$ radical. The change in the configuration of the SoxR protein upon oxidation by $O^{\cdot -}$ is schematically represented to show that in its altered configuration it can activate SoxS transcription, which in turn activates the individual genes of the SoxRS regulon.

mechanisms responsible for activating the synthesis of stress proteins and how these proteins enable the cell to survive stresses has increased significantly in recent years. These insights have potential practical benefits. For example, the molecular mechanisms responsible for the expression of genes during starvation conditions (involving the starvation promoters) offer the possibility of improving in situ bioremediation. Further, inasmuch as the stress genes and proteins are concerned with survival, their manipulation opens up the prospect of enhancing or diminishing bacterial life. Control of the former will improve bioremediation and ecosystem management, and of the latter, disease containment. The stress response, moreover, appears to be involved in the elevated antibiotic resistance of bacterial biofilms that cause diseases that are notoriously difficult to treat, and is therefore a suitable target for addressing this problem also.

THE STRESS PROTEINS PROTECT AT TWO LEVELS

As stated earlier, bacteria deal with stresses using two strategies, one is to attempt to neutralize and escape the stress and the other is to increase their capacity to repair the damage caused by that stress. I will consider these two strategies separately under the headings of "escape" and "robustness" responses. For example, when subjected to starvation, bacteria not only acquire additional skills to obtain food but also prepare themselves to better withstand the consequences of starvation. The same is true, by and large, of other stresses. The measures taken to escape a stress tend to be specific to that stress. Thus, escaping starvation necessitates synthesis of a set of proteins different from those required to escape oxidative or osmotic stress. However, the measures required to withstand the consequences of different stresses have a greater degree of commonality. This is because all stresses lead to a similar outcome, namely, damage to cellular macromolecules, such as proteins, nucleic acids, membranes, and disruption of the cell's ionic composition. Thus, although the escape response tends to be unique to different stresses, the robustness response shares many common ingredients. The fact that all stresses evoke a core robustness response is a relatively recent recognition (5).

Stress Proteins and Escape from Stress

This aspect of the stress response in the context of starvation and the oxidative stresses will be illustrated in the text that follows.

Starvation. Many proteins synthesized either de-novo or whose levels increase during starvation are concerned with alleviating the dearth of the limiting nutrients (Table 1). These proteins may act at all metabolic levels: transport, substrate capture, flux through the central pathways, and the capacity to use additional compounds. Phosphate-limited cells increase the amount of a porin in their outer membrane that facilitates the passage of phosphate compounds into the periplasm where a high affinity binding protein, also induced under phosphate limitation, promotes high affinity uptake; in the periplasm the phosphate compounds are hydrolyzed by bacterial alkaline phosphatase, which also increases under phosphate starvation. Concomitantly, a new transport system in the cytoplasmic membrane capable of transporting inorganic phosphate (P_i) with a high affinity, the Pit system, takes over in place of the low affinity Pst system (6). A similar change occurs during starvation for other nutrients. Under carbon starvation, high affinity periplasmic transport proteins enhance carbon scavenging (7), and under potassium limitation, Kdp a high affinity transport system, replaces the low affinity Trk system. Another example of shifting to a high affinity system relates to glycerol utilization. When glycerol becomes limiting, cells utilize a different pathway for its catabolism. This involves glycerol kinase rather than glycerol dehydrogenase as the first step in glycerol catabolism; because the kinase is a higher affinity enzyme, metabolism of low glycerol levels is facilitated (8).

Increase in the concentration of substrate-capturing enzymes further augments the scavenging capacity. For example, hexokinase and lactate dehydrogenase levels go up in glucose and lactate limited cells, respectively; and glutamine synthetase (GS) levels increase in ammonium-limited cells. (GS is the first enzyme in ammonium assimilation, catalyzing conversion of glutamate to glutamine.) A general increase in enzymes of central catabolic pathways occurs, which promotes channeling of low level catabolites through them. Thus, a combination of synthesis of high affinity enzyme and a general increase in enzyme levels are among the measures a cell adopts to maintain metabolism at rates consistent with survival in low nutrient environments (9,9a,10).

The starving bacterial cells also induce the synthesis of transport and catabolic enzymes for substrates that may not be present in the environment but that may serve as alternate sources of the missing nutrient. Thus, cells starved for glucose not only increase their ability to scavenge glucose but also, for example, scavenge lactose

Table 1. Enzyme/Transport Systems Induced in Nutrient-Limited Cells to Escape Starvation

Enzyme	Nature of Change	Function	Limiting Nutrient
Periplasmic binding proteins	Increase in level	Enhance transport (Maltose, ribose histidine)	Carbon substrates
Pst	Increased affinity	Enhance Pi transport	Phosphate
PhoE	Increased levels	Facilitate Pi passage through the outer membrane	Phosphate
Kdp	Increased affinity	Enhance K^+ transport	Potassium
Hexokinase	Increase in level	Substrate capture	Glucose
Lactate dehydrogenase	Increase in level	Substrate capture	Lactate
Glycerol kinase	Increased affinity	Substrate capture	Glycerol
Bacterial alkaline phosphatase	Increase in level	Substrate capture	Phosphate
Glutamine synthetase	Increase in level	Substrate capture	Ammonium
Glucose-6-phosphate dehydrogenase	Increase in level	Enhance flux through catabolic pathways	Carbon substrates
Phosphofructokinase	Increase in level	Enhance flux through catabolic pathways	Carbon substrates
Pyruvate kinase	Increase in level	Enhance flux through catabolic pathways	Carbon substrates
Aconitase	Increase in level	Enhance flux through catabolic pathways	Carbon substrates
Isocitrate dehydrogenase	Increase in level	Enhance flux through catabolic pathways	Carbon substrates
Malate dehydrogenase	Increase in level	Enhance flux through catabolic pathways	Carbon substrates
β-galactosidase	Increase in level	Amplify metabolic potential	Carbon substrates
CstA	Increase in level	Amplify metabolic potential	Carbon substrates

and peptides (11): the former by increased synthesis of β-galactosidase, the latter by that of the CstA protein, which is involved in peptide transport. Thus, even if the measures to better scavenge the dwindling supply of an existing substrate fail, the chances are improved that other substrates that may appear in the environment would be readily used, thereby relieving starvation.

For motile bacteria, an additional means of escape from stress is to make optimum use of their capacity to move away from a stressful environment: if all else fails, flight to potentially greener pastures might help! Toward this end, maximal flagellar synthesis and its optimum functioning are also a part of the stress response in bacteria (12).

Oxidative stress. Oxygen possesses two unpaired parallel electron spins and is electronegative, which give it a tendency for univalent reduction that generates highly toxic reactive oxygen species (ROS). The presence of certain compounds in the environment stimulates ROS generation and bacteria synthesize special enzymes to mitigate this problem. Compounds such as paraquat, nitrocompounds, chromate, quinones, and several dyes are subject to univalent reduction, whose products, being autooxidizable, set up a redox cycle, generating the ROS, $O_2^{\cdot -}$ (13). When compounds predisposed to univalent reduction are present, bacteria synthesize enzymes such as nitro-, chromate, and quinone reductases that catalyze their divalent reduction. These enzymes make nitro compounds, chromate, and others unavailable for univalent reduction and as the products of their divalent reduction are stable, ROS generation is minimized.

The bacterial cell is alerted to the presence of compounds predisposed to univalent reduction via the protein encoded by the *soxR* gene, which senses $O_2^{\cdot -}$ (Fig. 2; 14). In the presence of this radical, the SoxR protein, which is constitutively synthesized, becomes activated by direct oxidation by $O^{\cdot -}$. This protein is a homodimer with two [2Fe-2S] centers per dimer, which is where the redox changes occur, involving $[2\text{Fe-2S}]^{1+} \leftrightarrow [2Fe-2S]^{2+}$ conversion. The oxidized SoxR activates the transcription of the *soxS* gene, whose product in turn induces transcription of the *soxRS* regulon. The products of this regulon include the reductases mentioned earlier, which prevent $O_2^{\cdot -}$ formation, as well as manganese specific superoxide dismutase, and other enzymes that can decompose this radical. An additional enzyme is concerned with repairing the damage that $O_2^{\cdot -}$ can cause; this will be considered under the robustness response. At the end of the stress, SoxR is reduced by an NADPH-dependent reductase.

It may be an indication of the danger posed by the oxidative stress that bacteria employ another protein, OxyR, to sense the presence of H_2O_2. H_2O_2 directly oxidizes OxyR, and the resulting conformational change, which has been documented by crystal structure, enables OxyR to activate transcription of genes whose products decompose H_2O_2. In the absence of the H_2O_2 stress, OxyR is reduced by an enzyme called glutaredoxin 1 (14).

Stress Proteins and Cell Robustness

As various classes of stress proteins are synthesized (Fig. 1), cells acquire increasing resistance to stresses in general; this is termed the general stress resistance (GSR) response. Figure 3A illustrate this phenomenon for heat: cells starved for increasing duration acquire increasing resistance, but this occurs only if stress protein synthesis is allowed. Inclusion of chloramphenicol, or inhibition of protein synthesis by other means, prevents the resistance development (15). What is true of heat applies also to other stresses: starved cells show increased resistance to the stresses listed in Table 2. Figure 3A and Table 2 deal with this phenomenon in the context of starved cells, but cells subjected to other stresses also give the GSR response, as is illustrated for resistance to H_2O_2 developed by cells subjected to the individual stresses shown in Figure 3B; 16,17). Partial starvation, such as that experienced by bacteria in a low dilution rate chemostat culture, also elicits the GSR response; this is illustrated for ClO_2 resistance of *E. coli* (Fig. 3c). When grown at a dilution rate of 0.05 h^{-1} (14-hour doubling time) because of partial

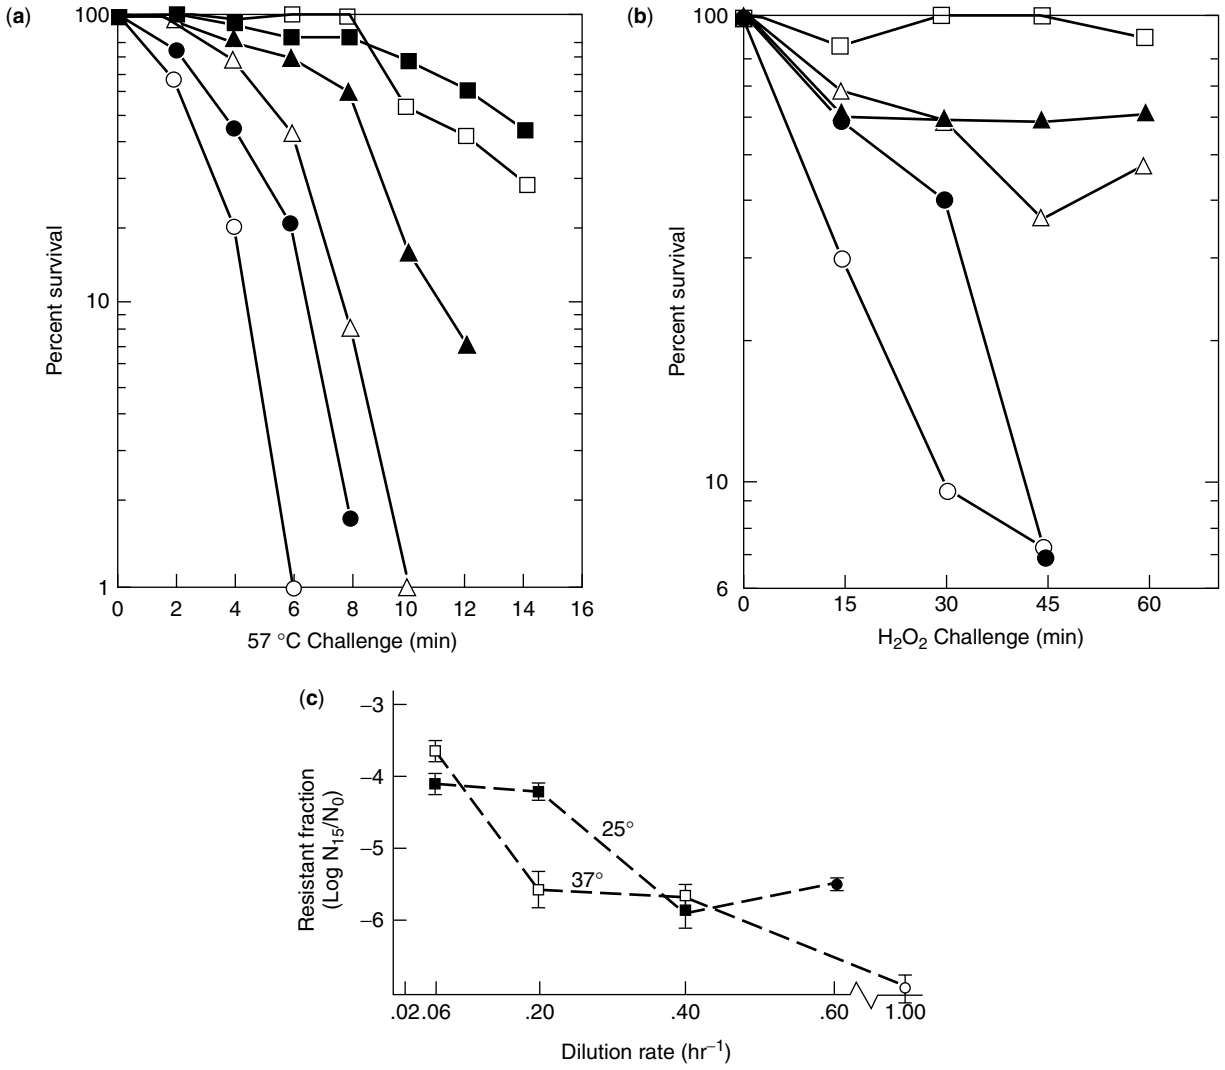

Figure 3. (**a**) Induction of thermal resistance in *E. coli*. starvation, this bacterium becomes several orders of magnitude more resistant to this stress than when grown at its maximal rate (18).

THE BIOCHEMICAL BASIS OF GSR

While the detailed mechanistic basis of how starvation proteins confer GSR remains to be elucidated, ongoing research continues to contribute to our knowledge. Clues are provided by the findings that the stress proteins associated with GSR can decompose ROS, repair cell proteins and DNA, and strengthen the cell envelope. ROS decomposition has been touched upon earlier; other processes will be briefly discussed in the following text.

Protein Repair. This is brought about by molecular chaperones, which constitute a large and diverse class of proteins with an indispensable role in cell physiology under all conditions. For example, during protein synthesis, they bind to nascent polypeptides to ensure proper folding of the mature proteins, and are necessary for the translocation of certain proteins through the cell membrane (19). Their protective role in stresses arises from the fact that they can minimize damage and/or renature proteins damaged by stress. The chaperones are slow ATPases, which, when bound to ADP, have a high affinity for unfolded proteins but a low affinity for them when bound to ATP. These characteristics determine the duration of their action on an unfolded part of a protein, and ensure the continuation of the process until renaturation is completed. The chaperone, DnaK, interacts with the proteins DnaJ and GrpE in this process (Fig. 4). DnaJ binds to the denatured protein and presents it to the DnaK-ATP complex. Repair proceeds while ATP of the DnaK is hydrolyzed, and results in a stable complex consisting of the substrate protein, DnaJ and DnaK-ADP. The substrate protein is recovered by a process in which GrpE plays a role, and involves the release of DnaJ from the complex, and conversion of DnaK-ADP to DnaK-ATP (20).

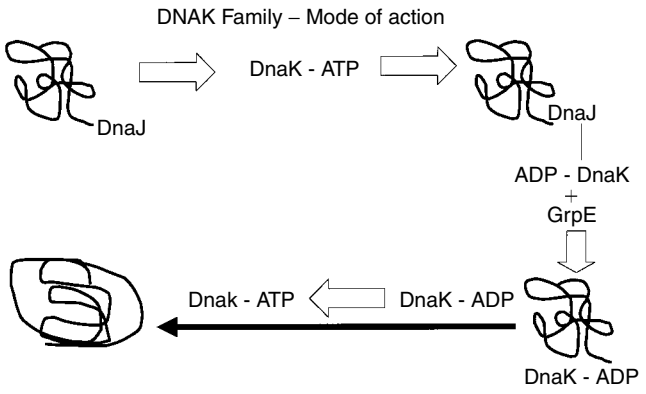

Figure 4. Repair of a denatured protein by the DnaK family of chaperones. Based on F. U. Hartl, *Nature* **381**, 571–580 (1996).

DNA Repair. Endonuclease IV is a part of the *soxRS* regulon discussed earlier: it participates in the repair of damage to DNA caused by oxidative and other stresses. Similarly, the stress proteins exonuclease III and AidB repair damaged DNA (20a), the latter by reversing DNA methylation. A major system for DNA repair is the so-called SOS response (21), which is activated by several stresses, namely, starvation, UV irradiation, and others that result in DNA damage. The proteins whose synthesis is activated by this response include those that promote DNA synthesis, inhibit DNA degradation as well as affect various kinds of DNA repair, such as long-patch repair, daughter-strand gap repair, and double-stranded break repair.

Envelope Reinforcement. The stress protein D-alanine carboxypeptidase increases peptidoglycan cross-linkage and thus accounts, at least in part, for the increased strength of the cell wall. The *otsBA* (*pexA*) operon-encoded proteins, by stimulating trehalose biosynthesis, increase the strength of cell membranes (22).

Molecular Regulation of the Stress Response

Synthesis of individual stress proteins is the result of regulation at all three levels of control, that is, transcriptional, translational, and posttranslational levels.

Transcriptional Control of Stress Genes. This occurs as a result of changes in the cellular concentration of sigma and transcriptional factors. Sigma factors are small proteins that, on association with the RNA polymerase *core* enzyme (abbreviated as E), determine if a promoter is recognized by the resulting RNA polymerase *holoenzyme*. Four sigma factors, σ^{70}, σ^{32}, σ^{s}, and σ^{54} have a role in the transcription of stress genes; their holoenzymes recognize sequences located, as a rule, in a region (called the promoter) that is 10 and 35 nucleotides upstream of the transcriptional start site. Different holoenzymes recognize different promoters.

Role of Eσ^{70}. The stress promoters transcribed by Eσ^{70} are generally weak promoters, that is, they deviate from the consensus promoter sequence for this holoenzyme. As a result, their transcription depends on the availability of ancillary transcriptional factors. This is the case with a large number of starvation genes (24); these are transcribed by Eσ^{70} if cyclic AMP (cAMP) is available. cAMP binds a protein called CRP and together they bind to the cAMP / CRP consensus sequence present upstream of the promoters of such genes. cAMP concentration is kept low in nutrient-sufficient cells but goes up as the cells experience nutrient scarcity, thus fulfilling the requirement for the transcription of these genes by Eσ^{70}. It is noteworthy that the starvation genes whose

transcription is cAMP dependent play no role in the GSR response because mutants deficient in cAMP, and therefore unable to induce transcription of these genes, are normal in the GSR response. What then is the role of cAMP-dependent stress genes? This question has been investigated only in the context of the starvation stress, and here their role is entirely concerned with providing escape from starvation. These genes encode proteins (such as those listed in Table 1) concerned with uptake and catabolic functions and which thereby enhance the scavenging capacity of the cell for the substrate whose supply begins to dwindle, as well as the cell's capacity to use alternate sources for the limiting nutrient.

Role of Other Sigma Factors. Most of the genes that encode stress proteins concerned with the GSR response require RNA polymerase holoenzymes that contain the stress sigma factors, primarily σ^s, and σ^{32} (25). These genes have a different promoter region than $E\sigma^{70}$-transcribed promoters, and they are either not transcribed, or transcribed at a low level in unstressed cells because the concentration of the stress sigma factors is low in such cells. In stressed cells, however, the levels of these "alternate" sigma factors increase, thereby elevating the $E\sigma^s$ and $E\sigma^{32}$ levels to a point as to permit high-level transcription of stress genes. Some of the increase in the concentration of these sigma factors under stress could be due to the increased transcription of their genes in stressed cells. However, the bulk of this increase occurs due to translational and posttranslational regulation, as is discussed later.

Stress genes transcribed by $E\sigma^{32}$ generally contain consensus sequences both for $E\sigma^{70}$, and $E\sigma^{32}$ in their promoters and many therefore are transcribed also in unstressed cells, but the transcription increases during stress because of the additional availability of $E\sigma^{32}$ (26). This makes sense because the products of many of these genes are molecular chaperones (also referred to as the heat shock proteins), which as we have seen, play essential roles in cell physiology under all conditions.

The $E\sigma^s$-transcribed genes possess a variation of a $E\sigma^{70}$-type promoter, and structurally σ^s closely resembles σ^{70}. Several promoters can be recognized by both $E\sigma^{70}$ and $E\sigma^s$ (27,28), depending on the presence of ancillary transcriptional factors. Thus, the increased expression of *pexB* (also called *dps*), which is involved in protection against oxidative stress, is dependent on $E\sigma^s$ under some stresses, but on $E\sigma^{70}$ under others, depending on the availability of the ancillary transcriptional factors (29,30). Changes in the core RNA polymerase or the cytoplasmic ionic composition can also effect this shift. These findings suggest that the regulatory apparatus of $E\sigma^s$-transcribed genes evolved from those transcribed by $E\sigma^{70}$, possibly to ensure flexibility in the transcription of these genes, permitting absence of transcription under unstressed conditions in which $E\sigma^{70}$ alone is primarily present, but nevertheless allowing transcription without $E\sigma^s$, under appropriate conditions.

The role of σ^{54} in stress response is also important. Genes regulated by this sigma factor play a role in nitrogen and carbon starvation and formation of pili (31a,32), which enable stressed cell to attach to appropriate surfaces, promoting survival. Transcription activation by $E\sigma^{54}$ does not generally involve an increase in the level of the sigma protein. Rather, it is the phosphorylation of a protein called NtrC that activates it. NtrC is a member of two-component systems, which are considered in the following text.

Posttranslational Regulation of Stress Gene Expression

These mechanisms are the major factor in regulating σ^{32} and σ^s levels and have been studied extensively in this context.

σ^{32}. The gene that codes for σ^{32} is called *rpoH*. Computer analysis shows that the 153–247 region of the *rpoH* messenger RNA (mRNA) can base pair with its "translational apparatus." The translational apparatus consists of the initiation codon, and sequences upstream to it, including the Shine-Dalgarno sequence, which are complementary to the ribosomal RNA. For the translation of an mRNA to occur, it is necessary that the translational apparatus is available for correct binding to the ribosomes. However, the 153–247 segment of the *rpoH* coding region can base pair with this apparatus, leading to its sequestration, thereby inhibiting translation (Fig. 5). It is thought that the secondary structure is transiently disrupted when cells are exposed to heat shock, thereby accounting for increased translation of the *rpoH* mRNA during this shock. Indeed, removal of the 153–247 region of the gene results in high-level expression of the (truncated) gene product, even without the heat shock. In essence the region 153 to 247 of the intact gene acts as an antisense element, resulting in the formation of a secondary structure of the *rpoH* mRNA that prevents translation under normal conditions. Heat shock breaks the hydrogen bonds, relaxing the mRNA secondary structure, and permitting translation (26).

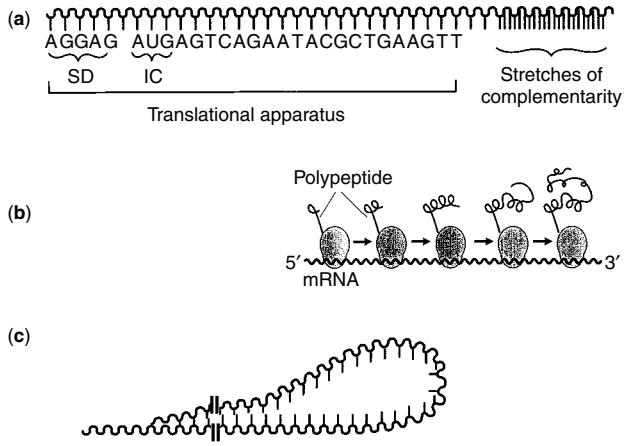

Figure 5. Schematic representation of sequestration of the translational apparatus of *rpoH* mRNA by the 153–247 complementary sequences in its coding region. (**a**) Representation of the *rpoH* gene sequence; (**b**) Translation of an mRNA with unsequestered translational apparatus; (**c**) *rpoH* mRNA with sequestered translational apparatus. Based on T. Yura, H. Nagai, and H. Mori, *Annu. Rev. Microbiol.* **47**, 321–350 (1993) and A. Matin et al., Microbial Ecology of Infectious Disease, American Society for Microbiology, Washington, D.C., 1999, pp. 30–48.

Another mechanism that contributes to σ^{32} increase under stress is the stabilization of the sigma protein. In unstressed cells, σ^{32} associates with the DnaK family of chaperones. This association keeps it in a conformation that is readily attacked by a variety of proteases, such as Lon, FtsH, ClpQY. The chaperones, however, have a higher affinity for denatured proteins. Thus, as the concentration of the latter increases during a stress, they attract the chaperones to themselves and away from σ^{32}. Free σ^{32} acquires a different configuration in which it is relatively immune to proteolysis. This may be the mechanism by which σ^{32} levels increase under starvation and other stresses.

$\sigma^s \cdot \sigma^s$ levels, which are about 140 pmoles per mg protein in the unstressed cells, increase by some fourfold to 520 pmole per mg protein in stressed cells. However, the σ^s synthesis rate decreases by some 50% in the stressed cells due both to diminished transcription of the *rpoS* gene (that codes for this sigma factor), as well as decreased translation of the *rpoS* mRNA. So why do σ^s levels increase in the stressed cells? The sigma protein becomes some seven times more stable in the stressed cells. The half-life of σ^s protein is approximately four minutes in unstressed cells, but increases to 27 minutes under stress (Fig. 6), thus accounting for the fourfold increase in the sigma factor concentration despite its reduced synthesis (33,34,35).

How σ^s becomes more stable in stressed cells is not known, but some interesting aspects of this phenomenon have come to light. We know, for instance, that a specific protease in the cell degrades this sigma factor and accounts for its instability in the unstressed cells (34). This protease is called the ClpXP protease and is made up of two proteins, ClpX and ClpP. Interestingly, ClpX by itself is a molecular chaperone and performs the role of a protein protector. But when combined with one of several partners, such as ClpP, ClpA, ClpC, and so on, it becomes a protease that can target certain proteins specifically (36). Thus, σ^s is attacked by the ClpXP complex and not by, for instance, by ClpXA.

Other proteases present in the cell also do not attack σ^s. Why this sigma factor is the target of a specific protease, and not others, is also not known, but investigations into this aspect of σ^s regulation are ongoing and promising. Bacterial and other cells are selective in what proteins they degrade under different environmental exigencies. How they are able to make this selection is not known. Therefore, what we learn about the mechanism of the ClpXP protease recognition of σ^s as its target, while leaving the nontarget proteins unscathed, will have much significance. An interesting finding in this regard is that the 173–188 amino acid region of σ^s is essential for its sensitivity to the ClpXP protease (Fig. 7). If this region is deleted, or certain amino acids in this region are altered, the resulting protein is not attacked by the protease (34,37).

Sensing Stresses. Heat stress is probably sensed via the melting of hydrogen bonds in the *rpoH* mRNA. This, as we have seen earlier, is believed to be the mechanism of increased *rpoH* mRNA translation leading to increased cellular σ^{32} levels and the heat shock gene transcription. An additional mechanism involves the DnaK chaperone family. As discussed earlier, this family of proteins dissociates from σ^{32} in the presence of denatured proteins leading to the stabilization of the sigma protein and the consequent triggering of the heat shock response. Thus, any stress that causes increase in cellular denatured proteins will activate the heat shock response.

The Two-Component Systems. Starvation for certain nutrients and other stresses are sensed and appropriate transcriptional activations affected via systems that involve two proteins, a sensor protein (HPK) and a response regulator protein (RR). HPK has the property of autophosphorylation at a histidine residue. P-HPK is unstable in unstressed cells, but becomes stable in the presence of a specific stress. It then phosphorylates

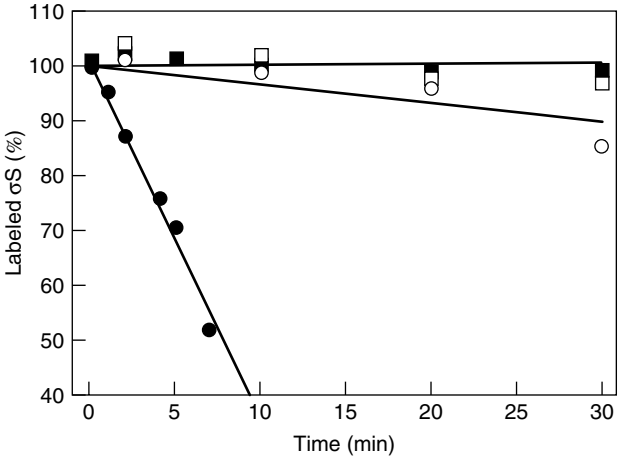

Figure 6. Comparison of half-life of σ^s in exponential phase (solid symbols) and stationary phase (open symbols) cultures in cells with (circles) and without (squares) ClpXP protease. (Reproduced with permission from T. Schweder, K. Lee, O. Lomovskaya, and A. Matin, *J. Bacteriol.* **178**, 470–476 (1996).

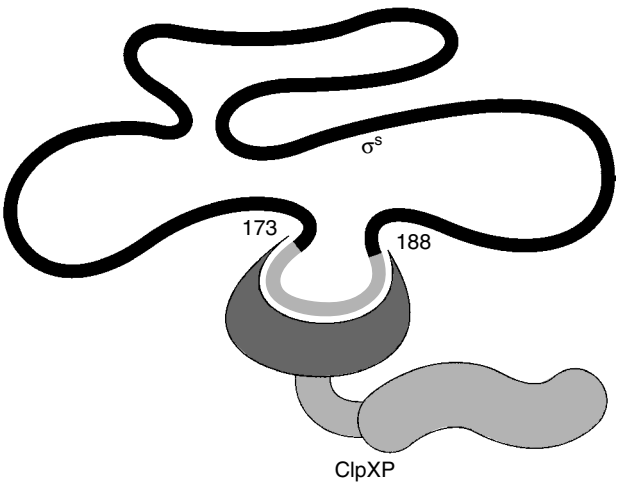

Figure 7. Schematic representation of the σ^s protein, showing that the 173–188 stretch of amino acids of the protein is targeted by the ClpXP protease. Based on Ref. 34.

RR at an aspartic residue, which enables it to activate the transcription of a number of genes. Several pairs of HPK and RR proteins, each involved in sensing a specific aspect of the environment, have been found. The HPKs of different systems share homology of about 100 amino acids in their C-terminal end; the RRs share homology in the 130 amino acid segments of their N-terminal end.

Phosphate and nitrogen starvations are sensed through such systems (6,31). The sensor protein for phosphate sensing is a membrane protein called PhoR. Its phosphorylated form is stabilized when the cell experiences phosphate scarcity. It then phosphorylates its cognate RR, which is called PhoB. Several genes concerned with increasing phosphate-scavenging capacity (refer to the earlier text) contain in their promoter region a specific sequence, called the phosphate box. P-PhoB (but not PhoB) can bind to this sequence and activate the transcription of such genes. The two-component system involved in sensing nitrogen scarcity consists of NtrB (HPK) and NtrC (RR). During ammonium scarcity, P-NtrC that is generated binds to a specific sequence activating the transcription of the gene *glnA*, which codes for glutamine synthetase.

A two-component system might operate also in sensing carbon starvation. A protein called SprE (or RssB) (37,38), which bears homology to the RR component of the two-component sensing system, has a role in regulating σ^s levels. In its absence the ClpXP protease is unable to degrade this sigma factor. The cognate HPK protein for SprE has not yet been found, but it has been shown that SprE gets phosphorylated under starvation conditions. P-SprE specifically makes σ^s sensitive to the ClpXP protease because other substrates for this protease are not affected (39). It is possible that P-SprE (but not SprE) alters the σ^s conformation in a way so as to make it susceptible to the ClpXP action, as is illustrated in Figure 8. If SprE in fact directly acts on σ^s, it would be an unusual RR in interacting with a protein instead of DNA.

Recently evidence has been obtained suggesting the involvement of a GTP-binding (G-) protein, called FlhF, in sensing stresses (40). This protein is present at one of the poles of the *Pseudomonas putida* cell very likely on the cell membrane. Its absence robs the cell of the ability of mounting the GSR response. Conditions such as starvation that result in GSR protection in the wild type, fail to afford this protection to the mutant. This is illustrated in Table 3. Although the starved wild-type strain fully resists exposure to different stresses, the mutant is overwhelmed by a similar exposure. Return of the gene encoding FlhF to the mutant restores the GSR mounting ability. Interestingly, besides its potential role in enabling *P. putida* to initiate a stress response, FlhF is also involved in correct placement of flagella on the cell. Although the wild type has flagella at one of the poles, the mutant shows a random distribution (Fig. 9). Restoration of the gene in multicopy or a single copy restores the polar location—in the former case with increased flagellar number. The mutant is incapable of directional motility. Because flagellar formation is also a part of the stress response (see earlier text), it is possible that FlhF has a sensor role and in its activated form coordinates gene expression concerned with the GSR response as well as correct flagellar assembly (Fig. 10).

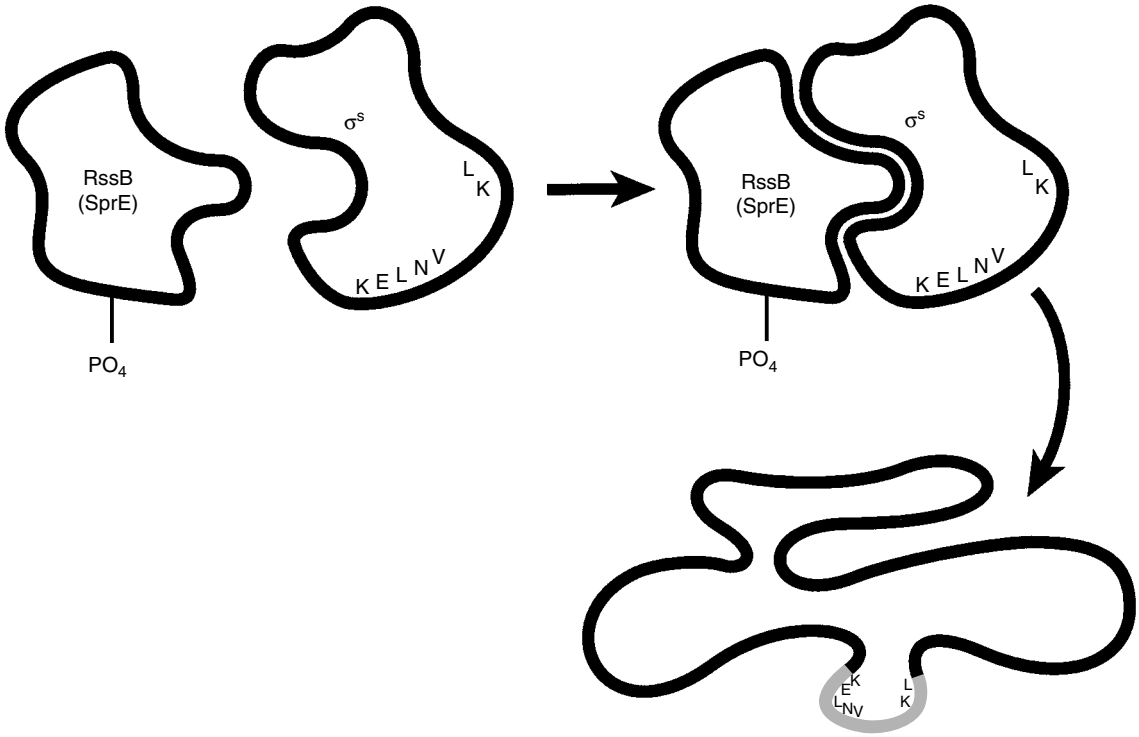

Figure 8. Schematic representation of the possible mechanism whereby phosphorylated SprE alters σ^s configuration in which it becomes susceptible to the ClpXP action.

Table 3. Effect Resistance of Mutation in *flhF* Gene on General Resistance

Strain	Percentage Remaining Viability After Exposure to:			
	Heat	H_2O_2	Ethanol	Starvation

MK202 (Compl.)	95	92	90	102

APPLICATIONS OF THE STRESS RESPONSE

Use of Starvation Promoters in Bioremediation. Environmental pollution is a serious problem as numerous Superfund sites lie scattered across the country and noxious chemicals from the Department of Energy (DOE) sites threaten to contaminate drinking water sources. Bacteria can degrade such chemicals and bacterial bioremediation is therefore a promising approach to address this problem. A hurdle that must be overcome

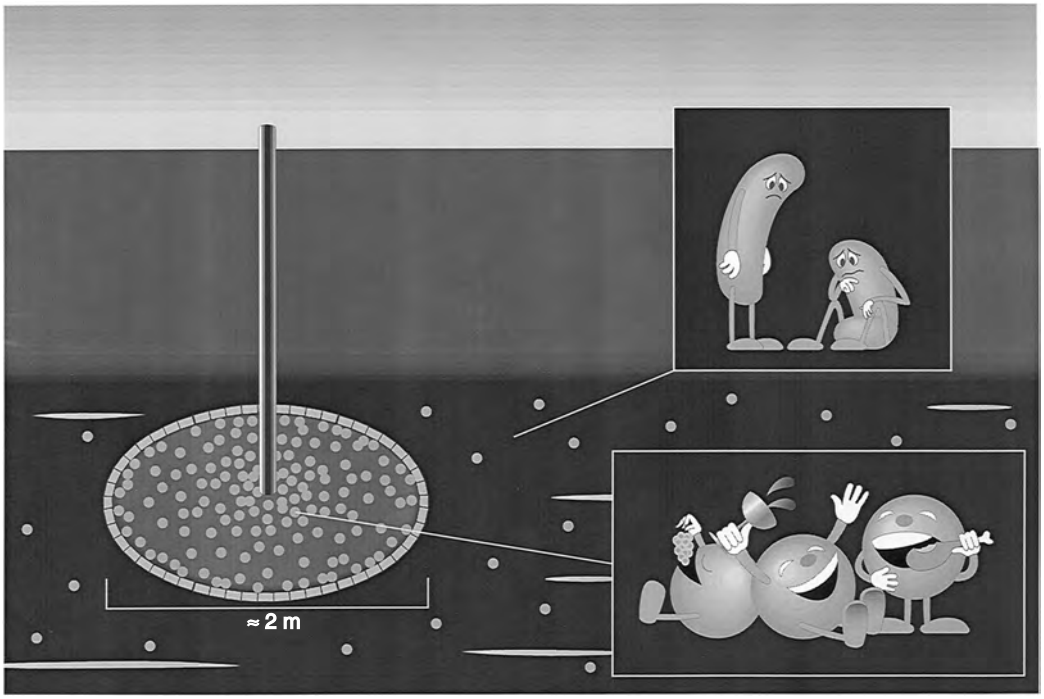

Figure 11. The effect of biostimulation on bacterial growth around the feeding port, resulting in the confinement of effective remediation to a narrow zone.

to make this workable is the low activity of bacteria in nature. Given that nutrient scarcity and other stresses are commonplace, bacterial growth in nature is very slow, and so is the expression of their activities, including those needed in bioremediation. One approach to address this problem is through biostimulation, wherein nutrients are added to polluted environments to stimulate the growth of indigenous bacteria. By this method, significant removal of the carcinogenic pollutant, trichloroethylene (TCE) has been achieved from contaminated field sites (41).

Biostimulation, however, has problems also. The growth of the indigenous flora around the feeding port can be so vigorous that the introduced nutrients are effective only in a narrow zone surrounding the port: a wall of biomass forms near the entry port that consumes the nutrients and physically prevents their further spread (Fig. 11). In a seminal study, significant remediation occurred in only a two-meter zone surrounding the feeding port (41). The problem of biomass formation is exacerbated by the fact that many reactions catalyzed by bacteria that are useful in bioremediation are cometabolic processes. This means that the bacterium catalyzing them does not benefit from these reactions, and thus spends minimal resources in bringing them about. As the bacteria would rather grow than remediate, by far the bulk of nutrients added to the environment is utilized in fueling biomass production (42). Thus, if a way could be found to dissociate expression of bioremediating reactions from the need for active growth, it would improve bioremediation.

This is where the starvation promoters may be useful (43). These are promoters that, as we have seen, are activated primarily in slow growing bacteria and thus afford a means of expressing a desired activity at a high level in such bacteria with minimal biomass formation. A starvation promoter-driven system for TCE bioremediation has been constructed in *E. coli* and *P. putida*. This was done by placing the *tmo* gene complex [which codes for toluene monooxygenase (TMO)] under the control of a starvation promoter. TMO, whose natural role is to enable bacteria to grow on toluene, can degrade

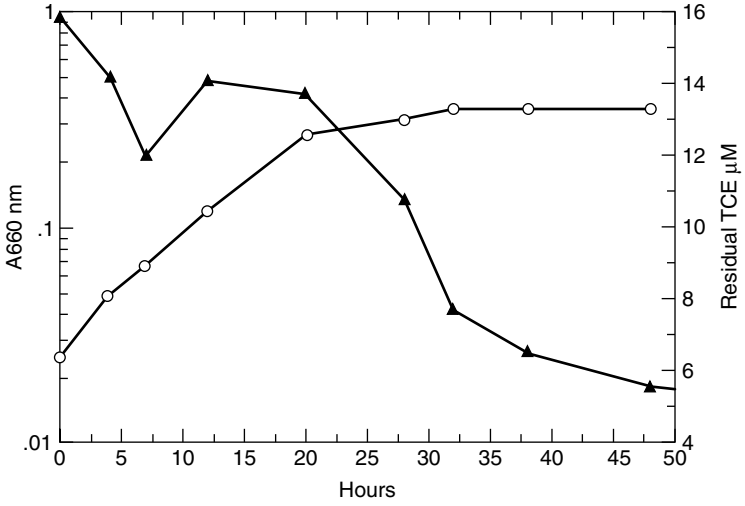

Figure 12. TCE utilization by engineered *E. coli* in different growth phases. [Reproduced with permission from A. Matin, C. D. Little, C. D. Fraley, and M. Keyhan, *Appl. Environ. Microbiol.* **61** 3,323–3,328 (1995).]

TCE cometabolically. Bacteria containing such genetic constructs degrade very little TCE during rapid growth, but show a high rate for this degradation when growth slows down (Fig. 12). Using this approach, it has been possible to reduce biomass formation per unit TCE removed by a hundredfold (44).

Metal and Radionuclide Bioremediation. Heavy metal and radionuclide contamination is among the more serious environmental problems. Chromate, for example, is carcinogenic and is a widespread contaminant of drinking water supplies; this and other heavy metals along with radiation-emitting radionuclides are among the most prevalent pollutants at DOE sites. The soluble form of these contaminants cannot be contained at the contaminated sites and threatens to seep into rivers and other sources of drinking water. An approach to address this problem is to convert, through microbial activity, the soluble salts of these pollutants into less soluble ones, to minimize the possibility of seepage. Cr(VI) and U(VI), for example, are very soluble but Cr(III) and U(III) are much less so.

Recent findings indicate that several enzymes that bacteria utilize for confronting the oxidative stress (see earlier text) can also reduce metals. As mentioned previously, nitroreductase can reduce Cr(VI) to Cr(III) and several other enzymes characterized as quinone reductases can also bring about this reaction. The genes coding for these different reductases bear a significant degree of homology. This makes it possible to use them as raw material in DNA shuffling technology for evolving superefficient reductases. DNA shuffling has proven to be highly effective in producing desired properties in a protein, and enzymes improved by several orders of magnitude have been engineered through this approach (45). Using the gene homologs mentioned previously of the reductases, it should be possible to engineer general-purpose reductases that are capable of reducing several metals with high efficiency and that are resistant to the inhibitory action of other contaminants present in a polluted site.

Manipulating Robustness. Through a study of the stress response, we have now an understanding of several gene products that protect bacteria and can, in principle, make them more robust. Altering the mix of molecular chaperones, the DNA repair enzymes, and those dealing with the management of ROS, and evolving proteins with a superior capacity to perform these tasks holds the possibility of generating bacteria that are better able to function in hostile environments. Conversely, by purposefully targeting the proteins critical for survival, it should be possible to eliminate bacteria when that is desirable. The two contexts in which having more resistant bacteria can help are discussed here. The first is bioremediation. Bacteria that can help address environmental problems can be made more effective if their ability to survive and function in the highly challenging environment of contaminated sites could be improved. In addition to the usual stresses of nutrient dearth and unpredictable deleterious changes, the contaminated sites often contain a mixture of toxic compounds. Maintaining robustness and activity in such environments is difficult and hampers the capacity of the resident bacteria to effect remediation. The second example in this context is the National Aeronautics and Space Administration (NASA) space program. NASA envisages colonization of space and generating self-sustained ecosystems in space stations and in human colonies on other planets. For these tasks, bacteria resistant to the hostile conditions of such locations would be needed.

Exploitation of the stress response can also help us meet the challenges of bacterial disease better. These are on the rise as bacteria have acquired resistance to many of the antimicrobial agents that had, over the past half a century, kept these diseases at bay. New therapeutic agents are therefore needed to again establish control over these diseases. Effective targets for such agents are the proteins that orchestrate the resistance response. Suitable candidates in this connection are the stress sigma factors, the sensing mechanisms and other critical molecules involved in conferring GSR.

STRESS RESPONSE IN BACTERIA: HEAT SHOCK

EVERLY CONWAY DE MACARIO
ALBERTO J. L. MACARIO
Wadsworth Center, New York State
Department of Health
The University at Albany (SUNY)
Albany, New York

This article deals with heat shock in a general way blending the old with the new, that is, traditional knowledge from the classics are discussed along with novel, more recent information mostly obtained by means of new methods. This trend will be apparent in the bibliography, which encompasses publications from the 1960s to the present.

Other articles elsewhere cover the same field but facets that are yet to be published are discussed here; or similar

themes already treated in the past are viewed from new standpoints. The expected result is an article accessible to all readers that will cover the main subjects of heat shock and stress response studies whether they are initiated in the field of heat shock or not.

Although an attempt is made to present a comprehensive picture of microbial stress, emphasis is placed on regulatory mechanisms and proteolysis because these are two of the areas in which considerable progress has been made in the last decade or so. In addition, the focus will be stress as it pertains to the prokaryotes bacteria because they are most relevant to environmental microbiology. The other prokaryotes that are also directly pertinent to environmental microbiology are the archaea, but they are treated in another entry of this Encyclopedia (STRESS RESPONSE IN ARCHAEA).

Each topic is explained with the aim of providing the general principles while unveiling the connections among themes in the same article, and with the aim of showing the connections between stress and its consequences (the stress response) with cell biology and environmental microbiology. Thus, critical reviews, overviews with novel viewpoints, short mini- and microreviews, and original articles will be quoted. The reader will thereby have the opportunity to consult various types of published literature depending on his or her interest or need, the general picture, the hypotheses, the hard evidence, the new data, the experimental details, the future prospects, or the possible ways toward the acquisition of more knowledge.

TERMINOLOGY

Heat shock is a classic term that indicates a sudden elevation of temperature affecting an object. The object may be inanimate (e.g., a piece of glass) or animate (e.g., a living cell). Here we are concerned with the latter.

Heat shock is a stressor that induces a heat-shock response (henceforth called stress response) in living cells, provided it is not of such strength that kills the cells immediately.

There are many stressors that induce a stress response in living cells and more complex organisms, Table 1 (1,2). A sudden temperature elevation, heat shock, is but one of the many stressors known.

The term heat shock is often used as synonym of stressor, and consequently heat- shock response is used as synonym of stress response (3). This usage of the terms heat shock and heat-shock response is due to several reasons. For example, the experiment usually cited as the seminal contribution to the literature on cell stress involved a "temperature shock" applied to the fly *Drosophila buschi* (4). This treatment induced a puffing pattern on the salivary gland chromosomes of the fly. The pattern was determined to be the reflection of gene activity unchained by the heat shock, and was accompanied by increased production of messenger RNA (mRNA). It was later demonstrated that the mRNA molecules encoded proteins that were named heat-shock proteins (Hsp). For this reason, to this day, stress genes and proteins are abbreviated *hsp* and Hsp, respectively, even when stressors other than heat shock are involved. However, this state of affairs is gradually changing and the more general terms stress genes and stress proteins are being used more and more often (5). The words heat-shock response, heat-shock gene, and heat-shock protein are reserved for cases in which the stressor heat shock is the protagonist. The abbreviations *hsp* and Hs, however, are still in widespread use to denote stress genes and proteins, regardless of the organism or stressor being considered.

RETROSPECTIVE AND DEFINITIONS

The study of cell stress in eukaryotes preceded its investigation in prokaryotes, as it may be inferred from reading the preceding section.

Table 1. Cell Stressors Relevant to Environmental Microbiology[a]

Type	Name Description
Physical	Heat; cold, several types of irradiation, including ultraviolet light
Oxygen	Oxygen-derived free radicals (ROS), hydrogen peroxide, anaerobiosis to aerobiosis shift, and hypoxia-anoxia.
pH	pH shift, alkalinity, and acidity.
Biological	Host reaction against an invading microbe.
Osmotic	Changes in the concentration of salt, sugars, other osmolytes (hyper- or hypoosmotic shock).
Nutritional	Starvation: multiple; specific (carbon, glucose, nitrogen, phosphate, and nitrate).
Antibiotics	Puromycin, tetracycline, and nalidixic acid.
Alcohols	Ethanol, methanol, butanol, propanol, and octanol.
Metals	Cadmium, copper, chromium, zinc, tin, aluminum, mercury, lead, and nickel.
Insecticides and pesticides	Lindane, diazinon, paraquat, thiram, and tributyltin.
Mechanical	Compression and shearing.
Other	Benzene and derivatives, phenol and derivatives, mutagens, arsenite, arsenate, amino acid analogs, and desiccation.

[a]Modified from A. J. L. Macario and E. Conway de Macario, in G. Fink ed., The Encyclopedia of Stress, vol. 2, Academic Press, San Diego, California, 2000, pp. 350–357 (3), with permission from the copyright owner. ROS, reactive oxygen species. These agents cause stress in cells from the three phylogenetic domains, Bacteria, Archaea (both prokaryotes), and Eucarya (eukaryotes).

Noteworthy landmarks in the progress of the science dealing with cell stress span many years of research. For instance, in 1962 it was reported that a "temperature shock" induced chromosomal puffing with increase in mRNA synthesis in the fruit fly, as described in the preceding text (4). Twelve years later, it was established that heat shock induced the production of a special group of proteins, the Hsp (6). By 1981, the heat-shock response of a bacterium, the archetypal experimental model for the gram-negatives, *Escherichia coli*, had been analyzed in some detail (7). This work pioneered the study of stress in the prokaryotes. Research with gram-positives such as *Bacillus subtilis*, the typical experimental model for this group of bacteria, showed that these organisms' heat-shock response shares some but no all the characteristics of the response of *E. coli*. *Bacillus subtilis* (8–15) and other gram-positives such as *Bradyrizobium japonicum* (11,16–18), *Agrobacterium tumefaciens* (19), *Caulobacter crescentus* (20), and *Streptomyces coelicolor* (21–24) show distinctive characteristics as compared with *E. coli*.

Another milestone was the development of the molecular chaperone concept to describe a special group of proteins that assist other proteins in the folding process (25,26). This process leads to the final, functional configuration of a protein, called the native configuration or state. Many Hsp are chaperones. This promoted the study of the stress response and stress proteins because they were found to participate in important cellular events, above and beyond the response to stress.

The understanding of the molecular chaperones progressed considerably with the identification of the chaperonins in bacteria (see later) and in archaea and eukaryotes and the complexes they form to assist in protein folding (27); see also this Encyclopedia, entry STRESS RESPONSE IN ARCHAEA. Also considerable progress has been achieved in the analysis, mostly *in vitro*, of the biochemical events that accompany the protein folding process (28–39).

One of the first molecules, if not the first, to be identified as playing a role in protein biogenesis was GroEL ("Gro," phage growth; "E," a phage-growth defect correctable by a mutation in the E phage-head gene; "L," large subunit). This nomenclature arose because it was found that GroEL is necessary for the assembly of the oligomer that joins the phage lambda head to its tail (40,41). This function of GroEL was discovered in the early 1970s. The name chaperonin was coined in the late 1980s to encompass GroEL and related proteins with a molecular mass of, or near to, 60 kDa. Thus chaperonins constitute a family of structurally similar and phylogenetically related proteins named the Hsp60 family (42–44). Members of this family discovered since the 1970s are involved in protein folding. In fact, it was the discovery of one its members' function that set the stage for the development of the molecular chaperone concept. Chloroplasts, organelles present in plant cells, contain a protein, the ribulose-biphosphate carboxylase-oxygenase (Rubisco) enzyme, which is a complex assembly of subunits. It was discovered in the 1990s that another protein was necessary for the assembling of Rubisco, but this assistant molecule did not become part of the final complex (25). In other words, the assistant molecule was performing a function somewhat akin to that of ladies that chaperoned young maidens in the old days so they would not go astray in their social relations. The molecular chaperones guide nascent ("young") polypeptides to avoid entanglement and reach a mature functional shape (29,30,45). The Rubisco-binding protein was later found to have an amino acid sequence about 50% identical to that of GroEL, which placed it within the chaperonin or Hsp60 family (46).

Similarly, the description of the molecular chaperone machine, and the elucidation of many of its biochemical reactions during protein folding and other cellular functions (28–39), helped the advancement of the study of the stress response and the elucidation of its intricate molecular mechanisms, including its own regulation.

The fields of heat shock, stress response, and chaperones were enriched by the discovery of the archaea, and the proposal that all living cells can be grouped into three main lines of evolutionary descent or phylogenetic domains: Bacteria (eubacteria), Archaea, and Eucarya (eukaryotes) (47). Bacteria and Archaea are prokaryotes; they do not have a nucleus that contains the main genome wrapped within a membrane — the nuclear membrane — as eukaryotes do.

Molecular chaperones and chaperonins were found to be present also in archaea, but their characteristics were thought to be somewhat puzzling in view of what was known for bacteria and eucarya. For example, the archaeal chaperonins resemble those of the eukaryotic cytosol despite the fact that archaea are prokaryotes (27,42,43). In contrast, the molecular chaperone-machine components Hsp70(DnaK), Hsp40(DnaJ), and GrpE in archaea are of bacterial type (27,48–50). Furthermore, several archaeal species do not have these chaperones, in sharp contrast to bacteria, which have these three molecules with no known exception (51). The same is true for eukaryotes; they all have in the cytosol the eucaryal homologs of the molecular chaperone-machine components (27). Also interesting is the fact that the chaperones and chaperonins present in the organelles (e.g., mitochondria) of the eukaryotic cells are of bacterial type, which constitutes a strong argument in favor of the bacterial origin of these organelles (43,46,49,50,52).

The findings discussed earlier in the three phylogenetic domains clearly show that in discussing the stress response, its molecular protagonists and their interactions and regulatory mechanisms, one must distinguish which species and cellular compartment are under consideration to be sufficiently precise so the data and ideas are properly understood. This basic tenet is of critical importance in the search for the role of stress and molecular chaperones in disease as pathogenetic or antidisease mechanisms (53,54).

BEYOND CELLS

A discussion of heat shock, and therefore stress, ought to be accompanied by clarifications on the true extent of the field. Stress has been studied since time immemorial, particularly in what concerns complex organisms, namely, humans. In modern times, in the 1950s there was a boom

in the recognition of stress as a cause of many bodily alterations via the neuro-endocrine system (55,56). Hans Selye studied the response of whole organisms, organs and tissues to stressors, mostly from the endocrinologic viewpoint. One of his definitions runs "stress is the nonspecific response of the body to any demand made upon it" (56). Although this portion of the larger field encompassed by stress will not be dealt with here, it is pertinent to say that in the last analysis microbial stress, cell stress, organismal stress, human stress, are all examples of stress due to environmental stressors, and they all share essential characteristics. All stressors cause in the end similar lesions. They alter the internal conditions of the cell (a microbial cell, or a cell from a uni- or a multicelled organism) in such a way that proteins are affected and tend to lose their native, functional configuration. It follows that molecular chaperones are key elements in normal and pathologic physiologies of any cell in as much as they promote protein folding, and refolding. Survival in the face of stress depends on the mechanisms that maintain the array of cellular proteins in functional shape. This is why the stress response involves mainly molecular chaperones and other stress molecules that protect the essential cell components from stressor-induced damage.

PROPERTIES

The impact of heat shock on a living organism, uni- or multicelled, is detectable at various levels: supracellular and intracellular, molecular, and supramolecular, and genetic (3,57). It follows that the methods for studying the stress response vary depending on the level targeted for analysis: the whole cell, a multicellular structure, a cell membrane, a molecule, or a gene or group of genes (3,27,58,59).

The typical property of the stress response is an increase in the Hsp (6,60–62). This is due to one or more mechanisms acting in parallel, such as the increase in the rate of: (*1*) *hsp*-gene transcription; (*2*) mRNA translation; (*3*) protein synthesis-maturation beyond translation and (*4*) increase in the life span of mRNA.

The increase in the Hsp levels is immediate and transient. For example, in bacteria, it starts very rapidly (seconds) after the stressor hits the cell, reaches the peak in a few minutes, and usually returns to near normal levels within 30 minutes. The mRNA is polycistronic (20,63–65). Whole clusters of Hsp genes that are arranged one after the other, in functional units called operons, are transcribed in series from one promoter upstream of the gene that lies at the beginning of the cluster, namely, at the 5′-end of the operon. A long mRNA is synthesized that is processed into shorter pieces representing individual genes, which are translated immediately.

Another typical property of the heat-shock response is that Hsp participate in their regulation as they are key players in regulating their own synthesis (21,66–68). This self-regulatory circuits will be discussed under Regulation, later.

The properties of the stress responses of archaea and eukaryotes are different from that of bacteria. Archaea and eukaryotes respond to heat shock with sustained increases of Hsp, the genes are induced (and probably also regulated) individually rather than in series or operons, which results in monocystronic mRNAs (69,70). The stress response of eukaryotes will not be treated here in any detail, and that of archaea is described elsewhere in this Encyclopedia, under the entry Stress Response in Archaea.

HEAT SHOCK AND OTHER STRESSORS

A stress response may be caused by any one of a wide array of agents in the environment in which an individual cell or organism lives. A list of stressors, including heat, salt, and alkali shocks, directly pertinent to environmental microbiology is displayed in Table 1 (58).

HEAT-SHOCK PROTEINS

The stress response is characterized by an increase in a variety of proteins. Some of them are molecular chaperones as explained in a preceding section, but many others are not; they are involved in different roles in a concerted effort to save the proteins and other cellular components from the damaging effects of stressors. These effects are usually caused by stressors via a pH change, or oxidation, or accumulation of a metal when the stressor is such.

A list of stress proteins is shown in Table 2, and a sample of Hsp in bacteria is displayed in Table 3 (3,58,71).

REGULATION

The stress response and the synthesis of Hsp are examples of self-regulatory systems via circuits of molecular interactions amenable to biochemical and genetic dissections. The whole event from the sudden action of the stressor, heat shock for instance, to the full fledged cellular response and its aftermath, includes several steps: sensing the stressor's impact and transducing the stress signal from the periphery to the DNA through membranes and cytosol, inducing the stress genes and the synthesis of stress proteins accompanied by downregulation of house keeping genes, sensing the abatement of the stressor's impact followed by a decline in the stress-induced molecular damages, and downregulation of the stress response with a return to normality or near normality at the end. The last two or three stages require not only a decrease in the Hsp production but also a return to normal levels of the proteins whose synthesis had been diminished as a consequence of the stress from the beginning of the stress response.

Stressors, whose damaging effects are protein and DNA injury, cause stress. Damaged proteins and DNA induce a series of repair mechanisms among which the molecular chaperoning system is paramount. The signal that a stressor generates at the cell's surface must be recognized — sensed — at this surface, after which sensing the signal must traverse the cell's outer structures and gain the cytosol and eventually reach the DNA to modify gene behavior. Signal transduction is then a major component of the stress response, or perhaps

Table 2. Stress Proteins[a]

Group	Examples
1	Molecular chaperones and chaperonins in organisms of the three phylogenetic domains: Bacteria, Archaea, and Eucarya. These proteins are classified into families according to their molecular mass, form the small to the large and very large heat-shock proteins (see Table 3).
2	Regulators of stress (heat-shock) genes: positive regulators or activators (e.g., heat-shock factor or HSF, in eukaryotes); sigma factors (e.g., sigma-32, sigma-E, sigma-B) in bacteria; negative regulators (e.g., HSF4 in eukaryotes; HrcA and HspR in bacteria); (See Table 4.)
3	Proteases: Clp family; Lon/La; HtrA; FtsH; in bacteria. Proteasome components and ubiquitin in archaea and eukaryotes.
4	Proteins in the intercellular connective material of multicellular structures formed as a response to stress (e.g., in the archaeon *Methanosarcina mazeii*).
5	Transport proteins (e.g., TrkA in the archaeon *M. mazeii*).
6	Enzymes and cofactors involved in the synthesis of other stress proteins listed above in 1–5), and other molecules such as thermoprotectants or "chemical" chaperones (e.g., trehalose in the yeast *Saccharomyces cerevisiae*; di-*myo*-inositol phosphate and cyclic diphosphoglycerate in some archaea).
7	All proteins, enzymes, cofactors, and gene-regulatory factors involved in sporulation (e.g., in the bacterium *B. subtilis*).

[a]Modified from A. J. L. Macario and E. Conway de Macario, in G. Fink ed., *The Encyclopedia of Stress*, Vol. 2, Academic Press, San Diego, California, 2000, pp. 350–357 (3), with permission from the copyright owner. Stress proteins are also called heat-shock proteins and are abbreviate Hsp (the genes are denoted *hsp*). See also reference (58).

Table 3. Classification of Stress Proteins (Hsp) and Examples of Bacterial Representatives[a]

Family Name(s)	Mass (kDa)	Bacterial Example
Heavy; high molecular weight; Hsp100	100 or higher	ClpE
Hsp90	81–99	HtpG
Hsp70(DnaK); Hsp70; DnaK; chaperones	65–80	DnaK; Hsc66
Hsp60; chaperonins	55–64	GroEL
Hsp40(DnaJ); Hsp40; DnaJ	35–54	DnaJ
Small Hsp; sHsp	34 or lower	GroES; Hsc20; GrpE; PPIase; other

Conway de Macario, *Frontiers Biosci*. 6, d262–d283 (2001). *http://www.bioscience.org/2001/v6/d/macario/fulltext.htm* (58), with permission from the copyright owner. Archaeal and eukaryotic counterparts can be found in references (27,53,54). See also the chapter STRESS RESPONSE IN ARCHAEA, this Encyclopedia.

more accurately of the initial phase of the response. Signal sensing and transduction precede the start of the antistress mechanisms per se. Immersed in these series of stages involving signal transduction and the initiation and action of the antistress mechanisms are regulatory circuits. These circuits monitor the levels of stress and of the stress response, and shut the latter down when the danger has passed.

REGULATORY CIRCUITS AND NETWORKS

Research on the regulation of the stress response has been going on for years. The focus has been more often than not on the response to heat shock and the regulation of the genes that encode Hsp, particularly the components of the molecular chaperone machine (*hsp70(dnaK)*, *hsp40(dnaJ)*, and *grpE*), and the chaperonins (the *groEL/S* system in bacteria).

Relatively little is known about stress signal recognition and transduction, but considerable progress has been made in the understanding of chaperone and chaperonin gene regulation especially in *E. coli* and *B. subtilis*.

In *E. coli*, one of the components of the RNA polymerase, a protein called heat-shock factor or sigma-32, probably recognizes a change in the secondary structure of mRNA caused by stress, and thereby proceeds to induce transcription of molecular chaperone and chaperonin genes by binding to the heat-shock promoter (67,68,79–81). Other sensing devices detect DNA supercoiling and melting, and protein unfolding (denaturation) (81).

At the other end, the molecular chaperone machine genes are downregulated by a process involving degradation of the heat-shock factors sigma-32 and sigma-E with participation of molecular chaperones (66,79,82,83). For example, in the absence of a distress signal due to the presence of denatured polypeptides, the machine is

partially idle: it only performs the basal chores of assisting in the folding of nascent polypeptides and promotes sigma-32 degradation via interaction with a protein called FtsH (a protease). However, when a stressor impacts on a cell, and stress occurs, many proteins become denatured to various degrees (those most severely damaged beyond repair by the chaperones are removed by proteases, as will be described later) and require immediate attention. The chaperones are called into action to restore the configuration of many proteins. As a result, sigma-32 is freed from the prodegradation action of the chaperones and thus becomes available to perform its function, which is to induce stress genes, the molecular chaperone genes included. Hsp increase and the stress response proceeds. When most denatured polypeptides have been restored to their normal configuration, chaperones are no longer needed and return to the task of sigma-32 degradation. This factor diminishes and the chaperone genes are down regulated.

In addition to this circuitry, others add to the increased production of Hsp during the stress response. Examples are an increase in the translation rate of the mRNA for sigma-32, which is produced by a gene named *rpoH* (19).

Also, in *E. coli* other stress genes are controlled by sigma-E (72,84,85). This factor belongs to a group that responds to extracytoplasmic stimuli, for example, denatured proteins in the periplasm.

A third group of genes in *E. coli* is controlled by sigma-54, which acts in conjunction with an activator (86).

In *B. subtilis*, a representative of the gram-positive bacteria, regulatory mechanisms differ from those described in the preceding text for *E. coli* — a representative of gram-negative bacteria. In *B. subtilis* there seems to be at least three different regulatory systems that sense the presence of a stressor such as heat shock, in different ways (8,9,11).

Class I stress genes, among which are those that code for the components of the chaperone machine and the chaperonins GroEL and GroES, depend for induction by stress on a factor called sigma-A, a *cis*-acting DNA site (element) named CIRCE (controlling inverted repeat chaperone expression) and a repressor (HrcA) that binds the CIRCE element. Class II stress genes are induced by another factor, sigma-B, whereas Class III stress genes are induced via other mechanisms that do not involve sigma-B or CIRCE-HrcA, Table 4.

In summary, stress gene regulation may be mediated by negative or positive mechanisms. Example of a positive regulation is the use of an alternative sigma factor, as is the case of sigma-32 in *E. coli*. Stress sets in motion a mechanism that activates genes that were "dormant" or functioning at very low rates (basal or constitutive levels of activity) prior to the impact of the stressor. Negative mechanisms involve repressors, which bind a DNA element (e.g., CIRCE) and keep the pertinent gene inactive. Stress causes the repressor (e.g., HrcA) to abandon the DNA site to which it is bound in the absence of stress and, thus, the pertinent gene can be transcribed by RNA polymerase. Posttranscriptional regulation also occurs (87).

Last and most important, negative and positive mechanisms coexist in many organisms and are used to regulate different groups of genes as required by the circumstances dictated by the presence of stressors in the environment. The result is that the cell has a network of interlaced mechanisms whose crisscrossing pathways are used as required. The network insures that a multitude of antistress mechanisms are ready to defend the cell against stressors on a very short notice and with the flexibility necessary to deal with a wide range of stressors.

Table 4. Examples of Stress-Gene Regulators in Bacteria[a]

Mechanism	Organism	Factor [DNA Element]	Regulated Gene(s) and Operons
Positive control	*Escherichia coli*	Sigma-32 (RpoH)	*dnaK*, *dnaJ*, *grpE*, *groEL/S*, other
		Sigma-E (sigma-24; RpoE)	*htrA*, *rpoH*, *rpoH* operon, other
		Sigma-54 (sigma-N; RpoN) + PspF	*PspABCDE*
	Bacillus subtilis	Sigma-B (SigB)	*gspA*, *csbA*, *katE*, other (Class II stress genes)
Negative control	*Bacillus subtilis*	HrcA [CIRCE]	*groEL/S*, *dnaK* operon (Class I stress genes)
		CtsR	*clpC*, *clpP*, other (Class III stress genes)
		Not yet identified	*htpG*, *fthsH*, *lon*, other (Class IV stress genes)
	Bradyrhizobium japonicum	[ROSE]	*hspA*, *rpoH1*, other
	Clostridium acetobutylicum	CtsR (?)	*hsp18*
	Leuconostoc oenos	CtsR (?)	*hsp18*
	Streptomyces albus	HspR [HAIR]	*dnaK* operon, *clpB*
		OrfY (RheA)	*hsp18*
	Streptomyces coelicolor	HspR	Not yet identified

PROTEOLYSIS

Stress causes protein denaturation, that is, unfolding. This may be extensive and irreversible for some or most molecules in a cell. In the latter case, cell death is likely to occur because of formation of precipitates by the damaged protein molecules (53,54). If polypeptide denaturation is not extensive enough to cause precipitate formation and cell death, the antistress mechanisms will promote protein refolding and restoration (38,39,88,89). In this process molecular chaperones are key instruments. In addition, the cell possesses the means to eliminate polypeptides beyond repair, and thus avoid precipitate formation when protein denaturation is not massive. Proteases are proteolytic molecules, that is, enzymes that digest polypeptides, which actively participate in the elimination of severely damaged polypeptides and incipient precipitates (75,90–96). Proteases associate with themselves and other auxiliary molecules including molecular chaperones to build proteolytic machines (95,97–101).

A sample of proteases is presented in Table 2 (group 3), and more information is available in the cited publications.

The interplay between chaperones and proteases is another example of a cellular mechanism in which molecules with seemingly opposing functions help each other in maintaining normal cell physiology and cell survival in the face of stress.

The interplay of chaperones and proteases in protein folding, refolding, and degradation has been studied in a few microbes, but most progress has been made using *E. coli* as the experimental model. The advantages of this organism as compared to many other gram-negative and gram-positive bacteria, is that it can be readily manipulated genetically. Genes can be introduced with ease into *E. coli* by means of vectors, after which it is possible to determine whether the transformed bacterium acquired properties derived from the functioning of the introduced gene. For example, a stress gene can be introduced and then its response to stressors can be assessed in the transformed host by measuring the levels of the gene's mRNA, or by evaluating the protein-folding capacity of the host. Furthermore, there are many, well-characterized *E. coli* mutants lacking one gene or another. These mutants can be examined in terms of stress responses and survival properties in the face of different types of stress. By correlating these properties with the presence and absence of a gene, one may be able to infer the gene's function and overall role.

CHAPERONES AND PROTEASES IN REGULATION

In *E. coli*, the chaperones trigger factor (TF), Hsp70 (DnaK), and Hsp40(DnaJ) participate in the folding of nascent polypeptides of nearly 350 different proteins ranging in size from 16 to 167 kDa (59). Long multidomain polypeptides are the most prone to misfolding and entanglement as they emerge from the ribosome, and therefore are those most helped by chaperones (45). In the absence of the chaperoning systems, these complex proteins would not reach their functional configuration. The GroEL/S chaperonins assist newly made polypeptides so these can fold correctly. Five to 15% of the *E. coli* proteins with sizes in the range 20 to 60 kDa are assisted by chaperonins (59). All these chaperoning functions are a quality control system, so to speak, for the cell. In addition, as described in a previous section, proteases also participate in maintaining a "clean" intracellular environment by removing damaged proteins and precipitates. Thus, the chaperoning and proteolytic systems cooperate with one another to maintain the cellular proteins within a functional range of shapes and concentrations in a cellular milieu devoid of debris and precipitates. Both systems also interact as they participate in the regulation of their own components and in the regulation of the stress response. This interaction may follow at least two pathways. In one, chaperones would present damaged polypeptides to proteases in a manner that favors the recognition of the polypeptide by the proteases and promotes the proteolytic activities of the latter. In this pathway chaperones and proteases cooperate with one another.

In the other pathway, competition rather than cooperation between chaperones and proteases is the central process. The pool of polypeptides would be composed of a series of populations exhibiting different degrees of denaturation from the native state to the irreversible, precipitation-prone extreme. This pool would be in a constant flow or kinetic partition between the chaperoning and the proteolytic systems. The more damaged a peptide, the more it will be taken up by the proteases, whereas the less damaged molecules will be refolded and recovered by the chaperones.

It is likely that the cooperative and competitive pathways coexist in the same cell, and that they are used as the cellular and environmental conditions dictate.

NEW LOOKS OF AN OLD THEME

Several novel ideas concerning the stress response, its regulation, and the role of stress and stress genes in life have been put forward recently. These ideas are either reinterpretations of earlier data, revisions of preexistent hypotheses and proposals, or fresh outlooks based on novel information provided by newly developed technologies such as genome sequencing and molecular phylogenetic analyses using complex software unavailable before.

The role of stress in evolution is being investigated (102,103) but the data are still incomplete and conclusions are not warranted. However, it is tempting to speculate that stress genes did play a role in positive selection during evolution, and that they play a similar role today in the face of stress. One can envisage that thousands of millions of year ago, when life was still in its earliest stages, the environment must have been loaded with stressors such as extreme acidity or alkalinity, and high temperatures (104). The survivors must have been equipped with powerful antistress mechanisms: cellular envelopes, stress genes and proteins, and the ability to form ultraresistant structures such as spores and multicellular aggregates surrounded by a protective shield. It will be difficult to say whether these ideas are correct because it is not possible to accurately repeat what

happened long ago. Nevertheless, experimentation and comparative analyses of genes and proteins and other molecules and supramolecular structures, as well as of cells and supracellular structures, should shed light on the role of stress and antistress mechanisms in survival both in the past and today.

Along the same lines of reasoning, the participation of stress genes and proteins in development has been investigated. Associations between stress-gene induction and synthesis of Hsp and embryonic development have been reported (105–108). Also, the same associations have been observed in relation to the development of specialized organismal structures (23), which means that stress genes and proteins may participate in the process of cellular differentiation. This idea should not be too surprising because a good portion of the stress proteins, particularly chaperones and chaperonins, play a role in protein biogenesis, as described in several sections in the preceding text. Protein biogenesis must be an integral part of the processes of differentiation and development, which in many organisms includes histogenesis, namely, the formation of multicellular structures (tissues and organs). In this regard, it is noteworthy that recent data suggest that not all cells in a cloned population respond to stressors in the same fashion (109). The stress response of individual cells submitted to the same stressor varies even if all the cells belong to a single clone. There is cell heterogeneity in terms of stress response among cloned cells.

THERMOTOLERANCE AND THE FUTURE

One of the consequences of the stress response is thermotolerance. This term describes the situation sometimes observed after stress caused by heat shock and characterized by increased resistance to a temperature elevation. For example, an organism with a temperature optimum for growth of 37 °C that is capable of mounting a stress response when exposed to 45 °C but dies at 55 °C, will survive the latter temperature if it was previously heat-shocked at 45 °C. This phenomenon has been explained in detail elsewhere (110). It is a very interesting biological mechanism: it offers the opportunity for developing means to enhance resistance to stressors in cells of practical value. Areas of potential applications are environmental microbiology, sanitary engineering, medicine, and surgery, and so on as described previously (111). Remarkably, stress caused by a given stressor, for example, heat shock, will make the cell more resistant to heat shock and also to other stressors. This cross-tolerance will, for instance, allow the use of a relatively harmless compound that causes a mild stress response to generate tolerance to another, harmful, agent. Here again, the established terminology is not adequate. The term thermotolerance ought to be replaced by stress tolerance in as much as heat shock and other stressors can induce resistance to the same stressor but also to others.

Still another potential application of stress genes and the stress response in environmental microbiology will be in the field of monitoring and detection. Certain microbes could be engineered to carry stress genes, or their promoters with reporter genes, which will be induced when in contact with toxic compounds (111). These manufactured organisms can be placed where monitoring and detection of contamination is necessary, in soil for instance, and then collected and examined for the presence of signs of a stress response such as an increased transcription of the stress or reporter genes. In this regard, the future prospects are very promising. Other promising fields of applications pertain to plants (112,113), plant pathogens (19,114,115), and symbionts (11,16–18).

SUBAERIAL COMMUNITIES

JAMES A. NIENOW
Biology Department
Valdosta State University
Valdosta, Georgia

The subaerial microorganisms are perhaps the most obvious, but most overlooked, group of microorganisms known. By definition they are found on surfaces above the soil and water lines, exposed directly to air (1–3). Rich growths, in the form of green, red, brown, or black streaks and coatings on rocks, trees, masonry, the roofs of many homes, wooden structures of all types (especially fences, telephone poles, and window sills), metal signs, and older automobiles, are readily apparent to microbiologists and nonmicrobiologists alike. Yet, there is remarkably little known of the ecology of these organisms. In this article, I will attempt to summarize what is known and to indicate areas for future research, with special emphasis given to the photosynthetic segment of the community.

DIVERSITY OF SUBAERIAL COMMUNITIES

Habitats

Subaerial communities are usually defined by the nature of the substratum (3). Epilithic communities are those found on the upper surface of stones. These can be either naturally occurring or the result of human activity (monuments and buildings). Epiphytic communities are those found growing on plants and plant parts. These are sometimes divided into the corticolous community found on bark, the lignicolous community found on exposed wood or wooden objects, and the phyllosphere community associated with living leaves, although, strictly speaking, it is only the segment of the phyllosphere community inhabiting the phylloplane, or leaf surface that is subaerial. Other specialized habitats can also be identified, for example, the surfaces of frescos or oil paintings (see review by Cifferi (4) and the references therein), or leather objects (5), but the communities found there are not usually given special names.

Organisms

Techniques of Analysis. Ideally, the identification of subaerial organisms should be made by direct observations of the community. This would allow relative numbers of individuals and spatial relationships to be assessed. However, the identification of heterotrophic bacteria through microscopic examination is next to impossible without some prior knowledge of the microflora. The situation is somewhat better for the structurally more complex cyanobacteria and eukaryotic algae, especially diatoms and desmids. However, many of the genera found in subaerial habitats are either morphologically simple, so that the descriptions of even unrelated genera tend to overlap, or morphologically pleomorphic, so that their appearance changes with changes in environmental conditions. In order to make a positive identification, it is necessary to study the organisms in culture so that their complete life-history and their complete range of metabolic processes can be determined (6–8). Perhaps the development of genetic markers and probes for each of the important taxa, which could be used on field samples, will solve the problem (9–11). The standard methods used to study both heterotrophic and autotrophic microorganisms begin with enrichment cultures. Techniques for obtaining enrichment cultures from subaerial environments have been reviewed by Hirsch and coworkers (12) and Jacques

and Morris (13). The use of enrichment cultures brings with it another set of concerns. First, the types of organisms recovered depend to some degree on type of medium used and on the culture conditions. For example, Hirsch and coworkers (14) report that the use of malt extract medium resulted in higher fungal counts than Sabourad dextrose agar and that the use of oligotrophic media such as PYGV resulted in 10-fold higher bacterial colony counts and greater diversity than copiotrophic media. In addition, incubation of enrichment cultures in dim light usually results in a larger number of morphotypes among the heterotrophic population, possibly in response to organic compounds released by photosynthetic cyanobacteria and algae. Second, the organisms selected for in the enrichment are not necessarily the dominant forms in the habitat. Cox and Hightower (15) acknowledged this problem explicitly when they noted that it was possible (but unlikely) that none of the algae identified in their study formed part of the normal bark flora of Tennessee.

Rölleke and coworkers (16) tried to overcome some the drawbacks of the traditional methods of community analysis by applying denaturing gradient gel electrophoresis to PCR-amplified gene fragments coding for 16S rRNA from a medieval wall painting. They were able to demonstrate the presence of five bacterial species not previously isolated from wall paintings. At the same time, acinetobacters, which could be easily isolated, did not form a strong band in the DGGE pattern, suggesting that their role in the community is not as great as might be inferred from enrichment cultures. There remains the problem, recognized by the authors, that the DNA amplified might not originate from active members of the community (4,16).

The identification of subaerial cyanobacteria is complicated by the existence of competing taxonomic systems (17). Traditionally, cyanobacteria were studied by botanists and the taxonomy of cyanobacteria, following the general approach of classical botany, was based primarily on the morphological characteristics of field specimens (18,19). This approach, with some modifications to allow the use of data from cultures and molecular investigations (20–24), is still widely used by field biologists. During the 1970s and 1980s, Stanier, Rippka, and their colleagues, emphasizing that cyanobacteria are first and foremost bacteria, began a revision of the group on the basis of bacteriological principles, with an emphasis on the use of cultures and biochemical and molecular data. Although still in its early stages, this is the system used in the second edition of *Bergey's Manual of Systematic Bacteriology* (25).

Cyanobacteria and Eukaryotic Algae. Floristic and ecological studies have implicated members of well over 200 genera of algae and cyanobacteria as participating in subaerial communities (26). Many of these are also common constituents of the soil microflora (27–29); to date no concerted effort has been made to separate the two groups. Within the subaerial algae, the most successful are those that form symbiotic relationships with fungi in lichen associations; these are discussed in more detail elsewhere. Second in importance are sheathed cyanobacteria, most notably members of the genera *Chroococcus*, *Chroococcidiopsis*, *Gloeocapsa*, *Phormidium*, *Schizothrix*, *Scytonema*, *Stigonema*, and *Tolypothrix*. As a group the sheathed cyanobacteria reach their maximum development in the tropics, where they dominate on most surfaces (1,2,30–35). However, they can be found just about anywhere in the world where suitable surfaces are exposed to sufficient light and periods of flowing water of sufficient duration (36–48); many of the same species grow epilithically both in the tropics and in temperate regions (35). If the flow of surface water is not frequent enough, and the surface porous enough, they may retreat into the rock surface, living as endoliths (49–52). Third in importance is the so-called *Pleurococcetum*. This community is dominated by spherical green algae of the *protococcoid* genera: *Apatococcus*, *Desmococcus*, *Pleurastrum*, and so on. In the past, these organisms were commonly referred to the genus *Protococcus* Agardh, a name that, although still used colloquially, has been discarded for nomenclatural reasons (53,54). The members of this group are particularly difficult to identify, and the serious student should consult the recent monographs by Ettl and Gärtner (28) and Andreeva (29). The name of the association is derived from *Pleurococcus* Meneghini, a name that some consider synonymous with *Protococcus*; Gärtner and Ingolic suggest changing the name of the association to the more meaningful and taxonomically correct *Apatococcetum* (55). The association tends to be restricted to the drier rock surfaces and to tree bark and bare wood (36,37,43,56–58). The frequency of this community decreases in tropical regions, possibly because the increased rainfall and higher temperatures favor the expansion of cyanobacterial communities (1,2). Also common, but rarely dominating, in subaerial communities are members of the unicellular genera *Chlorella*, *Chlorococcum*, and *Stichococcus*, and the filamentous genus *Klebsormidium*.

Trentepohlia, a chlorophyte with branched filaments, is often found on tree bark or in association with epilithic cyanobacteria in temperate regions (36,37). Typically, it forms characteristic wispy orange growths that are easily identified without magnification. The frequency and size of these tufts increase in tropical regions, where *Trentepohlia* may rival the growth of the cyanobacteria (56). Its relatives *Cephaleuros*, *Phycopeltis*, *Printzia*, and *Stomatochroon* are also common in tropical regions. *Phycopeltis* and *Printzia* are free-living epiphytes and epiphylls (59); *Cephaleuros* and *Stomatochroon* are endophytes, with *Cephaleuros* growing below the cuticle of the twigs, leaves, or fruits of the host plant, and *Stomatochroon* inhabiting the stomata of the host (59). Epiphyllous cyanobacteria, most notably species of the heterocystous genera *Scytonema*, *Stigonema*, and *Hapalosiphon*, are also common in the tropics (60–62).

Subaerial diatoms, although a common and diverse group, are usually minor constituents of the community, either interspersed among other algae or growing epiphytically on bryophytes and lichens (63–67). Rich growths dominated by diatoms can occur, but they are usually restricted to the wettest surfaces (36,68,69). The implication is that diatoms, as a group, are not as well adapted to the subaerial environment, perhaps because of their need for dissolved silica (3), but this has not

been investigated in any detail. Common genera include the motile forms *Achnanthes*, *Hantzschia*, *Navicula*, and *Pinnularia*.

The division of a particular subaerial flora into smaller associations has also been attempted. For example, Golubic (37) in his classic study of the epilithic community in portions of the former Yugoslavia, was able to discern nine associations of epilithic algae and to arrange them into two parallel series on the basis of the moisture and light regimes. Similarly, Foerster (32), working the forests of Puerto Rico, was able to determine a number of associations of corticolous algae and to correlate them with perceived changes in the microhabitat. However, this practice raises a number of issues. First, there is the question of the effects of environmental conditions on the morphology of microalgae, in general, and of cyanobacteria, in particular. Second, there is the more general ecological question of what constitutes a meaningful microbial community. Because the fidelity of most species to any particular subaerial association is low, the defined associations typically reflect the presence or absence of one or two dominant forms. It is more likely, then, that we are tracing the boundaries of individual species, not associations; this is a useful exercise in itself, but should be recognized for what it is.

Nonphotosynthetic Bacteria and Fungi. Subaerial epiliths have primarily been studied in the context of the biodeterioration of stone, masonry, and paintings. One of the most obvious features of the group is its variability in space and time, (4,12,14,70–73). However, a few comments concerning the general composition can be made. Representatives of the genus *Thiobacillus* are commonly associated with regions of gypsum formation on limestone and stucco (71,72); other sulfate-cycling bacteria may also be found (4). Nitrifying bacteria from the genera *Nitrosovibrio*, *Nitrosomonas*, and *Nitrosospira*, as well as species of *Nitrosobacter* have been recovered from building stones with high concentrations of ammonia in their surface layers (74). Species of *Arthrobacter*, *Bacillus*, *Geodermatophilus*, *Micrococcus*, *Pseudomonas*, and *Sarcina* are also common (16,73,75). The predominant species on frescoes from underground tombs and grottoes are members of the Actinomycetales, especially *Streptomyces* and, to a lesser extent, *Nocardia*, (4,16,48). Common genera of epilithic fungi include *Alternaria*, *Aspergillus*, *Aureobasidium*, *Candida*, *Cladosporium*, *Fusarium*, *Mucor*, *Paecilomyces*, *Penicillium*, *Phoma*, *Rhizopus*, *Sporobolomyces*, and *Urocladium* (14, 71). Black yeasts (14,76) and members of the genus *Urocladium* (71) have been implicated in the blackening of ancient marble and limestone buildings.

Phyllosphere bacteria and fungi are often involved in processes detrimental to the host plant, and so are studied from a plant-pathology perspective. A complete review of this topic is beyond the scope of this article; I will try to restrict my comments to items related to the general ecology of microorganisms living in a subaerial environment. Those wishing for a more detailed coverage are referred to recent reviews by Kinkel (77) and Hirano and Upper (78). Plant-pathogenic members of the genera *Pseudomonas*, *Xanthomonas*, and *Erwinia* are among the most commonly investigated heterotrophic bacteria in the phyllosphere (78). However, a number of free-living bacteria can also be found including: nitrogen-fixing bacteria of the genera *Beijerinckia* and *Azotobacter*, (60,78,79,80), pink-pigmented facultative methylotrophs of the genus *Methylobacterium* (78), and common heterotrophs such as *Bacillus*, *Micrococcus*, and *Serratia* (78). Sundin and Jacobs (81) cite evidence that a majority of bacterial isolates from the phyllosphere are pigmented.

THE SUBAERIAL HABITAT

The subaerial habitat is considered by some to be one of the most extreme habitats colonized by microorganisms (78). As will be seen, moisture, light, and temperature conditions not only reach extreme values, they can fluctuate from benign to harsh within minutes or hours, putting an additional stress on the organisms as it tries to adapt.

Determining the exact conditions in the habitat is difficult. First, there is the matter of scale. As pointed out by Andrews (82) and Hirano and Upper (78), even the surface of a leaf presents a topography punctuated by peaks, valleys, and craters. Therefore, we should expect physical conditions to vary significantly from those measured by standard microclimate monitoring stations. Changes can also occur within the habitat over distances of one or two millimeters. These facts have prompted Friedmann and his colleagues to use the term *nanoclimate* when referring to the physical conditions within the lithic environment (83,84). Measuring the environmental parameters at the appropriate scale is difficult and may require the construction of special sensors (83,85). Extra care must also be taken to ensure that the act of measurement does not change what is to be measured. Computer models can be used to alleviate this problem by allowing us both to verify field measurements and to extend them without damaging the system (86,87). Second, conditions change not only over periods of minutes and hours, but over months and years, so that long-term measurements are necessary to gain a full understanding of the habitat. Although automated recording devices now allow us to construct continuous nanoclimate records over periods of years, even in remote areas (82,83), their use is still limited.

Moisture Conditions

It is commonly assumed that "Microbes, regardless of their habitat, are aquatic creatures" (88); see also the review by Brown (89). Therefore, the availability of moisture is considered to be the primary environmental factor determining the development of subaerial communities. The importance of the moisture regime in the subaerial environment can be seen in the development of tintenstrich communities, dark-colored subaerial communities that trace the boundaries of rain tracks on rocks, trees, and buildings (47).

Moisture can reach the habitat in at least three ways: from the air as dew fall, rain, snow, or spray; as surface runoff or subsurface seepage from meltwater or rainfall; or as water vapor absorbed directly from the air. Clearly,

it is not sufficient for a surface to be occasionally wetted or all surfaces would be covered by dense growths of microorganisms. The frequency and the duration of the wetting events are also important. This led Danin and Garty (90) to propose the cumulative imbibition time as the most important environmental parameter in lithic environments. The cumulative imbibition time refers to the total period of time when the organisms are turgid from the assimilation or imbibition of water; Büdel and Lange (91) suggest that a turgid state is a prerequisite for metabolic activity. A similar concept, the leaf wetness duration, is used in phytopathology, in which it is a key determinant of fungal infectivity (92). The frequency of wetting events depends primarily on the local climate: how often does it rain, during which seasons does it rain, and so on. It can also depend on the nature of the substratum; Danin and Garty found that small stones in the Negev Highlands cooled more quickly at night and were thus subjected to increased dewfall (90). The duration of the wetting event is much more complex, involving interactions between the local climate and the substratum. The water reaching the community can continue to flow past, can soak into the substratum, or can evaporate. The flow rate depends on the slope and texture of the surface; smooth, vertical surfaces will not retain water for long periods, whereas rough, horizontal surfaces allow some degree of puddling. The amount of water absorbed by the surface depends on its porosity and water holding capacity; its main effects are related to the rate of evaporation. The rate of evaporation depends on the relative humidity and temperature of the surrounding air, the strength and direction of the prevailing winds, the degree to which the substratum is warmed by sunlight, and the amount of water retained in the substratum (57,82,93,94). As an additional complication, porous materials such as wood or sandstone may retain significant amounts of moisture for long periods of time, but the water may be available to surface dwelling organisms only as water vapor. A more or less steady supply of water vapor at high concentrations may also be available to bark and leaf organisms as transpiration through lenticels and stomata; Burkhardt and coworkers (85) found evidence that at least some transpired water vapor could be recondensed on the leaf surface.

Unfortunately, data regarding the duration of periods of water availability in subaerial environments are almost completely lacking. Turner (95) suggested that water, at least in the form of water vapor is never limiting in the subaerial community on larch trees; his measurements indicated that the relative humidity within a few millimeters of the surface of the bark remained above 60%. Bell (51) reached a similar conclusion for moisture in the endolithic habitat of the semiarid Colorado Plateau. However, as will be seen, it is not clear that water vapor alone is sufficient for the maintenance of metabolic activity in subaerial communities. Liquid water from rain events may be available to tropical epiliths as little as a few days per year in the dry savannah to nearly every day in the rainforest zone (35). In the Negev Highlands, Danin and Garty estimated that rainfall contributes from 25 to 130 hours per year to the cumulative imbibition time, dewfall an additional 250 to 600 hours for those stones on which dewfall was common (90). Friedmann and his colleagues arrived at similar values, 500 to 1,000 hours of activity per year, for the endolithic community of the dry valleys region of Antarctica; here the availability of moisture was estimated on the basis of changes in the conductivity of the substratum (83,84).

Two additional features of the moisture regime should be mentioned. Hirano and coworkers (96) found that raindrop momentum apparently triggers the growth *Pseudomonas syringae* in the phyllosphere. The mechanism is unclear. Strains of *Ps. syringae* and a handful of other phyllosphere-inhabiting species, are also well known as an ice-nucleating agents (78). Although the gene associated with ice-nucleating activity is well characterized, the role that ice-nucleation plays in the biology of bacteria expressing the gene is not.

Temperature Conditions

The temperature in subaerial habitats can be significantly (20 °C or more) higher than the ambient air temperature. In temperate regions, temperatures can reach 45 °C in bark communities (97), 73 °C in epilithic communities (36), and in excess of 85 °C on rooftops (98). In the tropics (47,99,100) or hot deserts (101), temperatures can reach 60 °C on a daily basis. Furthermore, the amplitude of the diurnal variation in these habitats is in excess of 30°. These conditions are all more extreme than would be encountered in an aquatic habitat from the same region. If the organisms were active at these temperatures, some degree of thermophily might be expected. However, they are typically desiccated before the more extreme temperatures are reached. The exact temperature regime of any particular community depends on the amount of solar radiation striking the surface, which is a function of the latitude of the site, the orientation of the surface, and the degree of shading by the surroundings, and the nature of the community and the substratum (86). Because light materials reflect more sunlight, they do not warm to the same degree as dark materials. This may explain the grayish appearance of some epilithic lichens in hot deserts. At the other extreme, it has been suggested that white sandstones in Antarctica never warm up sufficiently to sustain life (86). Polar communities must also survive freeze-thaw cycles with periods of 24 hours or less (102,103).

Wind Conditions

Wind can have both negative and positive effects on subaerial communities. First, as mentioned previously, it increases the rate of evaporation, thereby reducing availability of moisture in the community and the cumulative imbibition time. It also has the potential to remove parts of the community by erosion. At the same time, the wind probably contributes the most to colonization of fresh surfaces by supplying new recruits; this may explain some the diversity found on Sri Lanka (1,2) and Puerto Rico (32). It can also reduce the more extreme temperature conditions by increasing the rate of heat exchange with the surrounding air. The relative importance of each of these effects should be determined at each site. It is commonly noted, however,

that subaerial organisms grow primarily on the leeward side of trees and stones (3,42,43,57).

Light Conditions

Subaerial communities in exposed habitats can be subjected to photosynthetic photon fluxes greater than 2,000 μmoles photons $m^{-2} s^{-1}$. This level of solar radiation will not only contribute to the development of extreme temperatures, it can damage the members of the community directly. Photosynthesis by freshwater algae is typically saturated with respect to light at irradiances below 1,000 μmoles photons $m^{-2} s^{-1}$ (104,105). There is a growing body of evidence that the light responses of terrestrial algae are similar. Subaerial strains of *Gloeocapsa* and *Stichococcus* exhibited light saturation in the laboratory at photosynthetic photon fluxes below 250 μmoles photons $m^{-2} s^{-1}$ (106); it should be noted, however, that these strains are maintained at relatively low fluxes. Ong and coworkers (107) were able to demonstrate photoinhibition in an edaphic population of *Trentepohlia*. Lüttge and coworkers (108) reported at least some degree of decreased photosynthesis in light-stressed field samples from terrestrial environments. Weber and coworkers (109) demonstrated that endolithic strains of *Chroococcidiopsis* develop below the surface of artificial substrata in response to high surface illumination. Even if light saturation and photodamage do not occur while the alga is active, the organisms are often exposed to the same level of irradiation while dry; under these conditions the energy absorbed by their pigments cannot be dissipated and damage to DNA from the absorption of ultraviolet light cannot be repaired (98,110–112).

The Cave Habitat

The walls and ceilings of caves provide a unique habitat for subaerial microorganisms, with conditions that differ considerably from those just described. The relatively constant temperature and typically high humidity create some of the most favorable conditions associated with subaerial habitats. In addition, seep-water from the ground above the cave provides a more stable source of liquid water than is found in exposed habitats. The result can be a rich growth of algae, often dominated by members of the cyanobacterial genera *Geitleria*, *Leptolyngbya*, and *Scytonema* at the entrance of the cave (113,114). The growth of subaerial algae has been reported on frescoes in underground catacombs (4,45,48,115). Because the amount of light available for photosynthesis drops off rapidly, the growth of algae is restricted to within a few meters of the mouth of the cave (116,117). However, because conditions are otherwise so favorable, the provision of even low levels of illumination for tourism can lead to the growth of photosynthetic communities at these so-called light oases (4,115,116,118).

ADAPTATIONS TO THE SUBAERIAL ENVIRONMENT

The Moisture Regime

By definition, all subaerial microorganisms experience intervals when they are not surrounded by liquid water. As the water content of a cell drops during these intervals, metabolism and growth stop. Under ideal conditions, the organism would then enter a state of cryptobiosis lasting until the moisture regime improves and metabolic processes take up where they left off. However, the situation is not so simple. Changes in the concentration of solutes during the drying process can lead to imbalances in the cell's metabolic processes. The shortage of the water molecules required for the maintenance of macromolecules and subcellular structures such as cell membranes can cause irreversible damage and the death of the cell (98,112). The ability to survive even brief periods of desiccation, then, is one of the fundamental attributes of subaerial microorganisms. Once desiccated, the individual cell is still subject to chemical and physical damage, which cannot be repaired until metabolism restarts. If the damage incurred while in the desiccated state is too great, the cell is unable to make repairs fast enough, and dies. At the same time, the association as a whole is subject to losses by erosion and predation that cannot be replaced until cellular reproduction restarts. Any features that would either prolong the periods of activity or help the cell to survive the periods of desiccation, then, would be adaptive. The actual mechanisms used are varied and only now are beginning to be understood (89,98,112,119); the major mechanisms are summarized below. Note that many of these adaptations serve multiple purposes. For example, as will be seen, the presence of a sheath can serve to retard water loss, maintain cell membrane integrity, and protect against photodamage.

Adaptations to Prolong the Period of Activity. Higher plants and terrestrial animals thrive in the subaerial environment because they form complex multicellular structures with an essentially water-tight surface. The interior cells remain in an aqueous environment and the period of activity is extended indefinitely. This option is not open to unicellular forms. However, it is possible for microorganisms to use extracellular structures to accomplish the same end, albeit not as efficiently. Examples include the development of mucilaginous sheaths (98,120–125), growth on or within particulate substrata (49,93,122,126), or the inclusion in a complex, pseudomulticellular structure such as an algal mat or bacterial consortium (1,2,127) or the thallus of a lichen (126,128,129). Any of these structures may serve as water reservoirs, may help retard evaporation and, possibly, may condense water at high humidities. The development of a mucilaginous sheath is a particularly common, if not universal, attribute of subaerial cyanobacteria.

A second, less widespread, adaptation to prolong the period of activity is the ability to absorb sufficient moisture to sustain cellular activity directly from the air. The ability of some subaerial algae to maintain photosynthetic activity using only water vapor was first noted by Fritsch (120,121), Zeuch (130), and Edlich (97). More recent work has confirmed this ability in the chlorophyte genera *Apatococcus* (129,131), *Trebouxia* (126,129), *Trentepohlia* (107), and, to a lesser extent, in subaerial strains referred to *Chlorella*, *Klebsormidium*, *Stichococcus* (125). Members *Apatococcus* and *Trebouxia* are able to

carry on photosynthesis when equilibrated with air with a relative humidity as low as 70%. This adaptation seems to be restricted to eukaryotes (111,125,126,132–135). However, only a few species of algae have been tested, with the major emphasis given to species forming lichen associations. Lange and coworkers (136) have some evidence that the desert cyanobacterium *Microcoleus sociatum* may be able to use water vapor at very high relative humidities. The physiological basis of the ability to use water vapor and the reason that this adaptation is restricted to eukaryotes are unknown. As mentioned previously, Büdel and Lange suggest that the ability of the cell to become turgid through the absorption of water vapor is a requirement (90). The presence of hydrophobic material in the cell wall has been suggested as a contributing factor (131), although the mechanism is unclear; it is possible the hydrophobic character is more of an adaptation to resist restarting metabolism too soon (98).

The ability of *Apatococcus* and other green algae to use water vapor may explain the abundance of this group on tree bark and bare wood in drier climates. As previously mentioned, much of the moisture in this habitat reaches the surface community as vapor. If cyanobacteria are unable to use water vapor, the habitat is free for colonization by any green alga with this ability.

As a final note, the ability to use water vapor contradicts the assertion made earlier that all microorganisms are essentially aquatic. In one sense, these organisms are the only group fully adapted to life without liquid water.

Adaptations to Survive the Desiccation Process. We just are beginning to understand the mechanisms by which subaerial microorganisms survive desiccation. First, it should be remembered that osmotic water stress, on the one hand, and matric water stress and desiccation, on the other, are not equivalent (98,112). At low levels of osmotic water stress, compatible solutes such as proline, glycerol, and sorbitol, may be sufficient to maintain cellular activity (88,119,137). However, at the extreme levels of desiccation experienced in subaerial habitats, something more seems to be required. Current theory suggests that molecules such as the disaccharides trehalose and sucrose replace the water required to stabilize proteins and membranes, thereby maintaining important subcellular structures. In the desiccated state, the accumulated sugars form an aqueous glass. In the glasslike state, all molecules are essentially immobilized and rates of reaction greatly reduced (see (98,112,138–140)). Extracellular polysaccharides may also play a role in stabilizing membranes and preventing the fusion of cells (98,112). It is interesting, in this respect, to note that Grilli Caiola and coworkers (120,141) found that cyanobacteria with intact, lamellated sheaths had greater viability than those without.

Adaptations to Survive the Desiccated State. The attainment of a true cytoplasmic glass should greatly enhance the survival of desiccated cells. However, the protection is not 100%. There is increasing evidence of high mortality rates in desiccated communities with the exact mortality rate species-dependent (103,124,142). The source of this mortality is unknown but oxygen-mediated and light-mediated damage to DNA, membranes, and proteins have all been implicated (see reviews by Potts (98,112), Smirnoff (143), and Whitelam and coworkers (144)). It is not surprising then that nearly all subaerial microorganisms possess some mechanism to at least reduce the damage caused by light. The sheaths of terrestrial and subaerial cyanobacteria often contain the yellow-brown pigment scytonemin; this is the cause of the dark colors associated with rich growths of subaerial cyanobacteria. The broad absorption peak of this pigment around 370 nm implies strongly that it may serve as protection against UV-light and high-energy visible light (98,145–149). Garcia-Pichel and Castenholz (146) found that scytonemin production was stimulated by high light and by UV-A radiation. Although stimulation of scytonemin by high light is probably the rule in the subaerial environment, Pentecost (150) found that in some instances, most probably during times of high growth rates, there is a negative correlation between the two.

Most of the eukaryotic subaerial algae, in contrast, are sheathless, and not all sheathed cyanobacteria produce scytonemin. Therefore, other mechanisms must be at work. Some cyanobacteria produce mycosporin-like amino acids in their cytoplasm; these can absorb some of the incident UV radiation (149,151). Many of eukaryotic forms, notably members of the genera *Chlorella*, *Chlorococcum*, and *Trentepohlia* have the potential to develop oil droplets colored by pigments such as astaxanthin or zeaxanthin. These seem to provide a degree of photoprotection (152–154). However, the development of these pigments is not necessarily related to light stress. Older cultures of some strains turn red or orange, probably in response to nutrient depletion (155,156). Not all subaerial algae have the ability to make these pigments. It has been suggested that in at least some desiccation tolerant algae there is a decoupling of the light-harvesting complex from the photosystem II reaction center in the desiccated state (111,144,157). In the desiccation tolerant strain *Nostoc commune* UTEX 584, there is evidence that phycobilisomes, used for light-harvesting, are degraded during short-term drying in the light (112). These changes in light-harvesting complexes should reduce photooxidative damage by reducing the rate at which active oxygen is formed. Other mechanisms used by algae to avoid light stress include the development of a complex community structure and organization, with more heavily pigmented cells at the surface (127); incorporation into the thallus of a lichen with melanin-producing mycobionts (87); and growth in hypolithic and endolithic habitats (87,101,122). Some subaerial diatoms form internal valves that may have an as-yet unknown role in desiccation resistance (158).

The nonphotosynthetic component of the community must also cope with the possibility of light-induced damage in the desiccated state. Many of the fungi are dark-colored, chiefly through the production of melanin and melanin-like compounds (14,71,76). Like scytonemin, these absorb light preferentially in the lower wavelengths and may provide some degree of protection from damage by UV radiation. Tests among phyllosphere-derived strains of

bacteria indicated that those forming pink or orange pigmentation were more tolerant of UV radiation (81). In this case, the pigments may serve to scavenge active oxygen after its formation (149); Garcia-Pichel (159) has calculated that smaller cells, less than 1 μm in radius, cannot use internal pigments as sunscreens, but must rely on external sheath-pigments.

Adaptations to the Temperature Regime

The temperature regime in the subaerial environment can be almost as severe as the moisture regime, with temperatures reaching the extremes for the particular region. How the organisms survive these extremes is an interesting, but almost untouched question. In hot environments it is usually assumed that the highest temperatures are reached while the organisms are dry, and that the desiccated state confers some sort of heat protection (122). Some preliminary results are available, however. Tripathi (99,100,160) has demonstrated the presence of heat-stable chlorophyll and proteins in subaerial cyanobacteria from habitats subjected to extreme (60° or higher) temperatures; he suggests that the stability of the proteins is related to a higher number of sulfhydryl groups in the heat-stable proteins. At the other extreme, in Antarctica, cryptoendolithic algae are able to maintain photosynthetic activity down to at least −8° (84), and at least one, *Hemichloris antarctica*, can withstand repeated cycles between −5° and +5°, with temperature changes on the order of 1.5°/min (161).

SIGNIFICANCE OF THE SUBAERIAL COMMUNITY

Colonization of Bare Surfaces

Subaerial organisms are the first to colonize rock outcrops and other bare surfaces. The initial inoculum is presumably brought in by wind (14,78,162), but transport by runoff in wet areas and by arthropods are also possible (14,162). Attachment of epiliths to the substratum has not been studied extensively. Garty (163) suggests that the microtopography of the rock surface, including holes and pits produced by previous inhabitants, plays a key role by providing favorable microenvironments. The actual attachment seems to be mediated through extracellular polysaccharides (97,164,165). Some have suggested that hydrophobic substances in the cell wall or extracellular matrix may also be involved; Potts (98) points out that, although hydrophobicity may be important in aquatic systems, its role in subaerial and terrestrial systems is unclear. Romantschuk (166) has reviewed the attachment mechanisms for plant-specific bacteria. Here the evidence suggests that in addition to extracellular polysaccharides, different types of proteinaceous filaments, including fimbriae and pili, are involved.

The subsequent development of the community strongly depends on local environmental conditions, especially the availability of moisture. Under laboratory conditions with regular supplies of moisture, visible growth appears in less than two weeks, and thick films form within two months (106,167). In natural settings, development can take months or years. Pentecost (44) investigated the process in the United Kingdom by clearing visible growth from two subaerial epilithic sites. The wetter site recovered completely within one year; the drier site still showed signs of the clearing after 10 years. This matches my own observations of recovery after herbivory or artificial disturbances in the southern United States. Freiberg (59,60) found visible development of nonpathogenic epiphyllous organisms on two- and three-month-old leaves in a tropical rainforest; visible colonies of cyanobacteria, including *Scytonema*, appeared later.

Productivity

The annual productivity of subaerial communities, and its significance to the local ecosystem is generally unknown. This is, in part, a result of the difficulty in monitoring the environment. Active subaerial communities change their structure and their activity over the course of a year (31,70,73,77,145,168). Therefore, in order to make reasonably accurate determinations of the productivity, it is necessary to either monitor photosynthesis in the field for long periods of time and under a variety of conditions, or monitor the environmental conditions in the habitat, and compare them with laboratory measurements of the photosynthetic response of the community or its members; only the latter has been attempted so far, and only rarely. Turner (95) estimated the productivity of the *Pleurococcetum* in Europe as 0.9 to 1.8 g Cm^{-2} $year^{-1}$. Most of this presumably provided food for wood lice and other invertebrates. Büdel (35), using measured values of photosynthesis over short intervals and regional climate data, estimated that tropical epiliths fix carbon dioxide at a rate of 8.4 g CO_2 m^{-2} $year^{-1}$ in the thorn bush savannahs, 27 g CO_2 m^{-2} $year^{-1}$ in the dry savannah, and 12 g CO_2 m^{-2} $year^{-1}$ in the humid savannah. When the area of rock surface is taken into account, these values represent sizable fractions of the total productivity of the ecosystem of the semidesert and savannah ecosystems. Friedmann and coworkers (84) were able to make use of a five-year record of micro- and nanoclimate data to determine the total period of activity and the environmental conditions during the active period in the Antarctic ecosystem. These estimates were then coupled with laboratory data concerning the photosynthetic response of the cryptoendolithic community to arrive at a gross productivity of 1.2 g Cm^{-2} $year^{-1}$, with about half of the gross productivity consumed by respiration. Of the remaining 0.6 gm, almost all is thought to be lost to the environment through erosion and leaching.

Subaerial organisms are a source of food for many invertebrates including wood lice (95), mites (14), and terrestrial snails (14,169). Uneaten remains and chemical exudates are available for use by the soil community.

The Role of Subaerial Organisms in Biodeterioration

Epilithic communities, including lichens, are well known for their ability to weather bare rock outcrops (72,90,170,171), historic monuments (14,71,76,172) and buildings (39,45,74,173–176), glass (163), and frescoes (4). The basic mechanisms involved are the subject of several recent reviews (4,14,72,74,173). Briefly, two distinct processes occur. First, mechanical damage results

from the shrinkage and subsequent swelling of cells and sheaths because they are subjected to repeated wet and dry cycles. The forces exerted are thought to be sufficient to dislodge individual grains from the substratum. Second, the organisms are responsible for the production of acids that change the chemical makeup of the substratum. Fungi, in particular, are cited as producing a number of organic acids, including oxalate, formate, fumarate, lactate, and gluconate, which can demineralize the substrate, either through their activity as chelating agents or through altering the pH. The activities of sulfur-oxidizing (*Thiobacillus*) bacteria result in the production of sulfuric acid that can cause the conversion of calcium carbonate to calcium sulfate (gypsum); the increased activity of sulfur-oxidizing bacteria in response to increased sulfur dioxide in the atmosphere have been especially noted in the destruction of frescoes and limestone (4). Similarly, nitrifying bacteria, responding to higher levels of ammonium ions in the surface layers, can produce nitric acid (74). We should not forget the importance of these processes in the history of life on Earth. It is now recognized that the advent of terrestrial vascular plants was preceded by a long period during which the land was colonized by microorganisms and nonvascular plants. These organisms set the stage for the later radiation of vascular plants by contributing to the production of a true soil containing organic matter (177–179). It is distinctly possible that some of these original terrestrial microbes were also subaerial (177).

PROSPECTS

In this entry, I have tried to emphasize the adaptations displayed by subaerial organisms to what is in many respects an extreme environment, at the expense of some equally interesting topics in their biology. This ubiquitous group of extremophiles displays a number of unique traits, namely, desiccation resistance or resistance to photooxidative damage, which we have just begun to appreciate and investigate. The identification and characterization of the molecular bases of some of these is already beginning to bear fruit. For example, the characterization of ice-nucleating activity in *Pseudomonas syringae* led to the development of ice-minus strains with potential applications in agriculture (78). This and other, more distant applications, such as inclusion as components of the life-support system of spacecraft (106), or in terraforming other planets (180), are indicative of the potential of this young field.

SUBSURFACE MICROBIAL COMMUNITIES: DIVERSITY OF CULTURABLE MICROORGANISMS

DAVID L. BALKWILL
Florida State University
Tallahassee, Florida

Interest in the microbiology of the terrestrial subsurface has increased steadily since the early 1980s, when it was discovered that several comparatively shallow aquifers (<30 m below land surface) contained sizable populations of culturable microorganisms (see Reference 1 for a review of this research). During the past two decades, culturable microorganisms, especially bacteria, have been detected in saturated and vadose-zone subsurface environments that ranged in depth from near-surface to 2.7-km below land surface, and in ambient temperature from 8 °C to 65 °C. Moreover, bacteria have been cultured from a geologically diverse range of unconsolidated and consolidated subsurface materials. Unconsolidated materials yielding bacterial isolates include lacustrine (lake) sediments (2), paleosols (2–5), fluvial sands and gravels (2–4), deep mine-gallery clays (6), and Atlantic coastal plain sands and clays (7–13). Different types of subsurface rocks from which bacteria have been isolated include Triassic siltstones (14–16), basalts (and their associated clay-silt interbeds) (3), unwelded volcanic tuffs (17–19), granitic rocks (and associated groundwater) (20–22), and Cretaceous shales and sandstones (23,24). Substantial numbers of microbial isolates from these environments have been preserved, so that they can be studied and characterized; for example, the U.S. Department of Energy Subsurface Microbial Culture Collection (25) now contains more than 13,000 strains of aerobic and anaerobic bacteria.

Only a small percentage of the many bacterial strains that have been isolated from subsurface environments have been characterized in any detail. Yet, the characterization studies completed to date provide much information on the diversity and composition of the culturable microbial communities in certain types of subsurface environments and some insights on how the isolates are related to previously described bacterial species. The objective of this article is to review and summarize these studies, focusing primarily on the phylogenetic characterization of culturable subsurface bacteria by analysis of 16S ribosomal RNA gene sequences.

PHYLOGENETIC BACTERIAL DIVERSITY IN SELECTED TYPES OF SUBSURFACE ENVIRONMENTS

It is necessary to characterize either a large proportion or a good representative sample of the microorganisms isolated from a particular subsurface environment to develop a reasonably complete understanding of the species composition and diversity of the culturable microbial community living therein. Only a few subsurface microbial communities have been examined this thoroughly to date, possibly because it is tedious and expensive to do so when a large number of isolates must be examined.

Atlantic Coastal Plain Sediments at the Savannah River Site

Among the most extensively studied culturable subsurface, microbial communities are the aerobic and facultatively anaerobic chemoheterotrophic bacterial communities in Atlantic coastal plain (ACP) sediments, at the U.S. Department of Energy Savannah River Site (SRS) near Aiken, SC. The sediments at this site consist of sandy aquifers separated by periodic clay confining zones (26). The bacteria isolated from all 15 sample depths (ranging from 24 to 265 m) in borehole P24 at the SRS (26) have received the most attention, having been characterized morphologically (7), physiologically (8), and phylogenetically (27,28).

Morphological and physiological studies showed that the culturable heterotrophic bacterial communities at the SRS were quite diverse. For example, it was reported that a set of 1,112 isolates yielded 626 distinct patterns of response to 21 selected physiological tests (8). However, the actual nature of the diversity implied by these results (e.g., strain-level versus a much broader range of diversity) could not be understood without detailed phylogenetic information. To avoid unnecessary phylogenetic characterization of very similar strains, all of the 187 bacterial isolates from borehole P24 were prescreened with a restriction endonuclease analysis (REA) technique (27). This analysis placed 126 of the 187 isolates in 21 clusters of very closely related strains, based on their restriction fragment patterns. The other 61 isolates did not appear to be closely related to each other or to any of the strains that clustered.

Representative strains from each REA cluster were characterized phylogenetically by analysis of their 16S rRNA gene sequences (27,28). The genera to which these strains were assigned are listed in Table 1. When two or more strains from a single cluster were analyzed, they always appeared to be most closely related to the same genus. The strains within each cluster, then, were at least

Table 1. Taxonomic Assignments for Bacterial Strains Isolated from Atlantic Coastal Plain Sediments at the Savannah River Site[a]

Genus or Higher Taxonomic Unit	No of Strains Isolated
α-Proteobacteria	
Sphingomonas	6
β-Proteobacteria	
Comamonas	29
Alcaligenes	10
γ-Proteobacteria	
Acinetobacter	19
Pseudomonas	11
High-G + C gram-positive bacteria	
Arthrobacter	38
Terrabacter	10
Micrococcus	3

[a] On the basis of REA prescreening and phylogenetic analysis of 16S rRNA gene sequences; data condensed from Table 2, Balkwill and coworkers (22).

phylogenetically similar enough to be members of a single genus. The 126 isolates that clustered were assigned to a total of just five gram-negative and three gram-positive genera (Table 1). Moreover, 68% of these strains were placed in just three genera (*Arthrobacter*, *Comamonas*, and *Acinetobacter*). Therefore, the diversity detected in earlier morphological and physiological studies (7,8) did not appear to represent substantial genus-level diversity. Additional genera might be detected if the 61 isolates that failed to cluster during REA were sequenced and analyzed, because these isolates apparently were not closely related to each other or to those that clustered. Even so, most of the diversity detected by morphological and physiological analyses must be at the strain and species levels.

Morphogical, physiological, and phylogenetic studies of bacterial strains from the P24 borehole at the SRS all indicated that distinct groups of organisms had been isolated from different sample depths and geologic formations. In the phylogenetic studies, for example, 17 of the 21 REA clusters consisted entirely of strains that were detected at only a single depth. There were also distinct differences in the genera that were isolated from different depths and aquifers (27).

Saturated Sediments at the Hanford Site

The culturable aerobic (and facultatively anaerobic) chemoheterotrophic bacterial communities in deep saturated sediments at the U.S. Department of Energy's Hanford Site near Richland, WA are also among the subsurface microbial communities that have been characterized extensively. The sediments examined at this site ranged in depth from 173 to 220 m below land surface and were located within the Ringold formation (2,29). The types of material sampled included lacustrine sediments, paleosols (ancient buried soils), and fluvial sands and gravels. A total of 169 strains of bacteria were isolated from these materials on various plating media, and all of these were characterized phylogenetically, by analysis of their 16S rRNA gene sequences (27,30).

The major phylogenetic groups and bacterial genera to which the strains from the Hanford Site were most closely related (by analysis of 16S rRNA sequences) are detailed in Table 2. There appeared to be considerably more diversity among the Hanford isolates, than was detected among those from ACP sediments at the SRS (as mentioned earlier), although some of the difference might simply be due to the fact that only selected strains (representative of the 21 REA clusters) were characterized in the SRS study. In any event, the Hanford Site isolates could be assigned to six major taxonomic groups: the high- and low-G + C gram-positive bacteria; the alpha-, beta-, and gamma-subdivisions of the *Proteobacteria*; and the *Flexibacter-Cytophaga-Bacteroides* group. Moreover, the isolates were most closely related to at least 33 different bacterial genera within these groups. (A few isolates were not closely related to any genus in the current public 16S rRNA sequence databases and, thus, might represent novel genera.) Seventy percent of the isolates were gram-positive, and 60% of those were placed in the high-G + C group. *Arthrobacter* was by far the most frequently detected high-G + C gram-positive (40 of 73 strains), whereas all but one of the low-G + C isolates were strains of *Bacillus* or *Staphylococcus*. The most frequently noted gram-negative genera among the Hanford Site isolates were *Variovorax*, *Sphingomonas*, *Caulobacter*, and *Pseudomonas*. There was also a group of eight gram-negative isolates that were closely related to a 16S rRNA clone obtained from deep granitic groundwaters in the Stripa Mine (in Sweden) with direct molecular biological methods (31).

Table 2. Taxonomic Assignments for Bacterial Strains Isolated from Saturated Sediments at the Hanford Site[a]

Genus or Higher Taxonomic Unit	Number of Strains Isolated
Flexibacter-Cytophaga-Bacteroides group	
Flectobacillus[b]	1
Microscilla[b]	1
α-Proteobacteria	
Sphingomonas[b]	6
Caulobacter	5

Nocardioides	2
Dermatophila[b]	1
Aureobacterium	1
Genus affiliation uncertain	1

[a] On the basis of phylogenetic analysis of 16S rRNA gene sequences; data from Tables 3 and 4 in Balkwill and coworkers (22).
[b] Genus in 16S rRNA sequence databases to which strains in this group are most closely related; relatedness may not be sufficiently close in the case of one or more strains to be certain of genus assignment.

The Hanford Site isolates were similar to those from the SRS in that, the majority of them (74%) could be assigned to a relatively small number of genera (just 10 of the 33 genera detected at that site). Nevertheless, there were some clear differences between the culturable heterotrophic populations at these two sites. For example, no low-G + C gram-positive bacteria have been detected at the SRS yet, whereas *Staphylococcus* and *Bacillus* were among the most significant components of the culturable microflora at Hanford. In contrast, *Pseudomonas* and *Acinetobacter* were numerically predominant components of the culturable community at the SRS, but were detected only infrequently in the saturated sediments at the Hanford Site.

Vadose Zone Sediments at the Hanford Site

Balkwill and coworkers (32) recently characterized the culturable aerobic (and facultatively anaerobic), chemoheterotrophic bacterial communities in comparatively shallow vadose (unsaturated) zone sediments at the Hanford Site. The main purpose of this study was to compare the bacterial communities occurring at high- and low-recharge sites, to seek evidence for vertical transport of bacterial cells through the vadose zone. However, the information obtained during this study also facilitates a comparison of the culturable vadose-zone microbial communities to those occurring in the deeper, saturated sediments at the Hanford Site (as seen earlier). All of the isolates from several depths (ranging to 15 m below land surface) at one high-recharge and one low-recharge site were characterized in the vadose-zone study. Streptomycetes were identified by cell and colony morphological traits, and nonstreptomycete isolates were characterized phylogenetically by analysis of 16S rRNA gene sequences. The bacterial genera to which the isolates were assigned by morphological and phylogenetic analyses are listed in Table 3.

In general, the culturable bacterial community in the vadose-zone sediments was quite different from that isolated from the deeper saturated sediments at the Hanford Site. Overall genus-level diversity was far lower in the vadose zone, with 203 isolates falling into a total of only eight genera (as opposed to 169 isolates from the saturated sediments being assigned to at least 33 different genera; see in the preceding text). A large proportion (72%) of the vadose-zone isolates were found to be strains of *Streptomyces*, a genus that was only rarely isolated from the deep saturated sediments. Both culturable bacterial communities were mostly gram-positive, but the proportion of gram-positive strains was higher in the vadose zone (93% versus 70% for the saturated sediments). Moreover, all of the gram-positive bacteria isolated from the vadose zone were members of genera that either form spores (*Streptomyces* and *Bacillus*), or that, are known for having unusually good survival capabilities (*Arthrobacter*). The culturable vadose-zone communities at the Hanford Site, then, seem to be largely limited to a specialized group of bacteria that are well equipped to deal with very low moisture and nutrient levels.

Table 3. Taxonomic Assignments for Bacterial Strains Isolated from Vadose Zone Sediments at the Hanford Site[a]

Genus or Higher Taxonomic Unit	No. of Strains Isolated
α-Proteobacteria	
Azospirillum	6
Bradyrhizobium	3
Rhizobium	2
β-Proteobacteria	
Telluria	1
γ-Proteobacteria	
Pseudomonas	1
Xanthomonas	1
Low-G + C gram-positive bacteria	
Bacillus	37
High-G + C gram-positive bacteria	
Streptomyces[b]	146
Arthrobacter	6

[a]As determined by phylogenetic analysis of 16S rRNA gene sequences, unless otherwise noted; data from Table 1, Balkwill and coworkers (32).
[b]Determined by colony morphology, rather than by 16S rRNA sequence analysis.

Deep Mine Gallery Clays

Boivin-Jahns and coworkers (6) have characterized the culturable bacterial communities in deep mine gallery clays of the Boom formation at Mol, Belgium. The clays in this study were situated 224-m below land surface and were deposited by marine sedimentation 35 million years ago. Seventy-four bacterial strains were isolated from these materials and characterized phylogenetically by analysis of their 16S ribosomal RNA gene sequences. The genera or other taxonomic units to which the isolates were assigned by this analysis are listed in Table 4.

Table 4. Taxonomic Assignments for Bacterial Strains Isolated from Deep Mine Gallery Clays at a Site in Belgium[a]

Genus or higher taxonomic unit	Number of strains isolated
α-Proteobacteria	
Rhizobium/Agrobacterium[b]	1
β-Proteobacteria	
Alcaligenes	16
γ-Proteobacteria	
Pseudomonas	9
Acinetobacter	3
Moraxella	3
Low-G + C gram-positive bacteria	
Staphylococcus	17
Bacillus	4
High-G + C gram-positive bacteria	
Micrococcus	6
Arthrobacter	4
Corynebacterium	3
Nocardoides	2
Streptomyces[b]	2
Rhodococcus	1
Clavibacter[b]	1
Unidentified strains[c]	2

[a]As determined by analysis of 16S rRNA gene sequences; data condensed from Table 1, Boivin-Jahns and coworkers (6).
[b]Most closely related genus; actual genus-level identification uncertain.

Overall genus-level diversity in the mine gallery clays was lower than that noted in deep saturated sediments at the Hanford Site but higher than that detected in the other subsurface environments described earlier. The clay isolates could be assigned to eight gram-positive and six gram-negative genera. Gram-positive isolates were only slightly more abundant (55%) than gram-negative isolates at this site. *Staphylococcus* was the most frequently isolated gram-positive genus, whereas the most frequently noted gram-negative genera were *Pseudomonas* and *Alcaligenes*.

Deep Granitic Groundwater

Pedersen and Ekendahl (20) examined culturable microbial communities in the deep granitic groundwaters (maximum depth = 860 m) of southeastern Sweden. Most of the organisms that were detected by plating on a medium containing organic substrate were facultatively anaerobic, gram-negative, nonfermenting, heterotrophic bacteria. Seven isolates from the plate-counting medium were identified phenotypically and found to be members of just two bacterial genera: *Pseudomonas* and *Shewanella*. However, studies utilizing enrichment cultures showed that sulfate-reducing bacteria and microorganisms capable of growth on C-1 compounds and hydrogen (presumably methanogenic bacteria) were also culturable members of the granitic groundwater communities. The enrichment culture approach has also been used to survey physiological diversity in other subsurface microbial communities, including those in ACP sediments (9,11,12, and 33). Pedersen and coworkers (22) have since characterized the diversity of deep granitic microbial communities in more detail, using direct molecular methods that do not require culturing.

SPECIFIC GROUPS OF WELL CHARACTERIZED SUBSURFACE BACTERIA

Some characterization studies have dealt with specific groups of bacteria isolated from subsurface environments, as opposed to the composition and diversity of culturable subsurface microbial communities. In some cases, specific groups of subsurface bacteria have been characterized because they have unusual or potentially useful metabolic traits. In other cases, certain groups of isolates have been characterized, phylogenetically, to see how they are related to previously described bacterial taxa, especially to the most similar species known to live in topsoils and other surface environments. The primary objective of the latter studies has been to find out whether, and how subsurface bacteria differ from typical surface organisms.

Aromatic-Degrading *Sphingomonas* Isolates from Atlantic Coastal Plain Sediments

A small group of bacterial isolates from ACP sediments at the SRS (as mentioned earlier) were found to degrade a variety of aromatic compounds that frequently occur as environmental contaminants, including naphthalene, toluene, *p*-cresol, and xylenes (34). A preliminary phylogenetic analysis indicated that these isolates were strains of *Sphingomonas*, a genus that is differentiated from most other genera of bacteria by the presence of sphingolipids (35). Because aromatic-degrading *Sphingomonas* strains have been isolated from surface soils (36–39), it was of interest to see how similar the subsurface isolates are to these organisms. Surprisingly, an analysis of 16S rRNA sequences showed that the subsurface strains were not very closely related to the aromatic-degrading topsoil strains (40). In the resulting phylogenetic tree, the subsurface bacteria were assigned to a distinct and rather distant portion of the genus. They were most closely related to *Sphingomonas capsulata*, an organism that was isolated from a clinical source and that does not degrade aromatics. However, the subsurface bacteria did not actually cluster with any known *Sphingomonas* species, thus implying that they are novel species. A more detailed polyphasic taxonomic study involving analysis of cell lipids, determination of DNA-DNA reassociation values, and BOX-PCR DNA fingerprinting (40) confirmed that the five subsurface isolates examined in the study represented three new species: *Sphingomonas stygia*, *Sphingomonas aromaticivorans*, and *Sphingomonas subterranea*. The subsurface isolates, then, were phylogenetically rather distinct from the most physiologically similar topsoil isolates. More recently, it has also been shown that the genes for biphenyl and *m*-xylene degradation are located on plasmids in the subsurface strains, although the equivalent (and similar) genes are chromosomal in two topsoil *Sphingomonas* strains that are able to degrade aromatics (41). The subsurface strains, then, seem to differ in their evolutionary history from the otherwise similar topsoil isolates.

Arthrobacter Isolates from Saturated Sediments

Arthrobacter strains were one of the most frequently cultured bacterial forms in ACP sediments at the SRS and various types of deep saturated sediments at the Hanford Site (see in the preceding text). The phylogenetic and, in many cases, physiological characteristics of these microbes have been examined in detail in order to look for diversity among them and to determine how closely they are related to each other and to previously described species of *Arthrobacter* (27,30).

An analysis of 16S ribosomal RNA gene sequences for a group of *Arthrobacter* strains isolated from ACP sediments at the SRS produced the phylogenetic tree, as shown in Figure 1, in which the subsurface strains are separated into five phylogenetically distinct clusters (**A–E**). On the basis of the clustering and branching patterns of the established species of *Arthrobacter* that were included in the analysis for comparison, the subsurface clusters appear to represent distinct species and indicate definite species-level diversity among the subsurface strains. Additional diversity is also likely at the strain-level, as implied by the banding patterns seen during restriction endonuclease analysis (REA) of bacterial isolates from the SRS (as in the preceding text). None of the subsurface strains corresponded exactly to any of the previously described species of *Arthrobacter* included in the analysis, although two of them clustered with *Arthrobacter polychromogenes* and *Arthrobacter oxydans*, whereas two others clustered with *Arthrobacter atrocyaneus* (see

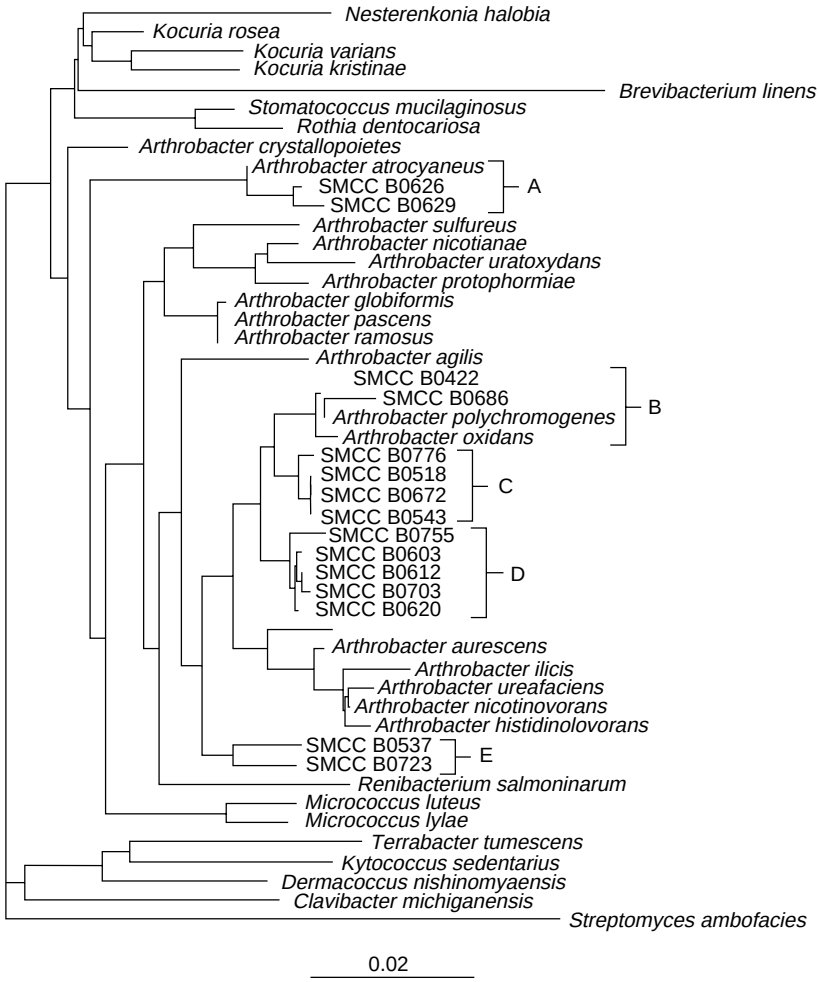

Figure 1. Phylogenetic tree produced by distance matrix analysis of 16S ribosomal RNA gene sequences for *Arthrobacter*-like isolates from the Savannah River site (designated by SMCC accession numbers), previously described species of *Arthrobacter*, and other high-G + C gram-positive bacteria that were included for comparison. *Streptomyces ambofaciens* was used as the outgroup. The subsurface strains fall into five distinct clusters (**a-e**), most of which are not closely associated with established *Arthrobacter* species. Scale bar represents 2 base substitutions per 100 bases.

Fig. 1). The other three clusters of subsurface strains were well separated from all of the established species of *Arthrobacter* (typically on independent branches of the phylogenetic tree), thereby indicating that they might contain novel species of this genus.

Similar results were obtained when 38 *Arthrobacter* isolates from deep saturated sediments at the Hanford Site were characterized (30). Phylogenetic analysis of their 16S rRNA gene sequences assigned these isolates to seven clusters that probably represented distinct species, thus indicating considerable species-level diversity among the subsurface strains. Five of the 38 subsurface isolates clustered with and, in some cases, were almost identical to established *Arthrobacter* species. The other 33 subsurface isolates, however, were well separated from all known *Arthrobacter* species in the phylogenetic tree and, as a result, may be novel species. As was the case with those from ACP sediments (as mentioned earlier), then, most of the *Arthrobacter* isolates from saturated sediments at the Hanford Site were phylogenetically distinct from species that are known to occur in topsoils or other surface environments. A detailed analysis of physiological traits (data not shown) indicated that the subsurface isolates and established species of *Arthrobacter* differed in some of their metabolic capabilities as well.

Acinetobacter Isolates from Atlantic Coastal Plain Sediments

Although some groups of subsurface bacteria have proven to be phylogenetically distinct from most similar (or physiologically equivalent) organisms that are found in surface environments, this is not the case for all subsurface isolates. Balkwill and coworkers (27) characterized 19 *Acinetobacter* isolates from ACP sediments at the SRS, by phylogenetic analysis of 16S ribosomal RNA gene sequences. In the resulting phylogenetic trees (not shown), the isolates were separated into four distinct clusters, implying approximately the same extent of species-level diversity that was detected earlier among subsurface *Arthrobacter* and *Sphingomonas* isolates. In this case, however, all but one of the subsurface isolates clustered with established *Acinetobacter* species, and most of them were nearly identical to those species in regard to their 16S rRNA sequences (sequence similarities >99.5%). The subsurface *Acinetobacter* isolates, then, did not differ noticeably from species and strains that have been isolated from surface environments.

Anaerobic and Thermophilic Metal-Reducing Isolates

Many of the bacteria cultured from terrestrial subsurface environments before the mid-1990s were aerobic or facultatively anaerobic mesophiles (mostly heterotrophs).

Strict anaerobes were detected or enumerated in most subsurface environments studied up to that point (using MPN assays and other methods), but there were few attempts to culture and isolate them. In recent years, though, anaerobic (both strict and facultative) and/or thermophilic forms have been cultured more frequently, as microbiologists have explored increasingly deeper and hotter environments. Several of the isolates obtained from such environments have been shown to reduce metals. This property is of interest to the U.S. Department of Energy and other agencies that are concerned about the fate of metal and radionuclide contaminants in the subsurface, especially in aquifers, in which the contaminants may migrate with the flow of groundwater. Microorganisms that can reduce metals could be significant in such environments, because many of the metals of interest (e.g., U, Tc, and Cr) are less soluble — and, therefore, less mobile — in their reduced forms. Selected examples of metal-reducing bacteria from deep subsurface environments are described later, to illustrate the diversity and metabolic characteristics of these potentially useful organisms.

Boone and coworkers (15) described a novel species of *Bacillus* — *Bacillus infernus* — that was isolated from a deep (2.7-km below land surface) soapstone within the Taylorsville Triassic Basin at a site in Virginia. *B. infernus* is a strict anaerobe (the only strict anaerobe in the genus *Bacillus* when it was first described) that can grow on formate or lactate with Fe(III), MnO_2, trimethylamine oxide, or nitrate (which is reduced to nitrite) as an electron acceptor. The organism also grows fermentatively on glucose. It is very slightly alkaliphilic (good growth at pH 7.8), halotolerant (growth up to 0.6 M Na^+), and thermophilic (optimum growth at 61.4°C). Geologic evidence suggests that microbes inhabited the Taylorsville Triassic Basin between 200 and 140 million years ago, when penetration of meteoric water into the basin was probably greatest. Since then, most of the groundwater flow has been preferentially funneled through the overlying permeable sediments. It is unlikely that any subsequent introduction of microbes has taken place because they would have to be transported through, approximately, 2.5 km of sedimentary rock with low porosity and permeability (14). There is a good chance then that *B. infernus* has survived in the deep subsurface for a very long time.

Kieft and coworkers (42) described a novel strain of *Thermus*, designated SA-01, that was isolated from groundwater in a South African gold mine. The groundwater was sampled from a horizontal borehole that was situated at a depth of 3.2 km and that penetrated 121 meters into the Witswatersrand Supergroup, a 2.9-billion-year-old formation composed of low-permeability shales and sandstones with minor volcanic units and conglomerates. The ambient temperature of the rock was approximately 60 °C. Strain SA-01 grows over a temperature range of 35 °C to 70 °C, and has an optimum temperature of 65 °C. It cannot grow fermentatively; an external electron acceptor is required for anaerobic growth. The organism can reduce soluble Fe(III), complexed with citrate or nitrilotriacetic acid (NTA). Only comparatively small quantities of hydrous ferric oxide are reduced unless the humic acid analog, 2,6-anthraquinone disulfonate, is added to the medium as an electron shuttle. Strain SA-01 is able to reduce Mn(IV), Co(III)-EDTA, Cr(VI), and U(VI) in the presence of lactate. It can also mineralize NTA to carbon dioxide and couple its oxidation to growth and the reduction of Fe(III). Strain SA-01 is the first *Thermus* isolate known to couple oxidation of organic compounds to the reduction of Fe, Mn, or S.

A novel strain of *Shewanella putrefaciens* (strain CN-32), with relatively versatile metal-reducing capabilities, has been isolated from Cretaceous period sandstone at a depth of 250 m in the Morrison formation of northwestern New Mexico (43,44). Strain CN-32 grows over a temperature range of 2.7 °C to 42 °C. It utilizes several organic acids and other simple organic compounds as sources of carbon. With lactate as the electron donor, it is able to reduce Fe(III), Co(III), Cr(IV), U(VI), and Tc(VII). Strain CN-32 can also reduce Fe(III) and Co(III) when complexed with chelating agents such as NTA or EDTA. This organism is of particular interest to researchers dealing with subsurface contamination at U.S. Department of Energy sites, where the movement of metals such as Cr(VI), U(VI), and especially Tc(VII) in the groundwater is a major concern. As noted earlier, microbially mediated reduction of these metals may limit their migration by reducing their solubility in the groundwater.

The aforementioned isolates and studies in which organisms were not necessarily isolated (45,46), may indicate that diverse populations of metal-reducing bacteria are widely distributed in the deep subsurface. For more information on the possible significance of these organisms on subsurface mineralogy and geochemistry, see Geochemical and Geological Significance of Subsurface Microbiology and Biomineralization by Bacteria, this Encyclopedia.

CONCLUSION

A wide variety of microorganisms (primarily eubacteria and archaea) have been cultured from terrestrial subsurface environments. These organisms are phylogenetically diverse, falling into dozens of different genera. Detailed studies on culturable microbial communities in selected subsurface environments indicate that most of the communities are quite diverse, although the numerically predominant forms often fall into a relatively small number of genera. Among the isolates that belong to a single genus, however, one usually sees a considerable amount of additional diversity at the species and strain levels. Given the diverse nature of many subsurface culturable communities, there is at least the potential for a wide range of microbially mediated chemical transformations (of organic and inorganic compounds) to take place in deep-earth environments.

Many of the bacteria cultured from the subsurface appear to be new species or, in some cases, novel genera, although some of them are phylogenetically indistinguishable from previously described species that were isolated from surface environments. Several subsurface

isolates that have been examined in detail have been shown to differ from the most closely related surface species in their physiological and/or genetic characteristics, most likely indicating that the subsurface organisms have a distinct evolutionary history. It seems likely, then that microorganisms cultured from deep subsurface environments represent a significant source of new genetic information. Some of these microbes also have potentially valuable metabolic capabilities, such as ability to degrade toxic organic compounds, or to immobilize metals and radionuclides in groundwater. Therefore, they may not only influence the fate of contaminants in the subsurface, but might also have applications in the field of bioremediation.

Although much information has been derived from the study of microorganisms cultured from subsurface environments to date, it is recognized that the cultured strains probably represent only a small fraction of the total communities in these environments. Direct molecular biological methods have detected a broad variety of as-yet uncultured microbes in many natural environments including several in the subsurface. Hopefully, information from direct molecular techniques will eventually facilitate the culturing of a larger proportion of subsurface microorganisms and, thereby, enable scientists to study their potentially novel or unique characteristics.

Microbiological data, interpretation, and conclusions from subsurface samples ultimately depend on the quality

and representative character of the samples. Subsurface samples for environmental microbiology ideally contain only the microbial community and geochemical properties that are representative of the subsurface environment from which the sample was taken. To that end, sample contamination by exogenous microorganisms or chemical constituents must be eliminated or minimized, and sample analyses need to begin before changes in the microbial community or geochemical characteristics occur.

The objective of this article is to present sampling methods and sample processing techniques for collecting representative samples from a range of subsurface environments. Factors that should be considered when developing a subsurface sampling program are discussed, including potential benefits, costs, and limitations; enabling researchers to evaluate the techniques that are presented and match them to their project requirements. Methods and protocols to address coring, sampling, processing, and quality assessment issues are presented in this chapter.

EVALUATING RESEARCH OBJECTIVES AND SAMPLE NEEDS

Subsurface sampling programs can be relatively expensive undertakings, and thus require considerable forethought and planning (1,2). Planning an effective and cost-efficient field sampling program starts with an assessment of the research program objectives, and subsequent determination of the samples required to test the research hypotheses or to provide survey data on extant subsurface microbial communities. This assessment process begins with the most obvious and intuitive questions and often evolves into more complex issues, such as how to determine whether the samples represent the environment from which they were collected. The sampling technologies and techniques that are ultimately employed will depend on the outcome of this assessment process.

Investigators can begin the assessment process by simply determining if they need solid phase lithologic samples (with attached microbial communities), liquid phase samples (with unattached or detached microbial communities), or both. The samples that meet the immediate needs of the survey or research project will typically be obvious. Consideration should also be given to potential longer-term objectives and sample or data correlations that, at present, may not be readily apparent. Simply stated, it is desirable to systematically collect an appropriate number of samples and as many different types of samples as is economically feasible because it is often difficult, if not impossible, to return to the sample location and collect additional materials. Thus, every effort should be made to ensure that sufficient sample numbers and volumes are collected to meet both planned and some level of unanticipated research needs.

Investigators should also determine whether contamination of field samples by exogenous microorganisms or other "contaminants" is of concern. In cases where analytical results may be biased by the presence of exogenous microorganisms or nonnative materials, it will be necessary to select sampling technologies and processing protocols that limit exposure of the sample to contaminants. This is most certainly the case in the vast majority of subsurface microbiological research programs, particularly where microbial ecology or community structure are key elements of the hypotheses being tested (1,3–11). However, not all subsurface microbial investigations are highly sensitive to contamination, as is the case in which specific microorganisms are stained or otherwise "tagged" and injected into the subsurface as tracers (1,12). If contamination is a concern, then investigators will typically need to implement quality control methods by which the degree and nature of the contamination can be estimated. Fortunately, a growing body of sample processing and sophisticated subsurface microbiological data is beginning to make it possible to assess the representative character of sample results by comparison with earlier results. An example of this type of assessment is discussed later.

Other questions that should be addressed include the number and volume of samples required, and whether samples require specific preservation both upon initial collection and during shipment. If samples are anaerobic in situ and the project requires data on culturable anaerobic microorganisms, steps must be taken to prevent exposure to oxygen during sample collection, processing, and shipping.

ASSESSING THE SAMPLING TARGET

While evaluating research objectives and sampling needs, investigators must simultaneously begin to assess the sampling target and address the questions of where they want to collect samples and why. In order to fully assess the sampling target, investigators must be knowledgeable of the information available on the field site geology, hydrogeology, and geochemistry.

The specific depths of sampling points or intervals must be specified early in the assessment process, since sampling depth is a key consideration in selecting a sampling technology. Sampling target depths are most commonly based on the hypotheses examined in relation to the site geology and the stratigraphic heterogeneity that is typical of most geological systems (4,7,11,13–15). To effectively pick precise target sample depths, investigators must have some knowledge of the site stratigraphy on a scale that represents the intrinsic chemical and physical heterogeneities that will impact the distribution of autochthonous microorganisms (16–18). Descriptions of nearby outcrops or borehole geophysical and core data from nearby wells can be invaluable for understanding the subsurface geology and in selecting sampling points or intervals (10,11,14). In addition to understanding stratigraphic relationships and correlative sediment types, the degree of consolidation exhibited by the targeted lithologies will have a major influence on the selection of sampling technologies and the quality control protocols that are employed (1,2). For example, deep indurated lithologies require drilling technologies that employ circulation fluids, whereas shallow unconsolidated sediments can ordinarily be sampled without the use of circulation fluids. Formations that are highly fractured, or that are subject to voids such as are typical in volcanic flow deposits or limestone karst environments, may require high viscosity circulation fluids or "drilling muds."

Circulation fluids significantly enhance the likelihood of sample contamination by providing an environment that is conducive to bacterial growth and thus transporting microorganisms from the surface (mud tanks) or from shallow depths to the sample target depth. Sampling under conditions utilizing drilling fluids requires more robust quality control protocols to improve sample quality and to evaluate the degree of potential contamination (19).

The degree to which the sample interval is saturated with pore fluids is also critical, as is some knowledge of the pore fluid chemistry. For example, dissolved oxygen concentrations will influence the selection of sample collecting and processing protocols to be employed, particularly in cases where obligate anaerobic bacteria, methanogens, or sulfate/iron–reducing bacteria are of interest to the research program, or where oxidation might otherwise alter the sample or have a deleterious impact on the autochthonous microbial community. In such cases, anaerobic sample processing may be required. Other extreme in situ conditions, including naturally high or low pH, or extreme pressures or temperatures, may also require special sample handling and preservation techniques.

Selecting Types of Subsurface Samples

Subsurface media comprise a remarkably diverse range of physical, geochemical, and microbiological characteristics. For example, lithified quartz sandstone at 1-km depth is extremely hard, typically consists of nearly pure SiO_2, and possesses a high permeability and relatively low microbial biomass. In contrast, a clay-rich soil at 1-meter depth exhibits complex chemistry and mineralogy, including a high organic carbon concentration, orders of magnitude lower permeability, and orders of magnitude higher microbial biomass and activity. Yet, both types of materials are sampled as a part of research projects on subsurface environmental microbiology and obviously require very different sample collection and sample processing approaches.

However, all subsurface samples possess solid phases consisting of minerals or naturally occurring glass and have some degree of porosity (space not occupied by solids), containing either liquid (commonly groundwater or petroleum) or gas (most commonly air, CO_2, or natural gas) or both. Microorganisms occur in the pores, either attached to solid phases or unattached in a liquid phase. Research suggests that orders of magnitude more microbes are attached to solid surfaces than are free-floating in a liquid phase (20), although making this determination is clearly difficult. Effectively separating fluid phases contained in pores from solid phases without modifying the ratio of attached to free-floating cells is virtually impossible. Nonetheless, microbiological analyses are routinely performed on both solid and fluid samples. Subsurface gas samples ordinarily are not characterized microbiologically because of the limited ability of a gas phase alone to provide physical support or habitat for cells. Sampling and microbial characterization of gases are therefore not discussed in this chapter. The kinds of sample materials typically encountered are discussed in the following section.

Condensed Subsurface Fluids

Groundwater. Groundwater is obtained most frequently by sampling wells and includes a wide range of dissolved and suspended constituents that are important sources of nutrients for microbial populations and indicators of microbial metabolic function (21). Before entering the bore of the well during sampling, groundwater resides in pores or fractures, and thus is actually pore water. Groundwater sampling in a conventional manner by pumping wells thus represents a volume-averaged sample of water-rich fluids occupying pores in the subsurface. Because groundwater samples contain a small, variable content of particulate and colloidal materials in addition to unattached microbes, sterile filtration can be used to separate and concentrate these materials from groundwater. Such samples are readily analyzed by standard culture methods or lipid analysis or DNA extraction and cloning techniques (see section on Groundwater Sampling).

Pore Water. Pore water refers to water-rich fluid samples obtained by removing (most commonly by centrifugation) the fluid contents from a solid sample after it has been extracted from the subsurface. Because of drainage that occurs during extraction of the solid sample, pore water ordinarily comes from a smaller size fraction of pores in the subsurface than does groundwater. Pore water samples originate from the volume of the solid sample, a much smaller volume (100 to 1,000 mL) than represented by a conventional groundwater sample that may interrogate several to hundreds of cubic meters.

Petroleum Hydrocarbons. Liquid petroleum hydrocarbons occupy pore space (usually at depths from a few hundred meters to greater than several thousand meters) instead of groundwater. Studies on the microbial populations in such fluids are limited but have demonstrated that microbial activity plays a very significant role in the evolution and formation of petroleum reservoirs. Samples are typically extracted by pumping. The petroleum equivalents of pore water samples ("porepetroleum" samples) are relatively unusual for microbial studies but, in principle, could be obtained from deep core samples.

Subsurface Solids

Sediment. Unconsolidated or poorly consolidated clastic (granular) sedimentary deposits formed in a variety of marine and nonmarine environments are sampled extensively for microbial studies. This is partly because they occur at relatively shallow depths, and partly because such sediments are typically the materials contaminated by industrial activities, and hence are the target for application of bioremediation of a wide range of contaminants. It also reflects the observation noted above that the bulk of microbial populations exist in the subsurface attached to solid materials, in this case sediment particles. Grain size of the particles ranges widely, from gravel size or larger to silt and clay sized. Typical unconsolidated sediments are in the sand to silt size (1.0 to 0.01 mm) range. Unconsolidated volcanic materials (many of which are essentially sedimentary in nature) are included in this group of materials.

Lithified Materials. From the perspective of sampling and sample processing, all lithified rock materials require similar treatment and are thus discussed as a group. A wide range of rock types and properties are included: all lithified sedimentary rocks, most igneous rocks, and metamorphic rocks. Material properties, such as compressive strength, porosity, and permeability vary significantly and strongly influence details of processing. Indeed, there is a continuum between unconsolidated sediments described earlier and fully lithified sedimentary rocks. Core samples most amenable to effective processing without cross-contamination or contamination with drilling fluids are actually those that are moderately lithified and with moderate to low permeability. Such samples are less likely to be impacted by exogenous materials (including drilling fluids) and can readily be carved with sterile tools, enabling removal of exterior parts of the core without generating dust particles.

What Sample Types Will Meet Project Needs?. All of the sample types listed earlier have been used to "probe" subsurface microbiology, no doubt with varying, but commonly unevaluated, degrees of success. Groundwater samples are thought to underrepresent both total subsurface microbial biomass and subsurface diversity because of the much lower biomass in groundwater compared to subsurface sediments (20). Furthermore, conventional groundwater samples interrogate a much larger volume of the subsurface than the typical sediment sample, making groundwater samples less precise in terms of spatial resolution. This is not always negative. For example, groundwater analyses combined with filtration have been successfully used to reveal remarkable diversity and key relationships between uranium concentration and specific clones of sulfate-reducing bacteria present (22). Emerging techniques may help reduce the need for subsurface sediment samples (see later), but for now, groundwater samples typically would be used mainly for exploratory sampling and surveys. Detailed definition of subsurface microbial communities requires sediment or lithified samples that are most productively used in combination with groundwater biogeochemistry information.

SELECTING A SAMPLING TECHNOLOGY

Once investigators have identified the types of samples required and have targeted sampling depths and intervals based on geology, hydrogeology, and geochemistry of the site, it is appropriate to select a sampling technology. In selecting the most appropriate sampling technology, three key elements to consider are sampling depth, degree of induration in the target interval, and budget. Shallow, friable lithologies can be sampled by a number of technologies, but as sample target depths get deeper, the numbers of available technologies decrease, while at the same time the relative costs associated with these sampling technologies increase, often dramatically (1,2). Various technologies for sampling the shallowest to deepest subsurface environments are described in the following sections, and each example presented is amenable to at least a minimum level of quality control to enhance sample integrity.

Shallow Sampling Technologies

Shallow sampling technologies can be employed from the surface to depths on the order of 10^1 to 10^2 meters below the ground surface. Shallow sampling may be as simple as scraping the face of a rock outcrop or a shallow backhoe trench, or employing manual or hand-held drilling equipment such as augers. These auger systems can be effective to depths up to approximately five meters below ground surface, but their application is limited to unconsolidated soils and sediments (without gravel or cobbles), Hand-held auger samples can be collected from the saturated zone in some subsurface environments, provided the sampling horizon and overlying materials are sufficiently cohesive to prevent collapse of the borehole wall. However, pore fluids may drain from the sample as it is retrieved. Sample sizes vary, but are typically on the order of 1.2 to 7.6 cm diameter $\times$ 15 to 30 cm length. Many small-scale auger systems offer sample liners or inserts to contain the sample and limit its exposure to contaminants. These simple auger systems are inexpensive and are available through numerous commercial soil and groundwater sampling equipment suppliers.

The single biggest advantage to sampling shallow, unconsolidated subsurface environments is that there are a number of sampling technologies, which are highly effective and that do not employ circulation fluids that can contaminate the sample. These sampling technologies include a variety of relatively inexpensive "direct-push" and percussion-type samplers. Direct-push technologies include cone-penetrometer testing (CPT) equipment, Shelby tubes, and pitcher barrels. While somewhat more costly than Shelby tubes or pitcher barrels, CPT samplers have the distinct advantage of providing real time subsurface characterization data before sampling with a variety of direct-push probes including gamma radiation, resistivity, oxidation reduction potential, seismic (with an external source), fluorescence, pore pressure, and tip or sleeve stress. Many of these probes, including the resistivity and tip/sleeve stress probes, can give detailed and highly accurate depictions of subsurface stratigraphy and thus facilitate selection of sampling points. CPT technology also allows for collection of both sediment/soil samples and groundwater samples. Sediment or soil samples are typically up to 3.8 cm in diameter $\times$ 60 cm in length, and can be captured inside plastic liners to minimize exposure to contamination. CPT groundwater samples can be collected in discrete intervals through screened samplers. These samples are collected via a dual tubing system in which one tube purges the sample chamber with pressurized gas, forcing the sample to the surface through the second tube. By using inert gases to purge the sample chamber, this system can maintain low dissolved oxygen concentrations in groundwater samples.

Disadvantages of CPT sampling technology are that it is typically limited to depths of 20 to 40 m below ground surface in unconsolidated soils or sediments, though in ideal conditions it can potentially reach greater depths. It

is also relatively expensive, typically $1,500 to $2,500 per day, depending on the applications employed, and most systems are operated from inside a 50-ton truck that can potentially restrict access to sites with limited space or difficult terrain.

Shelby tubes and pitcher barrels are usually conveyed on drill rods through hollow-stem augers. The borehole is first advanced to the sampling depth by adding sections, or "flights," of augers with a retrievable insert sealing the inside of the bottom auger flight. After augering to sample depth, the insert is retrieved and the Shelby tube or pitcher barrel is conveyed down the inside of the hollow augers to the exposed sample point at the bottom of the borehole. There, the samplers are pushed into the sediment by continuous pressure on the drill-string. After the sample is retrieved and the insert reinstalled, the augers can be advanced to the next sample point. Advantages of the Shelby tube and pitcher barrel sampling systems include their larger sample size, which is typically on the order of 0.6 m in length and a minimum of 5.0 cm in diameter, and the fact that the auger flights keep the borehole open as the sample is freely retrieved. These systems are readily available through most commercial drilling companies, and are somewhat less expensive than CPT technologies, with costs in the range of $1,000 to $1,500 per day. Auger rigs can also reach depths of up to 100 m under optimum conditions. Small auger rigs can be mounted on the back of all-terrain vehicles, but most are truck-mounted.

Another readily available and relatively inexpensive sampling technology that is also used in conjunction with hollow-stem augers or cable-tool drilling rigs is the split-spoon sampler. Instead of direct pressure on the drill-string, split-spoon samplers are driven into the sample interval by blows from a rig-powered weight or "hammer" at the top of the drill-string. Once the sampler is retrieved at the surface, both ends are removed, and the two halves of the sampler are laid open to expose the sample, which may or may not be contained inside a liner. Split-spoon samplers are more robust than Shelby tubes or pitcher barrels, and because they are driven into the sample horizon by hammer blows, they are capable of collecting samples from more compacted or dense samples. Split-spoon sample sizes are typically 60-cm long $\times$ 7.6 cm in diameter, though thick-walled split-spoons of 10-cm diameter have been used to collect microbiological samples (23).

Piston samplers have been designed to collect several kilograms of samples from unconsolidated saturated flowing sands (24). These samplers comprise a hollow sample barrel with an inner piston. As the sampler is advanced into the sample interval at the bottom of the borehole, the piston slides up the sample barrel and creates a vacuum that holds the sample in place as the sampler is retrieved at the surface. Piston samplers can be used with larger auger rigs as well as rotary drill rigs, but work well only in sand-sized unconsolidated materials with little or no gravel or cobble-sized materials.

A Geoprobe rig is a combination direct-push and percussion-type sampling technology that simultaneously pushes and hydraulically hammers a sample probe into the sample zone. Geoprobes can be mounted on small trucks or all-terrain vehicles, and are capable of collecting sediment samples that range from 61 cm $\times$ 3.2 cm to 1.2 m $\times$ 3.8 cm. They also have the ability to drive water samplers or piezometers. Geoprobe rates are typically in the $1,000 to $1,500 per day range, so are relatively inexpensive. However, they are generally limited to a maximum depth range of approximately 35 m below ground surface, although some larger models may penetrate more than 50 m in unconsolidated media.

Vibration or "vibra-coring" technologies also offer highly effective methods by which larger volumes of sample can be collected in unconsolidated sediments. Portable vibra-coring equipment that can be transported by a two-person crew is capable of collecting 1.8-m long $\times$ 7.6 cm diameter cores in liners. The vibrating head for these systems is attached to the outer casing that is then vibrated into the sediment. The casing is then retrieved with a manual "come-along" attached to an overhead tripod, and the inner liner is removed and capped. Vibra-core systems are economical at less than $1,000 per day, but they are not as commonplace as many of the other technologies that have been described, and they are limited to depths of 3 to 10 m in most soils or sediments.

The most sophisticated drilling technology that doesn't require circulation fluids is sonic drilling. A resonant sonic drilling head with counter oscillating roller bearings that oscillate at high velocities powers a sonic drilling rig, instead of simply vibrating through soil or sediment. This motion creates centrifugal force that translates into high frequency waves that deliver forces in excess of 280,000 foot-pounds down the drill-string (25). Sonic rigs are effective in unconsolidated sediments, semiconsolidated sediments, consolidated but friable sediments, course gravels, and even semi-indurated rock. Under optimum conditions, rotosonic drilling can advance through subsurface lithologies at rates up to several feet per second. This technology is capable of collecting core samples up to 3-m long and 8.9 to 20 cm in diameter, including 8.9-cm diameter cores in plastic liners. It can also be used to collect samples from angled boreholes. Sample quality is high, and sonic rigs have been used frequently in subsurface microbiological sampling programs (11). They are, however, relatively costly at rates of $3,500 to $4,000 per day, and they are typically limited to depths between 120 and 150 m, though a depth of 213 m was reached under optimum conditions (25). The dual-wall drill-string system allows downhole equipment to be conveyed where needed, such as packer systems that can isolate discrete water bearing intervals for sample collection. The vibration associated with sonic and vibratory drilling rigs has an as-yet unquantified impact on microbial communities. Possible effects include stimulation and redistribution of microbial communities; effects that are not thought to be significant, provided analyses are performed in a timely manner (see Section on Processing of Samples).

Shallow sampling, on the order of tens of meters, can be conducted with horizontal drilling technology, as well as in cases where restricted access might dictate horizontal or angled drilling. Samples are usually small, on the order of 5 $\times$ 30 cm, but these technologies require circulation fluids for their operation. Although not common, they are

nonetheless available from commercial horizontal drilling firms, at costs in the range of $1,000 per day or less.

Deep Sampling Technologies

Collecting samples from depths of several hundreds to thousands of meters requires that fluid media be circulated through the drill-string, and between the drill-string/borehole wall annulus (26). These circulating fluids serve different purposes, including cooling and lubricating the drilling assembly at the bottom of the hole, and preventing formation fluids under lithostatic pressure from flowing into the borehole. Their primary function, however, is to circulate rock fragments and dust, commonly referred to as "cuttings," from the bottom of the hole to the surface, thus keeping the borehole open. Circulation fluids vary in viscosity and include air, foam, water, and bentonite-based drilling "mud." The choice of which drilling fluid to use depends on a number of factors, including borehole wall stability, borehole depth, potential for formation fluid flow, and degree of induration. In highly indurated lithologies that maintain a stable borehole wall, low viscosity media, such as air or foam can be used, although higher viscosity fluids may be preferable for cooling the drill bit. As formations become more friable or exhibit a tendency to expand into the borehole, it may become necessary to use higher viscosity and higher density fluids or drilling "muds," which have a higher hydrostatic pressure in the borehole, and that build a dense "mud-cake" on the borehole wall. Boreholes of several hundreds to thousands of meters depth always require higher viscosity circulation fluids, since air loses both velocity and "carrying capacity" as it travels greater distances up the borehole annulus. Unfortunately for microbiological sampling, this fluid can serve as a source and incubator for microorganisms both from the surface and from shallower formations, particularly when fluid additives provide nutrient and energy sources. Similarly, fluids can alter geochemistry by adding, reacting with, or transporting contaminants throughout the borehole volume. Circulation fluids can also contaminate the sample zone at the bottom of the hole ahead of the sampling device, as well as during sample retrieval to the surface (1,2).

Fundamental research programs have employed more exotic and costly inert drilling fluids in order to minimize potential contamination by suspended microorganisms. Researchers at the Idaho National Engineering and Environmental Laboratory in Idaho Falls, ID used an air rotary rig to advance a borehole through interbedded basalt flows and sediment facies (27). Approximately three meters above each sample target, the circulating air was changed to 99.9% pure vaporized liquid Ar, to prevent the core sample from coming in contact with suspended allochthonous aerobic microorganisms. A research program operated by Pacific Northwest National Laboratory (Richland, Washington) attempted a similar approach at a research site in New Mexico, with liquid nitrogen flushed through an expansion unit before being circulated downhole. In the vast majority of situations, properly employed QA protocols and carefully selected sampling technologies, that are well suited to the subsurface geology are as effective, if not more effective, than these approaches at minimizing sample exposure to contamination and maximizing sample quality.

Sampling tools vary considerably for deeper sampling horizons. Both the programs described earlier employed a highly versatile sampling tool known as a core-punch, or "C-P" wire line coring assembly. Most sample core barrels are conveyed to the bottom of the borehole on the end of the drill-string, thus requiring the time-consuming and costly tasks of removing or "tripping" the drill-string out of the borehole, and then tripping back in, each time a core is collected. In contrast, a wire line core assembly can be quickly conveyed down the hollow center of the drillpipe on a wire line, and is locked in place inside the bottom-hole assembly. In soft friable sediments, the bottom "shoe" of the wire line coring assembly can extend beyond the drill bit into the sample zone, to minimize contact between the sample and the drilling fluids circulating through the drill bit. After the core has been collected, an "overlatch" mechanism is sent down the inside of the drill-string, on a wire line, that releases the locking mechanism and retrieves the sample. C-P core samples are 8.4 cm in diameter and 1.5-m long, and they are contained inside either stainless steel split core barrels or clear polycarbonate liners. Samples can be collected from depths of several hundred meters, and costs are typically in the range of $1,500 to $2,500 per day for the rig, equipment, and crew. Costs increase dramatically with multitruck operations. These sampling systems are provided by commercial drilling companies, and can be employed in conjunction with most circulation media. Wire line coring systems have been employed in a number of microbiological research programs, where rigorous quality control protocols were employed (3,4,7,27,28, and Fig. 1).

Deep sampling at hundreds to thousands of meters typically requires extremely large and costly drilling rigs (29), unless access to the formation is available via tunnels or mine adits. Investigators at the Nevada Test Site collected samples from tunnel faces that had been exposed by tunneling equipment, at depths from 50 to 450 meters (5,15,30,31). A comparison of samples collected from freshly exposed consecutive tunnel faces, and 4.7 cm $\times$ 75 cm cores drilled into each of the tunnel faces indicated, that contamination levels in the cores were higher due to the circulation fluid. Yet, the abundance, diversity, distribution, and distinct colony types were similar (5). However, opportunities to collect fresh sediment or rock samples from great depths by means other than drilling are relatively rare.

Drilling rigs that can reach depths of thousands of meters are of a scale in size that is typically found in the mineral exploration industry, with costs that can reach tens of thousands of dollars per day. As a result, sampling is generally done in partnership with mineral exploration ventures. Coring tools conveyed on the end of the drill-string can collect very large core samples on the scale of 15 cm $\times$ 10 m, and can core in highly consolidated or indurated rock. Many petroleum service companies offer coring technologies that can protect the core from fluid loss and exposure to drilling fluids by sealing the core in flexible membranes or gel coatings, and they can also maintain

Figure 1. A typical truck mounted, rotary wireline coring rig operating at the Shiprock, NM uranium mill tailings site. At the time of the photograph, the rig was being used for installation and operation of straddle packers for conducting stress tests, for estimating in situ permeability of Mancos Shale, underlying the permeable terrace gravels. Samples for microbiology were obtained from both alluvial gravel deposits and Mancos Shale. See color insert.

cores at the same lithostatic pressure, as that, from which they were collected. Such systems are designed to preserve petroleum contents of oil or gas reservoir rocks, and have been only rarely applied to microbiological sampling.

In addition to drill-string conveyed coring tools, petroleum service companies offer wire line conveyed coring tools that collect multiple small samples in the range of 6×2 cm from the borehole walls. These coring tools include rotary sidewall coring tools that are comprised of small-scale, hollow, rotary coring drill bits, which rotate 90 degrees from the suspended coring tool and core into the borehole wall. The bit and sample are then backed away from the borehole wall, and the bit rotates down into the suspended coring tool and the core is extruded into a holding chamber. Percussion sidewall cores are fired into more friable sample targets by a small explosive charge. The core "bullet" is attached to the core "gun" by a cable, and the sample is extracted as the gun is retrieved up the borehole. Unfortunately, samples collected by these methods can be highly contaminated, due to the fact that they are not protected from exposure to the circulation fluids. This is particularly true of percussion sidewall cores, which can fracture samples on impact. Nonetheless, these technologies were used successfully to collect microbiological samples from 2,630 m to 2,801 m below ground surface, in the Taylorsville Triassic Basin of Virginia (10,14,19).

Groundwater Sampling

Groundwater samples obtained from existing wells provide a relatively inexpensive means of interrogating the subsurface microbial community. The principal limitation of groundwater microbiology is that free-living microorganisms are primarily sampled, plus an unknown number of attached microbes are detached during groundwater extraction. Methods for extracting groundwater samples include bailers, suction systems, or pumps. Examples of pumps include peristaltic, positive displacement, bladder, inertial, or submersible pumps. Depth to the water table, flow rate desired, volumes required, and tests to be performed are major determinants of the water extraction system employed. Monitoring well construction involves placement of a screened zone at a depth that permits water to flow into the well, and at the same time prevents collapse of the borehole. Well construction also typically includes a sand pack to ensure that the well screen does not clog with fines. A sand pack is, sometimes, not used to eliminate the addition of foreign material to the subsurface. Screened zones vary in length from a fraction of a meter to several tens of meters or more. Conventional practice for monitoring wells is to minimize screen thickness (1 to 3 m) and place screens at multiple depths, if it is necessary to detect differences in target analytes as a function of depth. Because of the cost and low spatial resolution of this approach, a variety of systems have been developed for obtaining groundwater samples from specific depths within a well, including tubing-conveyed sampling probes and screens, dual or multiple packer systems, active multilevel sampler systems (e.g., Westbay), passive multilevel samplers (32,33), and inflatable sleeves with attached sampling ports. CPT technologies also permit groundwater sampling of discrete intervals during insertion of the penetrometer (see section on shallow sampling technologies).

Tradeoffs exist among these various approaches between high spatial resolution and available sample volume. For example, passive multilevel samplers (Fig. 2) have a maximum vertical spatial resolution of approximately 6 cm, but a sample volume of approximately 40 ml. At the other end of the spectrum, a 2-m screen zone in a permeable formation could produce a very large sample of 2,000 liters in a few to several hours of pumping, but the associated spatial resolution is on the order of several meters. Given the typical subsurface porosity of 15 to 30%, there is no way around this trade-off. It is tempting to assume that longer pumping times from closely spaced, down-well sampling ports will provide a large volume while maintaining a high spatial resolution. However, this is simply not the case because, as pumping proceeds, a larger and larger volume of the subsurface is sampled, both in a vertical and horizontal direction. Even in the case of the passive multilevel sampler, the actual horizontal resolution may be very large because the sampler integrates groundwater flow over a period of days to

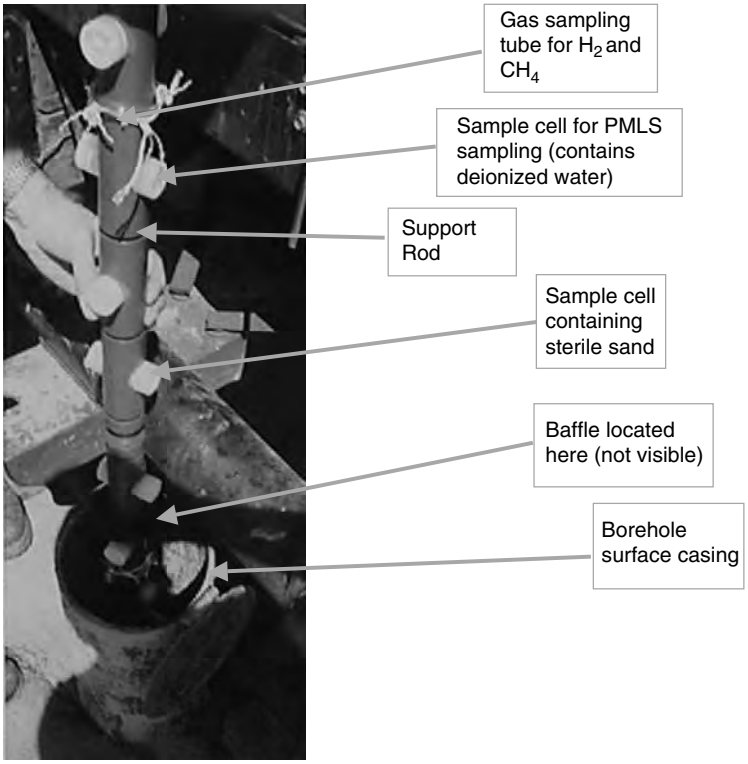

Figure 2. Photograph of the PMLS being inserted into a borehole. See color insert.

weeks. Regardless of the method used, care must also be taken to ensure that vertical flow or cross-connections are not smearing the microbial or geochemical signal in the groundwater sample.

The environmental conditions within and adjacent to a well may differ dramatically, from those in aquifers and subsurface formations. Consequently, it is imperative to purge water in and adjacent to the well bore before collecting samples for microbiological or geochemical analyses. Geochemical and microbiological properties of water associated with the well, reflect impacts from the well casing and installation materials, as well as altered permeabilities from installation procedures. Biofilms accumulate on well casings, well screens, and proximal subsurface materials. Biofilms and associated biogeochemical precipitates will detach with pumping, particularly at elevated pumping velocities. Ideally, three to seven well volumes should be purged before sampling. Monitoring of the pH, Eh, and turbidity of pumped waters can be utilized to determine when native formation water is discharged, as all monitored parameters become stabilized (34). Stabilization of the monitored parameters often occurs within three purge volumes, thereby eliminating excessive purging. Purging at too high of a velocity can compromise water quality by increasing turbidity of the water, altering concentrations of dissolved constituents, dewatering of pores, or drawing water from lower permeability areas of the screened zone (34). In addition, overpumping of relatively low permeability wells can result in lowering the water level in the well bore, below the water table in the surrounding formation. This causes cascading in the well, which among other effects noted earlier, will increase the dissolved oxygen in the sample. Accordingly, overpumping can alter both microbiological and chemical constituents of groundwaters.

Mined openings are an underutilized source of groundwater for environmental microbiological research. Pedersen has extensively studied groundwater from mined openings used for examining the feasibility of disposal of high level radioactive waste (35,36). Similarly, gold mines in South Africa have provided groundwater for microbiological studies (37). However, there are a very large number of mines worldwide where groundwaters have not been sampled for microbiological characterization. Care is required when sampling in such environments to avoid the effects of introduced oxygen such as acid mine drainage (unless, that is the objective of the study). Sampling flows that are isolated and have a sufficient flow rate to not be impacted by back-diffusion of oxygen are required to obtain samples that are representative of undisturbed (pre-mining) conditions (36).

When collecting groundwater samples for biogeochemical analyses, it is particularly important to use inert materials that can be autoclaved. If items cannot be autoclaved, disinfection is an option. For example, maintaining chlorine residuals for several hours, before and after use, provides effective disinfection. Collection of groundwater samples can be relatively straightforward. The simplest and most widely used approach, flushes and fills clean sterile glass bottles from tubing exiting the groundwater recovery system. Overflowing the bottles with continued flushing helps eliminate air in the bottle headspace. Flushing three volumes of water (after well purging) and removing air bubbles reduces oxidation of redox-sensitive constituents, and facilitates recovery of strict anaerobic

microorganisms. When using peristaltic, submersible, or suction pumps, care should be taken to eliminate air exposure resulting from pump cavitation or overpumping. These procedures are applicable for recovering bacteria, protozoa, or viruses (38).

Microbial concentrations in groundwater are typically between 10^3 and 10^5 cells per ml (20,39), so it may be desirable to concentrate the biomass for many analyses. Stevens and coworkers (39) used a sand-packed cartridge connected in-line to the water delivery system when selecting for bacteria that could attach to sand. Pedersen and Ekendahl (35) used cleansed slides in biofilm reactors to study microbial communities in deep bedrock. Kuwabara and Harvey (40) used hollow-fiber tangential-flow filtration to concentrate bacteria from groundwater for microscopic enumeration and lipid analyses. Fry and coworkers (41) also used hollow-fiber filtration to concentrate groundwater bacteria for nucleic acid probe and sequence analyses. Bacterial recovery efficiencies of greater than 90% can be achieved with hollow-fiber filtration, with somewhat less collection efficiency of smaller microorganisms. Importantly, tangential filters require effective disinfection and cleansing, before and after each use, to ensure bacteria are not entrained within the filter. Many of the available tangential filter systems can withstand repeated autoclaving while maintaining integrity of the filters even though the manufacturer may not recommend autoclaving. Filtration, using one to two liters of groundwater through Anodisc glass fiber filters, has also been successfully used for lipid and DNA analysis (22). One factor to consider in filtration is the sediment load in the groundwater. This is sometimes difficult to quantify, but is critical because sediment particles contribute to the total bacterial content of the sample. Samples that have apparently higher biomass may also contain higher sediment loading. Monitoring wells and other groundwater sources commonly vary a great deal in terms of the sediments they produce, depending on well construction, formation sediment or rock characteristics, and pumping rates.

QUALITY ASSURANCE

Sources of microbial and chemical contaminants that may compromise and adversely impact the quality of recovered subsurface materials include drilling fluids, groundwater-sediment slurry in the borehole, slough from overlying formations, and borehole sidewall materials. Contamination may occur before, during, and after coring and sampling operations. The most noticeable and common form of contamination associated with sediment or rock sampling is the intrusion of drilling fluids. Large numbers of bacteria and solute contaminants alter sediment and groundwater chemistry, as well as observed biogeochemical processes. Drilling fluid contamination also impacts sediment biogeochemical properties by altering pH, redox, and nutrient concentrations. Oxidation of sediments while drilling with air or gaseous drilling fluids is particularly problematic. The incorporation of multiple conservative tracers to mimic impacts of contaminants enables one to measure and quantify the extent of potential contamination, and then to evaluate sample integrity and quality. The discussion below focuses on tracers used to evaluate microbiological or geochemical contamination of cored subsurface materials.

Microbiological Tracers

(See TRACERS IN GROUNDWATER: USE OF MICROORGANISMS AND MICROSPHERES, this Encyclopedia)

"Serendipitous" bacterial tracers, representing microorganisms present and/or growing in drilling fluids can be present in high concentrations. Serendipitous histogical tracers observed in previrous projects includes *Gluconobacter* (42) or coliforms (43). Fluorescent microspheres are routinely used as bacterial surrogates. Microspheres are available in a range of bacterial-sized latex beads containing different fluors and charges. Microspheres are readily quantified using epiflorescence microscopy or flow cytometry. Some sediment/rock samples do contain materials that fluoresce at the same excitation wavelength as charged carboxylated latex 1-μm. YG microspheres are routinely employed as surrogate bacterial tracers during coring operations (28,44,45). Microspheres are typically deployed at/or near the interface between the coring tool and the formation by placing several ml of a concentrated solution containing $\sim 10^{10}$ microspheres in a Whirlpak bag, sometimes in concert with chemical tracers. The wire closures of the Whirlpak bag may then be wrapped around the base of a core catcher in the shoe of a coring tool. As cored materials enter the shoe of the coring tool, the bag ruptures, releasing the microspheres to be dispersed in and around the core. Intrusion of the microspheres into centermost portions of the core indicates a potential for coparticulates. Another approach for introducing biological and dissolved tracers is to add them to an aqueous solution that is placed inside the core-barrel liner.

Other approaches to estimate the level and extent of contamination include comparative biological analyses of core samples and drilling fluids. These analyses can include membrane lipid profiles, molecular-based probes for amplifiable extracted nucleic acid analyses, 16S rRNA sequencing (46), comparisons of clone libraries, and community level physiological profiles (19). Such community level measures can detect gross contamination, but may be ineffective for detecting low-level microbial or particulate contamination. Analyses of individual microbial isolates can also contribute to assessing sample integrity on a qualitative basis by comparing biochemical profiles, lipid profiles, or genetic fingerprinting between sample and drilling fluid isolates. Comparative approaches require caution because the microbiota of the contaminant source may be indigenous to the sampled subsurface (i.e., enriched in the drilling fluids during site operations).

Table 1 compares results gleaned by analyzing subsurface sediments independent of any tracer analyses. Accordingly, results may be compared to historical data sets to see if results derived from recent materials are representative of previous efforts. In Table 1, results from analyzing sediments obtained from 3–18 m depth of a semiarid U.S. site (designated site Z) are compared to

Table 1. Use of Historical Data as an Independent Indicator of Potential Issues Regarding Recovered Subsurface Materials*

Site Name and Description	Number of Sample Examined	Average Biomass (pmol/g)	Biomass Range (pmol/g)	Average Number of PLFA Quantified	Percent Samples with Branched PLFA	Percent with 2 to 10% Polyenoic PLFA	Percent with 10 to 50% Polyenoic PLFA	Percent with >50% Polyenoic PLFA

Site Z samples of low biomass (3–30 pmol/g) without branched PLFA (eukaryote dominated)	16	12	3–27	6	0	0	19	81

*Summary of data from several sites examined over the past decade. The Hanford sediments were similar to site Z in that they are from semiarid low-biomass sites. All samples compared were from three m or greater depth, to insure they were below the soil root zone and contained three or more pmol of phospholipid fatty acid (PLFA)/g of sediment, to insure that the PLFA biomass was at least threefold above detection limits. Each profile used in this comparison also contained five or more individual PLFA, so as to indicate a minimal level of diversity characteristic of membrane lipids of microbial communities.

other analyses from the past decade. The three comparative data sets obtained from the U.S. Department of Energy lands near Hanford, Washington, are also from a semiarid climate. The Oak Ridge National Laboratory site in eastern Tennessee and the Taylorsville Triassic Basin site in Virginia represent other data sets exhibiting relatively low phospholipid biomass.

Samples within the compared data sets typically exhibited less than 50 pmol phospholipid fatty acids (PLFA)/g, which is indicative of communities corresponding to less than 10^6 microorganisms per gram of sediment. For comparative purposes only, those samples beneath the soil root zone (deeper than three m below land surface), and those samples containing three or more pmol PLFA/g (threefold greater than detection limits) were scrutinized. Interestingly, each of the selected samples exhibited five or more PLFA's, indicating diversity characteristic of microbial communities. The average PLFA concentration within a grouping ranged from 8–48 pmol PLFA/g. The average number of individual PLFA's quantified from each site ranged from 10-31, with site Z appearing to fit well within expected ranges.

Upon closer scrutiny the PLFA from Site Z appeared distinct for the other data sets, in that, less than half of the samples revealed branched fatty acids, typical components of many bacterial members Half of the samples from Site Z contained more than 50 mol% of polyenoic fatty acids typical of eukaryotes, such as fungi and the dominance of polyenoic fatty acids appeared in samples with lower levels of PLFA indicative of lower biomass in those samples. Two subsets of lower biomass samples (less than 30 pmol PLFA/g) from site Z samples were further scrutinized based on the presence of absence of branched fatty acids. Branched fatty acids are not required in many bacteria, but evidence of branched PLFA is typically observed in bacterial communities. In contrast, polyenoic membrane components are indicative of eukaryotes with the polyunsaturated 18-carbon fatty acid, 18 : 2w6 being typical of fungi. The subset of Site Z samples that contained branched PLFA appears somewhat typical of subsurface samples, in that, samples containing >10 pmol PLFA/g typically exhibit more than 10 PLFA's including branched PLFA's. Somewhat atypical was the observance that 83% of the samples exhibited significant percentages (>10%) of polyunsaturated PLFA. While many samples from a myriad of sites revealed polyenoic PLFA's greater than 10 mol%, and several samples exhibit insignificant polyenoics of less than 2 mol%.

The site Z subset containing detectable (3 or more pmol PLFA/g of sediment) but low biomass less than 30 pmol PLFA/g that did not show evidence of branched fatty acids consists of 12 samples with an average biomass typical of the other sets presented in in Table 1. It is obvious that the number of PLFA represented in this subset is unusually low, and all of the samples within that subset exhibited between five and seven PLFA's, indicating very little diversity. More importantly, each of the samples exhibited high levels of polyunsaturated PLFA's. Unlike any sediment samples previously analyzed, 13 of the 16 sample subset exhibited >50 mol% of polyenoic PLFA's. The remainder of the PLFA's included straight-chain saturated PLFA's and the 18 : 1w7cis fatty acid, which is a precursor to a common fungal lipid fatty acid, 18 : 2w6. Interestingly, the observed PLFA patterns are typical of fungi and other eukaryotes, but are atypical of subsurface sediments from other sites.

While one should not conclude that there was overgrowth of fungi in the samples recovered from Site Z, one should evaluate the PLFA and other sources of available information within the context of sample storage times/conditions, previous experience, and other lines of evidence from the investigation. Based on the evidence in Table 1, one should conclude that samples from Site Z require detailed scrutiny and comprehensive examination before they are considered representative of the subsurface environment from which they were derived. While it is possible that Site Z represents a unique and novel subsurface community, it may also be hypothesized that post-sampling activities adversely impacted sample quality, enabling atypical microorganisms to proliferate over time. By examining tracer information, drilling and sampling procedures, postsampling processing and storage activities, procedural QA/QC and blank tests, sediment and groundwater geochemistry, and handling and shipping processes, investigators can develop multiple lines of evidence providing explanations of observed phenomena; be it representative of native subsurface materials or resulting from postcoring alterations.

Geochemical Tracers

Chemical tracers should be conservative, nonreactive, readily quantified, inexpensive, and easily distinguished from native materials. Rhodamine and fluorescein dyes (2,47) have often been used to trace drilling fluids because their fluorescence is easily detected at low concentrations in the field. Fluorescent dyes do tend to adsorb to bentonite drilling muds, and are typically sensitive to oxidizing agents and pH. Bromide is routinely used as a nonreactive solute tracer because it is normally present at low concentration in groundwater, has low toxicity, and can be measured in the field using an ion-specific electrode. Potassium has also been used as an ionic tracer, but potassium sorbs to clays in the drilling fluids, and can be present at high background concentrations in some groundwaters. Sulfate can be used as an anionic tracer, but sulfate is biologically reactive under anaerobic conditions (i.e., sulfate reduction), and is present naturally and as a contaminant at many sites. Inert perfluorocarbon compounds have recently gained favor as inert chemical tracers; added either as gaseous or aqueous tracers. Despite their limited solubility in aqueous solutions, perfluorocarbons can be detected at extremely low concentrations by gas chromatography with electron-capture detection (48,49). Different perfluorocarbons such as perfluorohexane and perfluoromethylcyclohexane can be used at different intervals in the same borehole as a check on the potential for contamination from the previous core run (48). Perfluorocarbons are quite volatile so precautions should be taken whenever samples are processed in an enclosed space, such as a glove bag to prevent volatilization from, and cross-contamination of, samples. Solute tracers such as bromide can be used to trace the

intrusion of borehole slurry into cores. Bromide or other solute tracers as well as microbiological or inorganic particulate tracers can be prepared as a concentrated solution and added to the borehole using a bailer, placed into whirlpak bags for dispersal at the bit-sediment interface, or added to the drilling fluids. For example, ionic salt solutions or perfluorcarbons may be added directly to the mud tank during making of the drilling muds. In the case of ionic salts, a concentration of 100 to 500 mg per liter may be maintained in the circulating drilling muds throughout the drilling operations. In the case of perfluorcarbons, a standing concentration of a mg per liter may be sufficient for detection at a dilution of a millionfold. Alternatively, perfluorcarbons can be metered directly into drilling fluids via an HPLC pump minutes before coring, so that the tracer-containing fluids are uniform throughout the corehole before sampling. Metered and staged tracer additions are particularly useful in the subseafloor coring, where drilling fluids are for single use and not recirculated, and where constant addition over weeks of operations would be cost prohibitive.

State, local, and site regulatory agencies must be consulted before the introduction of microbiological or chemical tracers to subsurface environments. However, the advantages of a thorough tracer regimen cannot be overstated. Even when sampling the vadose zone, contamination from particulates may fall into the borehole from overlying sediments, from surface soil, or from corehole sidewall slough. Contaminating particulates may also enter with the drilling tools. A dry tracer mix consisting of glass beads (used as an inert carrier), fluorescent microspheres as a microbial surrogate, and tungsten carbide particles as a chemical tracer was developed for use during cable-tool coring (50). This mixture was placed at the bottom of the borehole using a bailer before each sampling event. Rotary drilling methods employing recirculating aqueous drilling fluids exhibit the greatest potential for introducing contaminants into cores as compared to hollow-stem augering or/and cable-tool coring methods. Due to the thousands of liters of drilling fluids required for rotary drilling, it is not economical to mix fluorescent microspheres directly into drilling fluids. In contrast, chemical tracers can be introduced directly into the fluid. Because of regular losses of drill muds over time, and dilution with groundwater, it is necessary to monitor and periodically adjust the concentration of tracers in the muds.

SAMPLE PROCESSING

Processing Overview

Regardless of care taken in sample acquisition, inappropriate sample processing or shipping from the point of collection to the point of analysis will readily compromise analytical results and thus resulting interpretations. In this section, we discuss techniques used for processing samples that will increase the probability that samples will retain their representative character (see introduction). The need for performing analyses on representative samples imposes rigorous constraints that are difficult both to meet and to assess. Nonetheless, at minimum, it is appropriate to match processing protocols with project objectives to maximize the likelihood that data from analyzed samples, appropriately and consistently represent subsurface microbiology and geochemistry.

It is neither desirable nor possible to provide prescriptive protocols to cover even a limited range of sample processing. Rather, the objective of this section is to present the sampling processing techniques that have been employed, so project managers and researchers can quickly match available techniques to their requirements while gaining an understanding of potential benefits, costs, and limitations. It is our experience that there is considerable room for improvement in sample processing techniques. Unfortunately, sample processing, commonly, is given limited consideration and resources. Areas for future technique development and evaluation are therefore identified.

Sample processing takes samples as they are obtained from the sampling device (e.g., core barrel or groundwater pump line), and converts them into samples provided to specific researchers or analytical laboratories for analysis or experimentation. In some cases, this is a very simple process such as placing a groundwater sample into a container meeting particular requirements. In other cases, this is a complex process in which a core sample is systematically dismembered in a glove bag under an inert atmosphere such as Ar or N_2 gas (Fig. 3). In the case of complex processing, specific objectives for sample preservation should be defined and traded off against each other, and against cost to arrive at a specific sequence of events that best meets sampling objectives. There are few, if any, absolutes in establishing a workable protocol. For example, if assessing the anaerobic microbial community is an important objective, then processing samples under anaerobic conditions (usually an inert atmosphere) is a requirement. The questions are, how anaerobic and how inert? It is well established that Ar or N_2 atmospheres in glove bags are not totally oxygen free, suggesting the need for a H_2-CO (or similar redox couple) atmosphere to maintain a strictly anaerobic atmosphere. However, H_2 is an electron donor for hydrogen utilizers, including fungi, and this creates the potential for undesirable changes in community structure as a result of exposure to H_2. Typically, the trade-off is to accept some loss of the anaerobic community due to O_2 toxicity, in order to avoid the potential impacts of H_2 exposure. However, each project needs to assess these types of trade-offs. In some projects, it may be desirable to include a separate glove bag in which strict anaerobic conditions are maintained for processing a subset of the samples (Fig. 3).

Sample Processing and Shipping Sequence

The sequence of sampling processing and shipping typically includes the following steps:

- Transport of samples from sampling point to processing facility
- In-field processing steps and requirements (subsampling, preservation requirements, and methods)
- Sample Shipping

Each of these steps is discussed next.

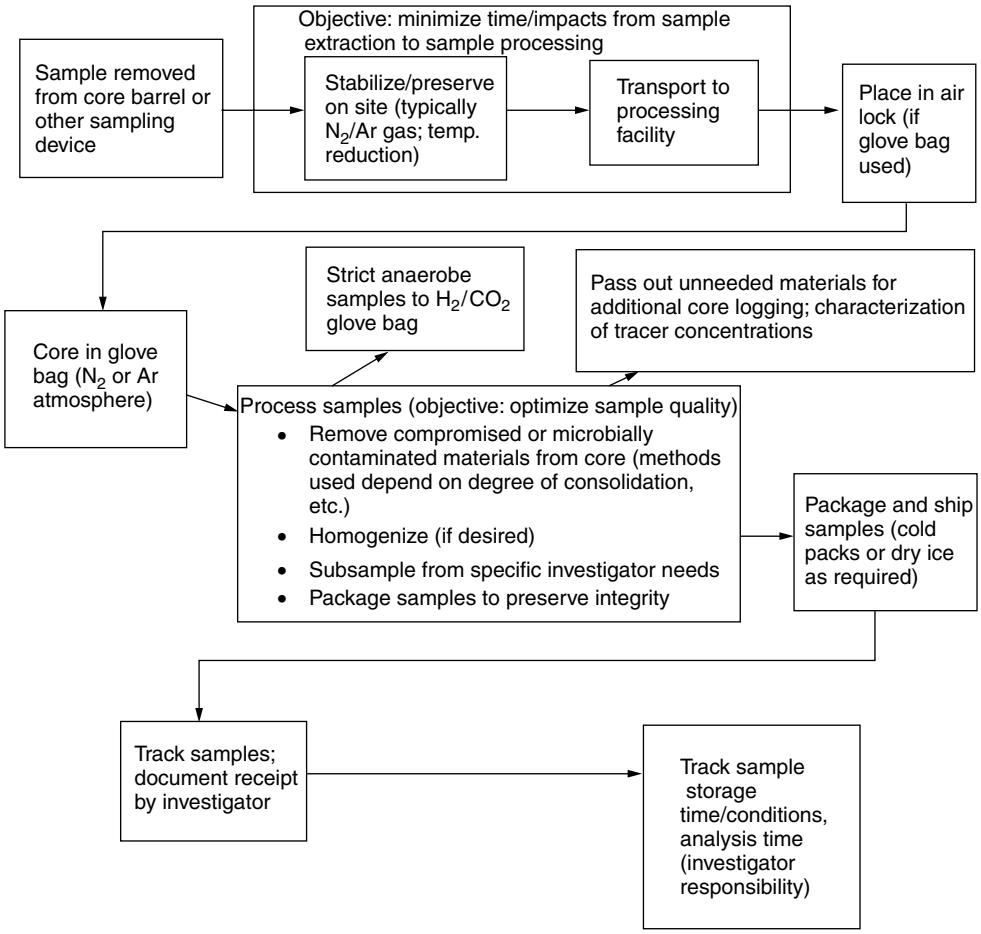

Figure 3. Typical core sample processing flow sheet.

Transport of Samples from Sampling Point to Processing Facility. Distance of the drilling rig, backhoe pit, wellhead, drill ship, or other point at which a sample is extracted from the subsurface may be a minimal or a significant distance from the point at which in-field processing occurs. It is highly desirable to minimize this distance and, for this reason, it is common to have one or more field processing trailers (or shipboard processing facilities) at a drill site to house glove bags and other on-site processing equipment. The objective here is to minimize the time involved in sample extraction, sample processing, and the initiation of analyses or experiment on those samples.

At the other end of the spectrum, entire core segments are preserved on-site by placing immediately in gas-tight PVC, flushing with an inert gas, and shipping to a laboratory for processing. This has the disadvantage of not permitting immediate preservation such as freezing (desirable for PLFA analyses and DNA extraction). Also, it extends the time between extraction from the subsurface and shipping of subsamples to individual investigators. The benefit is reduced cost of in-field processing, but it is necessary to make sure that this type of approach is consistent with the objectives of the sampling project. Some studies (51) have combined immediate emersion of samples in Ar and short transport of samples (two to five minutes) to an in-field processing facility. Future possibilities include controlling the well bore atmosphere or otherwise minimizing oxygen content from the time of sample extraction in the subsurface to the point of sample processing.

Another approach that minimizes field costs and transport time is to process samples in air but focus on immediate enclosure of samples in sterile containers with no headspace. While this is typically used with relatively inexpensive shallow sampling techniques (e.g., backhoe sampling) in relatively oxic environments, it has been shown that significant parts of anaerobic microbial communities survive this treatment. The keys to this and similar approaches that flush container headspace with Ar gas are rapid sample enclosure, maintenance of samples at near in situ temperatures, and same-day overnight shipping to ensure arrival at the receiving laboratory within 24 to 48 hours of sample collection.

To summarize, the objective is to minimize sample impact during transport from point of extraction to sample processing point. This is done mainly by minimizing time of transport, but also may involve controlling the atmosphere to which samples are exposed. This is linked closely to decisions on the degree of in-field processing. Few, if any, studies have systematically evaluated the effects of different approaches to this phase of sample collection, and we suspect that there is room for both assessment of and improvement to typical practice.

In-Field Processing Steps and Requirements. Sample processing should occur under an inert atmosphere to minimize chemical or biological alteration of sample materials. Exposure to air causes oxidation of reduced species such as Fe(II) and sulfides, inactivation of anaerobic and microaerophilic microorganisms, and drying of the sample. Stimulation of biological activities resulting from coring disturbances (38,50,52,53,54), is reduced by processing under inert, nutrient-limited conditions. Anaerobic chambers filled with argon or nitrogen gas, typically modified with a core transfer tube (Coy, Ann Arbor, MI) (4), are routinely used for sample processing (see 29 for pictures of glove bags and coring paring processes). Cores should be processed as soon as possible upon recovery to minimize perturbations, and to separate representative material from drilling fluids, slough, and contaminants. In practice, this means adjusting the number and size of glove bags to the maximum rate of core removal. Alternatively, it may be necessary to intentionally slow the rate of drilling and core removal, with an obvious increase in cost and the possibility of in well contamination of uncored samples if pressure head in the well exceeds the hydraulic head in the formation. On-site processing also provides opportunities for on-site evaluation of sample quality and allows opportunities for modifying site operations.

Core liners containing materials are placed into the transfer tube, which is then flushed and evacuated for three or more cycles with an inert gas to displace the oxygen within air. After three or more flush and evacuation cycles, materials are transferred to the processing chamber. Shorter and unconsolidated cores can often be extruded from core liners. Core liners may have to be scored or cut to retrieve tightly packed or consolidated materials. If liners require cutting, that may best be accomplished before their entering the transfer airlock. This creates greater exposure to oxygen but reduces processing time, because cutting core liners within processing chambers is difficult, slow, and may involve safety risks. Each project needs to assess the relative merit of each approach, committing necessary resources to ensure an effective and safe process. Upon exposure, cores can be examined and geologically logged and evaluated. If the core material appears disturbed, mixed, impacted with drilling fluid, or chemically compromised, the core is not suitable for microbiological or chemical analyses.

Removal of outer core material that has the greatest potential for being contaminated should be standard practice, especially for low-biomass subsurface materials. Drilling fluids are typically most concentrated at the ends and outermost edges of the core. These regions must be carefully pared with sterile tools. If a visible tracer such as rhodamine dye was used, the distance of penetration can be used as a guide for paring. Unconsolidated sediments are typically pared and subcored with sterile knives, spoons, spatulas, or chisels. Consolidated sediments or rocks may require use of chisels or hydraulic splitters to pare outer portions of a core from the innermost representative materials. Hydraulic core splitters can further be used to subsample pared sections. Crushing in a sterilized Plattner mill or a hammer mill can further disaggregate materials. Between uses, the hydraulic splitters should be thoroughly disinfected, removing both particulates and fluids.

Subsamples of drilling fluids, outer portions of the core, and representative materials from inside the core should be collected and analyzed for tracers. Tracers as well as contamination will not be distributed evenly along a core, thus making it necessary to sample multiple fractions of edges, ends, parings, and innermost samples from different locations along the length of the core. All tracer samples should be preserved in sealed containers. Methanol should be added to all perfluorocarbon-containing tracer samples, as they are volatile. These core and paring samples should be compared to samples of drilling fluids, borehole slurries, materials from the coring shoes, samples from the processing chamber, and numerous blanks and controls. Rigorous subsampling and analysis of tracers, as well as scrutiny of comparative measures and geochemical modeling, permit quantification of the extent of contamination and evaluation of sample quality.

Before sample disbursement and transport, samples can be homogenized (if desired), segregated, transferred into sterile Whirlpak® bags, and placed into sealable canning jars. To minimize exposure of samples to air during transport, jars should be flushed with oxygen-free nitrogen or argon gas via a cannula before sealing. This can be accomplished inside the anaerobic chamber. A novel approach for storing anaerobic samples during transport has been described by Cragg and coworkers (45) who used heat-sealable nylon-aluminum-polyethylene "wine bags." Subsamples can be placed in these bags with a commercially available O_2-absorbing system used for culturing anaerobic bacteria.

Sample Shipping. Sealed samples can be transported to laboratories or shipped by overnight express carrier, with cold packs to keep samples cool during transport. The inclusion of cold packs protects samples from elevated temperatures that can occur during transport. Analyses of macromolecules such as lipids and nucleic acids require that those samples be frozen immediately on-site using a standard $-20\,^{\circ}C$ freezer. Dry ice or liquid nitrogen can also be used. Samples must remain frozen during transport, enabling the preserved materials to be thawed and analyzed at a later time. Shipping containers are typically cardboard boxes lined with Styrofoam, but standard coolers also work well, especially for mason jars, which can be encased in foam and used repeatedly. Ideally, trial shipping runs are made with recording thermometers to ensure that samples remain at approximately $4\,^{\circ}C$ during shipping. It is important also to ensure that cold packs are not sufficiently cold and in direct contact with samples to actually freeze samples. This is a real possibility, especially during cooler times of the year, which also present the possibility of nighttime freezing of samples, if sample containers are left in vehicles overnight. For longer shipping times or extremely hot conditions, special shipping containers designed for maximum thermal performance are commercially available.

The importance of timely receipt and initiation of sample analysis cannot be overemphasized. If samples

are left on a hot loading dock for 24 hours after receipt or samples are not analyzed for days after receipt in spite of being stored under desired conditions, results will almost certainly be altered (17,52,53,55). Essentially, the entire investment in sample acquisition, processing, and shipping is placed at risk. Good communication between sample shipper and sample recipient is therefore essential. E-mailing or telephoning tracking numbers for each shipment to recipients serves to remind recipients of incoming packages and to enable them to track their own packages, if they fail to arrive as planned.

Quality Control for Sample Processing

Subsampling within a glove bag environment creates the possibility of cross-contamination from one sample to the next, and from compromised outer rinds of core samples to nominally pristine parts of core. Systematic evaluation of such contamination is rarely attempted. Anecdotal evidence suggests that indurated samples are more likely to be cross-contaminated than unconsolidated samples. This is attributed to creation of dust from splitting of solid samples within the glove bag. Placing sterile petri dishes in the glove bag during processing provides one indication of the level of dust contamination. Results from analysis of the petri dishes should be compared to those from analysis of core subsamples, to assess the proportion of the microbial community that could be attributed to in-glove-bag contamination. Additional particulate or coating tracers (including known microbial species) have been used with limited success. The concept is to coat the exterior of a core segment before processing. Detection of tracer in processed samples then provides a basis for estimating the effectiveness of the core paring and processing procedure. Cost, typically limits extensive use of this type of quality assurance procedure, suggesting that innovative approaches to this problem are needed.

FUTURE DEVELOPMENTS

Consistently collecting and analyzing the microbiology and associated geochemistry of subsurface samples is a difficult task that is clearly still in its infancy. There are major limitations on our understanding that derive from the limited data set on subsurface microbiology, and from limitations on our ability to more effectively collect and process subsurface samples. In this section, we discuss the most promising future developments.

1. Systematic Analysis of Sample Size and the Heterogeneous Distribution of Microbial Colonies from a Range of Rock Types and Subsurface Environments. A limited number of studies have attempted to assess in situ microbial heterogeneity, and even fewer have related microbial heterogeneity to sample size (56). A greater understanding of typical microbial heterogeneity in different rock types and subsurface environments would significantly improve our ability to estimate needed sample size in advance, to achieve a desired level of repeatability and uncertainty in resulting data. At the present, sampling sizes and requirements are largely driven by investigator needs for a given analytical technique. It is particularly important to note that homogenization alone is unlikely to address this problem because of both the difficulty in complete homogenization and because of unknown effects of homogenization on colony viability.

2. Use of Colonization Surfaces in Subsurface Environments. Placing colonization surfaces in the subsurface, usually in a well bore and allowing microbial populations to attach to the surfaces provides a microbial sample that is specific to depth and the microbial population present in the well bore and, to some unknown degree, the surrounding formation. Several approaches have been developed including the use of rock or mineral coupons, holders with sterile quartz sand or other granular materials, and collection of samples from the surfaces of devices placed in the well bore for other reasons. Techniques for systematically obtaining these samples and interpretation of microbial analyses of such samples are still under development (57), but, with appropriate control of groundwater circulation within the well bore and adjacent sand pack, this approach may yield a high spatial resolution.

3. More Effective, Partially Automated Hydraulic Paring Devices. Removal of contaminated outer rinds of core samples or other types of solid samples is commonly the rate-limiting step in sample processing. Therefore, it would be highly advantageous if this process could be accelerated, particularly for indurated samples such and shales and sandstones. Hydraulic paring devices are available, but they have not been adapted or optimized for use in a glove bag.

4. Rapid, Inexpensive, In-field Tracer Analyses. Field and sampling reality is that more tracers are deployed than are taken full advantage of in sample or paring analyses. At this point in the development of subsurface microbiology, there is a tendency to accept uncritically the results from subsurface samples, with or without tracers. Rapid and routine in-field analysis of particulate and chemical tracers is needed to make the cost of appropriate QA practices affordable.

5. Direct Linkage of Pore Water or Groundwater Geochemistry with Microbial Community Data on a Scale of a Few cm to a Few Tens of cm. Scale differences between bulk groundwater samples and individual microbial core samples are large, commonly exceeding an order of magnitude. New techniques are needed that will enable efficient linkage of pore water chemistry and microbiology on a fine scale. Combining passive multilevel samplers and microbial colonization surfaces offers considerable promise, but the degree to which formation microbial communities are reflected in well bore microbial communities is currently unknown. Research in this area is potentially difficult and expensive, but could yield very important advances.

6. Systematic Assessment of the Loss of Anaerobic Community Members as a Function of Limited Exposure to O_2 Under Field Conditions. Heterogeneity issues make it difficult to perform an assessment of anaerobic microbial community survival rates under varying concentration of O_2 (field conditions). Such an assessment is critical both to decision on processing protocols and interpretation of existing data.

7. Adaptation of Coiled Tubing Drilling Technology to Environmental and Subsurface Microbiological Sampling. The petroleum industry has developed drilling technology that uses coiled steel tubing and a steerable drilling head for drilling directional and multiple completion of oil production wells. New, compact designs that will provide improved control of drilling speed and direction, and minimization of drilling fluid impacts are under development (58). Adaptation of this technology to terrestrial environmental applications and exploration for life on mars is very attractive (59). For microbiological sampling, potential miniaturization of the drilling string and sampling devices is particularly advantageous, enabling collection of samples while drilling on a scale comparable to heterogeneities that commonly exist in sedimentary strata. A number of downhole sensors are under development, and that information could be directly associated with microbiological and geochemical samples obtained from a given depth (60).

Appropriate and effective sample collection and processing continues to be critical to the development of subsurface microbiology. Advances in the next 10 years will play a key role in advancing our understanding of the subsurface microbial world.

SULFATE-REDUCING BACTERIA: ENVIRONMENTAL AND TECHNOLOGICAL ASPECTS

LARRY L. BARTON
RICHARD M. PLUNKETT
University of New Mexico
Albuquerque, New Mexico

Sulfate-reducing bacteria (SRB) are a unique physiological group of prokaryotes that couple growth with sulfate respiration. Because of the production of high levels of sulfide by sulfate-reducing organisms, they are members of the sulfidogenic group that converts thiosulfate, sulfite, or elemental sulfur to hydrogen sulfide. The anaerobic electron flow with sulfate as the terminal electron acceptor occurs with several genera in both the *Bacteria* domain and the *Archaea* domain. General information about the biology of these anaerobic sulfate-reducing bacteria can be found in recent monographs (1–3).

Table 1. Reactions in the Dissimilatory Reduction of Sulfate by Microorganisms (4)

	Reaction	$\Delta G^{0'}$
(1)	$SO_4^{2-} + ATP + 2H^+ \rightleftharpoons APS + PP_i$ (Activation)	+46 kJ/mol
(2)	$APS + H_2 \rightarrow HSO_3^- + AMP + H^+$ (Reduction)	−68.6 kJ/mol
(3)	$HSO_3^- + 3H_2 \rightarrow HS^- + 3H_2O$ (Reduction)	−171.7 kJ/mol
(4)	$SO_4^{2-} + 4H_2 + H^+ \rightarrow HS^- + 4H_2O$ (Overall Reaction)	−152.2 kJ/mol

The energetics of sulfate reduction does not favor the use of this compound as an electron acceptor because sulfate must be activated by adenosine triphosphate (ATP) before it can be reduced. As shown in Table 1, the equivalent of two moles of ATP are used for every mole of sulfate activated. Following activation by ATP, there are two sequential reactions in the eight-electron reduction system. The use of sulfate as a terminal electron acceptor is referred to as *dissimilatory sulfate reduction*, which is in contrast to the reduction of sulfate for biosynthesis of amino acids, and is designated as *assimilatory sulfate reduction*. Dissimilatory sulfate reduction is the only electron acceptor system used by microorganisms in which energy is required for electron-accepting activity. Perhaps this unique energy requirement accounts for sulfate reduction being less widely distributed than nitrate reduction.

INVOLVEMENT OF SRB IN BIOGEOCHEMICAL CYCLES

In addition to sulfate reduction, these organisms participate in reactions involving portions of several important nutrient and element cycles. As indicated in Figure 1, SRB interact with various aspects of the global cycles of nitrogen and carbon. It is increasingly apparent that SRB have an influence on the environmental cycling of iron, manganese, selenium and molybdenum. In addition, SRB affect the geochemical cycling of chromium, uranium, and mercury.

Carbon

The most common carbon sources that support growth of SRB are lactate and pyruvate; however, utilization of these carbon compounds is not universal because there are a few isolates that are unable to grow with lactate or pyruvate. Generally, strains of *Desulfovibrio* (*D.*) and *Thermodesulfobacterium* oxidize lactate or pyruvate with the accumulation of acetate, whereas other SRB have complete oxidation with CO_2 as the end product (5). The

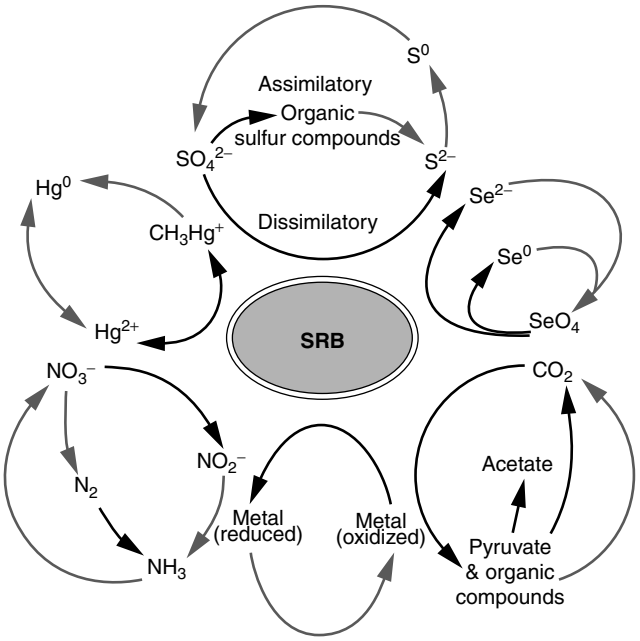

Figure 1. Interaction of SRB with geochemical cycles.

acetate-producing SRB may form syntrophic relationships with methanogens or other acetate-utilizing anaerobes. A number of SRB are autotrophic with growth on H_2 and CO_2 (5) and the metabolic pathways for CO_2 fixation have been well established (6).

The SRB have an extremely diverse metabolism in which about 100 different organic compounds will serve as electron donors resulting in growth. These carbon compounds include hydrocarbons, alcohols, monocarboxylic acids, dicarboxylic acids, amino acids, sugars, aromatic compounds, and complex organic compounds. The individual compounds and their utilization have been enumerated in previous reviews (5,6) and will not be listed here. Although there has been considerable interest in finding a sulfate-reducing bacterium that can oxidize methane, no pure cultures that have this feature have been obtained. Several strains of SRB can dismutate carbon compounds in the absence of sulfate where the organic compound is both the electron donor and acceptor. When the organic compound serves as an electron acceptor, it is an example of bacterial fermentation. With SRB, dismutation is seen with fumarate, malate, choline, and cysteine (5).

Several strains of SRB can metabolize recalcitrant compounds and these SRB have the potential for environmental remediation. Specific strains of SRB that detoxify organic compounds have been reviewed in considerable detail by Ensley and Suflita (7). Recent isolates of SRB will oxidize toluene (8), dehalogenate 2,4,6-tribromophenol (9), or reduce trinitrotoluene to triaminotoluene (10,11).

Sulfur

SRB can use a variety of sulfur oxy-anions in addition to sulfate for dissimilatory reduction. Although tetrathionate, trithionate, thiosulfate, and sulfite are reduced by SRB, these compounds do not accumulate in the environment, but are transiently formed because of SRB metabolism. *D. dismutans* and *Desulfobacter curvatus* can use sulfite and thiosulfate with one sulfur atom oxidized and one reduced. Recently it has been demonstrated that *Desulfobacter proprionicus* can disproportionate elemental sulfur (12). The disproportionation reactions are given in Table 2, and the electron-accepting activity of the sulfur atoms has been suggested to represent inorganic fermentation (13).

Table 2. Disproportionation of Sulfur Compounds Associated with SRB (13)

	Reaction	$\Delta G^{0'}$
(5)	$4SO_3^{2-} + H^+ \rightarrow 3SO_4^{2-} + HS^-$	−235.6 kJ/mol
(6)	$S_2O_3^{2-} + H_2O \rightarrow SO_4^{2-} + HS^- + H^+$	−21.9 kJ/mol
(7)	$4S + 4H_2O \rightarrow SO_4^{2-} + 3HS^- + 5H^+$	−56.2 kJ/mol*

*With SO_4^{2-} and HS^- at 1 mM and pH = 8.0.

The oxidation of sulfur compounds by SRB has only recently been considered important for their persistence in various environments. To accomplish the oxidation of reduced sulfur compounds, appropriate levels of molecular oxygen are required to function as the electron acceptor. Certain strains of *D. desulfuricans* will oxidize thiosulfate, sulfite, and hydrogen sulfide to sulfate with the reduction of oxygen (14). Growth will occur in these cells because coupled with the formation of sulfate is the production of ATP that is produced by the reverse of Reaction 1 in Table 1. Elemental sulfur is oxidized by *D. desulfuricans* to thiosulfate but not to sulfate. In a highly intriguing report, Dannenberg and coworkers (14) indicated that *D. proprionicus* oxidizes sulfide with NO_3^- or NO_2^- as the electron acceptor, resulting in the formation of NH_3. Certain strains of *D. desulfuricans* will oxidize sulfite and thiosulfate to elemental sulfur (S^0) with nitrite as the electron acceptor.

During oxygen limitation, *D. desulfuricans* establishes a syntrophic relationship with *Thiobacillus thioparus* (15). In this situation, *T. thioparus* produces S^0 and not sulfate as a product of sulfide oxidation. *D. desulfuricans* uses the S^0 as a dissimilatory electron acceptor with growth. Another mini-sulfur cycle occurs with the association of SRB with an anaerobic phototroph. As reviewed by Fauque (16) a stable syntrophic relationship is formed in which *Desulfovibrio* reduces sulfate to sulfide and the sulfide is oxidized to sulfate by *Chlorobium limicola*.

In addition to the use of inorganic sulfur compounds as electron acceptors, several strains of *Desulfovibrio* have been shown to use sulfonates (17). The sulfur atom in sulfonate was reduced to sulfide and the organic carbon fraction of the sulfonate molecule could serve as the electron donor. Not all sulfonates are utilized by the SRB, but those that are include isethionate (2-hydroxy-ethanesulfonate), cysteate (alanine-3-sulfonate), and sulfoacetaldehyde (acetylaldehyde-2-sulfonate). In a provocative report that examined SRB colonization in the gastrointestinal tract of mice, it was reported that SRB were most prevalent in those regions where sulfomucin

was abundant (18). Thus the sulfur atom of sulfomucin may also serve as the electron acceptor for SRB. Clearly, SRB are involved in many facets of the sulfur cycle and under appropriate environmental conditions many different sulfur compounds can be either electron acceptors or electron donors.

Nitrogen

Several strains of SRB will fix nitrogen (N) and grow with N_2 as the sole nitrogen source. Diazotrophy has been demonstrated by direct cultivation in N-free medium, by following $^{15}N_2$ incorporation, by measuring acetylene reduction, and by hybridization studies using the *nifH* gene from *Klebsiella pneumoniae* (19). Although the genes for N_2-fixation appear to be genomic and not plasmid-carried, many isolates do not have genes for N_2-fixation. The rates of N_2-fixation are sufficient to enable microorganisms to grow in N-limited environments; however, the impact of SRB on the global nitrogen cycle has not been thoroughly examined.

Some of the common strains of SRB can use nitrate in dissimilatory reduction. As reviewed by Moura and coworkers (20), the best-characterized system is that of *D. desulfuricans* ATCC 27774, which has a periplasmic nitrate reductase. Nitrite generated by the nitrate reductase is reduced to ammonia by a transmembrane nitrite reductase. The nitrite reductase in *D. gigas* will energize transmembrane transport of protons and establish sufficient proton motive force on the plasma membrane to generate ATP by anaerobic oxidative phosphorylation (21). This dissimilatory reduction of nitrite to ammonia is common in bacteria and may be widely distributed in SRB. Thus far SRB have not been demonstrated to produce N_2 from the reduction of nitrate.

Iron and Manganese

The reduction of iron and manganese also occurs with SRB, in part because of the copious production of H_2S. The potential for dissimilatory reduction of Mn(IV) and Fe(III) to be coupled with cell growth has been demonstrated with the growth of *Desulfotomaculum reducens* (22). An interaction of the sulfur and manganese cycles has been demonstrated with *D. desulfuricans*, which couples the oxidation of Mn(IV) with the reduction of S^0 (12). Iron sulfide is generally produced in the amorphous form; however, nanosized deposits of magnetic iron sulfide have been produced by SRB (23). It has also been reported that hematite (α-Fe_2O_3) dissolution can occur in the presence of *D. desulfuricans* owing to hydrogenase reduction and H_2S oxidation, resulting in ferrous sulfides in the form of pyrrhotite (24).

Selenium

Although some anaerobic bacteria can use selenate or selenite as an electron acceptor by growth-supporting respiration, this has not been demonstrated in SRB. Selenium is assimilated by SRB to produce a selenium-containing hydrogenase (5) and a formate dehydrogenase. Selenium is an essential trace element for SRB, but at high concentrations, selenium in the form of selenate, Se(VI), and selenite, Se(IV), are toxic to SRB. As previously reported (25), growth of *D. desulfuricans* is inhibited by Se(IV) at a lower concentration than by Se(VI), and resistance to Se(IV) and Se(VI) is achieved after previous exposure at sublethal concentrations. Selenate and selenite are structurally similar to sulfate and sulfite, respectively. Selenate inhibits Reaction 1 and selenite inhibits Reaction 3 in Table 1. Although the mechanism of reduction is not known, *D. desulfuricans*, and presumably numerous SRB, will reduce selenate or selenite to elemental selenium. Resistance and reduction of selenium oxy-anions are distinct mechanisms because the formation of Se^0 was not apparent with either Se(IV) or Se(VI) until *D. desulfuricans* entered the stationary phase (25).

Molybdenum

Molybdate has been commonly used to limit the growth of SRB by interfering with Reaction 1 shown in Table 1. However, molybdenum is also required by SRB for the various molybdoproteins that these organisms use (5). At sublethal concentrations of molybdate, several species of *Desulfovibrio* will reduce Mo(VI) molybdate to Mo(IV) with the production of molybdenum disulfide (26,27).

Uranium

The pursuit of SRB-mediated metabolism of metals was initiated with the report by Lovley and colleagues (28) demonstrating the conversion of soluble uranyl, as U(VI), to insoluble uranite, U(IV). Many strains of SRB can reduce U(VI) but currently only *Desulfovibrio* strain UFZ B490 (29) and *Desulfotomaculum reducens* (22) have been demonstrated to grow with dissimilatory uranium reduction. The mechanism for reduction of uranyl ion remains to be established.

Chromium

With the exception of *Desulfotomaculum*, SRB do not produce spores and, therefore, remain in the environment as a result of continuous growth. Overcoming metal toxicity is one of the apparent requirements for SRB to persist in the environment. Chromate, Cr(VI), and other strong oxidizing agents have been used to prevent bacterial growth in cooling towers. At sublethal concentrations, Cr(VI) is reduced by *D. vulgaris* to Cr(III) by a hydrogenase-cytochrome system (30). *Desulfotomaculum reducens* is one of the few SRB that can couple growth to dissimilatory reduction of Cr(VI) (22).

Mercury

SRB have an important role in the biogeochemical cycle of mercury. Although mercury salts in the environment are toxic, dimethyl mercury, $(CH_3)_2Hg$, is highly volatile and a potent neurotoxin. Many different bacteria, including SRB, methylate Hg^{2+} to produce methyl mercury, CH_3Hg^+, and at aerobic/anaerobic interfaces SRB are the principal group of bacteria that convert methyl mercury to dimethyl mercury. *D. desulfuricans* has been demonstrated to transfer the $-CH_3$ moiety from methyl cobalamine in the production of dimethyl mercury (31).

As reviewed by Hobman and coworkers (32), CH_3Hg^+ will react with H_2S, which is unstable, and HgS is formed along with dimethyl mercury. Demethylation of methyl mercury has been reported by Oremland and coworkers (33), and it is unresolved if this is due to the spontaneous degradation of $(CH_3Hg)_2S$ or an enzymatic process. Once HgS is formed, it remains in sediments until oxidation reactions produce Hg^{2+} and S^{2-}. It is important to note that under acidic conditions dimethyl mercury is unstable and slowly decomposes to CH_4 plus Hg^0.

DISTRIBUTION OF PHYSIOLOGICAL GROUPS OF SULFATE REDUCERS

SRB are broadly distributed in anaerobic areas of the earth, existing at temperatures that span from 82 °C to 4 °C, withstanding high pressures in water columns, and having varying salt requirements (Table 3). Although most SRB belong to the *Bacteria* domain, the only genus of the *Archaea* domain that is a sulfate reducer is the hyperthermophile *Archeoglobus*. Distinguishing the various species of SRB are cellular characteristics and metabolic activities including the unique electron donors used to support growth. There are a large number of new species isolated every year and a comprehensive listing of the SRB species is beyond the scope of this review. Specific metabolic and cellular characteristics associated with various SRB strains are given in recent reviews (2,3,13). In addition to SRB existing as single agents or in consortia with other bacteria, they are also found associated with different eukaryotes, and some of these associations are listed in Table 4. Numerous new species, and even genera, of SRB may be identified from ciliates, clams, or polychaete annelids. Of considerable interest is the presence of bacteria on the dorsal integument of the polychaete annelid, *Alvinella pompejana*, that grows along deep-sea hydrothermal vents. Through molecular techniques, the annelids have been found to harbor bacteria that contain sulfite reductase, which catalyzes Reaction 3 of Table 1; however, these bacteria have not been cultivated. When SRB have been found in the various regions of animals including humans, they have generally been one of several bacteria isolated. The only SRB that has been considered to contain some disease producing activity in humans is *Desulfovibrio fairfieldensis* (34) and additional studies are needed to clarify the virulence of this strain.

Table 3. Environmental Distribution of Sulfate-Reducing Bacteria Based on Temperature, Salinity, and Pressure Requirements

Physiological Group	Optimal Conditions for Growth	Habitat	Genus	Species	Reference
Hyperthermophile	82 °C	Marine hydro-thermal vents	*Archaeoglobus (A.)*	*fulgidus, profundus*	35
Thermophile	65–70 °C	Hot springs and warm oil field water	*Thermodesulfo-bacterium (Td.)*	*commune, mobile*	36
	55–65 °C	Soil and sediments	*Desulfotomaculum (Dm.)*	*geothermicum, knuznetsovii, nigrificans, thermoacetoxidans*	36
Mesophile	27–37 °C >0.2% salt required	Soil and sediments	*Desulfovibrio (D.)*	*vulgaris*, desulfuricans**	16
			Desulfobacterium (Dbm.)	*hydrogenophilus**	
			Desulfobulbus (Dsb.)	*elongatus*	
			Desulfococcus (Dc.)	*niacini*	
			Desulfonema (Dn.)	*magnum**	
			Desufosarcina (Ds.)	*variabilis*	
			Desulfomicrobium (Dsm.)	*aspheronum*	
			Desulfomonas (Dmn.)	*pigra*	
	Moderate salt (2.5%)	Marine sediments	*Desulfobacter (Db.)*	*postgatei*	37
			Desulfovibrio	*salexigens, Africanus*	
	Halophilic/halotolerant (5–17%)	Salt lake sediments and oil fields	*Desulfohalobium*	*retbaensi*	38
			Desulfotomaculum	*halophilum*	39
			Desulfovibrio	*gabonensis,*	40
				halophilus,	41
				senezii,	42
				vietnamensis	43
Psychrotolerant	4 °C	Oligotrophic lake sediments	*Desulfovibrio*	*cuneatus, litoralis*	44
Barotolerant	100–150 atm	Deep marine sediments	*Desulfovibrio*	*profundus*	45

*There are numerous species in these genera; only the most commonly found are listed.

Table 4. Interactions Between Sulfate-Reducing Bacteria and Eukaryotes

Sulfate Reducer	Eukaryotic Association	Reference
Unidentified SRB	Ectosymbiont on marine ciliates	46
Unidentified SRB	Epizoic SRB on shell of clam, *Artica islandica*	47
Unidentified SRB	Deep-sea polychaete annelid *Alvinella pompejana*	48
D. zosterae	Roots of macrophyte *Zostera marina*	49
Desulfovibrio	Root cortex of sea grass *Halodule wrightii*	50
D. intestinalis	Hindgut of flower termite, *Mastotermes darwinensis*	51
D. giganteus	Gut of soil termite, *Cubitermes speciosus*	52
D. termitidis	Hindgut of termite	53
Desulfotomaculum	Intestine and cecum of neonatal mice	18
D. desulfuricans	Bacteremia in dog	54
Desulfovibrio	Human colon	55
D. fairfieldensis	Brain abscess and blood of humans	34
Desulfovibrio	Pyrogenic human liver abscess	56
Desulfovibrio	Intracellular infection in ferrets with bowel disease	57
Desulfobacter, *Desulfovibrio*	Periodontal pockets of human mouth	58

PRESENCE OF SULFATE REDUCERS IN DEEP SUBSURFACE

The range of SRB is not limited only to marine and surface terrestrial environments, but SRB have been found in deep subterranean rock. When a sandstone core was extracted from the United Kingdom Continental Shelf oil field at the 1,000 m depth, it was found to contain SRB (59). The unique feature of these SRB was the formation of a stable community with other anaerobes. In another case, SRB were detected in a natural gas formation at a depth of 2,800 m where the bacteria were apparently trapped inside the pores that contained formation water (60). The localized presence of SRB at the interface of sandstone and shale layers from depths down to 247 m has also been detected (61). Although microbial activity is limited in shale because of restrictive pore size, electron-donating organic material from the shale could diffuse into the more permeable adjacent sandstone, helping to explain the presence of SRB and other microorganisms near the interfaces. It appears that SRB are distributed to great depths of the earth where cell survival and growth would be a tremendous accomplishment.

ACTIVITIES OF SULFATE REDUCERS IN BIOLOGICAL COMMUNITIES

Biofilms can form on any surface in contact with an aqueous environment. Also known as biofouling, microorganisms (including, but not limited to bacteria, fungi, algae, and protozoa) adhere to the surface by such means as extracellular polysaccharides or specialized adhesion structures, forming microcolonies. Other organisms can capitalize on this initial colonization and diverse microbial communities may develop. SRB are commonly found in biofilms or biomats in artificial aquatic settings, marine environments, and hypersaline lakes. The microbial diversity in biofilms increases with time, and SRB become established relatively late in biofilm development. Studies conducted using a combination of microsensors and molecular techniques indicated that a lag time exists between initial formation of a biofilm and sulfide production. Concomitant with the appearance of sulfate reduction is the detection of *Desulfobulbus* and *Desulfovibrio* (62).

Biofilms can be divided into three zones of aerobicity; permanently oxic, fluctuating oxic and anoxic, and permanently anoxic. On the basis of molecular detection methods, SRB have been found to be present in all three regions. The anaerobic zones provide an ideal environment for the growth of SRB, but a surprising number of SRB can be found living in oxic regions, particularly *Desulfobulbus* and *Desulfovibrio* species (62), and species similar to *Desulfonema* and *Desulfococcus* (63). The microenvironments in biofilms are typically heterogeneous, and it has been shown that SRB-containing biofilms have high sulfide flux in the interface between oxic and anoxic zones (62). The sulfide produced by SRB did not diffuse out of the biofilm; rather it was rapidly oxidized to SO_4^{2-} or other oxidized S compounds. These compounds, in turn, were reduced by SRB in a sulfur cycle that involves a very small pool of reduced sulfur compounds with a high turnover rate, resulting in a high sulfide flux and high SRB activity at the oxic/anoxic interfaces within the biofilm. It has long been known that SRB display a tolerance to molecular oxygen, and recently aerotaxis with oxygen-dependent growth has been demonstrated (64,65). Thus low levels of oxygen in biofilms would enhance SRB activities.

Another example of the cycling of sulfide occurs in root-associated biofilms that contain both SRB and *Beggiatoa*. As reviewed by Larkin and Strohl (66), both SRB and Beggiatoas exist in the transition zone between oxic and anoxic environments. There is a rather intricate relationship between rice roots, SRB, and Beggiatoas. In the absence of Beggiatoas, sulfide produced by SRB is toxic to rice. Oxygen excreted by plant roots supports the metabolism of the aerobic Beggiatoas and sulfide is oxidized to sulfate.

SRB are commonly found associated with plant roots in underwater environments. Although SRB have been detected on root surfaces, they also can be found deep in the root cortex. Intracellular colonization of roots by SRB has been demonstrated in rice plants (67), and in sea grass, in which SRB including *Desulfovibrio* species were found on all epidermal cells, and up to 60% of the deepest cortex cells (49). As observed in other biofilms, SRB-inhabiting plant roots are found in anoxic and oxic regions, and seem to be tolerant to oxygen exposure (49,68). SRB are not found alone on plant roots, but are generally part of microbial populations that include

acetogenic bacteria, methanogens, sulfide oxidizers, and other microorganisms that, with the plants, comprise complex communities (49,67,69).

Interspecies interactions are quite important to the formation and maintenance of biofilms. For example, subsurface biofilms containing SRB may form in the sandy soil of artificial golf courses and create an impermeable "black plug layer," so named because of the black sulfides produced and the inability of water and oxygen to cross the fouled zone. Current remediation strategies involve excavation and reconstruction of the affected area. Using bacteria isolated from a black plug layer it has been demonstrated that microbial consortia produce this layer, whereas individual species do not form black plug layers (70). In particular, SRB may interact with cyanobacteria to produce black globules found in such layers (71).

The metabolism of H_2 can be an important determinant for growth of anaerobes. Hydrogen transfer between species of *Desulfovibrio* and H_2-oxidizing anaerobes has been reviewed by Fauque (16). Certain SRB cannot grow with ethanol in the absence of sulfate owing to the accumulation of H_2; however, SRB will grow if H_2 is utilized by a methanogen, thereby serving as the electron acceptor. In the situation where H_2 is the electron source in the environment, anaerobes that are H_2-scavengers will be in competition for the H_2. Because the hydrogenase of SRB has greater affinity for H_2 than hydrogenase from methanogens, SRB can outcompete methanogens for H_2.

BIOGENIC HYDROGEN SULFIDE PRODUCTION

In some oil fields, there is considerable sulfide present, resulting in oils known as "sour oil," whereas oils from fields with no sulfide are "sweet oils." The souring of oil is generally a reflection of SRB converting sulfate to sulfide in hydrocarbon reservoirs. Frequently, this is found with offshore drilling operations in which seawater, which contains 28 mM sulfate, is used to balance pressures in the subterranean oil reservoirs. In cases where fresh water is pumped into the reservoirs, sulfate in the environment is dissolved, and similar problems result. Control of SRB to prevent souring frequently requires the addition of biocides that may include glutaraldehyde, chlorine, cetylpyridinum chloride, or alcohols. Many of the specific conditions and procedures used in the oil industry to inhibit the growth of SRB have recently been reviewed (72,73) and will not be enumerated here.

Appreciable quantities of H_2S can be produced by SRB and can accumulate to toxic levels. Perhaps one of the best examples of H_2S accumulation is seen in the coastal bottom waters of the Baltic Sea (74). Nitrogen and phosphorus accumulated because of additions to the Baltic Sea from agriculture and papermills. Eutrophication occurred and produced anoxic conditions in benthic sediments where only H_2S-tolerant organisms survive.

In some instances biologically produced hydrogen sulfide is used to immobilize toxic metals. As reviewed by Barton and Tomei (75), SRB have been effective in the removal of Cd^{2+}, Cu^{2+} and Ni^{+} from mine and smelter wastes. In Budel-Dorplein, The Netherlands, there is a large commercial production for removal of Zn^{2+} from groundwater, which uses SRB to produce hydrogen sulfide that precipitates Zn^{2+} as ZnS. SRB may be useful for the immobilization of heavy metals in acid-mine drainage because SRB remain metabolically active in bioreactors at pH 3.25 (76).

APPLICATIONS OF SULFATE-REDUCING BACTERIA

Because of the numerous activities of SRB, there has been some interest in technologies for the application of enzymes and cells for industrial development. The potential for use of hydrogenase and electron carriers from SRB for commercial H_2 production by biophotolysis has been reviewed by Barton and Tomey (75). The hydrogenases from SRB are unique because they are not denatured by exposure to oxygen and have been immobilized by a variety of support media. Clearly there is the potential to use several of the enzymes from SRB for remediation of the environment or for development of bioprobes for monitoring of environmental processes. With respect to control of environmental pollution, SRB have a broad role in treatment of commercial effluents. The precipitation of heavy metals in various waste streams as sulfides has already been presented. (See Biogenic hydrogen sulfide production). Technologies have been developed for the treatment of waste streams from distilleries and fish canneries, and for the treatment of wastewater containing methanol, furfural, and molasses (75).

SRB are being evaluated for various applications in energy technologies. Although SRB cannot utilize sulfur compounds in bitumen (77), *D. desulfuricans* has been found useful for removing sulfur dioxide from flue gases with the formation of hydrogen sulfide (78). It has been suggested that SRB have been involved in tar-sand deposits (79) and that SRB may be used to increase oil production in existing wells. SRB of several taxonomic groups have been reported to synthesize alkanes using lactate as the carbon source with an atmosphere of H_2:CO_2 at a ratio of 9:1 (80).

THE ROLE OF SULFATE REDUCERS IN BIOCORROSION

Corrosion attributed to microorganisms can occur in any environment where biofilms develop. The term *biocorrosion* has been used to describe corrosion of metals, alloys, composites, or any material in contact with biofilms or microbial mats that suffers increased rates of corrosion or decomposition as a result of biological activity. Recently, however, the more general phrase "microbially influenced corrosion" (MIC) has been replacing "biocorrosion" in the literature, and this reflects the limitations of our understanding of specific corrosion processes associated with microbial activity; in some cases biofilms have even been shown to inhibit rather than accelerate corrosion (81). The role of SRB is significant in commonly encountered examples of iron and mild steel corrosion. There are, however, reports of SRB involvement (either acceleratory or inhibitory) in the corrosion of stainless steel and some transition metals (82,83).

The role of SRB has been addressed in reviews of MIC (81,82). In basic terms, MIC occurs at the surface of materials that are exposed to microbial activity in an aqueous environment. SRB-mediated biocorrosion can involve enzymatic (hydrogenase) reduction and hydrogen sulfide oxidation. On a microscopic scale, an electrochemical cell can form on metal surfaces under anaerobic conditions. It then becomes possible for localized cathodes and anodes to form on the metal because of differential aeration cells in the biofilm. Corrosion consists of metal dissolution at one site coupled with electron uptake by an acceptor at a cathodic site (82). In the cathodic depolarization model of iron and corrosion, SRB containing hydrogenase remove accumulated cathodic hydrogen from the surface of the iron, which in turn forces the dissolution of iron at the anodic site. Accelerating the process is the cathodic reduction of microbially produced H_2S, yielding S^{2-} as a product, and the corresponding acceleration of the anodic reaction because of the formation of iron sulfide, FeS (81). Another role for SRB in MIC of iron and mild steel involves active electron transport where bacterial cytochrome and hydrogenase siphon electrons directly from the metal and accelerate H_2 production (84). The most comprehensive review concerning the role of SRB and hydrogenase in corrosion of ferrous metal is provided by Laishley and colleagues (85).

The biological and chemical processes associated with corrosion were recently reviewed and Odom (72) indicates that the magnitude of the ferrous corrosion problem is such that in an industrial country it accounts for about 4% of the gross national product. There are about a million miles of concrete sewer conduits in the United States, and concrete may be degraded by a process attributed to SRB (86). The anaerobic sediment and wastewater in the conduits contain SRB, which results in the copious production of H_2S. As H_2S reaches the upper portion of the conduit, S^0 is produced as a result of chemical reaction between H_2S and atmospheric oxygen. *Thiobacillus* and other sulfur-oxidizing bacteria will oxidize the hydrogen sulfide and S^0 to sulfuric acid, which promotes decomposition of the concrete conduit.

Several methods have been used to evaluate the effectiveness of biocides in preventing microbial colonization on ferrous surfaces. The American Petroleum Institute (API) recommends a procedure for screening biocides against SRB that requires 28 days, but Zhou and King (87) have developed a bactometer method based on impedance microbiology principles that requires only one day. Another test for microbial activity in biofilms is the microcalimetric method, which provides the capability to measure the efficacy of biocides (88).

DETECTION OF SULFATE REDUCERS

The difficulty in culturing SRB resulted in a need for quick tests to detect these organisms in oil fields, and this has encouraged the development of numerous presumptive tests. A lactate–sulfate medium containing appreciable levels of iron was developed to detect SRB, and it has been recommended for use by the API (89). The formation of a black precipitate owing to FeS is used to indicate the presence of SRB in the inoculum. The medium for this test is commercially available. An amphimetric test for growth of SRB was developed (90); however, the instrumentation needed did not lend itself to performing a large set of samples in a single oil field. Laishley and coworkers (91) observed that most species of SRB have hydrogenase and developed a rapid test that uses reduction of methyl viologen to indicate the presence of SRB. This hydrogenase test kit is commercially available (Caproco (1987) Limited, Edmonton, Alberta, Canada). An immunoassay was developed using an antibody against ATP sulfurylase, the enzyme associated with Reaction 1 of Table 1 (92). The antibody reaction is performed in microtiter plates similar to standard enzyme-linked immunosorbent assay (ELISA) tests. Kits for the antibody are commercially available. Another test developed to detect only a few hundred *Desulfovibrio* is the fluorimetric detection of sulfite reductase, the enzyme of Reaction 3 in Table 1 (93). With the addition of alkali to SRB, a specific fluorescence associated with the sulfite reductase provides for the rapid detection of 10^3 SRB cells/ml. A radiometric test has been used to quantify SRB in estuaries (94). Where SRB produce radiolabeled hydrogen sulfide from $Na_2^{35}SO_4$, the amount of radiolabeled sulfide produced is used to indicate the number of cells present. All of these tests can be compared to standards or to actual numbers resulting from viable counting of SRB as established by Gibson and coworkers. (95). Detection of deep subterranean SRB has been accomplished by Krumholz and colleagues (61) using a modified ^{35}S method. The faces of rock core samples from as deep as 300 m were pretreated with radiolabeled sulfate and then placed in contact with oxidized silver foil. The $H_2^{35}S$ produced was trapped by foil as $Ag_2^{35}S$, which could be detected by radio-image analysis. This method not only gives a quantitative measure of sulfate reduction, but also yields two-dimensional distribution of the activity within the rock.

More definitive identification of SRB is sometimes required, and several varieties of molecular identification methods have been developed that can be especially useful when confronted with mixed cultures. The use of ribosomal RNA sequences for identification of microorganisms has found widespread application, and several techniques can be used to detect the presence of SRB, and in some cases individual SRB species. It is possible to use radio- or fluorescently-labeled oligonucleotide probes designed specifically for 16S or 23S rRNA sequences for in vitro or in situ hybridization studies to identify SRB (96). Table 5 lists some of the 16S rRNA sequences useful for molecular identification of some strains of bacteria.

Oligonucleotides specific to 16S or 23S rRNA sequences may also be used as polymerase chain reaction (PCR) primers for selectively amplifying and sequencing rRNA from mixed samples for identifying or classifying microorganisms (99). Molecular methods based on the physiology of SRB have been used to detect SRB. Minz and colleagues (63) have used the sequencing of physiology-linked genes (e.g. dissimilatory sulfite reductase) to indicate the presence of SRB in heterogeneous microbial mats. For mixed microbial communities a method has been developed that uses total genomic DNA as a probe for

Table 5. Specificity, Target Sites, and Sequences of 16S rRNA Oligonucleotide Probes

Specificity	Target Position*	Sequence	Reference
All organisms (Prokaryotes and Eukaryotes)	907–928	5′-CCGTCAATTCCTTTGAGTTT-3′	62
Bacteria (not including *Archaea*)	341–357	5′-CCTACGGGAGGCAGCAG-3′	62
Most δ-proteobacteria, and a few gram-positive bacteria	385–402	5′-CGGCGTCGCTGCGTCAGG-3′	96
Desulfovibrio spp. and some members of the following genera: *Geobacter, Desulfomonas, Desulfuromonas, Desulfomicrobium, Bilophila*, and *Pelobacter*	687–702	5′-TAACGGATTTCACTCCT-3′	62
Desulfobacterium spp., *Desulfobacter* spp., *Desulfococcus multivorans, Desulfosarcina variabilis, Desulfobotulus sapovorans*	804–821	5′-CAACGTTTACTGCGTGGA-3′	62
Desulfococcus multivorans, Desulfosarcina variabilis, Desulfobotulus sapovorans	814–831	5′-ACCTAGTGATCAACGTT-3′	97
Desulfovibrio spp.	687–702	5′-TACGGATTTCACTCCT-3′	97
Desulfobulbus spp.	660–679	5′-GAATTCCACTTTCCCCTCTG-3′	97
Desulfobacterium spp.	221–240	5′-TGCGCGGGACTCATCTTCAAA-3′	97
Desulfobacter spp.	129–146	5′-CAGGCTTGAAGGCAGATT-3′	97

*Position in the 16S rRNA of *Escherichia coli* (98).

detection of individual species, using a "reverse genome" approach (100). A feature of this technique is that it allows economical analysis of mixed samples and can accurately describe SRB present.

SULFUR BACTERIA IN DRINKING WATER

RICHARD F. UNZ
The Pennsylvania State University
University Park, Pennsylvania

Microorganisms of interest in the drinking water environment appear relegated to three categories, namely, biological indicators, primary and opportunistic waterborne pathogens, and nuisance organisms. Certain sulfur bacteria are rightfully included in the group of nuisance organisms and may potentially contribute directly or indirectly to several economic problems in potable water systems, including microbially influenced corrosion, tastes and odors, turbidity, chlorine demand, and in the case of groundwater wells, clogging and deterioration of well screens and casings. In addition, sulfur bacteria may facilitate or assist formation of biofilms, within which the retention and protection of coliform bacteria and pathogenic organisms from antimicrobial agents, for example, chlorine residuals, is possible.

Chemically, sulfur may exist in valence states, ranging from +6 (highest oxidation state) to −2 (lowest oxidation state). Thus, sulfur, like nitrogen, can undergo chemical transformation on several valence levels, and specific microorganisms have evolved in response to the favorable thermodynamic properties of such reactions. As a group, the sulfur bacteria occur in both aerobic and anaerobic environments, and are represented by the nutritional modes of photolithotrophy (principal energy provided by light with reducing power obtained from molecular hydrogen or reduced, inorganic sulfur compounds), chemolithotrophy (both energy and reducing power supplied by reduced, inorganic chemical compounds), and mixotrophy (carbon derived from organic sources and energy and reducing power supplied by inorganic chemical compounds, most notably, reduced sulfur species). Phototrophic and lithotrophic sulfur bacteria, typically, utilize carbon dioxide as their major carbon source; however, many chemoorganotrophic (carbon, energy, and reducing power acquired from preformed organic matter) bacteria, not labeled sulfur bacteria as such, contribute to the genesis of sulfide through desulfuration of sulfur-containing organic matter, most notably, proteins.

SULFUR CYCLE

A Series of Oxidation-Reduction Reactions

The major mineral form of sulfur is sulfate. Sulfate may be present in both ground and surface waters and derived from natural and artificial sources. The principal forms of sulfur reaching the earth from atmospheric deposition, is sulfate and sulfur dioxide; the latter originating in a major way from fossil fuel combustion. Other important sources of sulfate in aquatic systems are mineral deposits. Groundwaters may contain high concentrations of sulfate, owing to aqueous dissolution of certain minerals, for example, barite ($BaSO_4$), epsomite ($MgSO_4 \cdot H_2O$), gypsum ($CaSO_4 \cdot 2H_2O$), weathering of sulfidic minerals, for example, pyrites (FeS_2), and, in coastal regions, salt water intrusion. Surface waters are typically subject to direct catchments of acidic, sulfur-bearing precipitation and anthropogenic pollution, deriving from mining and mineral processing, paper and pulp production, textile manufacturing, and tanneries (1).

Examination of the microbiologically mediated sulfur cycle (Fig. 1) reveals several biogeochemical niches for physiological groups of the sulfur bacteria. Broadly speaking, these niches may encompass sulfur oxidation (linked and nonlinked to energy conservation) and sulfur reduction. Lentic water bodies may provide the appropriate conditions for interactive behavior between photosynthetic sulfur bacteria, sulfur-oxidizing bacteria, and sulfate-reducing bacteria; an arrangement referred to as a "sulfuretum." In the context of potential problems for potable water facilities, activities of sulfate- (sulfur) reducing bacteria are most conspicuous.

The Sulfur Bacteria

Sulfur bacteria are of interest in potable water systems, principally for their potential to lend an aesthetically displeasing quality to the water or to, directly or indirectly, impact the stability of the physical facilities involved in water treatment and delivery. Currently, there are no known public health concerns related to the sulfur bacteria. Natural aquatic habitats in which the sulfur bacteria may be found are morphometrically diverse. Since both surface and groundwaters serve as sources of potable waters, various forms of sulfur bacteria and their influences on the chemical quality of the water may be encountered at some level of treatment. A brief overview of the relevant groups of sulfur bacteria is presented in the following section.

Photosynthetic Sulfur Bacteria. The photosynthetic sulfur bacteria are a morphologically diverse group and are

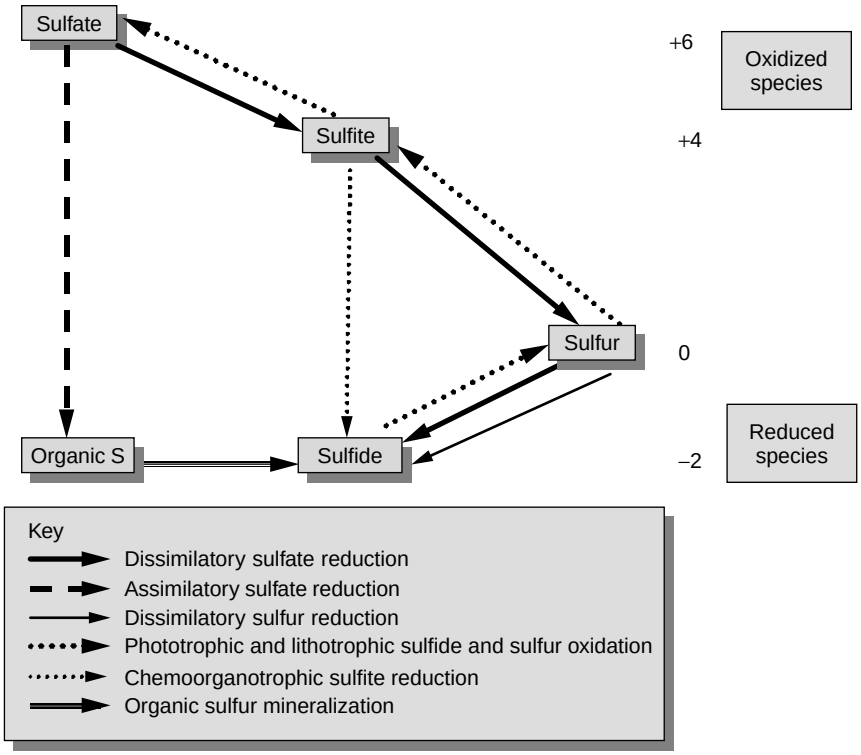

Figure 1. Microbiological sulfur cycle. Sulfur species are aligned with valence state of sulfur, shown in vertical scale at the right of diagram.

delineated according to pigmentation, as green (brown) sulfur, purple sulfur, and purple nonsulfur bacteria. The green bacteria are obligately anaerobic, and all groups function anaerobically when in the photosynthetic mode. Major requirements for the bacteria during photosynthesis are radiant energy (sunlight) and a source of reducing power, which for the green and purple sulfur bacteria is typically molecular hydrogen and reduced sulfur compounds, for example, hydrogen sulfide (H_2S). Phylogenetically, green sulfur bacteria are distinct from the purple sulfur bacteria; the former occupying Kingdom VII and the latter Kingdom I (γ subgroup of Proteobacteria) of the Domain Bacteria. On the contrary, many of the purple nonsulfur bacteria, which are represented in the α- and β-subgroups of the Proteobacteria and typically, derive reducing power from certain organic acids and ethanol, are capable of using low concentrations of hydrogen sulfide to meet this requirement. In addition, this group is classically characterized by a photoheterotrophic metabolism of several organic compounds as carbon sources while obtaining energy from a radiant source (Table 1).

Photosynthetic bacteria thrive in static waters, at precise levels in the water column, where they may absorb specific wavelengths of electromagnetic radiation and obtain reducing power. When reduced sulfur forms are the source of reducing power, zero valence sulfur is a by-product, which typically is transiently stored within the cells of the purple bacteria, or externally precipitated by the green bacteria. Worldwide, biogenic sulfur deposits, especially of aquatic origin, are the result of the precipitation of elemental sulfur during acquisition of reducing power by photosynthetic sulfur bacteria. Unlike aerogenic microorganisms, for example, cyanobacteria that are capable of deriving reducing power from the splitting of water, photosynthetic sulfur bacteria depend for reducing power on the by-products of putrefactive and sulfate-reducing microorganisms located in aquatic sediments and deep oxygen-deficient water strata. Green sulfur bacteria are more efficient in light scavenging than the purple bacteria, hence they may be found in deeper water strata. Stratified, raw water impoundments, reportedly may attain hypolimnial levels of sulfide up to 10 mg/L in midsummer (2) through sulfate reduction and desulfuration of organic matter in the sediments. Hence, photosynthetic sulfur bacteria of deep lakes and reservoirs serving as raw water supplies could potentially assist in the improvement of water quality through the removal of odor-producing hydrogen sulfide. In fact, purple sulfur bacteria have been credited with the transformation of sulfide species in wastewater lagoons and in industrial wastes (3). As may be the case with certain algae and cyanobacteria, photosynthetic sulfur bacteria are not known to be toxigenic and their contribution to turbidity in water, if any, would probably pale in comparison with the aerogenic photosynthetic populations stimulated by cultural eutrophication.

Sulfur-Oxidizing Bacteria. Sulfur-oxidizing bacteria, frequently referred to as *colorless sulfur bacteria*, are well distributed in the natural environment. A dominant genus of the sulfur-oxidizing bacteria is *Thiobacillus*; a morphologically unspectacular group of rod-shaped bacteria with species relegated to the α-, β-, and γ-subgroups of Proteobacteria. *Thiobacillus* species occupy a wide pH range with respect to pH optima for growth, hence appear in many different environments, for example, acidic mine

Table 1. Characteristics of Some Representative Genera of Major Groups of Photosynthetic Sulfur Bacteria and Their Potential Relationship to Potable Waters

Bacteria and Genera	Descriptive Features	Residence in Potable Water System	Biogeochemical Features	Economic Relevance
Green, sulfur	Anoxygenic, nonmotile	Deep, lacustrine water bodies	H_2S oxidized with sulfur precipitated external to cells	Minor
Chlorobium	Straight or curved rods; nonvesicular			
Pelodictyon	Network of branched rods; gas vesicles			
Purple, sulfur	Anoxygenic, morphologically diverse; motile and nonmotile; vesicular and nonvesicular	Meromictic, deep water bodies	H_2S oxidized with sulfur precipitated internal to cells	Minor
Chromatium	Ellipsoid or rod-shaped; motile; nonvesicular			
Thiopedia	Plates of tetrad spheres; nonmotile; nonvesicular			
Purple, nonsulfur	Morphologically and metabolically diverse; fix N_2	Environmentally ubiquitous	Principally photoheterotrophic with small, fatty acids and amino acids as carbon sources	Possible turbidity associated with bloom episodes
Rhodospirillum	Spirillum-shaped cells; motile			
Rhodopseudomonas	Rod-shaped cells, motile; budding			

drainage, sulfur springs, soils, wastewaters, and seawater (Table 2). Sulfur-oxidizing bacteria transform several reduced species of sulfur including sulfide, elemental sulfur, di-, tri-, and polythionates, and thiosulfate to sulfite and sulfate. Hydrolysis of the end-products of sulfur oxidation in the absence of alkaline cations produces sulfurous/sulfuric acids, thus lending a corrosive nature to the surrounding. Acidic weathering of concrete sewer pipes by the combined action of sulfate-reducing and sulfur-oxidizing bacteria remains a serious economic liability (4).

Among troublesome microorganisms in ferruginous (iron-bearing) groundwater systems are the filamentous iron and sulfur bacteria. Accelerated growth of these organisms in the summer months exacerbates the problem of meeting peak water demands in communities. Microbial biomass collected at the surface of well screens and casings severely reduce the well yields in the short-term and enhances corrosion and subsequent deterioration of the well components over time. Prominent filamentous sulfur bacteria in freshwater environments are species of *Beggiatoa* and *Thiothrix*; both of which belong to the γ-subgroup of Proteobacteria. The latter genus is often identified in suspended growth forms of biological wastewater treatment as the etiologic agent of a condition of poor biomass settleability known as filamentous activated sludge bulking (5). Filamentous sulfur bacteria are aerobic but thrive under microaerophilic conditions, and have been observed to reduce partially oxidized sulfur compounds, for example, thiosulfate, to sulfide in the absence of oxygen. Axenic isolates of *Thiothrix* spp. have demonstrated chemolithotrophic (6,7), chemoorganotrophic (8,9), and mixotrophic (8,9) behaviors. Thus, filamentous sulfur bacteria are endowed for survival under a variety of physiological and nutritional conditions.

Sulfate (Sulfur)-Reducing Bacteria. Of the various groups of sulfur bacteria, those members that are capable of utilizing oxidized and partially oxidized sulfur species as

Table 2. Characteristics of Some Representative Genera of Major Groups of Sulfur-Oxidizing Bacteria and Their Potential Relationship to Potable Waters

Bacteria and Genera	Descriptive Features	Residence in Potable Water System	Biogeochemical Features	Economic Relevance
Unicellular, sulfur-oxidizing	Aerobic and facultatively anaerobic; obligate and facultatively lithotrophic; obligately acidophilic and neutrophilic species	Iron, and concrete surfaces as may pertain to surface water (pipes, valves, fittings) distribution and storage and groundwater procurement (well screens and casings)	Aerobic and anoxic oxidation of reduced inorganic sulfur species to sulfate with potential for sulfuric acid formation	Aid the corrosion and deterioration of facilities; acidify water; solubilize heavy metals
Thiobacillus	Rod-shaped cells; motile		One species (*Thiobacillus ferrooxidans*) oxidizes ferrous iron to ferric iron in addition to inorganic sulfur species	
Filamentous, sulfur-oxidizing	Extended length filaments; lithotrophic, mixotrophic, and heterotrophic species	Locales of high sulfide levels, for example, active regions of sulfate reduction, that is, certain biofilms and aquatic sediments; sulfur springs	Oxidation of sulfide; disproportionation of thiosulfate to sulfur granules and sulfate	Clogging of well screens; biofilm resident
Thiothrix	Filaments in rosettes; cells contain sulfur granules; specialized cells (gonidia) show twitching motility			
Beggiatoa	Filaments exhibit gliding motility; cell contain sulfur granules			

ultimate electron acceptors have received greatest attention as contributors to undesirable events in both water and wastewater treatment facilities. As previously noted, well water systems are especially susceptible to anaerobic corrosion, and sulfate-reducing bacteria are chief mediators of iron dissolution through electron transport ultimately to sulfate in the groundwater. Furthermore, the end-product of the reduction of sulfate is the odorous and noxious hydrogen sulfide. At circumneutral pH values, approximately 50% of free, dissolved sulfide exists as hydrogen sulfide and 50% as the bisulfide (HS^-). In the anaerobic biogenic corrosion cycle, sulfide readily reacts with soluble ferrous iron released from the corroding metal to form ferrous sulfide, which may precipitate on base metal. Ferrous sulfide is a relatively poor passivating (protective) agent for the metal surface and may even augment electron conductance by catalyzing the cathodic reduction of protons to hydrogen, thereby promoting the corrosion event. In addition, metal sulfide particles and iron-impregnated biomass may be dislodged from the well screen through pumping of the groundwater. Remnants of these materials, particularly where little treatment of the water other than disinfection takes place, can offer both disagreeable tastes and odor and discoloration to the finished water. Accelerated rates of sulfide production in the presence of ferrous iron can produce deep discoloration and a condition known as *black water*, which is not to be confused with another form of "black water" stemming from the presence of substantial oxidized manganese.

Sulfate-reducing bacteria are obligately anaerobic thriving best at oxidation-reduction potentials in the vicinity of −100 to −200 mV (pH 7). Several morphological forms of sulfate-reducing bacteria (Table 3) exist and their primary sources of carbon and energy are the metabolic end-products of organic matter fermentation, most notably lactic and pyruvic acids and molecular hydrogen. The ability to use acetic acid varies among sulfate-reducing bacteria, resulting in two groups of the bacteria on the basis of this metabolic feature. The phylogenetic placement of sulfate- and sulfur-reducing bacteria is the δ-subgroup of the Proteobacteria, with the exception of *Desulfotomaculum*, which belongs in Kingdom II (gram-positive bacteria). Of the many genera of sulfate-reducing bacteria, *Desulfovibrio* and *Desulfotomaculum* are predominant in freshwater systems.

Sulfate-reducing bacteria may contribute to the form and stability of biofilms (10) through elaboration of extracellular (matrix) polysaccharides (11). Although ferrous sulfide formation may occur in the aqueous phase, it has been shown that the biofilm can entrap the iron sulfide, bring it in contact with susceptible surfaces, and facilitate corrosion (10). Further augmenting the corrosion-promoting action of the biofilm is the spatial heterogeneity (patchiness) of immobilized microbial aggregates on the

Table 3. Characteristics of Some Representative Genera of Major Groups of Sulfate (Sulfur)-Reducing Bacteria and Their Potential Relationship to Potable Waters

Bacteria and Genera	Descriptive Features	Residence in Potable Water System	Biogeochemical Features	Economic Relevance
Sulfate-reducing	Morphologically diverse; obligate anaerobes; both mesophilic and thermophilic species; some mixotrophic and lithotrophic species	Aquatic sediments; distribution system and well screen and casing biofilms	Reduce sulfate and partially reduced sulfur species to hydrogen sulfide; dinitrogen fixation by some species	Major contributor in anaerobic corrosion of iron and copper pipes; taste and odor
Desulfovibrio	Gram-negative; nonsporing; curved rods; motile	Acetate not oxidized		
Desulfotomaculum	Gram-positive; spore-forming; rod-shaped; motile	Acetate not oxidized		
Desulfobacter	Gram-negative; nonsporing; rod-shaped, may be motile	Acetate oxidized		
Sulfur-reducing	Obligately anaerobic; nonsporing; rods or vibrios; motile	Found in habitats similar to those of sulfate-reducing bacteria	Zero valence sulfur and some partially reduced sulfur species are reduced but not sulfate; acetate oxidized	
Desulfuromonas	Gram-negative; straight rods		Some species exhibit reductive dechlorination.	

metallic substratum and the thickness of the anoxic zone within the aggregates. Irregularities of this sort in thickness and surface distribution facilitate a discontinuity in biofilm structure (12). Of primary importance to sulfate-reducing bacteria are the chemical and nutritional gradients that prevail in the depths of the biofilm, especially, pertaining to dissolved oxygen and metabolic end products (certain organic acids and hydrogen) formed by the fermentative members of the film community. Sulfate-reducing bacteria demonstrate sensitivity both to the presence of dissolved oxygen and the end-products of sulfate reduction, particularly, hydrogen sulfide. In mixed culture, sulfate-reducing bacteria derive benefit from chemoorganotrophs capable of creating an anaerobic environment through oxygen consumption and the formation of utilizable electron donors.

POTABLE WATER SYSTEMS

Drinking Water Chemical Composition

The concentration of sulfate in water supplies varies widely depending on the source (Table 4). Groundwater quality is largely related to hydrological and mineralogical characteristics of the subsurface. Concentrations of mineral ions in groundwater are often related to the depth and geology of the aquifer and the drainage capacity of pertinent soils; poorly drained soils, that is, soils with high clay content promote slow movement and long contact times of percolating waters resulting in greater yield of inorganic solids to groundwater. The effect of depth is exemplified by the comparative data in Table 4 for groundwater C versus groundwaters D and E. Typically, groundwaters contain appreciably greater levels of total dissolved solids than surface waters; however, surface waters are greatly susceptible to adulteration by anthropogenic activity. For example, agricultural drainage to the Colorado River appreciably elevated the concentrations of dissolved salts (Table 4). The Federal Safe Drinking Water secondary maximum contaminant limit (SMCL) for sulfate is 250 mg/L. It is estimated that only about three percent of finished waters in the United States exceed the SMCL for sulfate; however, some community drinking waters in South Dakota may contain up to 1,350 mg sulfate/L, with private wells reaching 2,000 mg sulfate/L (13). In the case of some surface waters with low sulfate concentrations, introduction of metallic sulfate coagulants in water purification schemes to treat turbidity will actually increase the sulfate concentration over background levels. Interestingly, however, results of controlled kinetic studies on sulfate-reducing bacteria (14) support the possibility that these organisms could thrive in distribution systems even at very low concentrations of constantly available sulfate. Natural systems have been characterized wherein dissolved sulfate was nearly nonexistent but sulfate-reducing activity was possible owing to mineral reservoirs of sulfate that slowly diffused into the water phase (15). It appears that sulfate reduction within mature biofilms may proceed at rates unimpeded by sulfate diffusion limitations (15). Therefore, sulfate-reducing bacteria seem suited for persistence and activity within biofilms of water distribution systems.

It is difficult to separate chemical and microbiological discussions on the consequences of iron and sulfur in the groundwater environment. The phenomenon of "ferric clogging" (16), which was alluded to earlier as a detriment to maintaining well pumping yields, is generally thought to involve a number of bacterial genera including *Gallionella*, *Sphaerotilus*, *Siderocapsa*, *Toxothrix*, *Crenothrix*, *Clonothrix*, *Siderococcus*, *Thiobacillus*, and, most probably, some of the slime-producing manganese bacteria. Many of the aforementioned genera have not been characterized by axenic culture studies.

The presence of dissolved iron under sulfate-reducing conditions can actually reduce the odor accompanying dissolved hydrogen sulfide through iron sulfide precipitation if rates of formation exceed those of sulfate reduction (12). Usually, however, sulfate-reducing and sulfur-oxidizing bacteria, under gradients of anaerobic to microaerophilic regimes, act in well water systems to cooperatively promote corrosion of metal surfaces (Fig. 2), and by virtue of the presence of these bacteria and their acidic by-products, for example, acetic acid together with hydrolyzable sulfates and insoluble mineral products of chemical action, for example, iron sulfides, lend to rapid deterioration of screens and casings (16).

Distribution System

Potable water distribution systems are subject to invasion by microorganisms through connections with "open reservoirs; enclosed, unchlorinated reservoirs; new construction that disturbs the existing distribution system; main breaks (which will become an increasing problem as systems age); back pressure; dead ends in mains and stagnant water; living organisms that protect bacteria but that may release

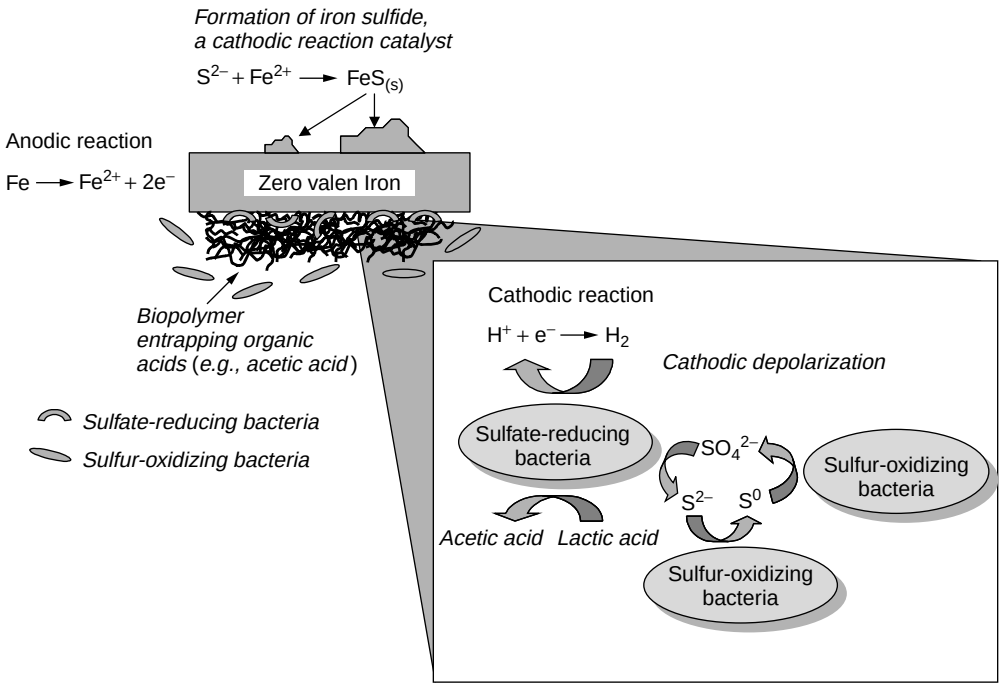

Figure 2. Anaerobic corrosion of iron with subsequent formation of sulfide. Sulfate-reducing bacteria are embedded in oxygen-deficient regions of the biopolymer close to the metal surface and promote the flow of electrons to protons by oxidizing hydrogen via. reduction of sulfate. In addition, acetic acid formed in the transformation of lactic and pyruvic acids create an aggressive environment within the biofilm. Sulfide may precipitate ferrous iron in the vicinity of the metal surface or be transformed to sulfate by the action of sulfur-oxidizing bacteria.

bacteria into the drinking water when mains are disturbed; and sewage cross-connections" (17). In addition, entry of bioavailable organic matter, use of deteriorative construction materials in piping and fittings, insufficient or intermittent maintenance of a protective disinfectant residual, and water temperatures in excess of 15 °C can augment the survival and development of microbial communities (18,19). The water treatment facility proper may include unit processes, for example, sand filters and activated carbon columns, that promote nonspecific bacterial proliferation and a source of organisms entering the distribution system. *Thiobacillus* spp. have been suggested to be capable of survival on sulfur-containing caulking compounds in water pipes (20). Despite the well-recognized ability of sulfate-reducing bacteria to develop on metallics used in potable water systems (21) and the documented presence of sulfate-reducing bacteria in corroding mains (22,23), understanding the role of these organisms in distribution system biofilms remains topical among the overall research needs in drinking water microbiology (24–26).

Potable water distribution systems carry oxygen-containing waters and the oxidation-reduction potential, especially in loop systems, may be too positive for the development of sulfate-reducing bacteria. Furthermore, some mains are constructed of noncorrosive materials, for example, asbestos cement and polyvinyl chloride. Nevertheless, cast iron ductile piping and metallic appurtenances are in major use in modern distribution systems and are susceptible to biofilm formation and corrosion. In these regimes, the sulfate-reducing bacteria exist deep in occlusions formed on the surface of piping and where the presence of dissolved oxygen and a disinfectant residual is minimal or absent (27). These occlusions appear in the form of iron tubercles and biofilms and set up chemical gradients, which can promote corrosion reactions. Continued development of tubercles over time may result in severe reduction of water flow through the pipe. Microscopic examination of tubercles has revealed the presence of bacteria of varied morphologies including (28) or not including (23) filamentous bacteria. Sulfate-reducing bacteria were detected in 80% of iron tubercles sampled from cast iron water distribution piping in Columbus, Ohio, and their presence correlated strongly with background heterotrophic pour plate counts (29). A cultural enumeration of microbial groups, including sulfur bacteria, present in source (untreated) water and a distribution system transporting very low temperature and soft (treated) water is presented in Table 5 (30). Recovered from iron tubercles in larger numbers than sulfate-reducing bacteria were sulfide-forming chemoorganotrophs, for example, *Clostridium* spp. and species of *Enterobacter* and *Klebsiella*, which reduce sulfite and thiosulfate, respectively (30). Chemoorganotrophs must have a supply of preformed organic matter for sustained existence. Even sulfate-reducing bacteria apparently utilize specific by-products of anaerobic fermentation, for example, lactate, as the primary electron donor in respiration as opposed to cathodically generated hydrogen (31), thus underscoring the importance of bioavailable organic compounds for respiration by these organisms. It has been suggested that corrodible pipes carrying dissolved organic matter are at greater risk of deterioration by sulfate-reducing

action than ones that transport waters essentially free of bioavailable organic matter (32).

Home Water System

Difficulties attributed to bacterial reduction of sulfur species, especially taste and odor, water discoloration, and metal corrosion, may occur in the household water pipes, fixtures, and appurtenances. Corrosion not only destroys the metallic parts directly but also permits release of heavy metal ions, for example, copper, into the drinking water. The hot water outlet of the household water heater has been identified as a site of sulfate-reducing bacterial activity in situations in which malfunction or intentional lowering of the thermostat results in sublethal temperatures to the bacteria. Also implicated as a contributing factor to sulfide generation is the magnesium rod sometimes inserted in the water heater to act as a sacrificial anode. Electrons released from the rod can combine with protons to produce hydrogen, which serves as an energy source for the bacteria with consequent reduction of sulfate to hydrogen sulfide. Aluminum and zinc rods have been employed in place of magnesium to reduce the rate of electron flow.

CONTROL OF SULFUR BACTERIA

Concerns about the presence of sulfur bacteria in potable water systems are principally directed at sulfate-reducing bacteria. Attempts to curtail the activities of these organisms in drinking water require procedures applicable to the specific task at hand.

Wells

A popular method aimed at eliminating general bacterial populations, including sulfur bacteria, from individual and community well water systems is shock chlorination. Typically, sufficient chlorine (Cl_2) is added to the well to produce a concentration of 200 mg Cl_2/L; a concentration that is arrived at by determining the volume of water in the well and the concentration of chlorine in the disinfectant employed. The volume of water in the well is estimated from the diameter of the well casing and the depth of the well. Shock chlorination is practiced for newly constructed wells and well systems that have undergone repair or were subject to flooding. Before shock chlorination, systems should be thoroughly cleaned and pumped to remove dislodged suspended matter from the well screen and casing. The disinfectant should remain in contact throughout the system for at least 12 to 24 hours followed by backflushing to remove all chlorine from the well and distribution system. It is important to note that sulfide species exert a chlorine demand. Therefore, a determination of soluble sulfide should be made and allowance of 2 mg Cl_2/L made for each 1 mg sulfide/L. In addition, other chlorine demand may exist in the form of reduced iron and manganese and organic matter.

As previously noted, sulfate-reducing bacteria are suppressed in contact with dissolved oxygen. Increased aeration or ozonation of well water systems has been recommended in this regard.

Public Distribution Systems

As is the case for microorganisms in general, controlling the proliferation of sulfur bacteria in water distribution networks is a matter of prevention rather than remediation. Since major detriments that may involve sulfur bacteria are likely to be associated with the presence of biofilms and tubercles, preventive measures to preclude formation of such deposits on the walls and joints of piping should be exercised. Particularly important in this regard are (*1*) maintenance of uninterrupted water flow and positive pressure at all times, (*2*) maintenance of a protective disinfectant residual, and (*3*) maintenance of dissolved oxygen, particularly, as pertains to suppression of sulfate-reducing bacteria. The hydraulic features of the distribution system are important because soil–water infiltration and accompanying bacterial and organic matter contamination of the potable water, may occur under low pressure and extensive formation of microbial films are promoted in low water flow (stagnating) systems (33). The type of disinfectant employed in water purification may factor in the establishment of a microbial consortium in the distribution system through, for example, alteration of complex organic matter to a bioavailable form (chlorine, ozone), inability to act as a protective or persistent residual (ultraviolet radiation, ozone), rapid dissipation in reactions with organics and metals (chlorine), and ineffective biocidal action at low concentrations (chloramine; 34).

CONCLUSION

Notwithstanding the well-recognized contribution of sulfate-reducing bacteria to the anaerobic corrosion of metals, the role of these organisms and those of the sulfur bacteria in all phases of potable water production remains to be elucidated. In addition, much of the available literature reporting the existence of filamentous sulfur bacteria among microbial residents of biofilms and tubercles in water systems may be questioned with respect to the accuracy of the identification of the organisms and the absence of quantitative data on their existence. Curiously, modern detailed investigations directed at revealing and characterizing the microbial composition of biofilms in distribution systems, generally, have not included specific efforts to detect sulfur bacteria(34). Oligonucleotide probes have been employed in the analysis of the microbial composition of biofilms recovered from three locations in a German water distribution system and it was found that the γ-subgroup of the Proteobacteria, to which certain filamentous sulfur bacteria belong, was a very minor percentage of the total cells; δ-probe was not used(35). Application of modern microbiological analytical techniques to the specific determination of the types and roles of sulfur bacteria in areas of biofilm and tubercle formation is needed and until the results of such studies become available, the extent to which these nuisance organisms are a liability to the water industry will be based largely on circumstantial evidence.

SULFUR CYCLE. See SEDIMENTS: SULFATE REDUCTION IN MARINE SEDIMENTS

SULFUR CYCLE IN SOILS

JAMES J. GERMIDA
STEVE D. SICILIANO
University of Saskatchewan
Saskatoon, Canada

GLOBAL SULFUR CYCLE

Sulfur is an essential element for the growth and activity of all living organisms. It is one of the ten major bioelements required by organisms in relatively high concentrations (i.e., $> 10^{-4}$ M). Sulfur also is an important source of metabolic energy for many bacteria. For example, certain chemoautotrophic (i.e., chemolithotrophic) bacteria obtain energy for cell growth and division by oxidizing reduced sulfur compounds.

Microorganisms are an important component of the global sulfur cycle. Sulfur is volatilized as hydrogen sulfide, carbonyl sulfide, dimethyl sulfide, and so on from

marine algae, marshlands, mud flats, plants, and soil, with dimethyl sulfide being the principal sulfur compound entering the atmosphere. Dimethyl sulfide is converted photochemically to methanesulfonic acid, which is degraded by a wide range of bacteria to carbon dioxide and sulfate (1). Plants primarily assimilate sulfate (2) that is then immobilized as sulfoquinovosyl diacylglycerol (SQDG) or volatilized as dimethyl sulfide (3). Microorganisms degrade SQDG releasing sulfate and closing the terrestrial sulfur cycle (Fig. 1) (4). However, most of the sulfur that cycles through the atmosphere is due to human activities. In fact, since the industrial revolution, increased burning of fossil fuels has almost doubled the rate of sulfur entering the atmosphere by approximately 1.5×10^{11}-kg sulfur per year. Soils subject to atmospheric pollution receive sulfur from the atmosphere largely in the form of dilute sulfuric acid. Thus, sulfate is the main sulfur ion entering soils from the atmosphere; smaller quantities of sulfite and bisulfite may also contaminate these soils. Atmospheric pollution deposits, consisting largely of soot, may also be locally important sources of reduced sulfur compounds particularly in areas adjacent to industrial plants, such as coking and steel works. Because sulfate is the major sulfur ion entering soil from atmospheric pollution, the major sulfur transformations will involve sulfur mineralization and sulfur reduction rather than sulfur oxidation. However, reduced sulfur compounds deposited from atmospheric fallout are rapidly oxidized.

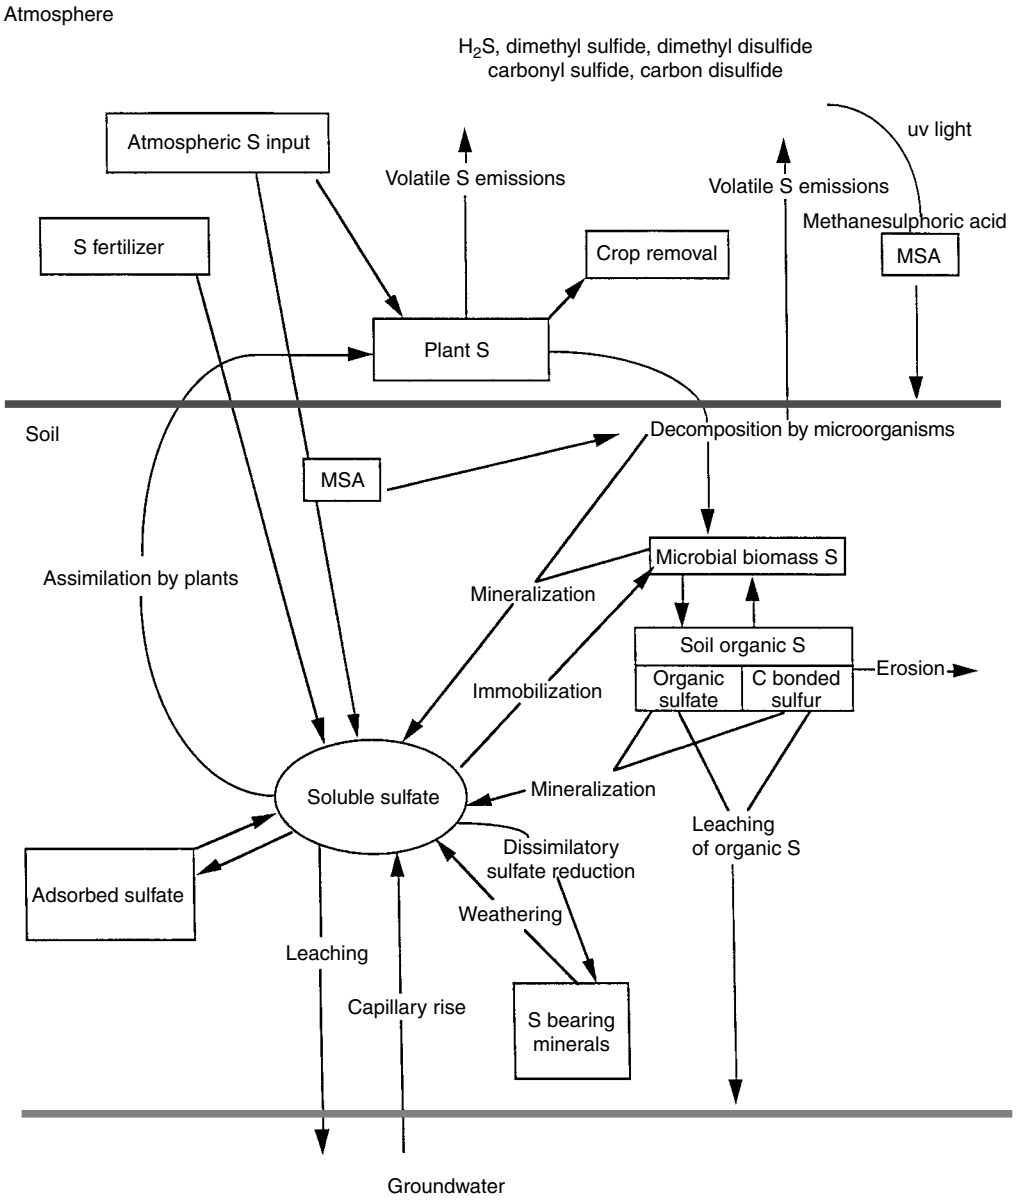

Figure 1. Terrestrial sulfur cycle. Modified from J. J. Schoenau and J. J. Germida, in R. W. Howrarth, J. W. B. Stewart, and M. V. Ivanov, eds., *Sulfur Cycling on the Continents: Wetlands, Terrestrial Ecosystems, and Associated Water Bodies-SCOPE 48*, John Wiley & Sons, Chichester, U.K., 1992, pp. 261–277.

Ivanov, *Sulfur Cycling on the Continents, Wetlands, Terrestrial Ecosystems, and Associated Water Bodies-SCOPE 48*, John Wiley & Sons, Chichester, U.K., (1992).

The nature and quantities of the various sulfur pools in surface soils are the basis for sulfur cycling in terrestrial environments. Pedogenic factors such as climate, regional vegetation, and local topography influence these sulfur pools. For example, the total sulfur content of soils ranges from 0.002 to 10%, with the highest levels found in tidal flats, saline, acidsulfate, and organic soils. To a large extent, the impact of pedogenic factors on sulfur pools in soil can be attributed to alterations in pH, cationic nutrients, and microbial activity (5,6). The comparison of sulfur values of soils from diverse geographic areas illustrates the importance of pedogenic factors in total sulfur concentrations Table 1 (7,8).

Nature and Forms of Organic and Inorganic Sulfur in Soil

Organic sulfur constitutes more than 90% of the total sulfur present in most surface soils. However, because of the polymeric nature of many organic sulfur compounds in soil, their chemical structure is not yet clear. Organic sulfur is grouped into two broad categories — organic sulfates and carbon-bonded sulfur (C–S). Organic sulfates (R–O–S) include sulfate esters (C–O–S), sulfamates (C–N–S) and sulfated thioglycosides (N–O–S). Organic sulfates constitute 30 to 75% of total organic sulfur in soil. C–S includes the sulfur present in amino acids, proteins, polypeptides, heterocyclic compounds (e.g., biotin and thiamin), sulfinates, sulfones, sulfonates, and sulfoxides (Fig. 2). A large portion of C–S present in soil is yet to be identified; however, in some cases, the C–S of amino acids may constitute up to 30% of the organic sulfur in soil. Carbon-bonded sulfur is more stable than organic sulfates and not liable to chemical hydrolysis. One particular sulfonate of interest is the sulfolipid, SQDG, which is one of the most abundant sulfur-containing organic compounds after the amino acids, glutathione, cysteine, and methionine (3). A variety of photosynthetic and nonphotosynthetic organisms use SQDG as a low phosphate replacement of anionic lipids under phosphate-limiting conditions.

Inorganic forms of sulfur account for less than 25% of the total sulfur in most agricultural soils. Sulfur exists in

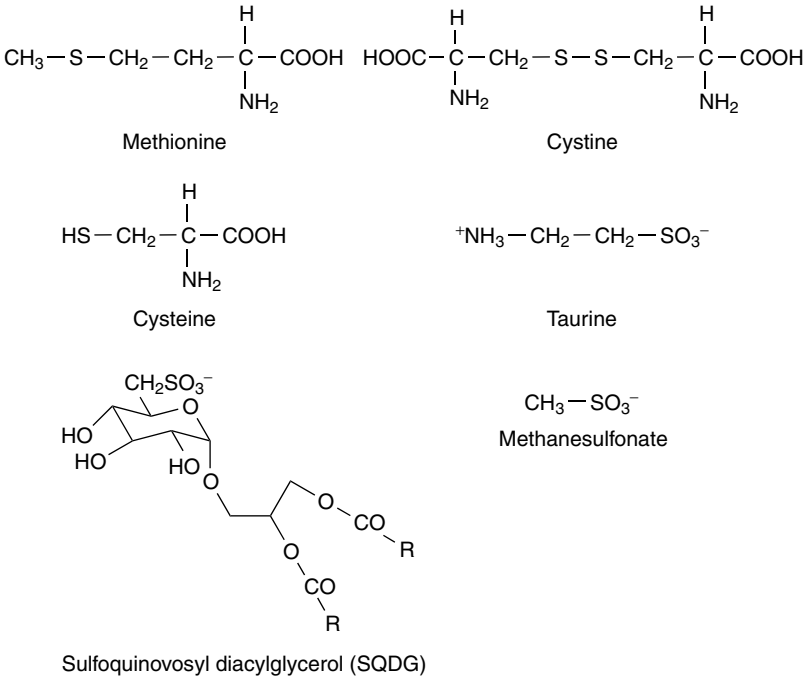

Figure 2. Examples of important organic sulfur compounds containing C–S bonds in the terrestrial environment.

Table 2. Important Forms of Sulfur and Their Oxidation States

Compound	Formula	Oxidation State(s) of Sulfur
Sulfide	S^{2-}	−2
Polysulfide	S_n^{2-}	−2,0
Sulfur[a]	S^0	0
Hyposulfite (dithionite)	$S_2O_4^{2-}$	+2
Sulfite	SO_3^{2-}	+4
Thiosulfate[b]	$S_2O_3^{2-}$	−1,+5
Dithionate	$S_2O_6^{2-}$	+6
Trithionate	$S_3O_6^{2-}$	−2,+6
Tetrathionate	$S_4O_6^{2-}$	−2,+6
Pentathionate	$S_5O_6^{2-}$	−2,+6
Sulfate	SO_4^{2-}	+6

[a]Occurs in an octagonal ring in crystalline form.
[b]Outer *S* has a valence of −1 inner *S* has a valance of +5.

a number of forms with a wide range of oxidation states (Table 2) (9). Sulfide, S^0, sulfite, thiosulfate, tetrathionate, and sulfate are the main forms of inorganic sulfur in agricultural soils. Sulfate is the most common form of inorganic sulfur found in well–aerated agricultural soils. In contrast, sulfides account for less than 1% of total sulfur, and measurable quantities of thiosulfate and tetrathionate are usually detected only in soils treated with sulfur fertilizer or those receiving pollutants. The adsorption of inorganic sulfur to soil is highly pH-dependent, with little or no sorption of sulfate observed at pHs greater than 6.0.

MICROBIAL TRANSFORMATIONS OF SULFUR (SEE ALSO SULFUR CYCLE IN THE MARINE ENVIRONMENT, this Encyclopedia)

Microbial transformations of sulfur are the result of organisms metabolizing sulfur-containing compounds as a source of sulfur for their own anabolic needs, or else, sulfur- containing compounds are used as electron acceptors or donors. This activity regulates the fluxes of sulfur between different sulfur pools in soil (inorganic sulfate, labile organic sulfur, and resistant organic sulfur pools). It can also lead to losses of sulfur from soil by converting complex organic sulfur compounds into mobile forms that may be lost by leaching or by volatilization to the atmosphere. Much of the organic sulfur present in soils is not readily available for assimilation by microorganisms or plants. In fact, it has been shown that organic sulfur added to soil must first be processed by microorganisms to sulfate before plants can assimilate it (2). This sulfur is rapidly immobilized into the microbial biomass as various forms of inorganic and organic sulfur and then remineralized as predators consume microbes. However, the mineralization of immobilized sulfur is not complete and a small fraction of the sulfur enters the "resistant" pool of organic sulfur present in soil (10). Organic sulfur present in the resistant pool is normally found in large (> 5, 000 Da) polymers that must be depolymerized before the sulfur can be mineralized (11). The depolymerization of these polymers is not energetically favorable and many of these polymers are protected from microbial attack by their close association with clay in soil aggregates. Thus, there is a continuum of organic sulfur complexes in soils ranging from very old, stable (e.g., organic sulfur found in soil humus) fractions to very young, short-lived (e.g., organic sulfur found in the amino acid cysteine) fractions. The microbial biomass is the engine for the conversion of passive fractions into active fractions (and vice versa) (Fig. 3) (12).

Assimilation and Mineralization of Sulfur

Biological mineralization and immobilization are processes that occur concurrently and exhibit a strong relationship with the soluble sulfate pool in the soil. Immobilization occurs as a result of the microbial assimilation of nutrients that are then rendered unavailable for further plant or microbial uptake until the cell dies and is "remineralized." Immobilization of sulfur may also involve precipitation as metal sulfide, especially pyrite, as in salt marshes. Soil factors that influence the growth and activity of microorganisms (such as pH, temperature, and moisture) will also affect the rate of sulfur transformations because microbes mediate these transformations. To estimate or predict the available sulfur status of soils, it is necessary to understand the factors that influence these processes.

Assimilation (immobilization)

Microbial assimilation and conversion of inorganic SO_4^{2-} into organic sulfur through the assimilatory sulfate reduction pathway leads to temporary immobilization of sulfur from plant or microbial availability. This process involves ATP sulfurylase and two energy-rich sulfate nucleotides, that is, APS (adenosine 5′-phosphosulfate) and PAPS (3′-phosphoadenosine-5′-phosphosulfate). The overall reaction of SO_4^{2-} incorporation into amino acids is depicted in Figure 4 (13). Typically, the addition of inorganic SO_4^{2-} to soil leads to its quick incorporation into the organic sulfur fractions via microbial assimilation. The presence of an energy source (e.g., the presence of labile organic matter or addition of easily degradable carbon sources such as glucose) increases sulfur assimilation. Later, much of this accumulated sulfur is found in the fulvic acid fractions, especially as organic sulfates.

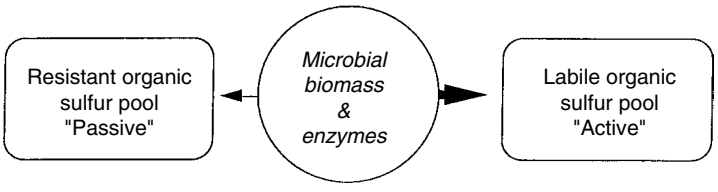

Figure 3. Microbially mediated cycling of organic sulfur between the passive and active sulfur pools in soil. The relative flux of sulfur between pools is reflected in the arrows depicting microbial conversion (12).

Microbial assimilation of aromatic sulfonates is controlled by the sulfate stimulation-induced (SSI) operon. The SSI genes are upregulated in the presence of aromatic sulfonates, but repressed by the presence of sulfate, cysteine, or thiocyanate (14). Aromatic sulfonates are extracellularly bound and transported across the cell membrane. Once inside the cytoplasm, the C–S bond is cleaved by a monooxygenase, and the sulfite produced enters the sulfite assimilation pathway at the level of sulfite reductase as depicted in Figure 4 (13). In contrast, the use of aromatic sulfonates as a source of carbon and energy is substrate-induced and involves dioxygenases that are typically encoded on plasmids.

The use of alkane sulfonates as sources of cellular sulfur is mediated by either α-ketoglutarate-dependent dioxygenases, used only for taurine or $FMNH_2$-dependent monoxygenases, used for methanesulfonate and other alkanesulfonates. Taurine desulfurization involves a dioxygenase, which is only used with taurine, that introduces molecular oxygen into the sulfonate and α-ketoglutarate that degrades to aminoacetaldehyde. This reaction, mediated by *TauD* is specific for taurine, with no desulfonation activity seen for alkane sulfonates less than C6. In contrast, the sulfonate monooxygenase *SsuD*/*MsuD* is used for a variety of alkane and aromatic sulfonates, with only a single molecular oxygen being introduced into the sulfonates (Fig. 5).

Most of the sulfur accumulated by microorganisms is in the form of amino acids in proteins; however, microorganisms also accumulate sulfate-esters, sulfonates, vitamins, cofactors, and so on. Some microorganisms such as fungi accumulate large amounts of sulfate-esters in particular. This is important because organic sulfates (e.g., sulfate-esters; thioglucosides) are considered to be the most labile form of organic sulfur in the soil, and may comprise up to 30 to 70% of the organic sulfur in surface soils. The relative proportion of fungal biomass to bacterial biomass in the soil (ca. 2 : 1) underscores the potential importance of microorganisms accumulating ester-sulfur compounds.

The assimilation of sulfate-esters occurs through a variety of enzymes that can be classified as alkaline sulfatases with pH optima of 8.3 to 9.0 or as acid sulfatases with pH optima of 6.5 to 7.1. These arylsulfatases contain an active glycine site. This glycine is hydrated and attacks the sulfate ester, breaking the sulfur–oxygen bond and forming a brief covalent bond with the SO_3 group (15). The sulfite enzyme complex decomposes to regenerate the enzyme and sulfate (15). Almost all arylsulfatases are repressed by the presence of inorganic sulfate indicating that these enzymes are involved in the assimilation of sulfur from sulfate esters (14). In contrast, only two alkylsulfatases, lithocholate sulfate sulfatase (16), and cholinesulfatase (17) are involved in sulfur assimilation with the remainder of the known alkylsulfatases providing carbon and energy to the organism. Novel arylsulfatases are postulated for those organisms that are able to anaerobically assimilate sulfur from sulfonates but do not possess the typical arylsulfatases (18).

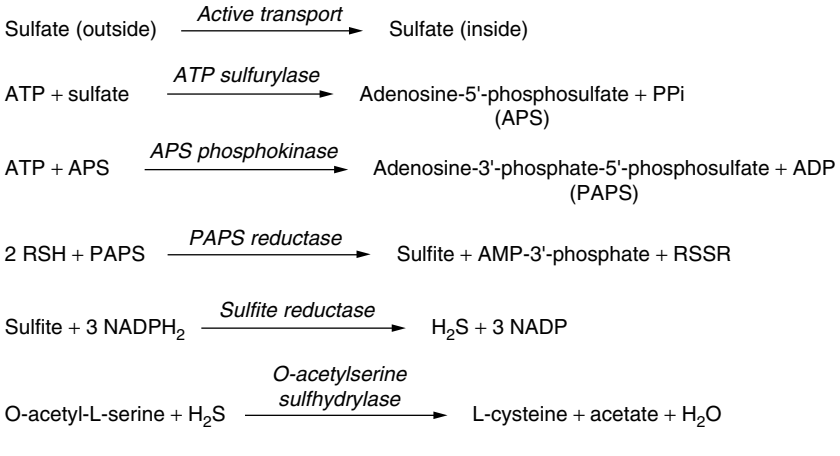

Figure 4. Assimilatory reduction of sulfate and formation of cysteine. RSH stands for thioredoxin; its reduced form is regenerated from the oxidized form (RSSR) through reduction by $NADPH_2$ [13].

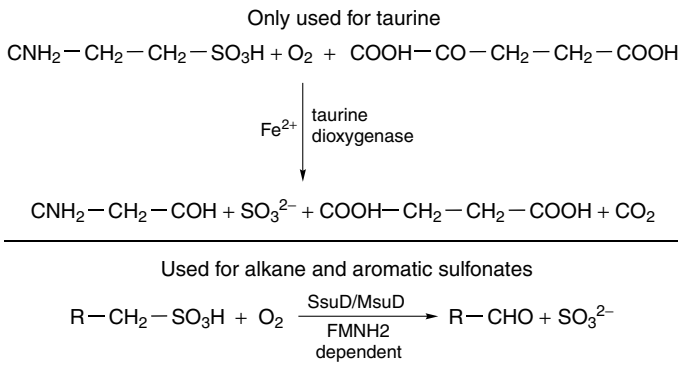

Figure 5. Two different pathways of organosulfonate assimilation. The sulfite produced by both systems is used in the typical cysteine pathway.

Mineralization

Mineralization of organic sulfur in soil is mediated by soil microorganisms. The various known pathways of sulfur mineralization are summarized in Figure 6 (19). Carbon–bonded sulfur is mineralized either through oxidative (aerobic) decomposition or desulfurization (anaerobic) processes, whereas various sulfatases are involved in the mineralization of sulfate–esters. The mineralization process may be direct (i.e., biological mineralization), involving viable microbial cells, or indirect (i.e., biochemical mineralization), involving extracellular sulfatase enzymes. In the case of direct mineralization, elements (e.g., nitrogen, and sulfur) in direct association with carbon are mineralized as microorganisms oxidize the organic carbon compounds to obtain energy. Heterotrophic soil microorganisms decompose organic sulfur compounds to grow, and as the C–S bond is broken, the sulfur is released, usually as sulfide. Because this process involves actively growing microorganisms, their requirement for sulfur may meet or even exceed the sulfur supplied by the substrate. Thus, the net mineralization of sulfur by this process may not be reflected by increases in the sulfate-sulfur pool in soil. In the case of indirect mineralization, those elements that exist as sulfate-esters are hydrolyzed by intracellular or extracellular enzymes. This process, also known as enzymatic mineralization, occurs mainly outside the cell and may be regulated by end-product inhibition (i.e., the level of SO_4^{2-}). Other pedogenic factors such as percentage of organic carbon and soil type have a significant influence on indirect mineralization. For example, activities of arylsulfatases in four different soil types varied between 79 and 308 μg *p*-nitrophenol $g^{-1}h^{-1}$ (20). Furthermore, the dependence on the reaction rate of sulfur concentrations also varied between soils indicating that the enzymes themselves may also differ between soil types (21). Direct mineralization is controlled by the microbial need for carbon and energy sources, whereas indirect mineralization is controlled by factors influencing enzyme synthesis, activity, and kinetics.

Mineralization is generally measured as net mineralization, that is, the amount of SO_4^{2-}-sulfur accumulated during the period under study or the differences between gross mineralization and assimilation. Thus, for higher net mineralization to occur, the mineralization-assimilation process has to be driven toward mineralization. A breakeven point for mineralization and immobilization can be calculated based on C : S ratio of the substrate, the decomposer organisms, and the yield coefficient. For example, if we consider the decomposition of crop residues, net mineralization will generally occur with a C : S ratio of 200 or less, whereas net sulfur immobilization occurs when the ratio is greater than 400 : 1. Because microbial activity is the driving force for these two processes, they are significantly influenced by all factors affecting microbial metabolism; energy and nutrient supply, C : S ratio, abundance of organic sulfur, water availability, pH, temperature, and redox potential (Eh).

For example, actively growing plants may significantly increase sulfur mineralization in soils. Plants supply energy sources to the rhizosphere in the form of root exudates, which increases microbial growth and activity, thus increasing sulfur mineralization. However,

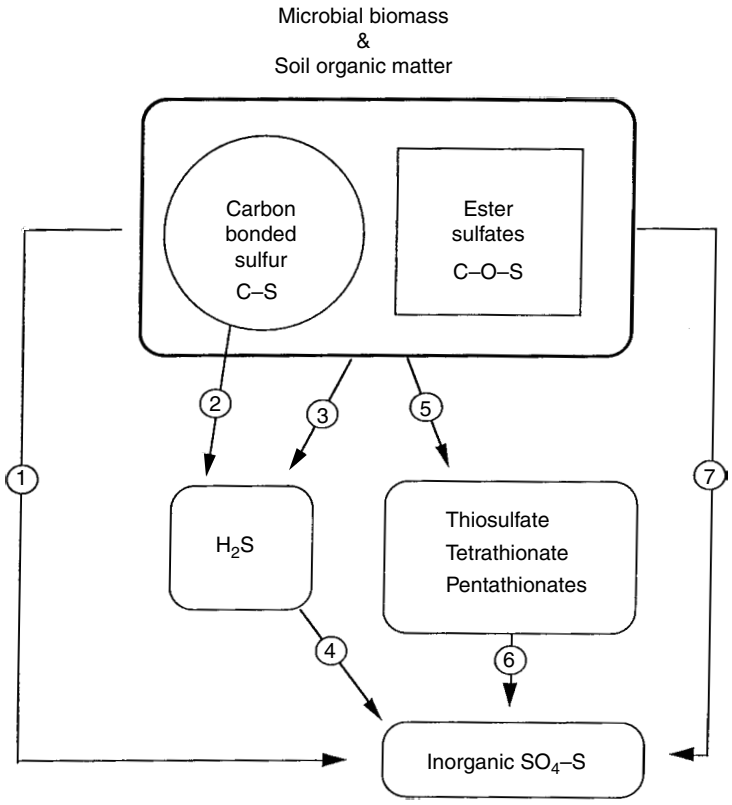

Figure 6. Conceptual pathways for the mineralization of organic sulfur compounds in soil: (1) biological (direct) mineralization during the oxidation of carbon as an energy source; (2) hydrolysis of cysteine by cysteine desulfhydrolase; (3) anaerobic mineralization (desulfurization) of organic matter; (4) biological oxidation of hydrogen sulfide and sulfite; (5) incomplete oxidation of organic sulfur into inorganic sulfur compound; (6) biological oxidation of tetrathionate to sulfate through sulfide; and (7) biochemical (indirect) mineralization when sulfate esters are hydrolyzed by sulfatases (19).

the reassimilation of inorganic sulfates released by the growing microorganisms may not result in an increase in the "plant available" sulfur pool and may even result in reduction of the "plant-available" sulfur pool when the microbial demand exceeds the rate of sulfur mineralization (2). A good example of this can be seen in a study by Ghani and coworkers (22) in which the effect of glucose amendments on the mineralization of sulfate was compared. These authors found that 50% less sulfate was mineralized by an active microbial biomass when compared with a more dormant community. The mineralization and/or assimilation balance can also be shifted by the amount of available sulfate in the soil (6). Soils that have low amounts of available sulfur rapidly assimilate radiolabeled sulfate that is added to it. However, in the presence of added sulfate, little of the biomass is labeled with the radioisotope tracer indicating that the microbial community is not assimilating the added sulfate (10).

The direct mineralization of aromatic sulfonates can occur by two major pathways and results in the release of sulfite from the aromatic sulfonate as shown in Figure 7. In the first pathway (Fig. 7a), sulfate is removed from the aromatic ring before cleavage by the action of a dioxygenase. This type of pathway has been established in an *Alcaligenes* sp. and *Comamonas testosteroni* strain during the metabolism of *p*-toluenesulfonate (23,24). Alternatively, the sulfate can be removed after ring cleavage by a hydrolytic reaction (Fig. 7b) as is typified by the pathway elucidated in *Hydrogenophaga palleronii* SI and *Agrobacterium radiobacter* S2 (25).

Direct mineralization can also occur under anaerobic conditions. Initially, the ability of organisms to use organic sulfonates as a terminal electron acceptor was discounted as experimental error. However, in recent years it has become evident that a wide range of bacteria can use sulfonates as terminal electron acceptors and some strains can ferment these compounds (26–28). The fermentation of sulfonates results in the release of thiosulfite, whereas the use of sulfonates as terminal electron acceptor releases sulfide as an end-product. It appears that the use of sulfonates or sulfates as terminal electron acceptors occurs by two discrete regulatory pathways with cells accustomed to using sulfate as a terminal electron acceptor, preferring sulfate to sulfonate and vice versa. In addition to their use as terminal electron acceptors, some sulfonates can serve as electron donors with nitrate acting as an electron acceptor (29). This unique reaction performed by an *Alcaligenes* sp. links the sulfur cycle to the nitrogen cycle, with taurine acting as an electron donor. Sulfate and nitrogen gases are produced as a result. The prevalence of sulfonate-using denitrifying bacteria remains to be seen.

MICROBIAL OXIDATION OF INORGANIC SULFUR COMPOUNDS

The abiotic oxidation of reduced sulfur compounds occurs to a limited extent in soils, however microbial reactions are clearly the dominant mechanisms for sulfur oxidation. For example, the biological oxidation of sulfide in soils apparently takes place via the following sequence of reactions although some of the products may result from abiotic side reactions

$$S^0 \rightarrow S_2O_3^{2-} \rightarrow S_4O_6^{2-} \rightarrow SO_4^{2-}$$

Many different microorganisms are important for the oxidation, reduction, and cycling of sulfur in the soil and other ecosystems (Table 3) (30). In the case of sulfur oxidation, the microorganisms can be divided into the following groups

- chemoautotrophs (lithotrophs) such as members of the genus *Thiobacillus*
- photoautotrophs, including species of purple and green sulfur bacteria (photosynthetic bacteria)
- chemoheterotrophs (organotrophs), including a wide range of bacteria and fungi

The chemoautotrophs and heterotrophs are largely responsible for oxidizing sulfur in most aerobic, agricultural soils.

Many chemoautotrophic bacteria (e.g., thiobacilli) are capable of oxidizing reduced inorganic sulfur compounds. The biochemistry of sulfur oxidation by thiobacilli

Source: Adapted from R. B. Cook and C. A. Kelly, in R. W. Howarth, J. W. B. Stewart and M. V. Ivanov eds., *Sulfur Cycling on the Continents, Wetlands, Terrestrial Ecosystems, and Associated Water Bodies-SCOPE 48*, John Wiley & Sons, Chichester, U.K., 1992, pp. 145–188.

growing in vitro has been extensively reviewed, and detailed information can be found elsewhere (31,32). For acidophilic thiobacilli, the most common sequence of reactions involved in sulfur oxidation is as follows

$$S^0 \rightarrow SO_3^{2-} \rightarrow SO_4^{2-}$$

A variety of thiobacilli, ranging from obligate acidophilic chemoautotrophs to facultative chemoautotrophs (thiobacilli that grow autotrophically with reduced inorganic sulfur compounds as energy sources, but are also capable of heterotrophic growth) to mixotrophs (thiobacilli able to utilize mixtures of inorganic and organic compounds simultaneously), can be isolated from natural habitats. The thiobacilli differ in their physiological characteristics and in the reduced sulfur compounds used as energy sources (Table 4) (33–35). The majority of these thiobacilli are obligate aerobes, although some such as *Thiobacillus denitrificans* can grow anaerobically using nitrate as a terminal electron acceptor (36). Other species of thiobacilli use electron donors such as ferrous iron (*T. ferrooxidans*) and thiosulfate (*T. thioparus*) in addition to sulfur. Although thiobacilli can oxidize sulfur to plant-available SO_4^{2-} in some soils, it is evident that this process is also mediated by many different heterotrophic soil microorganisms including the genera: *Thiomicrospira*, *Thiosphaera*, *Thiovulum*, *Beggiatoa*, *Thiothrix*, *Thioploca*, *Thiodendron*, *Thiobacterium*, *Macromonas*, *Achromatium*, *Thiospira*, *Paracoccus*, *Hyphomicrobium*, *Alcaligenes*, *Pseudomonas*, and *Hydrogenobacter*. Some bacteria can oxidize thiosulfate or sulfite and couple this to the reduction of nitrate to ammonia (37).

The view that thiobacilli play the dominant role in sulfur oxidation in soils is largely based on the observation that these bacteria achieve rates of sulfur oxidation in culture far greater than those achieved by heterotrophs growing under the same conditions. The fact that most thiobacilli are facultative or obligate chemoautotrophs means that they are able to oxidize sulfur independent of the supply of available carbon. Marked increases in numbers of thiobacilli generally follow the addition of reduced forms of sulfur to some soils, supporting the concept that populations of thiobacilli are important oxidizers of the added sulfur. However, no consistent correlation has been found between sulfur-oxidation rates and the incidence of thiobacilli, except that rates of sulfur oxidation are generally low in soils that lack these organisms and are accelerated in soil inoculated with thiobacilli. It is probable that in many

soils, the initial oxidizers of reduced sulfur compounds will be heterotrophic organisms until the pH is reduced sufficiently to permit oxidation by chemolithotrophs. In addition, there is good evidence that consortia of heterotrophs and auototrophs working together bring about the oxidation of sulfur in agricultural soils. Recent work has shown that there is a dynamic cycling between oxidized and reduced forms of sulfur in the rhizosphere of rice paddies (38). Plant roots provide electron donors, that is, energy sources necessary for the sulfate-reducing bacteria to reduce sulfate to sulfide. This process is aided by the low-oxygen conditions surrounding the root system and the development of anoxic microsites such as the formation of iron sulfide aggregates. Sulfur-oxidizing bacteria such as *Thiobacillus* quickly oxidize the reduced sulfur back to sulfate and the cycle is complete.

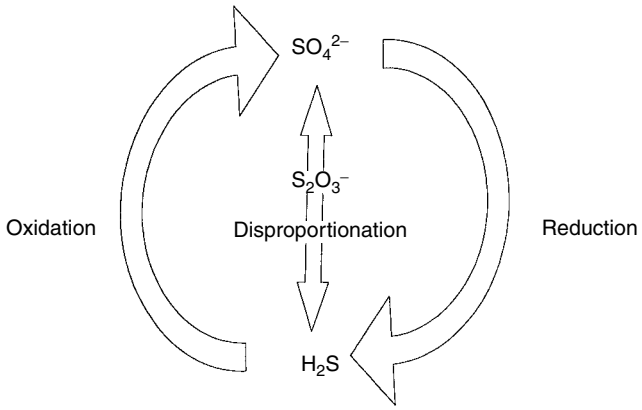

Figure 8. The thiosulfate shunt in anoxic sediment (41).

Thiosulfate Shunt

In the late 1980s, it was discovered that bacteria can disproportionate thiosulfate or sulfite (39,40). A disproportionation reaction, also called fermentation, takes place when one portion of the molecule acts as an electron donor and another part acts as an electron acceptor. In the case of an isolate of *Desulfovibrio sulfodismutans*, this results in the following reactions

$$S_2O_3^{2-} + H_2O \rightarrow SO_4^{2-} + HS^- + H^+$$

$$4SO_3^{2-} + H^+ \rightarrow 3SO_4^{2-} + HS^-$$

This discovery was quickly followed up by the realization of the importance of this disproportionation reaction to the global sulfur cycle and was termed *the thiosulfate shunt* (Fig. 8) (41). Its effects on sulfur flow in sediment is dependent on the oxygen status of the sediment, with sulfate predominating in the upper oxic sediment layers and sulfide in the lower anoxic layers. Similar results have been found for sulfonates, with the bacteria fermenting taurine and disproportioning the sulfonate to sulfate and sulfide. In fact, this group of bacteria has been proposed as a new genus *Desulfonispora*, because there appear to be a number of isolates capable of disproportionating organic sulfonates (28,42). This shunt has been found to predominate in marine sediment, (43) but its importance in upland terrestrial systems is not yet clear. However, this process has been found to account for approximately 60% of the thiosulfite transformation in oxic sediments, and thus one could expect the presence of this process to occur in terrestrial systems as well.

Other Sulfur Bacteria

Other bacteria may also oxidize sulfur compounds. The gliding sulfur oxidizers include those bacteria whose cells are arranged in trichomes that show a gliding motion on the substrate. The most important members of this group in relation to sulfur oxidation in soils are species of *Beggiatoa*, the bacteria that participate in sulfide oxidation in the root zone of rice. All strains of *Beggiatoa* deposit sulfur in the presence of H_2S. (see SOIL BACTERIA, this Encyclopedia) Phototrophic bacteria, such as *Chromatium*

and *Chlorobium* also play an important role in sulfide oxidation in rice paddy soil, but not in aerobic agricultural soils. A number of nonfilamentous, chemolithotrophic sulfur- oxidizing bacteria, such as *Sulfolobus*, *Thiospira*, or *Thiomicrospira*, have also been isolated from special habitats, but the importance of these bacteria in sulfur oxidation in soils is yet to be determined. The activity of different groups of sulfur-oxidizing bacteria might be predicted on the basis of the relative turnover rates of inorganic sulfur compounds and organic substrates.

Biogenesis and Oxidation of Metal Sulfides

Metal sulfides may be formed through biotic or abiotic reactions. In both cases the metal sulfide results from the interaction between a metal ion and a sulfide ion:

$$M^{2+} + S^{2-} \rightarrow MS$$

Many sulfate-reducing bacteria, such as *Desulfovibrio* spp. or *Desulfotomaculum* spp. are involved in the biogenesis of sulfides of antimony, cobalt, cadmium, iron, lead, nickel, and zinc. The extent of metal sulfide genesis depends on many factors, the most important of which is the relative toxicity of the metal ion. In nature, this toxicity is probably reduced when the metal ions are adsorbed on clays or complexed with organic matter. The formation of metal sulfides during the mineralization of organic sulfur compounds is also possible, although little is known about this phenomenon.

The oxidation of metal sulfides in soil involves both chemical and microbial processes and, as a result, is a more complex process than the oxidation of S^0. Chalcocite (Cu_2S), chalcopyrite ($CuFeS_2$), galena (PbS), pyrite (FeS_2), and nickel sulfide (NiS) are just a few examples of metal sulfides that are subject to microbial transformations. For example, the biological oxidation of pyrite (FeS_2) can follow one of two pathways. The first follows a series of oxidation steps described in equations 1 to 4. The second mechanism of pyrite oxidation involves thiosulfate as an intermediate, but in the end, requires the oxidation of elemental sulfur to sulfate by *Thiobacilli* (45). The reader is invited to two excellent reviews for further details of this area (46,47). These biotic oxidations are responsible for the formation of acid mine drainage and acid soil formation in surface mine spoils. (see ACID MINE DRAINAGE, this Encyclopedia) First, ferrous sulfate is formed as the result of an abiotic oxidation step:

$$2FeS_2 + 2H_2O + 7O_2 \rightarrow 2FeSO_4 + 2H_2SO_4 \qquad [1]$$

This reaction is then followed by the bacterial oxidation of ferrous sulfate generally by *T. ferrooxidans:*

$$4FeSO_4 + O_2 + 2H_2SO_4 \rightarrow 2Fe_2(SO_4)_3 + 2H_2O \qquad [2]$$

This reaction occurs chemically but can be accelerated 10^6 to 10^8 times by thiobacilli. This bacterial oxidation of ferrous ion plays an important role in the bioleaching of metal sulfides in the environment because it cycles the iron between +2 and +3 and the iron is then free to abiotically oxidize sulfide minerals (Fig. 9) (48).

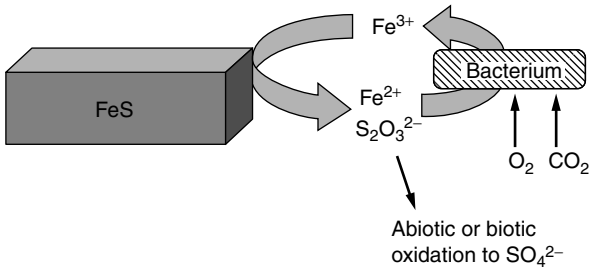

Figure 9. Indirect mechanism by which bacteria oxidize pyrite (48).

Subsequently, ferric sulfate is reduced and pyrite oxidized by a strictly chemical reaction.

$$Fe_2(SO_4)_3 + FeS_2 \rightarrow 3FeSO_4 + 2S^0 \qquad [3]$$

$$2S + 6Fe_2(SO_4)_3 + 8H_2O \rightarrow 12FeSO_4 + 8H_2SO_4 \qquad [4]$$

The elemental sulfur produced is finally oxidized by *T. thiooxidans* and *T. ferroxidans*, and the acidity produced helps the whole process to continue.

$$2S^0 + 3O_2 + 2H_2O \rightarrow 2H_2SO_4$$

Note the net production of 10 molecules of H_2SO_4 during the process.

Although several sulfur-oxidizing thiobacilli and heterotrophs can be isolated from acid sulfate soils in which pyrite is being oxidized, they appear not to play an important role in the process, with the exception of *T. ferroxidans*. The biological oxidation of sulfides and other reduced sulfur compounds can have severe consequences for the environment. For example, acid mine drainage contaminates several thousand miles of streams in the Appalachian coal mining region of the United States. (see ACID MINE DRAINAGE, this Encyclopedia)

MICROBIAL REDUCTION OF INORGANIC SULFUR COMPOUNDS

Bacterial Sulfate Reduction

The reduction of sulfate to hydrogen sulfide is mediated mainly by anaerobic bacteria, typically referred to as sulfate-reducing bacteria (SRB). This process may be significant in anaerobic soils (i.e., waterlogged soils), but is usually not important in well-aerated agricultural soils except in anaerobic microsites. Nevertheless, sulfate reduction is a major component of the sulfur-cycle in soils exposed to waterlogging or periodic flooding, especially where readily decomposable plant residues are present.

Microorganisms reduce oxidized sulfur compounds by either an assimilatory or dissimilatory process. Assimilatory sulfate reduction is used by organisms to meet their sulfur requirements (see preceding section). In dissimilatory sulfate reduction, bacteria use sulfate as a terminal electron acceptor, and large quantities of hydrogen sulfide (H_2S) are excreted. Dissimilatory sulfate reduction

Table 5. Dissimilatory Sulfate-Reducing Bacteria

Genera	*Desulfobacter*, *Desulfobulbus*, *Desulfococcus*, *Desulfonema*, *Desulfosarcina*, *Desulfovibrio*, *Desulfomicrobium*, *Desulfomonas*, *Desulfobacterium*, *Desulfococcus*, *Desulfomonile*, *Desulfotomaculum* - Gram positive, endospore former *Thermodesulfobacterium* - thermophilic *Archaeoglobus*–archaeal thermophilic
General characteristics	Anaerobes Grow at mildly acid to mildly alkaline pH Generally mesophilic, but some species thermophilic Some species can use alternative electron acceptors such as nitrate or oxygen.
Substrates	Most SO_4^{2-} reducers will also reduce sulfite and thiosulfate Some species reduce elemental S Organic matter utilization varies with genus and species As a group, capable of completely oxidizing fatty acids from C1–C18, lactate, pyruvate, low-molecular-wt. alcohols, and some aromatic compounds
Habitats	Anaerobic sediments of freshwater, brackish water and marine environments, thermal regions, marine and animal intestines; water logged soils

Sources: Adapted from P. A. Trudinger, in M. A. Tabatabai ed., *Sulfur in Agriculture*, American Society for Agronomy, Madison, Wis., 1986, pp. 1–22 & H. F. Castro, N. H. Williams, and A Ogram, *FEMS Microbiol. Ecol.* **31**, 1–9 (2000).

is a strictly anaerobic process. In this case, it is carried out by bacteria such as *Desulfovibrio* spp., *Desulfomonas* spp., and *Desulfotomaculum* spp. (Table 5) (49,50) These bacteria utilize end-products of other fermentations such as lactate, malate, and ethanol as electron donors.

When a soil is flooded, electron acceptors become reduced in an ordered sequence: first oxygen, followed by nitrate, nitrite, manganic, and ferric compounds, and lastly sulfate and carbon dioxide. Although the reduction of one compound does not have to be completed before another is reduced, oxygen and nitrate must be removed before the reduction of ferric and sulfate ions can occur. Because of this reaction sequence, there are generally sufficient ferrous ions available to react with any H_2S produced, and as a result, free H_2S is rarely liberated from soils. Sulfate reduction increases during the period of soil submergence and following the addition of organic matter. Sufficient organic substrates to stimulate the process are also liberated from seeds and from roots into the rhizosphere, with the result that in paddy soils, blackening caused by ferrous sulfide deposits often occurs in the root region. (see FLOODED SOILS, this Encyclopedia) There is evidence, however, that rice roots can aerate the soil sufficiently such that ferric iron is observed on the root surface. In general, the rate of sulfate reduction increases with decreasing Eh, with the optimum being a function of soil pH, around −300 mv at pH 7. Sulfate reducing bacteria are active in habitats such as soil, sediments, polluted water, oil-bearing strata, and shales. Their activity may be beneficial or detrimental to the surrounding environment and have serious economic consequences.

Recent work has identified alternative metabolic strategies for SRB that live in environments low in sulfate. Sulfate reducing bacteria can live in close association with methanogens (51). In environments, rich in organic substrates but low in electron acceptors such as sulfate, SRBs transfer the reducing equivalents produced by degradation of organic compounds, to methanogens living in close proximity Fig. 10 (51). The methanogens then use this hydrogen to produce methane and keep the hydrogen partial pressure in the appropriate range that makes the extracellular transfer of hydrogen a feasible alternative for SRB (52). Alternatively, SRB can use a variety of sulfonic acids such as isoethionate or cysteate as terminal electron acceptors. The pathway used by SRB differs from that used for the reduction of sulfate in that it does not appear to use ATP sulfurylase or APS reductase (53). The ability to use alternative electron acceptors among the SRB may be limited to only a few specialized strains and the relevance of these alternative electron acceptors to field situations is still not clear (54). In the presence of sulfate, SRB revert to their normal metabolic processes because the use of sulfate as an electron acceptor is metabolically the most efficient compared with the alternatives.

Sulfate-reducing bacteria also cause significant environmental problems because of the production of the corrosive hydrogen sulfide as well as the methylation of mercuric ions. For example, SRB are a major cause of corrosion of underground iron pipes, causing damage between $1.6 and $5 billion in the United States in 1990. Turf managers find that SRB can produce a black layer in golf course putting greens by using the organic matter in root exudates to reduce soil sulfates to ferrous sulfides. The methylation of the inorganic mercuric ion by SRB is one of the mechanisms by which flooding of previously dry soil severely affects the soil. Aerobic soils in which SRB were not dominant may become flooded and eventually anaerobic. Consequently, SRB become active and methylate mercuric ion present in the soil (now

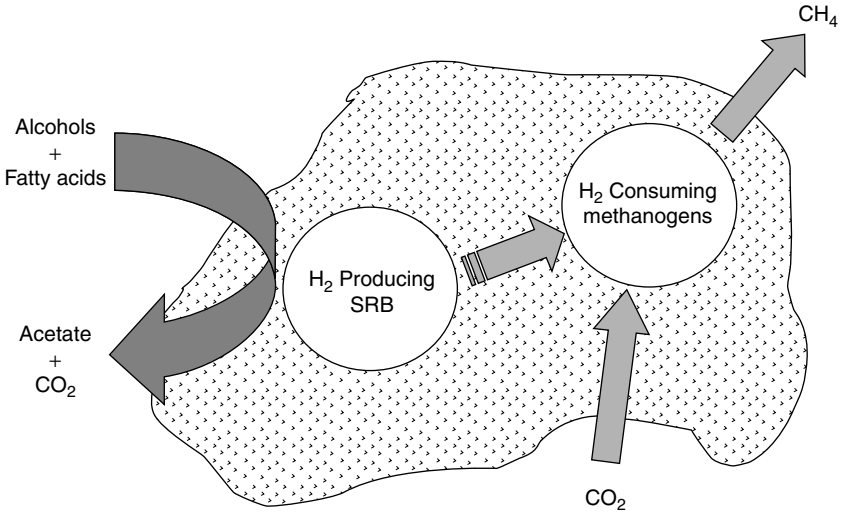

Figure 10. Close association of hydrogen-producing sulfate-reducing bacteria and hydrogen-consuming methanogens allows sulfate-reducing bacteria to be active in the absence of sulfate [51].

sediment) (55). Even when sulfate is depleted, SRB can continue to methylate mercuric ion by transferring hydrogen to methanogens (56). This methylated mercuric ion is toxic and bioaccumulates in the food chain. Mercury is methylated as a side reaction of normal SRB metabolic processes and is not a detoxification reaction (57,58).

CONCLUSION

The cycling of sulfur through aquatic, terrestrial, and atmospheric ecosystems is similar to that of other elements such as carbon and nitrogen, and is influenced by natural and anthropogenic processes. Sulfur exists in a number of oxidation states as inorganic and organic compounds that undergo a number of biotic and abiotic transformations. A large variety of microorganisms mediate the biotic transformations of sulfur and influence its bioavailability and toxicity. Understanding how key processes in the sulfur cycle respond to environmental factors (e.g., construction of models of mineralization and volatilization processes that include temperature, moisture, substrate, and microbial composition response functions) will help us predict accurately the impact of changes, either induced by humans or natural, on sulfur fluxes in all components of the biosphere.

JOHN DORAN
USDA–Agricultural Research Service
University of Nebraska
Lincoln, Nebraska

The natural processes that sustain life on earth are threatened by anthropogenic influences such as increasing human populations, resource consumption, social instability, and environmental degradation (1,2). These natural processes, especially microbial processes, can be managed to reduce the negative impact of these anthropogenic influences. Global climate change, depletion of the protective ozone layer, reduction in species biodiversity, loss of productive agricultural lands, and degradation of soil, water, and air are among the most pressing concerns associated with our technological search for a higher standard of living for an ever-growing human population. Past management of agriculture and other ecosystems to meet population and development needs has taxed the resiliency of soil and natural processes to maintain global balances of energy and matter (3,4). To preserve and protect the world

for future generations, the focus must be on ecosystem sustainability and development of production systems that rely less on nonrenewable, petrochemical-based resources; more renewable resources from the sun and soil must be relied on for food, fiber, and energy needs; and the ecological intensification needed to meet the increased future food demand must be achieved (5). Microorganisms can play a critical part in remedial efforts.

As strategies are developed to attain sustainable systems, the dilemma is to balance the immediate goal of economic viability and survival of the land manager with the long-term efficient and wise use of resources for a safe and clean environment (6). To this end, strategies that include soil microorganisms to better use natural supplies of energy and nutrients and reduce reliance on nonrenewable fossil fuels and petrochemicals can help achieve this balance.

HIGH-INTENSITY AGRICULTURE AND SOCIETY

In the twenty-first century, population growth rates and standard of living expectations will more than double the need for food supplies to feed a population twice its current size. While the human population is increasing, agricultural lands are shrinking, with little new land being placed into production. Degradation and loss of productive agricultural lands are our most pressing ecological concerns, rivaled only by environmental problems caused by humans, such as global climate change, depletion of the protective ozone layer, and serious declines in biodiversity (7). Under our current industrial model for food production, achieving the required agricultural production to support increasing food needs will require increased inputs, further stressing our natural and nonrenewable resources and increasing the potential for environmental pollution (8,9).

Excessive cultivation for seed bed preparation, pest control, and continuous cropping systems have, over the years, led to erosion of valuable topsoil and degradation of organic matter reserves (10). An estimated 40% of the earth's arable land has been degraded by adverse anthropogenic impacts such as soil erosion, atmospheric pollution, extensive soil cultivation, overgrazing, land-clearing, salinization, and desertification (11). Agriculture is considered the most widespread contributor to nonpoint source water pollution in the United States (12). In addition, nitrate nitrogen is a major water contaminant in North America and Europe. The principal sources of nitrate nitrogen are conversion of native land to arable use, animal manures, and fertilizers. Human alterations of the nitrogen cycle have doubled nitrogen inputs to terrestrial ecosystems over the past 30 years, resulting in large increases in the transfer of nitrogen from land to the atmosphere and to rivers, groundwater, estuaries, and coastal oceans (13–15). Land management practices can influence atmospheric quality through changes in the soil's capacity to produce or absorb important atmospheric gases such as carbon dioxide, nitrous oxide, and methane, and many are governed by microbial processes (16,17). The present threat of global climate change and ozone depletion, through elevated levels of greenhouse gases and altered hydrological cycles, can be ameliorated through a better understanding of the influence of land management on soil processes and adequate remediation strategies, particularly microbial aspects (18).

If soil parameters are to be used as indicators of sustainability of land management practices, they must respond to changes in management. As stated in Doran and Parkin (19), "indicators should be sensitive enough to reflect the influence of management and climate on long-term changes in soil quality but not be so sensitive as to be influenced by short-term weather patterns." Soil microorganisms are useful indicators of sustainable land management because they are (*1*) sensitive to variations in management, (*2*) well correlated with soil function, and (*3*) useful for elucidating ecosystem processes (20). The challenge before us is to use soil microbial analyses that can aid decision-making processes and are easily accessible to land managers.

SOIL — AN ESSENTIAL LINK IN THE CYCLE OF LIFE

Soil is a dynamic, living, nonrenewable resource whose condition is vital both to the production of food and fiber and to global balance and ecosystem function (21). The number of living organisms in one teaspoon of fertile soil (10 g) can exceed nine billion, which is 1.5 times the human population of the earth. Microorganisms have been isolated from all environments including hot springs and ice flows in Antarctica. Like water, soil is a vital natural resource essential to civilization but, unlike water, soil is nonrenewable on a human timescale. Soils form slowly, averaging 100 to 400 years per centimeter of topsoil, through the interaction of climate, topography, living organisms (microorganisms, animals, plants, and humans), and mineral parent material over time (22,23). Soils are composed of different sized inorganic mineral particles (sand, silt, and clay); reactive and stable forms of organic matter; a myriad of living organisms such as earthworms, insects, bacteria, fungi, algae, nematodes, and so on; water; and gases including O_2, CO_2, N_2, NO_x, and CH_4. The physical and chemical attributes of soil regulate soil biological activity and interchanges of molecules or ions between the solid, liquid, and gaseous phases, which influence nutrient cycling, plant growth, and decomposition of organic materials. The inorganic components of soil play a major role in retaining cations through ion exchange and nonpolar organic compounds and anions through sorption reactions. Essential parts of many global cycles occur in soil, including carbon, nitrogen, phosphorous, and sulphur, and water cycles. Large portions of these cycles are microbial processes. Soil functions as a filter for a large portion of our groundwater supplies, and soil organic matter is a major pool for carbon, nitrogen, phosphorus, and sulfur. Soil organisms in their constant search for food and energy sources are continually altering the cycling rate and availability of these elements.

The sun is the basis for most life on earth and provides radiant energy for heating the biosphere and for the photosynthetic conversion of carbon dioxide and water into food and oxygen sources for consumption by animals and other organisms. Most living organisms use oxygen to

metabolize these food sources, capture their energy, and recycle heat, carbon dioxide, and water to the environment to begin this cycle of "life" again.

$$\text{(Radiant)} \xrightarrow{\text{Photosynthesis}} \text{(Food)}$$

$$6CO_2 + 6H_2O + \text{Energy} \qquad C_6H_{12}O_6 + 6O_2$$

$$\text{(Heat)} \xleftarrow[\text{Decomposition and combustion}]{} \text{(Fuel)}$$

A simplified version of this "Equation of Life" is depicted in Figure 1.

The amount of carbon dioxide in the atmosphere is small and represents less than 0.04% of all gases in the atmosphere. If all the combustion and respiration processes on earth were halted, the plant life of the earth would consume all available carbon dioxide within a year or two. Thus, there is a fine balance between carbon dioxide production and utilization in the biosphere. Decomposition processes in soil play a predominant role in maintaining this balance, both in recycling carbon to the atmosphere as carbon dioxide and in the formation of soil organic matter, which serves as a sink for atmospheric carbon. These processes are brought about by a complex web of organisms in soil, each playing unique roles in the physical and chemical breakdown of organic plant and animal residues. Decomposition is a critical responsibility of the microbial world. In the food web, almost 95% of all material must cycle through the microbial portion (24). Together, fungi, actinomycetes, and bacteria possess a vast array of biochemical pathways that are capable of mineralizing any naturally occurring organic material. The physiological diversity of this decomposer community, however, enables continued activity over a wide range of conditions, an essential attribute in a soil environment that is continually changing. Soils play a major role in transforming sunlight and stored energy and recycling matter through plants and animals. Decomposition processes, as mediated by organisms in soil, play a predominant role in completing this cycle of life. This capability is essential for the completion of biogeochemical cycles and continuation of life on earth. The capacity to degrade natural organic compounds is also the key to the use of microorganisms for bioremediation of organic pollutants such as pesticides, solvents, and propellants made by humans. Many of these compounds can be degraded to some extent, using the same biochemical pathways used to degrade natural organics. These microorganisms, as recyclers, provide building block nutrients to plants and C as CO_2 to the atmosphere. Thus, the thin layer of soil covering the surface of the earth and the microbes contained within it are the major interface between agriculture and the environment and represent the difference between survival and extinction for most land-based life (21). The health and quality of soil and thus the functioning of the microorganisms with the soil are integral in directing agricultural sustainability (25), environmental quality (26), and plant, animal, and human health (27).

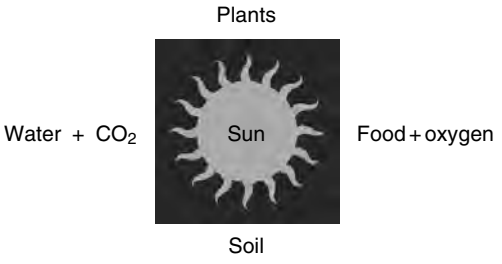

Figure 1. Soil — an essential link in the cycle of life.

SOIL HEALTH AND SUSTAINABLE MANAGEMENT

Interest in the quality and health of soil has been stimulated by renewed awareness that soil is vital to production of food and fiber, global ecosystems function, and the maintenance of local, regional, and global environmental quality (28,29). Soil plays a key role in the health of humans by being the medium for food production, serving as a major interface with the environment, affecting the quality of the drinking water, and quality of air breathed. Soil health and quality assessments can be used to predict the sustainability of systems or management practices (30). Soil health or quality can be broadly defined as the capacity of a living soil to function within natural or managed ecosystem boundaries, sustain plant and animal productivity, maintain or enhance water and air quality, and promote plant and animal health (21,31). Soil quality and health change over time because of natural events or human impacts such as management and land-use decisions. Sustainable practices will result only when the multiple functions of soil are included in decisions. Management strategies that consider only single functions such as crop productivity but not environmental impact or vice versa will not be successful. Indicators of soil quality and health should be designed to adequately describe ecosystem processes through physical, chemical, and biological properties. These indicators also need to be sensitive to management and climatic variations, accessible, and easy to use (32). As illustrated in Figure 2, soil quality is conceptualized as the major linkage between the strategies of conservation management practices and achievement of the major goals of sustainable agriculture (30,33). Soil quality or health assessment and the direction of the change of select indicators with time can be the basic indication of sustainable land management.

Profitability and environmental protection are both goals that need to be attained if sustainability is to be achieved. For example, one framework for determining the sustainability of hill country agriculture in the Philippines employs indicators that consider both the satisfaction of farmer needs for productivity, profitability, stability, and viability, and those needed for conservation of soil, water, and air resources (34). In this example the threshold values, or trigger values, for sustainability were identified relative to the average local conditions for crop yield, profit, risk, soil depth, organic matter content, and so on. Modifications of this framework for assessment of sustainability can be expanded to include other needs of society and environmental conservation (35). In reviewing

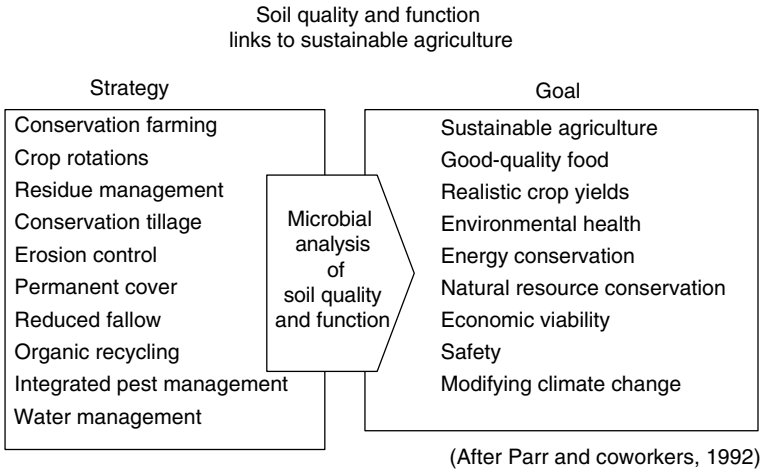

Figure 2. Soil quality and function links to sustainable agriculture.

microbiological indicators of soil quality, Stenberg (36) presented a similar approach developed by a research network in Europe to assess soil quality and sustainability. However, this approach emphasized the shortfall of results from a desired optimum instead of defining minimum thresholds, normalized for local conditions.

MICROBES AND SUSTAINABLE AGRICULTURE

Soil microorganisms are key to sustainability because they are responsible for a variety of functions that impact soil dynamics and agroecosystem health (Table 1; 37). The biological component of the soil is responsible for soil humus formation, cycling of nutrients, pesticide degradation, and building soil tilth and structure along with a myriad of other functions (38,39). Knowledge of microbial functioning is limited, and presently, fully manipulating soil microbial communities has not been successful. By increasing knowledge of microbes and microbial ecology, the ability to manage ecosystems for optimum sustainability is enhanced.

Biodiversity

Microorganisms are responsible for biochemical processes that are needed to sustain life; however, microorganisms can also provide us with information on life processes and evolution (Table 2). They provide sources of genetic material and function as indicators of environmental change (40). Knowledge of soil microorganisms may increase our understanding of biological interactions and aid in conservation and restoration biology. Over 100,000 microbial species may exist, but only a fraction of them are actually identified (41). There is a vast wealth of unknown genetic potential in the biodiversity found in the soil. Soil microbial diversity is thought to overshadow diversity found within higher life-forms (42,43). Little is known about life on earth; less than 10% of microbial species have been identified (41). This untapped potential of genetic material in soil is ready for discovery. Sustainability may in part be tied to the changes in this diversity. Also, the status or health of a system may be assessed by the diversity of that system. The functional and even taxonomic diversity within a given population of microbes may be helpful to determine changes with disturbance or cultural practices. Microbial diversity decreased in chemically or heavy metal–stressed soils (44,45). Diversity may play a critical role in an ecosystem's resilience or ability to buffer the effects of extreme disturbances (46) so that monitoring diversity as an indicator of change or in response to a stress may yield valuable information. However, meaningless changes in diversity and species number should not be misleading. Species composition may not be as defining as

Table 1. The Functions of Soil Microbes in Agriculture Systems

Decomposition of organic residues with release of nutrients
Formation of beneficial soil humus by decomposing organic residues and through synthesis of new compounds
Release of plant nutrients from insoluble inorganic forms
Plant growth enhancement
Improved plant nutrition through symbiotic relationships
Transformation of atmospheric dinitrogen to plant-available nitrogen
Improvement of soil aggregation, aeration, and water infiltration
Antagonistic action against insects, plant pathogens, and weeds (biological control)
Pesticide degradation

Table 2. Justification for Investigations of Soil Microbial Ecology (from ASM, 1994)

Microbes are an important source of knowledge about life strategies and limitations
Microbes are key to understanding evolutionary history
The untapped diversity of microorganisms is a resource for new genes and organisms of value to biotechnology
Microbes and microbial diversity patterns can be used as indicators of environmental changes
Microbial communities are key to understanding biological interactions
Microbes play a key role in conservation and restoration biology of higher organisms
Microbes are critical to sustainability

the flux of species within a system, and the functioning of individual species within that system. The diversity within the soil system allows for exploration of greater genetic potential and understanding functional diversity changes with management.

Soil Organic Matter

The microbial processes that have the greatest impact on sustainability are those processes involved in residue decomposition and organic matter formation. Decomposition processes, as mediated by organisms in soil, play a predominant role in supplying key elements. The processes of soil humus formation, cycling of nutrients, and building soil tilth and structure (38,39) are distributed among a large number of different genera and species. Soil organic matter is the basis of soil quality and soil health. Organic matter consists of organic components, decomposition products, and the soil biomass. The labile fractions of soil organic matter are rapidly turned over, whereas the more biologically resistant fractions and chemically recalcitrant fractions form soil organic matter. Organic matter increases water-holding capacity and nutrient availability, improves soil physical properties, and acts as a cementing agent to bind soil particles together. Organic material can provide sites for bacterial and fungal growth and thus control colonization and community development. Incorporation of crop residues, crop rotation, and addition of animal and green manures can increase soil organic matter.

Residue management is critical to soil organic matter dynamics and is a major factor in determining soil fertility and productivity and in preventing soil erosion (47,48). The residues remaining after harvest can serve as a cover to protect the soil. With practices such as conservation and no-till drilling, more residue is left on or near the soil surface, giving more cover, conserving organic matter, reducing erosion, and often increasing yield. More soil moisture is retained for crop growth, with no-tillage than with conventional tillage (49). The residue and the remaining relatively undisturbed roots serve as a source of food for microbial activity, with significantly higher microbial biomass in no-tilled soils compared to conventionally tilled soils (50). Decomposing roots provide nutrients for microorganisms and also result in the formation of particulate organic matter, a labile fraction of organic matter, most susceptible to loss with intensive cultivation (51). Residue management is critical to nutrient-cycling dynamics in cropping systems, and management strategies that consider microbial processes will lead to sustainability.

When wheat decomposition rates in conventional and no-till systems were compared by evaluating carbon and phosphorus losses, more carbon and phosphorus were lost from fields under conventional tillage than from those under no-till management (52). It was concluded that no-till management, over a period of time, leads to a significant accumulation of carbon and phosphorus, whereas in conventional systems, carbon and phosphorus are lost during the decomposition. Residue retention and decomposition have greater consequences than merely soil protection and yield potential. Recent interest in changes in the global carbon cycle and nutrient cycling (53,54) have increased the focus on determining the potential for agricultural systems to store carbon. Consequently, agricultural soils are recognized not only for their continued potential for producing food and fiber but also as a major interface with the environment, affecting the air and drinking water. These studies have demonstrated a potential for biological management of agricultural cropland soils to sequester carbon and help mitigate the greenhouse effects, atmospheric carbon dioxide, and global climate change (55). Proposals to provide economic incentives to farmers to build soil organic matter and offset industrial emissions of carbon dioxide into the atmosphere heralds a new era in which environmental quality is recognized as a potential novel product of agriculture.

Nutrient Cycling

Microbial processes are integral to the breakdown of organic material and nutrient cycling. Microorganisms are primary decomposers and are critical in the soil food web. It has been estimated that more than 90% of all nutrients pass through this group of organisms to higher trophic levels. Soil microbes constitute a large dynamic source and sink of nutrients in all ecosystems and play a major role in plant litter decomposition and nutrient cycling (51,56,57). Most natural and xenobiotic compounds can be broken down or at least transformed by soil microorganisms.

Certain bacteria have the enzymes necessary for dinitrogen fixation. The symbiotic relationship between bacteria and legumes is one of the most widely studied and applied plant–bacterial interactions (58). The bacterium *Rhizobium* forms nodules on the roots of the legume plant, takes nitrogen from the air, and transforms it to plant-available nitrogen (i.e., NH_4^+, NO_3^-). The plant provides nodules and photosynthate for the bacteria, whereas the bacteria give the plant the nitrogen it needs. Inoculation of legumes with nitrogen-fixing *Rhizobium* can add appreciable amounts of nitrogen to the soil.

Carbon and nitrogen cycling was studied in a comparison of three agricultural systems for corn production (59). One system was the traditional corn and soybean rotation, with high inputs of fertilizer and pesticide use. The other two systems consisted of organic practices and relied on lower inputs of nonrenewable resources in which either manure or legumes were used as "renewable" nitrogen sources. Over a 10-year period, the three systems produced similar yield and were similar in profitability. Their carbon and nitrogen cycling were, however, significantly different. Organic nitrogen increased dramatically in the manure-based system and somewhat in the legume-based system, and was reduced or unchanged in the conventional system. Increasing rotation diversity, altering the carbon to nitrogen ratio of the crops selected, and addition of manure can alter the carbon and nitrogen storage without compromising yield and farm profit. At the Rothamsted Experimental Station in the United Kingdom, similar results have been found (60). Wheat yields on manured fields were equal to NPK-fertilized plots, but the soil organic matter and total soil nitrogen contents increased dramatically, further indicating the benefit of manure-based systems to soil carbon and nitrogen storage.

Plant Growth

Microorganisms are also responsible for many transformations in soil directly related to plant nutrition and health. Although potentially harmful effects from soil microorganisms include plant diseases, production of plant-suppressive compounds, and competition for nutrients, the majority of soil organisms are beneficial to plant growth (38). Specific microorganisms can be manipulated to produce beneficial effects for agriculture; for example, rhizobia to increase plant available nitrogen (58); mycorrhizal associations to enhance nutrient uptake (61); or biological control of plant pests to reduce chemical inputs (62,63). Beneficial soil bacteria can enhance plant performance by increasing mineral solubilization, the production of hormones, and the suppression of harmful pathogens.

Plant species can influence microbial activities and in turn can be greatly influenced by soil microbes. Microbial communities in agroecosystems change with management history. In continuous cropping systems, cycling of pathogens and antagonists of pathogens, and changes in crop yields can often be seen because of the alteration in disease pressure over time. An example of this is the decline of a disease in wheat called "take-all," which results from a change in the soil microbial community. After several years in continuous wheat, the microbial community shifts to favor growth of antagonists of the pathogen *Gaeumannomyces graminis* var. *tritici*, which in turn results in decline of the disease (64). Crop rotation is a critical strategy used in sustainable systems to enhance beneficial microbial species and interactions, interrupt devastating cycles of pathogens, and reduce weed populations. Legumes in crop rotations supply symbiotically fixed nitrogen to the system, aid in maintaining proper water status, and reduce pathogen loads. The benefits of crop rotations to plant growth have been attributed, in part, to changes in the bacterial community composition (65,66). In other studies, continuous monocropping also caused changes in the soil community. The pathogen load was higher and barley growth lower in grains grown in monoculture compared to multiple-crop rotation (67). The populations and aggressiveness of pathogens were altered with crop rotation, indicating the effect of management on microbial numbers and function (68).

Mycorrhizae are nonpathogenic fungi that form symbiotic associations with plant roots. These beneficial mycorrhizal fungi can enhance plant growth by increasing nutrient (62) and water uptake (69). Mycorrhizal fungi have been found growing in association with 90% of terrestrial plants examined (70). Mycorrhizal associations are most important in stressed environments, phosphorus-deficient soils, eroded sites, and acidic or reclaimed lands. This association may be key in plant productivity and nutrient cycling (71,72). Wheat plants inoculated with vesicular arbuscular mycorrhizae (VAM) and subjected to water stress had greater grain yield and biomass than uninoculated plants (73). In Pacific Northwest soils, mycorrhizal fungi lessened the severity of water stress in winter wheat. Plant growth increases were especially notable in soil from eroded ridge tops (58). Vesicular arbuscular mycorrhizae species, abundance, and spore distribution are affected by tillage and crop inputs (74,75). In a comparison of a conventional corn and soybean system and low-input systems, lower levels of VAM fungi were found in the conventional farmed system when compared to the low input with cover crops versus green and animal manures (74). *Glomus occultum* numbers were higher under no-till, whereas other *Glomus* species were more abundant under conventional tillage in a corn and soybean rotation (75). The interaction involving mycorrhizal fungi and rhizobia may further affect the host plant by reducing the need for nitrogen and phosphorus inputs (72). These interactions are specific, further illustrating the complexity of the plant–microbe interaction and the changes in diversity of various microbial groups that can affect plant growth or impact other soil features.

Microorganisms may influence plant competition either through mutualistic or antagonistic relationships. Rhizosphere microorganisms may affect plant growth directly (76) or indirectly by their effects on each other and on soil physical and chemical properties. The effect of microorganisms on competitive plant interactions can be manipulated (77,78). Both bacteria and fungi can be used to control insects, pathogens, and weeds either by lowering the populations of the pest or by reducing the pest's impact (79). An example of the practical application of soil bacterial diversity is the emerging area of biological control of plant pathogens (62). Bacteria have the potential to be used in biological control, which is the suppression of one pest by using its natural pest or antagonist. Bacteria and fungi that produce different types of antibiotics can be used to control many plant pathogens (62).

Weed management may also benefit from the use of soil microorganisms (63,80). Investigations of plant-suppressive bacteria have led to changes in crop management practices (76) and show potential for biological weed control of several weed species (63,81). Research on weed-inhibitory microorganisms has led to the concept of managing soils for weed-suppressiveness and utilizing the community, rather than just one organism of microorganisms for suppression of plant species (80). Biocontrol is critical to sustainable agricultural systems, but a greater understanding of soil microbes, their ecology, and the identification of practical indicators of system performance is required before biological control can be successfully implemented. The wealth of genetic material contained within the soil can potentially enhance sustainability practices, and investigations into this natural resource will also benefit other areas of science.

Pesticide Degradation

The fate of pesticides in soil is a microbially mediated process whose rate depends on abiotic factors as well. Many pesticides are readily degraded, whereas others tend to be more recalcitrant. The degradation process is dependent on the soil and environmental conditions and on the presence of specific bacteria that possess the active degradative enzymes (82). Also, the degradation rate is often greater in soils with higher soil organic matter content, and inorganic nitrogen has been shown to enhance degradation of atrazine (82). Although chemical

degradation has been shown, the presence of microbial populations are critical to pesticide dissipation (83). The microbial processes can be managed for reduction of herbicides as potential pollutants.

Soil Structure

Good aggregation reduces erosion and improves water infiltration and soil aeration. Stable aggregates reduce sealing of the soil surface because of increased infiltration. Once grassland is plowed, however, aggregate stability and soil microbial processes decrease rapidly. Microbes play a major role in the formation of soil structure (84,85). Hyphal threads produced by fungi and actinomycetes help bind soil particles together. Bacteria and fungi produce extracellular polysaccharides that also bind soil particles together, assisting in building soil structure. Humic materials from microbial action form organic matter or clay complexes. This action reduces erosion, allows for good water infiltration, and maintains adequate aeration of the soil. Soil aggregation influences the distribution of both pores and water (86). Soil aggregation can be increased by the addition of residues, resulting in additional microbial activity (87). The available carbon and nitrogen pools regulate microbial biomass, decomposition rates, and production of polysaccharides (88). Carbohydrate content and microbial biomass influence soil macroaggregate stability.

Crop rotation and cover crops can influence aggregation because crop diversity leads to a carbohydrate fraction that is more varied and fosters a more diverse microbial community (89). The ability of fungi and bacteria to influence aggregation varies with species and is substrate-dependent (90). Limited availability of nitrogen in the soil solution reduces biomass while increasing polysaccharide production, leading to greater aggregation (46). Soil stability may be managed by addition of different amendments to stimulate microbial activity (91).

Soil aggregate stability increases with conservation management (92). No-till and chisel-plow soils had greater microbial biomass and carbohydrate carbon per unit total organic carbon than conventionally tilled comparisons, which suggests labile carbon sequestration in conservation management systems. Relatively high ratios of microbial biomass carbon:total organic carbon, and carbohydrate carbon: total organic carbon, found in no-till and chisel-plow soils compared to conventional soils, suggested a sequestration of labile carbon in conservation management systems. Similarly, indicators of labile carbon, for example, particulate organic matter, were higher in no-till when compared to conventional tillage (92). Light fraction organic matter and macroorganic matter measurements were the most responsive carbon indicators to changes in soil management in eastern Canadian soils (93). These are favorable attributes to study when evaluating soil quality changes with alterations in short-term management.

DISTURBANCE AND SOIL MICROORGANISMS

Microorganisms are sensitive to variation or disturbances in their environment, such as tillage or addition of toxic compounds and pollutants (46). This sensitivity may allow them to function as early indicators of changes in soil health and quality. Microbial populations and their functions change rapidly as their environment is altered. These changes may contribute to the understanding of soil quality and the development of sustainable agroecosystems (94,95). Sustainability may be connected to a soil's resilience or the ability of the soil to recover after disturbance. Reduced tillage and increased crop rotations and management to improve soil health can improve soil resilience (46). In addition, crop rotations longer than three years, decreased disease-related problems (96), which can also increase crop resilience. The impact a stress may have on soil health will depend on the type of stress.

In agricultural soils, tillage may affect the general biological status, whereas pesticides or other stressors may affect only individual functional groups (97). The microbial community after minimum tillage practices will be vastly different from that after tillage for seedbed preparation (92,98–100). Tillage greatly alters the soil structure and components supporting growth of the bacterial population by altering the soil's physical and chemical properties. In no-till agricultural systems, microbial activities are stratified with depth, with the greatest microbial activity occurring near the no-till surface; in the tilled system, activities were more evenly distributed throughout the plowed layer (99). Fungi, protozoa, and several bacterial and fungal feeding groups increased in no-till situations, whereas total bacterial numbers were not affected by tillage (101). The composition of the microbial community influences the rate of residue decomposition and nutrient cycling in both no-till and conventionally tilled systems (92). Fungi dominated residue decomposition in the no-till system, whereas in conventionally tilled systems, the bacterial component was found to be responsible for a greater portion of the decomposition of residue. These studies illustrate the alteration of the makeup of the microbial communities and possibly the diversity of basic microbial groups, with changes in management systems. In comparisons of conventional and conservation tillage practices used on former conservation reserve program (CRP) lands, fatty acid methyl ester analyses indicated that no-till practices maintained the microbial community structure most similar to those found in 10 years of undisturbed grass (102). However, the benefits accrued during CRP can be lost in a relatively short time when these lands are plowed for conversion to row cropping (103). Sustainable systems will likely need to adopt low-disturbance conservation tillage practices to ensure ecological continuity of microbial and biological communities. Further, establishing the relationships between microbial communities, soil health, and soil resilience will lead to a greater understanding of microbial indicators of sustainability.

STRATEGIES FOR SUSTAINABLE MANAGEMENT

In defining sustainable agricultural management practices, Doran and coworkers (104) stressed the importance

of holistic management approaches that optimize the multiple functions of soil, conserve soil resources, and support strategies for promoting soil quality and health. They initially proposed use of a basic set of indicators to assess soil quality and health in various agricultural management systems. The microbial-oriented indicators, some of which are the most sensitive, include respiration, enzyme analyses, and organic matter. Although many of these key indicators are extremely useful to specialists (i.e., researchers, consultants, extension staff, and conservationists), many of them are beyond the expertise of the producer (105). Also, it is possible that the measurement of soil quality and health will do little to improve the sustainability of the system under which the soil is managed. In response to this dilemma, Doran and coworkers (21,106) presented strategies for ensuring sustainable management, which included generic indicators of soil quality and health. These are measurable by and accessible to anyone and are not overly time-consuming to conduct, as given in Table 3. Note that soil organic matter serves as a primary indicator of soil quality and health for both scientists and farmers and is controlled by microbial processes (107). Soil organic matter is also a major source of food for soil microorganisms. Consequently, whenever organic matter is increased by management, soil microbes benefit, especially in low organic matter soils.

Scientists make a significant contribution to sustainable land management by translating scientific knowledge and information on soil function into practical tools and approaches by which land managers can assess the sustainability of their management practices (108,109). Specifically, assessment of soil quality and health is needed to identify problem production areas, make realistic estimates of food production, monitor changes in sustainability and environmental quality, and assist government agencies in formulating and evaluating sustainable agricultural and land-use policies (Fig. 3). Use of a given approach for assessing or indexing soil quality is fraught with complexity and precludes its practical or meaningful use by land managers or policy makers (110). However, the use of simple indicators of soil quality and health that have meaning to farmers and other land managers will likely be the most fruitful means of linking science with practice, in assessing the sustainability of management practices (111,112). For example, Gajda and coworkers (113) have demonstrated the utility of simplified procedures for soil quality, such as particulate and total soil organic matter by weight loss-on-ignition, in assessing the sustainability of conventional and alternative management systems in the Central Great Plains of the United States.

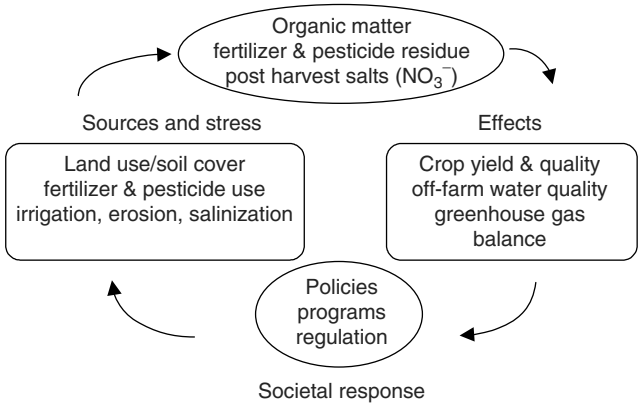

Figure 3. Soil condition and quality.

Table 3. Strategies for Sustainable Agricultural Management and Proposed Indicators of Crop Performance and Soil and Environmental Health

Sustainability Strategy	Indicators for Producers
Conserve soil organic matter through maintaining soil C&N levels by reducing tillage, recycling plant and animal manures, and/or increasing plant diversity, where C inputs > or = C outputs as microbial respiration	Direction and change in organic matter levels with time (visual or remote sensing by color or chemical analysis); Specific OM potential for climate, soil, and vegetation; Soil water storage
Minimize soil erosion through conservation tillage and increased protective cover (residue, stable aggregates, cover crops, green fallow)	Visual (gullies, rills, dust, and so on.) Surface soil properties (topsoil depth, organic matter content and texture, water infiltration, runoff, ponding, % cover)
Balance production and environment through conservation and integrated management systems (optimizing tillage, residue, water, and chemical use) and by synchronizing available N&P levels with crop needs during year	Crop characteristics (visual or remote-sensing of yield, color, nutrient status, plant vigor, and rooting characteristics) Soil physical condition and compaction Soil and water nitrate levels Amount and toxicity of pesticides used
Better use renewable resources through relying less on fossil fuels and petrochemicals and more on microbial processes, renewable resources and biodiversity (crop rotations, legumes, manures, IPM, and so on.)	Input/output ratios of costs and energy Leaching losses/soil acidification Crop characteristics (as listed above) Soil and water nitrate levels

In his article entitled "The Greening of the Green Revolution," David Tilman concluded that the uncertainties of sustaining a high-intensity agriculture have renewed the search for practices that can provide sustainable yields with fewer environmental costs (114). Since the beginning of agriculture, farmers had countered declines in fertility caused by agriculture by manuring fields, alternating crops that increase fertility (such as nitrogen-fixing legumes) with other crops. In a 15-year research trial in eastern Pennsylvania, Drinkwater and coworkers (70) demonstrated that organic management systems, employing animal manure and legumes for nitrogen supply, were equally as profitable as higher input conventional systems. The organic management systems tended to be more environmentally benign with lower leaching losses of nitrogen and higher levels of organic carbon and nitrogen stockpiled in soil. The organic management practices enhanced soil health and supported the major strategies for agricultural sustainability of conserving soil organic matter, minimizing erosion, balancing production with environmental needs, and making better use of renewable resources. Research has clearly demonstrated that initial yield reductions with organic management are more than offset by environmental benefits of soil organic matter buildup and synchronization of nitrogen availability with crop needs during the growing season. Research is needed to help agricultural managers assess the sustainability of agricultural management using indicators of soil quality and health to which they have access.

CONCLUSION

The multifaceted and changing nature of sustainability is difficult to define but is aptly captured by an Iowa farmer's simple definition of sustainable agriculture as, "an agriculture that sustains the people and preserves the land." Soil microorganisms play a major yet quiet role in these actions. Agricultural input alternatives that reduce reliance on nonrenewable fossil fuels and petrochemicals, ensure productivity, and maintain the quality of air, water, and soil resources are needed. Soil health and quality indicators, and the changes in those indicators and the microbes associated with those processes, can be a major link between the strategies of conservation management practices and achievement of the major goals of sustainable agriculture.

Microorganisms are key to the integrated functioning of nutrient cycles and decomposition, soil structure, and plant growth in agricultural systems. Research is needed to increase our understanding of the ecology and functioning of microbial communities, their response to management practices, their impact on soil health and quality in agroecosystems, and their role in sustainability. Investigations of residue management, organic matter formation, nitrogen and carbon cycling, soil structure maintenance, and biological control will assist in discovering system approaches that are both profitable and environmentally friendly. The challenge ahead is to gain an understanding of the wealth of microbial life in the soil and the resiliency of the biological community to maintain a quality ecosystem, thus fostering sustainability.

One of the greatest challenges for researchers is in "translating science into practice" through identifying indicators of system performance that are useful to farmers and land managers in assessing the economical, ecological, and environmental components of sustainability. Because so many processes are microbially mediated, defining the role of microorganisms is complex and challenging as many functions are unknown at this time. Management strategies need to optimize the microbial component of soil using practices such as crop rotation for greater diversity and tighter cycling of nutrients, reduction of soil disturbance to maintain soil organic matter and reduce erosion, and development of systems that make greater use of renewable biological resources. Crop rotation, legume companion crops, and animal manuring practices can reduce reliance on nonrenewable fossil fuels and petrochemicals. Ultimately microbial processes and functioning, indicators of soil health, and strategies for sustainable management must be linked to the development of management systems that foster reduction in the inputs of nonrenewable resources, maintain acceptable levels of productivity, and minimize impact on the environment. A healthy soil through soil management will result in a healthy soil microbial population efficient in cycling and balanced in its microbial diversity, which in turn supports a sustainable agricultural system.

THERMOPHILES: ANAEROBIC ALKALITHERMOPHILES

Juergen Wiegel
University of Georgia
Athens, Georgia

Several excellent reviews on mesophilic and aerobic alkaliphiles and their habitats have been published in the past and the reader is referred to these extensive publications (1–8). This article deals only with a more recently observed group of bacterial and archaean extremophiles, the anaerobic alkalithermophiles, covering them on the order of their habitats from which they have been isolated. It is assumed that alkaline water bodies had existed early on when life evolved, although there is no unequivocal agreement on whether the Hadean Ocean really was alkaline (9–12). Zavarzin (13) suggested that the microbial communities in alkaline environments, especially in alkaline soda lakes, are remnants of communities from the early Proterozoic era when "epicontinental soda lakes were the centers of nascent terrestrial biota." If, as the author of this article believes, life originated under thermobiotic conditions, this statement should be even more true for the alkalithermophiles. Today alkaline environments, more mesobiotic than thermobiotic in nature, can be found all over the world. Although most of the earth's surface is covered by slightly alkaline ocean water (usually around pH 7.5 to 8.5), relatively few alkaliphilic microorganisms have been isolated from this environment. In particular, only two anaerobic alkaliphilic thermophiles have been isolated from marine hydrothermal locations. One reason could be that many of the vent fluids are more neutral or even acidic and the temperature gradient is very steep, that is, the mixing of the hot vent fluid with the cold alkaline ocean water does not produce a thermobiotic alkaline marine environment. Alkaline environments differ greatly in their geographic distribution, origins, water and geochemistry, stability, and their extent (large bulk environments vs. microniches in an otherwise neutral milieu) (1,2,14 and references).

Besides various natural environments, there are various anthropogenic ones that include niches, such as those related to the storage of waste products or in waste streams from industrial processes using NaOH or $Ca(HO)_2$ or producing alkaline compounds such as amines, as products. Examples include waste from olive and other food-processing plants, waste streams from NaOH-using pulp processes, alkaline bleaching, extraction of metals in mining processes, alkaline electroplating, production of cement caused by the formation of $Ca(OH)_2$, waste storage tanks kept alkaline in attempts to "prevent" or at least reduce microbial growth (such as the radioactive waste tanks from the production of weapons grade plutonium or storage tanks of spent fuel rods), and in some cases, around manure disposal sites in high-density livestock facilities caused by heavy ammonia formation. Natural habitats include those where bauxite is found or more generally where calcium-silicate minerals are weathering under the formation of $Ca(OH)_2$, alkaline hot springs (geothermally heated), various soda lakes and soda deserts that can reach pH values above 11.5, and most importantly for this article, can have thermobiotic temperatures around 45 °C (sun heated) or more than 100 °C geothermally heated) or contain hot springs such as the Mono Lake in California, the Lower, Middle, and Upper Alkaline Lakes (California and Nevada), and the soda lakes in the East African Rift Valley that are heated by both the sun and volcanic activity.

DEFINITION OF "EXTREME"

The term *extremophiles* means simply microorganisms that love extreme conditions. When using such an anthropogenic term, one has to keep in mind that extreme is defined by what is outside of the norm and the norm, defined by default, is what is suitable and comfortable to humans and our microbial "pets," *Escherichia coli*, and their inherent biochemistry and physiology. In other words, for the various so-called extremophiles, the optimum growth conditions for *E. coli* are extreme and stressful and in some instances, even outside the conditions for survival, for example, halophiles, will undergo lysis in the absence of high salt concentrations.

MESOPHILIC AND THERMOPHILIC ALKALIPHILES HAVE BEEN STUDIED ONLY RECENTLY

The study of true alkaliphiles is more recent than for most other extremophiles, except for the hyperthermophiles growing above 100 °C. The isolation of one of the first alkaliphilic microorganisms was reported by the Dutch microbiologist Vedder in 1934 (15) who isolated them from human and animal feces. More systematic study started in the early 1970s when Horikoshi and coworkers searched for alkali-stable proteases (16), which lead to the well-known application of the alkali-stable and alkaliphilic protease from *Bacillus* now sold by Novo Industries for use in laundry detergents. However, this does not mean that alkaliphilic microorganisms were not used in the past. One example is the centuries-old Asian practice of dying cloth blue using the indigo plant. This process used

a mixture of alkaliphilic microorganisms, some of which were finally isolated in 1960 (17) and in 1999 (18) The moderate thermophilic (T_{opt}50 °C; T_{max}55 °C) *Clostridium isatidis* (18) was isolated from a fermenting wood vat prepared as was done in the medieval times in Europe. Although its pH_{opt} is around 7.2, it grows in the pH range from 5.9 to 9.9 and thus, it is a pH-tolerant thermophile. Alkalithermophiles (also called *thermophilic alkaliphiles*) were unknown until a few years ago when the research group of the author, similar to Horikoshi years ago, searched for alkali-stable proteases, which were active and stable at elevated temperatures (above 60 °C) for laundry detergents to be used for high-temperature washing cycles. One reason for the lack of serious attempts to search for alkalithermophiles in the past was that most of the hot springs in the world are acidic, whereas most alkaline lakes are mesobiotic. Furthermore, it was assumed that microorganisms could not exist under the combined condition of high temperatures and alkaline pH because of hydrolysis of the protein and ester bonds. However, as reported in this entry, such microorganisms indeed exist. This entry summarizes the microbial diversity and their habitats from which they were isolated. Similar to the numerous and more thoroughly studied mesophilic alkaliphiles, the alkalithermophiles are widely distributed in thermobiotic and mesobiotic environments with slightly alkaline to acidic bulk-pH values. The author is convinced that, so far, only the tip of the iceberg of the diversity within this group has been observed (19).

ALKALITHERMOPHILES

Alkalithermophiles belong to the category of extremophiles. They are extreme in two or even three properties, that is, requiring or at least tolerating elevated temperatures (thermophilic), alkaline pH (alkaliphilic), and some of them because of the nature of alkaline (soda) lakes, requiring high salt concentrations (halophilic). Several of the described alkalithermophiles are halotolerant to various degrees, but to date no obligately halophilic anaerobic alkalithermophile has been validly described (i.e., published in the *International Journal of Systematic and Evolutionary Microbiology* directly or in one of the validation lists therein). Table 1 gives simplified definitions (as used by the author) for the terms *thermophilic, alkaliphilic*, and *halophilic* using the cardinal temperatures, pH values, and salt concentrations for growth.

Several of the thermophilic anaerobes and a few aerobes can grow up to $pH^{25\,°C}$ 8.5 [the superscript denotes the temperature at which the pH was determined; see text and (19)] or even 9.0, [e.g., the well known *Thermoanaerobacter* (basonym *Clostridium*) *thermosaccharolyticum*, *Thermoanaerobacter* (basonym *Clostridium*) *thermohydrosulfuricus*, or some strains (biotypes) of the archeaon *Methanothermobacter* (basonym *Methanobacterium*) *thermautotrophicus* (see following text]; however, because their pH optima are below pH 8.0, only some are briefly mentioned in this article, which is primarily concerned with anaerobes with pH optima for growth above $pH^{25\,°C}$ 8.0 and T_{opt} above 50 °C.

THERMOPHILIC "SUPERBUGS" AMONG VALIDLY DESCRIBED SPECIES OF EXTREMOPHILES

Because anaerobic alkalithermophiles have to cope with more than one extreme condition, it is useful to compare them to the "champions," that is, to the thermophilic microorganisms that exhibit the most acidic or alkaline pH_{opt} (Table 2).

The upper temperature limit for isolated microorganisms is held by an anaerobic archaeon, *Pyrolobus fumarii*, with a T_{max} of 113 °C and a T_{opt} of 106 °C (20). The highest values for a (eu)bacterium are below 100 °C, for example, *Aquifex pyrophilus*, with a T_{opt} of 85 °C and T_{max} of 95 °C (21). It is evident from the examples in Table 2 that not all extreme environments and growth conditions are equally populated by bacteria and archaea and that it appears that some groups are more able to adapt than others to the extreme conditions. It is important, however, to keep in mind that we probably know less than 3% of the

Table 1. Simplified Definitions of Alkaliphiles, Thermophiles, and Halophiles

Thermophiles	T_{min} —	$T_{opt}>50$ °C	$T_{max}>60$ °C
Extreme thermophiles	T_{min} usually >60 °C	$T_{opt}>75$ °C	$T_{max}>85$ °C
Alkalitolerant microorganisms	pH_{min}*	$pH_{opt}<8.5$*	$pH_{max}>9.0$*
Alkaliphiles		$pH_{opt}\geq 8.5$*	$pH_{max}\geq 10.0$*
Facultative	$pH_{min}<8.0$*		
Obligate	$pH_{min}>8.0$*		
Halotolerant Microorganisms	$[NaCl]_{min}$** 0	$[NaCl]_{opt}<1\%$	$[NaCl]_{max}>3\%$
Halophiles:**			
Facultative (haloversatile)	$[NaCl]_{min}>0$	$[NaCl]_{opt}>1\%$	$[NaCl]_{max}>10\%$
obligate,	$[NaCl]_{min}>1\%$		
moderate	$[NaCl]_{min}>2\%$	$[NaCl]_{opt}>3\%$	$[NaCl]_{max}>5\%$
extreme	$[NaCl]_{opt}$ usually >10%	$[NaCl]_{opt}>15\%$	$[NaCl]_{max}>20\%$

*The values depend on the temperature at which the pH was determined and the pH meters were calibrated. Depending on the medium, temperature, and the pH range, the differences can be as large as 1 pH unit (see Fig. 2 in cit. 19). Since this is frequently not stated, the presented data from the literature are difficult to compare. In the presence of elevated salt concentrations the pH value is even more difficult to measure. The above values are the ones usually used by the author, however, various definitions exist and there is no uniformous agreement among scientists.

**A more detailed definition is given by Grant et al. (3).

Table 2. The Most Acidophilic and Alkaliphilic Thermophiles Among Validly Published Species*

	Acidophile	pH_{opt}	T_{opt}	Alkaliphile	pH_{opt}	T_{opt}
Archaea						
Aerobic	*Picrophilus oshimae*	0.7	60	*Aeropyrum pernix* (facultative)	7.0	93
	torridus			*Pyrobacculum* spec.	3.0	100
Anaerobic	*Sulfuricoccus mirabilis*	2.0	72	*Thermococcus alcaliphilus*	9.0	85
	yellowstonii	2.5	62			
Methanogens	*Methanococcus igneus*	5.7	88	*Methanothermobacter thermoflexus*	8.1	55
(Eu)bacteria						
Aerobic	*Sulfobacillus acidophilus*	2.0	50	*Bacillus palidus*		
				Sphaerobacter thermophiles	8.5 55	63
Anaerobic	*Thermoanaerobacterium aotearoense*	5.2	62	*Clostridium paradoxum*	$10.3^{(25\,^{\circ}C)}$ $9.3^{(58\,^{\circ}C)}$	55

*Validly described species are species published in the *International Journal of Systematic and Evolutionary Microbiology* (former *International Journal of Systematic Bacteriology*) either directly or included in the table of microorganisms published outside of the Journal.

estimated existing microorganisms and that this distribution depends on the presently culturable microorganisms. This distribution could have changed by the time this article has been printed. Novel microorganisms are presently described at an elevated rate because of renewed interest in biodiversity and the easiness of obtaining 16S rDNA sequence data as a tool for discriminating isolates and for demonstrating that unknown microorganisms exist in a given environment (environmental 16S rDNA sequences). The problem frequently is to find the right conditions to grow the "not yet cultured" microorganism under laboratory settings.

An elegant way to show the diversity of the alkalithermophiles with respect to temperature and pH is to plot the optimum growth temperature versus the optimum pH (Fig. 1). The majority of isolated bacteria through all categories are neutrophiles and grow optimally between pH 6.5 and 7.5 (not shown in Fig. 1 for clarity). An exception is the obligately aerobic archaea, which with one or two exceptions, grow optimally at the acidic pH ranges between 1 and 2.5. The data in Figure 1 suggest a phenomenon that also has been seen among strains of a species, that is, the more alkaline the pH optimum for a bacterium is, the lower is its temperature optimum. This leads to the occurrence of a "white spot" in the upper left side in this diversity map (Fig. 1) created by the void of observed microorganism with optimum growth temperatures above 65 °C and optimum $pH^{25\,^{\circ}C}$ values for growth above 9.0.

BIOGEOGRAPHY AND BIOGEOCHEMISTRY

Alkalithermophiles require alkaline conditions and elevated temperatures for growth. Does this mean they can only be found in very distinct niches where both conditions are obviously provided, such as alkaline hot springs, alkaline (soda) lakes with geothermal or solar heat sources?

The more general question is an old one, already asked in a broader sense by Beijerinck as cited by Baas-Becking (37) saying, "Everything is everywhere, but the milieu selects." In other words, the question from the view of biogeography is, are indeed all bacteria everywhere (i.e., ubiquitous) and the subsequent question from the view of biogeochemistry is then whether only the geochemistry and environmental conditions determine which of the microorganisms are prevalent in a given habitat. Presently, this question cannot be answered even for the small percentage of microorganisms that have been described because of lack of data. On the other hand, one can speculate that most bacteria are somewhat "ubiquitous" because many microorganisms, especially when adsorbed to dust particles, can withstand various states of dryness and thus are distributed worldwide by wind. Ash particles from volcanic eruption such as Mt. Helena have traveled around the globe within a few days, and after big sandstorms in the Sahara, the sand can be collected on the west coast of the United States. Tiny water droplets containing microorganisms can also be distributed by strong air movements. The question, "How often does this occur?" remains to be answered through more sophisticated studies. As example, the author has isolated from antarctic snow thermophiles also found in steam vents from the volcano Mt Erebus, miles away from the site where the snow was collected (unpubl. results). So, theoretically, "all" bacteria should be more or less distributed around the globe. But the question then is whether the receiving environments will support the survival of the "seeded" microorganisms and, furthermore, whether these organisms can compete successfully against the existing microbial population.

Returning to the original question with respect to alkaliphiles and specifically to the anaerobic alkalithermophiles, Horikoshi and Aiba (38) showed that one could isolate mesophilic, aerobic alkaliphiles from soils with neutral and acidic bulk pHs. The same is true for the anaerobic alkalithermophiles (19). Although only a few anaerobic alkalithermophiles have been validly described,

	pH_{opt}	pH-range	T of pH-det.* * (°C)	T-range (°C)	T_{opt} (°C)	Habitat or Location of Isolation	Ref.

**Only the strains that were originally described as *Methanobacterium thermoalcaliphilum*, now belonging to *M. thermautotrophicus*.

Figure 1. Anaerobic Alkalithermophiles and Anaerobic Alkali-tolerant Thermophiles

a great variety of distribution patterns have been observed: a species can be found

1. only in one very restricted location (= narrow biogeography),
2. only in one type of environment but at different geographic locations (= narrow and restricted biogeochemistry), and
3. apparently ubiquitously distributed (= relaxed biogeography and biogeochemistry). However, for nearly half of the known anaerobic alkalithermophiles, only one or two strains have been described and no reports have been made of failed attempts to isolate them from other locations or other environments. Thus, their distribution cannot be discussed. The presently known anaerobic alkalithermophiles and alkali-tolerant thermophiles with pH_{opt} of and above 8.0 will be discussed later in order of these four groups.

SOME COMMENTS ON METHODS FOR STUDYING ANAEROBIC ALKALITHERMOPHILES

The cultivation of the anaerobic thermophiles in the laboratory requires a few precautions, which have been

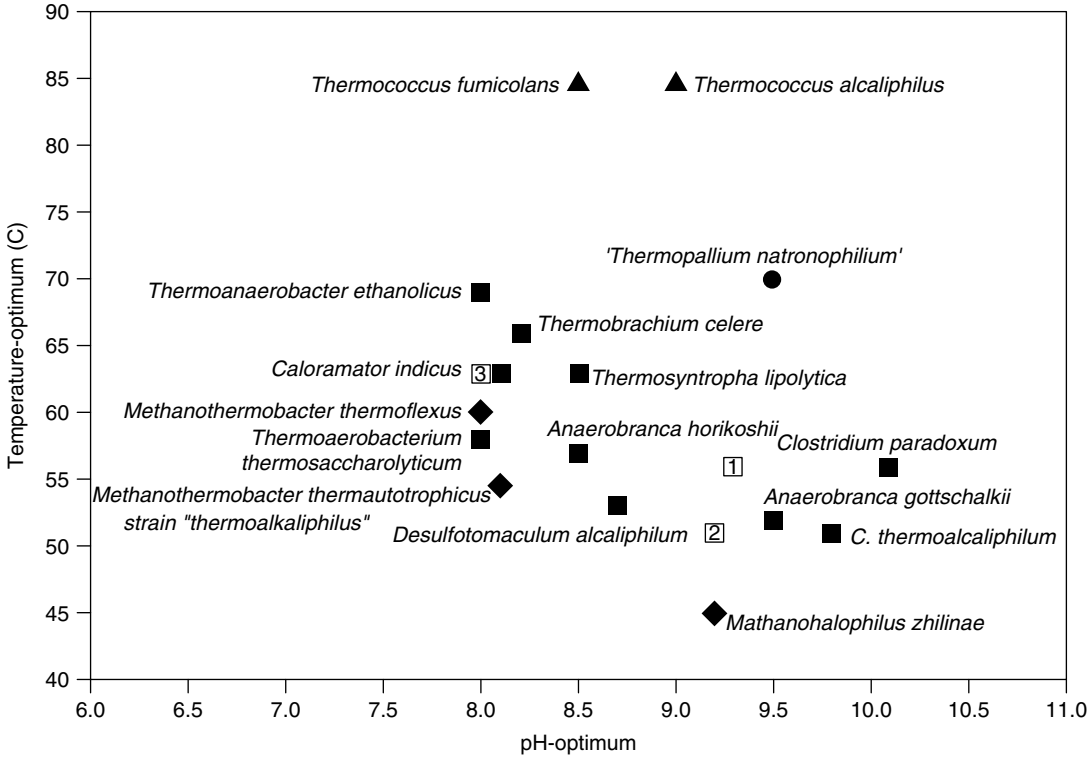

Figure 2. Distribution of anaerobic alkalithermophilic alkali-tolerant thermophilic bacteria and archaea in an optimum growth temperature versus optimum growth pH chart. Keep in mind that the optima are some times very broad, and thus an intermediate value has been chosen for clarity (see text and Table 3 for details). Furthermore, in several instances, it is not clear how authors had determined the pH, and thus a direct comparison of the published pH_{opt} data is not always proper (see text) ■, □ gram-type positive anaerobic bacteria; □ pH values determined at the actual growth temperature: 1 *Clostridium paradoxum*; 2: *Clostridium thermoalcaliphilum*, 3: *Thermosyntropha lipolytica*; • gram-type negative anaerobic bacteria; ♦, ⅄ anaerobic archaea. with ♦ for methanogens.

described in detail previously (39). The precautions used when working with mesophilic alkaliphiles are naturally also to be observed for thermophilic ones. In addition, at high pH and elevated temperatures, substances other than agar must be used to solidify growth media; these include products such as Gelrite or Phytogel (both Sigma, St. Louis) or silica gel (39–41). As already indicated earlier, one problem encountered when comparing reports on alkali- or acidophilic extremophiles is that in the descriptions no indications are given as to how the pH was determined or that the reported pH was measured at room temperature or with a pH meter containing a temperature probe without proper calibration of the pH meter. Thus, it is very difficult to compare the published pH data. Depending on the medium used, the differences at pH 10 and 60 °C can be around one whole pH unit. Around pH 7.0, the error is usually relatively small, about +/− 0.2 pH units. The proper way is to determine the pH with a pH meter and electrode calibrated with standards kept at the elevated temperature and their value accordingly corrected. The author suggested indicating how the pH was measured by a superscript, for example, $pH^{65\,^{\circ}C}$ when determined correctly at 65 °C or $pH^{25\,^{\circ}C}$ when measured at 25 °C (19). Another problem can be caused by the instability of bicarbonate at temperatures above 50 °C forming carbon dioxide and carbonate, but on the other hand, when carbon dioxide is provided in the gas phase beyond the equilibrium for the given temperature, it will be adsorbed into the alkaline medium, again potentially changing the pH, especially if the medium is slightly buffered. The distribution of the $CO_2/HCO_3^-/CO_3^-$ species is described by the Henderson-Haselbach equation. At high salt concentrations one appropriate method is to analyze the salt components and theoretically calculate the pH (42–45). Knaus and coworkers (44) and Mesmer (45) discuss the use of cells without liquid junction to minimize the salt effect. Other typical problems include chemical reactions mimicking biological activities. For example, when studying alkaliphilic iron-reducing thermophiles, it is important to run proper substrate controls because at the elevated temperatures many compounds (including glucose and other sugars and carbohydrates with reducing ends) reduce iron (III) fast in the growth media. Furthermore, at elevated temperatures and alkaline pH, many substrates will undergo increased modifications with increased pH values or react with other compounds in the medium forming potentially inhibitory products. One other point to be aware of is that many antibiotics are not stable at elevated temperatures. Peterrandel and coworkers (31)

investigated only neutral and slightly acidic pH values at 50 and 70 °C but demonstrated that some antibiotics quickly lose their activity totally, whereas some others yielded the breakdown products that were more potent than the parental compounds. Unfortunately, these data are missing for the alkaline growth conditions. If an antibiotic, however, is bacteriocidal for the bacteria or archaea in question, regardless of the antibiotic's stability, it will still work for enrichments or discrimination against resistant strains as long as no spores are present, which could later germinate when the antibiotic has become ineffective.

ANAEROBIC ALKALITHERMOPHILIC BACTERIA AND THEIR HABITATS KNOWN THUS FAR

Anaerobic Alkali-Tolerant Thermophiles/Alkalithermophiles Found in Only One Location

Anaerobranca horikoshii **(Firmicutes).** All strains isolated so far originated from only one relatively small, geothermally heated area near Old Faithful Geyser, Yellowstone National Park. Nine strains of this alkalithermophile were isolated and described by Engle and coworkers (29). No similar strains could be isolated from other sites in Yellowstone National Park or from samples collected from geothermally heated locations in New Zealand, Italy, or Japan despite using the same or similar isolation procedures. One of the peculiarities is that this little-researched geothermal field contains slightly acidic and slightly alkaline hot springs intermingled and just a few yards apart from each other. *Anaerobranca horikoshii* was isolated from both, the acidic and the alkaline pools. Recently, a new species, *Anaerobranca gottschalkii* (46), was isolated from the alkaline lake Bogoria in Kenya (pH 9 to 10, temperature 50 to 80 °C), from which two other anaerobic alkalithermophiles were isolated so far (for description see following text).

Anaerobranca horikoshii is gram-type positive. This species was the first published anaerobic thermophile exhibiting truly branched cells. Cells are flagellated and usually show a sluggish tumbling motility. The G + C mol% is 33 to 34 mol%, which places it in the middle range of the low G + C gram-type positive branch. Spore formation has not been observed, but characteristic sporulation genes are present (27). Its growth characteristics reflect the two types of pools from which it was isolated: $pH^{60\,^{\circ}C}$ range is 6.5 to 10.3; optimum 8.5 to 8.8 (strain dependent), and temperature range for growth is 30 to 66 °C; optimum approximately 57 °C. The bacterium is proteolytic and in contrast to *A. gottschalkii* (46) does not show any growth with carbohydrates. The fermentation products from yeast extract are mainly acetate carbon dioxide and hydrogen. Interestingly, this bacterium can also use fumarate as an electron acceptor forming succinate. In the absence of fumarate, however, 1 mM succinate is growth-inhibiting.

[this term was introduced to differentiate between "gram" as taxonomic term (i.e., gram reaction or gram-staining result) and the use as systematic term (gram type). Both terms can be different for one bacterium, as for example, is seen for many clostridial species that systematically belong to the gram (type)-positive (i.e., absence of LPS) Firmicutes branch but stain negative at all growth phases; (47,48)].

Anaerobic Thermophiles/Alkalithermophiles Found Only in One Type of Environment But at Various Geographic Locations

Clostridium paradoxum **and** ***Clostridium thermoalcaliphilum*** **(Firmicutes).** *Clostridium paradoxum* is presently the most alkaliphilic thermophile among the validly published microorganisms growing optimally above 50 °C (28,33). Its exclusive habitat is sewage sludge and it has been found in samples from sewage plants on three different continents. One strain was isolated from a New Zealand hot spring, which, however, was contaminated with wastewater in the past ((19), and unpubl. results). The temperature range for the growth of *C. paradoxum* is around 30 to 63 °C with an optimum at 56 °C and for *C. thermoalcaliphilum* between 27 to 57.5 °C with an optimum at 51 °C. For both, the pH range is between $pH^{25\,^{\circ}C}$ 7.0 and 11 with optimum at $pH^{25\,^{\circ}C}$ 10.1 ($pH^{55\,^{\circ}C}$ 9.3) and $pH^{25\,^{\circ}C}$ 9.8 ($pH^{50\,^{\circ}C}$ 9.2), respectively (28,33). The pH in the sludge at the Athens sewage plants and similarly at a plant in California reveals that the temperature does not exceed peak values of 40 °C and $pH^{25\,^{\circ}C}$ of 7.8. None of the plants from which samples were obtained had recorded peak $pH^{25\,^{\circ}C}$ values above 7.8 and/or peak temperatures above 40 °C. Because the bulk temperatures and pH values of the investigated sewage plants exhibited values that are at the lower growth limit of this bacterium, one would not expect to find this bacterium in relative high numbers. Enumerations, however, that did not discriminate between *C. paradoxum* and the physiologically very similar bacterium *C. thermoalcaliphilum*, yielded between 100 and 10,000 colony forming units per milliliters of sewage sludge. Also, surprisingly, the bacterium was found in similar numbers in the samples from the anaerobic digesters and from the aerobic (activated) sludge. The authors were not able to isolate these bacteria either from the samples of the discharge water leaving the sewage plant in Athens Georgia, or from the samples of the river sediment collected between 100 m and 3 km downstream of the plant's discharge point. *Clostridium thermoalcaliphilum* was only characterized by strains from the sewage plant in Atlanta, Georgia, and is apparently less abundant than *C. paradoxum* but should be present in most other sewage plants. Unfortunately, no 16S rRNA probes have been made and used for elucidating the distribution. Although spores could not be detected in *C. thermoalcaliphilum* cultures, and the culture is not transferable after three to four days from cultures tubes stored between 4 and 50 °C, it contains representative sporulation genes (27). In contrast, in a two-day-old culture, up to 99% of *C. paradoxum* cells exhibited sporulation. Cells that start to sporulate become very motile. After an additional one to two days, the cells lyse and release the spores, which form aggregates in a matrix of carbohydrate-like material (28). We assume that this feature is responsible for the spores becoming trapped in the slime and then attached to particles in the sludge and thus retained in the sewage plant. Surprisingly, it appears that this occurs to 100% because, as mentioned earlier,

no viable cells (or spores) could be recovered from outside the sewage plants except from the stored dewatered sludge dredged out of the settlement ponds. The relatively high numbers of colony-forming units determined in agar shake-roll tubes (40) suggests that these bacteria, especially *C. paradoxum*, must be able to grow under the bulk neutrophilic and mesobiotic conditions of the sewage plant. The author assumes that two features contribute to the relatively high numbers of *C. paradoxum*–like bacteria in the sewage systems: (*1*) The occurrence of microniches with elevated temperatures and alkaline pH as a result of various microbial activities (production of metabolic heat during high microbial metabolism of fast degradable substrates and release of ammonium ion from amines and amino acid–rich waste components) and (*2*) the short doubling times of 16 (*C. paradoxum*) and 19 minutes (*C. thermoalcaliphilum*), which allow these bacteria to take advantage of temporary microniches (28,33).

Both bacteria are peptidolytic and glycolytic, using sugars such as glucose, fructose, sucrose, maltose, cellobiose, and xylitol, depending on the strain. None of the strains grew with xylose or ribose. Main differences between *C. paradoxum* and *C. thermoalcaliphilum* are in sporulation (as discussed earlier) and in their cell wall types despite only about 2% difference in the evolutionary distance based on the 16S rDNA sequences. *Clostridium paradoxum* has the meso-diaminopimilic direct type cell wall and exhibits a combination of the restriction and septation mechanism during cell division, whereas *C. thermoalcaliphilum* has the L-Orn-D-Asp type of cell envelope and the regular septation mode of cell division. Cells of both gram-type positive species stain gram-negative because of a relatively thin cell wall (28,33), but LPS is absent as demonstrated by the LPS-polymyxin B test (48). Growth of both microorganisms is enhanced in the presence of supplemented sodium (the base medium contains around 5 mM Na^+). In the presence of 100 mM K^+, 20 mM Na^+ are required for growth. The optimum sodium-ion concentrations for *C. paradoxum* were 50 to 100 mM and 50 to 500 mM at pH 9.6xs and 7.5, respectively, and in the presence of 100 mM KCl, the optimum concentration for Na^+ shifted to 150 to 300 mM. However, under all conditions, 1 M inhibited growth completely, whereas *C. thermoalcaliphilum* could tolerate up to 1.25 M (7.3 %) NaCl and thus can be classified as a moderate halotolerant alkalithermophile. *Clostridium paradoxum* did not sporulate below 10 mM Na^+ and motility was also sodium-ion and pH dependent. The analyzed sewage fluids contained between 0.5 and 1.5 mM K^+ and 3 to 3.5 mM Na^+, values clearly far below the optimum of the purified cultures, and should not allow *C. paradoxum* to sporulate. However, the sewage samples contained spores because *C. paradoxum* could be easily isolated from pasteurized (85 °C for 20 minutes) samples (unpubl. results). Obviously, other compounds in the sewage must substitute for the low Na^+ concentration.

Both species are sensitive to several common antibiotics at $pH^{25\,°C}$ 7.5 and 10.5. A comparison of the phospholipid fatty acids showed that *C. thermoalcaliphilum* had a similar profile to that of *C. paradoxum* cells grown at pH 7.5 but was different for the profile from cells grown at $pH^{25\,°C}$ 10.5. The main difference at the two pHs was the abundance of *i*17 : 0, but under all conditions both the species had *i*15 : 0 as the main fatty acid. In summary, from the earlier analysis and from the analysis of the fatty acid composition of *Caloramator gottschalkii* (46) and *Tb. celere* (36), no unusual or, for anaerobic alkalithermophiles, specific fatty acid pattern has emerged.

Ubiquitous Anaerobic Alkali-Tolerant Thermophiles/Alkalithermophile

***Thermoanaerobacterium* (basonym *Clostridium*) *thermosaccharolyticum* and its Tartrate-Using Biotype '*Clostridium tartarivorum*' (Firmicutes).** *Thermoanaerobacterium thermosaccharolyticum* ($pH^{25\,°C}$ optimum around 7.8 to 8.0, $pH^{25\,°C}_{max}$ of 8.5 to 8.8; T_{opt} of 55 to 60 °C, T_{max} 67 °C) is an alkali-tolerant thermophile and among those it is a truly ubiquitous, spore-forming, saccharolytic anaerobe found in both mesobiotic and thermobiotic soil and sediment worldwide ((49) and Wiegel unpubl. results). This bacterium is well known as the can-swelling ("hard swelling") agent in the canning industry because it can produce carbon dioxide to pressures of several atmospheres from various carbohydrates including starch and pectin. For the reason that spores of this species survive frequently in sugar-refining and vegetable-canning processes, industrial research has focused on its formation of heat-resistant spores (D_{10}-time four minutes at 121 °C) (50). However, it should be mentioned here that these spores are not the most heat-resistant spores: spores of *Moorella thermoacetica* strain 4 have a D_{10}-time of nearly 2 h at 121 °C (51). The previously described alkali-tolerant species, '*C. tartarivorum*', which uses tartrate, is now recognized only as a different strain (biotype) of *Th. thermosaccharolyticum* (52). Fermentation products from glucose include the typical products also observed with many other anaerobic thermophiles such as ethanol, butyric acid, acetate, lactate, carbon dioxide and hydrogen. Whether mainly ethanol or butyric acid is formed depends on the strain and applied growth conditions (53). Propan-1,2-diol can also be a major product from glycerol.

This is the only species among the anaerobic thermophiles for which a plasmid has been clearly isolated and characterized (54).

***Thermobrachium celere* (Firmicutes).** *Thermobrachium celere* is the second truly ubiquitous alkali-tolerant anaerobic thermophile described so far; however, it is able to grow at more alkaline conditions ($pH^{25\,°C}_{max}$ 10.1) than *Th. thermosaccharolyticum* ($pH^{25\,°C}_{max}$ 8.8). *Thermobrachium celere* grows in a $pH^{66\,°C}$ range from $pH^{66\,°C}$ 5.0 to 9.3 for *Th. thermosaccharolyticum* with an optimum $pH^{66\,°C}$ between 8.1 and 8.6 and in the temperature range from greater than 37 to 75 °C (no growth at 77 °C) with an optimum around 60 to 67 °C. As the species name indicates, one of its main characteristic features is a fast growth rate. For the type strain JW/YL-NZ35, the doubling time under optimum growth conditions is 10 minutes in batch and continuous culture ((36) and unpubl. results). For other strains, it is between 10 and 25 minutes. The type strain was isolated from a mixed water sediment sample of a hot spring receiving human wastewater from a bathhouse in

Ohinimutu, New Zealand. It is the same spring from which the only nonsewage sludge-derived strain of *C. paradoxum* was isolated. The in situ temperatures of the sampled site ranged from 56 to 75 °C and the pH ranged from 7.4 to 7.8. The mixed sample had a pH of around 7.7. Many other strains were isolated from various thermobiotic samples including samples from several pools in Yellowstone National Park and a slightly acidic pool in the thermal area in Larderello (Toscani, Italy) with a water pH of 4.8 and a temperature of 60 to 65 °C. Interestingly, this sample had been stored for more than five years at 4 to 7 °C before the enrichment was done, and no spores or heat-resistant (15 minutes 85 °C) forms observed for any of the strains from this species. Again, however, Brill and Wiegel ((27); unpubl. results) demonstrated that characteristic sporulation genes are present in this species. In contrast to the cells in the sediment samples, in which the cells survived for several years, grown cultures tended to lyse when stored at or below room temperatures within a few days or months depending on the strain tested. The mesobiotic sources for isolation included sediments from the Platte River in Argentina (pH 5.0) and wet soil samples from its floodplain meadows (pH 6.8) and River Elbe in Brunsbuettel (Germany) (pH 7.0). Both rivers are regarded as highly polluted by industrial and urban sources. We also isolated a strain from the alkaline Mono Lake in California, ($pH^{25\,°C}$ 9.0, ambient sediment at the edge of the Lake). Several strains were also isolated from anthropogenic environments such as horse manure compost at the University of Georgia (pH 7.8; ambient to 55 °C). Many other strains that appear physiologically similar, exhibit similar protein profiles, and thus are assumed to be strains of this species were isolated from many other mesobiotic (United States) and thermobiotic places (e.g., Iceland, Thailand, Fiji Island), however their 16S rDNA sequence has not been determined. All strains tested required yeast extract for growth. The typical fermentation products for thermophilic glycolytic/peptolytic anaerobes, acetate, carbon dioxide, hydrogen and ethanol and the less common product among thermophilic anaerobes, formate, are formed from some hexoses and pentose. However, no lactate was found as a fermentation product. Interestingly, neither pyruvate nor lactate could serve as substrate. Thus, this bacterium neither competes with lactate/pyruvate-using sulfate reducers for substrates, nor does it become involved in the lactate-based substrate-product-substrate food web. Considering the wide distribution and different environmental conditions of the samples from which they originated, it is not surprising that a wide morphological variability among the strains is observed. No microaerophilic growth or growth in oxidized media was observed with any strain tested, characterizing this as an obligate anaerobic bacterium. However, short exposures to oxygen does not kill this bacterium.

The type strain JW/YL-NZ35 contained structures resembling defective bacteriophages. However, we were not able to isolate any lytic or lysogenic phage particles from any of the samples (including sewage sludge) or strains (D. Byrer, dissertation, 2001; University of Georgia). It is interesting to note here that no virus has been described for any of the anaerobic thermophilic Firmicutes, despite several attempts to isolate them. Only one plasmid has been characterized thoroughly and made available (54). The few descriptions of other detected plasmid in anaerobic thermophiles could not be reproduced in the author's laboratory, nor has their confirmation been reported in the literature.

Bacterial Species That Comprise Only One or Two Strains Isolated From One Location But Without Published Attempts to Isolate Them From Other Areas

The old fashioned tradition of having several strains isolated from more than one location for the description of novel microorganisms has vanished, lately with the increased description of anaerobic extremophiles. Thus, for several of the alkalithermophiles, only one or two isolates from the same location have been described. To the author's knowledge, neither accounts of additional isolations of the novel strains of these species nor reports of failed attempts have been published. Thus, at this time, it is not clear to which of the aforementioned categories these species belong. In a few instances, relatively similar environmental 16S rDNA sequences have been obtained. The possible conclusions that the occurrence of relatively similar environmental 16S rDNA sequences demonstrates that additional strains or at least physiologically very similar strains exist elsewhere, however, is to be taken with great caution. In the laboratories of the author (55), and from others, it has been observed in several instances that similar 16S rDNA (>98% similarity) sequences do not necessarily indicate a similar physiology. Thus, environmental sequences are not considered in this article and the readers are referred to the gene banks for their own analyses and conclusions.

Species from Geothermally Heated Environments

Lake Bogoria

Anaerobramca gottschalkii. *Anaerobramca gottschalkii* (46) is with a $pH^{25\,°C}$ range from 6.0 to 10.5 (optimum $pH^{25\,°C}$ 9.5) and 30 to 65 °C (optimum at 50 to 55 °C), a true alkalithermophile and was isolated from the inlet of Lake Bogoria (East African Rift Valley, Kenya). It is one of the three anaerobic thermophiles isolated so far from this alkaline lake, which contains hot springs and has only recently been studied in some depth. In contrast to the other alkalithermophiles described earlier, this isolate grows well on several monosaccharides including glucose, ribose, mannose, fructose, and polysaccharides such as starch, xylan, pullulan, and cellulose. Besides being glycolytic, it is also proteolytic, growing on peptone, tryptone, and yeast extract. This species requires NaCl and is slightly halophilic. Under optimum growth conditions, the doubling time of 48 minutes is significantly longer than the doubling times reported for the earlier discussed alkalithermophiles from mesobiotic environments. Prowe and coworkers (32) studied energy transduction in this halophilic, alkaliphilic, anaerobic thermophile and concluded that the uptake of amino acids required Na^+ and that leucine uptake occurred by an obligately Na^+-symport. Using inside-out membrane vesicles, they

obtained a stimulation of the ATPase activity by Na^+ and Li^+ ions, which suggests that the primary mechanisms of energy transduction depended on the cycling of Na^+ ions. The anaerobic thermophilic communities have not been studied in most of the saline alkaline lakes. Because one expect that alkalithermophiles are involved in the other breakdown reactions of autotrophically produced biomass or using autotrophic substrates in the sediment, it is very likely that more and physiologically different species will be described in the future.

Thermosyntropha lipolytica (Firmicutes). Thermosyntropha lipolytica, a nonmotile, slightly curved rod-shaped and gram-stain negative bacterium, is the second species that has been isolated only from samples of Lake Bogoria (Kenya). Three different strains, showing different lipolytic patterns, have been isolated from different samples, but all came from the same sampling site. Because this bacterium uses only the fatty acids and not the glycerol from the lipids, it is obligately syntrophic (i.e., requiring a hydrogen-utilizing partner) when growing on lipids. Linear saturated and unsaturated fatty acids with 4 to 18 carbons are used apparently because of the presence of at least two different lipases/esterases (unpublished observations). As to be expected, evennumbered acids yield mainly acetate and oddnumbered fatty acids also yield additionally 1 mol propionic acid per fatty acid degraded. Although hydrogen (100%, vol/vol, gas phase) is not inhibitory during growth on yeast extract, however, a low-hydrogen partial pressure is required during growth on lipids because H_2 = producing the fatty acid degradation is thermodynamically unfavorable (positive delta $G^{o'}$). Thus, the reaction needs to be "pulled" by maintaining a low-hydrogen partial pressure through interspecies hydrogen-transfer by either methanogens reducing carbon dioxide-moieties to methane or sulfate reducers reducing sulfoxy anions to H_2S. Free fatty acids above 1 mM are inhibitory and therefore the equimolar addition of Ca^{++} ions is necessary for maintaining growth. The lipase activity of the *Ts. lipolytica* in the three tested strains was constitutive (we are presently investigating the lipase(s) in more detail); thus, growth is inhibited by the fatty acids when grown in pure culture in the presence of lipids such as olive oil because of the detergent action of the free fatty acids. *Thermosyntropha lipolytica* is the first thermophilic syntrophic bacterium described and its 16S rDNA sequence places it in the phylogenetic neighborhood of the mesophilic syntrophs *Syntrophospora* and *Syntrophomonas*. Similarly, to the mesophilic syntrophs, crotonate serves as a good substrate to purify this thermophile. Growing on yeast extract under optimum conditions the doubling time is around one hour. The $pH^{25\,^\circ C}$ range is between 7.1 and 9.5 with an optimum between 8.1 and 8.9 ($pH^{60\,^\circ C}$ 7.6–8.1). The temperature range is 52 to 70 °C with an optimum at 60 to 66 °C. Among the tested sugars, only ribose and xylose, but not glucose, fructose, mannose, arabinose, raffinose, galactose, sucrose xylan, or starch are used. Betain and pyruvate serve as good growth substrates. The main organic fermentation product from glucose was acetate (production of carbon dioxide and hydrogen was not analyzed). Thiosulfate could serve as an electron acceptor, as probably could elemental sulfur, but not sulfate (56).

Surprisingly, *Ts. lipolytica* is relatively sensitive to elevated salt concentrations. It tolerates 0.5% (wt/vol) NaCl, but not 1% and growth is totally inhibited by 2% (~350 mM).

The presence of this novel type among the anaerobic thermophiles in the alkaline lake is not surprising taking into account the high concentration of primary organic matter producers such as cyanobacteria and algae, which die off and become part of the anaerobic sediment (1,5), requiring the presence of microorganisms to degrade the large volume of lipids so produced.

'Thermopallium natronophilum' (Thermotogales). Jones and coworkers (5) and Meijer and coworkers (35) described the most alkaliphilic one among the extreme thermophiles, *'Tp. natronophilum'*, the third species isolated only from Lake Bogoria. It grows optimally at 70 °C (T_{max} 78 °C) at pH 9.5 (pH_{max} 10.5). To date, it is the only gram-type negative (LPS present in the cell envelope) among the alkalithermophiles and the only extreme thermophile among the true alkaliphilic anaerobic bacteria, which are the main reasons that this bacterium is mentioned here despite that it has not been validly or formally published. The other reason for mentioning this species here is that its discovery starts to make the "white spot" on the map of the diversity of alkalithermophiles (Fig. 1) smaller and shows that probably there are many more alkalithermophiles to be isolated. *Thermopallium natronophilum* is a heterotrophic bacterium with a sheetlike outer structure ("toga"), characteristic of *Thermotogales*, although the temperature range is somewhat lower than for other members of the *Thermotogales*. *Thermopallium natronophilum* has a distinct requirement for carbonate.

Yellowstone National Park

***Thermoanaerobacter ethanolicus* (Firmicutes).** *Thermoanaerobacter ethanolicus* (57) is the type species of the genus *Thermoanaerobacter*, a genus that so far only contains thermophilic species. Most are neutrophiles and have been isolated from various mesobiotic and anthropogenically and geothermally heated thermobiotic environments. From the same and similar environments, physiologically similar species of the related genus *Thermoanaerobacterium* have been isolated (58). This genus also contains only thermophilic anaerobes. Besides the differences in the 16S rDNA, the main taxonomic difference between these two genera of the Firmicutes is that generally the latter forms sulfur granules from thiosulfate, whereas the former reduces it all the way to H_2S (with the exception of *Thermoanaerobacter 'sulfurigignens'*, Dashti and Wiegel, unpublished results).

Thermoanaerobacter ethanolicus is a somewhat special case among the alkali-tolerant thermophiles and facultative alkalithermophiles. It exhibits an extremely broad flat $pH^{25\,^\circ C}$ optimum between 5.5 and 8.5 and thus falls under both definitions for a facultative alkaliphile and alkali-tolerant microorganism. Usually, a value in the middle of a broader optimum, is given, but for the type strain JW 200 practically no difference in the doubling time was

observed between pH 5.5 and 8.5. Although several of the *Thermoanaerobacter* species can grow at pH values around pH 9.0, all other species have a distinct, although frequently broad, pH_{opt} in the neutral pH range of 6.5 to 7.5. So far only one true (by 16S RDNA sequence analysis) *T. ethanolicus* strain, the type strain JW 200, has been published (57). For the second strain JW 201, so far, no 16S rDNA sequence has been obtained; the strain was assigned to this species by the authors on the basis of the similar physiology. Both were isolated from hot springs at Yellowstone National Park, strain JW 200 from the famous Octopus Spring area with a slight alkaline pH 8.8 and strain JW 201 from the slightly acidic (pH 5.5) Dragon's Mouth in the Sulfur Caldron area. For the other widely studied and published strain, *T. ethanolicus* 39E ((59) and references cited therein, (60)), also isolated from the Octopus Spring (Yellowstone Natl. Park), the 16S rDNA sequence reveals that it should be reclassified in its own species. It exhibits a more narrow pH optimum. A strain apparently similar to strain 39E (61) was isolated as a contaminant from the culture-collection culture of *Clostridium thermocellum* JW 20 [originally isolated from Louisiana cotton bales; (62)].

Thermoanaerobacter ethanolicus is a glycolytic thermophile requiring, as do most of the *Thermoanaerobacter* and *Thermoanaerobacterium* species, yeast extract, peptone, or tryptone for growth and for significant metabolic activity of resting cells (could not be substituted with amino acids). The most interesting physiological features is that similar to yeast, it can ferment glucose to ethanol at ratios of up to 1.9 mol ethanol per used glucose. In addition, it also produces ethanol from other hexoses and pentoses, such as xylose, which most yeast cannot ferment. Its industrial application is hampered by the lack of a genetic system to develop a robust industrial strain. The flagellated rods frequently exhibit uneven cell division leading to coccoid cells dispersed among chains of typical rod cells (57). At the time of isolation and characterization, no spores or heat-resistant forms were detected; however, according to the definition of Brill and Wiegel (27), *T. ethanolicus* is not asporogenic (= absence of sporulation genes) because it contains representative sporulation genes and thus can also be called *cryptic spore formers* (58). In the past, when spores were occasionally observed in long time subcultured *T. ethanolicus* cultures, they were attributed to contamination with the sporulating and ubiquitous *T. thermohydrosulfuricus* (found in mesobiotic and thermobiotic environments, including dust from the inside of buildings). The detection of representative sporulation genes in this bacterium suggests that it may indeed form spores on rare occasions, similar to what has been observed in *Thermoanaerobacter brockii* (63).

With respect to the growth response (doubling time) to temperature, *T. ethanolicus* exhibits a biphasic curve. This property is shared by several other *Thermoanaerobacter* and *Thermoanaerobacterium* species and some other bacterial (e.g., *Geobacillus stearothermophilus*) and archaeal species (e.g., *M. thermautotrophicus*), which grow in an extended temperature range from about 30 upto 78 °C, that is, a temperature span above 35 °C. It has been interpreted that these microorganism contain additional sets of genes for the rate-limiting steps either for the lower or the elevated temperature range (64). This enables these microorganisms to thrive in the upper mesobiotic and in the full thermobiotic temperature range, for example, in the hot water of the pools and in the cooler runoff waters and along the temperature gradient in the sediments. It is not known whether the doubling of the genes and obtaining genes (64) by horizontal gene transfer is a more recent adaptation to expand their habitats, for example, a response to changing temperatures around hot springs and geothermally heated environments or whether it may represent an adaptive step early during evolution (34). Although formulated as a hypothesis based on physiological observation, this question might be answered in the near future when more than one of the genome sequences for microorganisms with this feature have been published and thoroughly been analyzed and compared [e.g., from bacteria such as *T. ethanolicus, T. thermohydrosulfuricus, G.* (basonym Bacillus) *stearothermophilus* and archaea such as *M. thermautotrophicus*]. In contrast to *G. stearothermophilus* that only at temperatures above 50 °C can grow anaerobically with the concomitant formation of ethanol, the fermentation balance for *T. ethanolicus* does not change with the growth temperature.

Thermobiotic Artesian Spring

Caloramator indicus (Firmicutes). This alkali-tolerant thermophile described by Chrisostomos and coworkers (30) was isolated from deep-seated, nonvolcanically heated water of an artesian aquifer in the Surat District of the Indian Gujarat State. The aquifer samples had a temperature of 60 and 65 °C and exhibited no mat formations at the borehole. The in situ measured pH was 7.7 to 7.8. Although phenotypically similar strains were isolated from a parallel sample, this species has not been isolated from other locations. On the other hand, it is physiologically very similar to the ubiquitous *Tb. celere*; thus, it is speculated that additional strains could also be found in other geothermally heated environments (such as the Australian deep-seated aquifer) and may even be found in mesobiotic environments as well (see in the preceding text for the discussion on biogeography and biogeochemistry). Phenotypically similar isolates could be obtained from the same sample even after two years' storage, however, similar to observations with *Tb. celere* strains, cultures of the isolated strains grown to the stationary phase in laboratory media tended to lyse easily within several weeks, especially in media with pH values around 7.2 compared to pH 8.1.

The nonmotile rod-shaped cells of *C. indicus* stain gram-negative despite the typical gram-type positive cell wall. Filamentous cells up to 100 μm in length were frequently observed; however, no branched cells, as observed with *Tb. celere*, were reported. Also, no heat-resistant spores were observed. Growth on tryptone-yeast extract glucose agar plates did not occur (no training on soft agar was attempted), and thus isolation was by end point dilution series. The type strain IndiB4 grows in a temperature range of about 38 to 75 °C with an optimum between 60 to 65 °C and within a pH range of 6.0 to above pH 9.2 (the exact pH_{max} has not been published) classifying this

species as alkali-tolerant thermophile. Under optimum growth conditions, the doubling time for the type strain is 20 minutes; thus, it is the fastest growing alkali-tolerant thermophile to be isolated only from thermobiotic water. *Caloramator indicus* ferments carbohydrates including starch, dextrin, sucrose, cellobiose, glucose, and fructose, but not cellulose and dextran. The main fermentation products from glucose are ethanol, acetate, lactate, carbon dioxide, and hydrogen. In addition, branched fatty acids were observed, probably formed from the required addition of yeast extract or trypticase peptone. Similar to *Tb. celere*, storage granules have been observed.

Animal Feces

Desulfotomaculum alcaliphilum (Firmicutes). This spore-forming alkalithermophile with a $pH^{50\,^{\circ}C}$ 8.6 to 8.7 and a T_{opt} 50 to 55 °C was isolated from mixed cow/pig manure samples (Moscow region). Although manure can have alkaline pH values because of production of ammonia, these samples had pH values ranging from pH 6.0 to 70 (65). Most of the thermophiles isolated, so far, from manure have their pH_{opt} in the neutral range but are able to grow well above $pH^{25\,^{\circ}C}$ 8.5, for example, *Clostridium thermobutyricum* with a pH-range from $pH^{25\,^{\circ}C}$ 5. 8 to 9.0 and a $pH^{25\,^{\circ}C}_{opt}$ of 7.0 (66) and *M. thermoacetica* (25). However, this sulfate reducer is obligately alkaliphilic because it is not able to grow below $pH^{50\,^{\circ}C}$ 8.0. Neither did it grow in the absence of sulfoxy species in yeast extract–containing glucose-peptone medium. The bacterium requires low NaCl concentrations; no growth was obtained without the addition of NaCl to the mineral media in which Na_2S and Na_2CO_3 were replaced by potassium salts. As the strain was not isolated from an alkaline natrono lake, it is not surprising that the optimum salt concentration is low, that is, 0.1% to 1% NaCl. Five percent NaCl slowed growth down, whereas 7% totally inhibited growth, values that are typical for many of the anaerobic neutrophilic heterotrophic thermophiles isolated from geothermally heated springs (58). Furthermore, this alkaliphile requires obligatory carbonate (the range of optimum concentrations has not been given). However, this strain could tolerate (with extended lag times) 5% NH_4Cl and grew without any inhibition at 1.5%, surely an advantage for this organism's existence in manure.

To date, *D. alcaliphilum* is the only alkalithermophilic sulfate reducer and is described as an obligate anaerobe. The growth substrates used are typical for sulfate reducers: hydrogen and acetate (also used as carbon source), lactate, pyruvate, formate, and ethanol. The addition of vitamins is required for growth. Sulfate, thiosulfate, and sulfite can serve as electron-acceptors, but not sulfur or nitrate.

ARCHAEAL SPECIES AND THEIR KNOWN HABITATS

Among the archaeal alkalithermophiles and alkali-tolerant thermophiles are species belonging to the heterotrophic *Thermococcales* branch within the *Crenarchaeota* and to the methanogenic branch within the *Euryarchaeota*. *Thermococcus alcaliphilus* represents the species among the alkali-tolerant and alkalithermophiles with the highest optimum growth temperature of 85 °C, although growing optimally at pH of 9.0. So far, there are no reports of (extreme) thermophilic methanogens from any environment growing optimally above pH 9.0. Again, similar to many of the earlier discussed bacteria, only one strain of each of the archaeal species discussed later was isolated and characterized from one location. Thus, at this time one cannot make any conclusions about the biogeography of the archaeal alkalithermophiles, except that as a group they have been isolated from a variety of geothermally and anthropogenically heated environments similar to the alkalithermophilic bacteria.

Geothermally Heated Environments

Hyperthermophilic Heterotrophs

***Thermococcus alcaliphilus* and *Thermococcus fumicolans* Among.** the alkalithermophilic anaerobes growing optimally at or above $pH^{25\,^{\circ}C}$ of 8.5, these two species exhibits the highest T_{opt} (85 °C) for growth. *Thermococcus fumicolans* grows in a temperature-range of 73 to 103 °C and a relatively wide pH range of 4.5 to 9.5 with a pH_{opt} of 8.5 (22), whereas *Tc. alcaliphilus* has a $pH^{25\,^{\circ}C}_{opt}$ of around 9.0 and a pH range from 6.5 to 10.5 but exhibits a lower T_{max} of around 95 °C (26,67). Thus, both are hyperthermophilic, facultative alkaliphiles. Interestingly, again the species with the higher T_{max}, *Tc. alcaliphilus* (103 °C), has the lower pH range and optimum. Both species are marine isolates exhibiting a NaCl optimum around 2 to 4%. *Thermococcus fumicolans* was isolated from a deep-sea hydrothermal vent in the North Fiji Basin, whereas *Tc. alcaliphilus* came from a shallow hydrothermal vent at Vulcano Island in Italy. Both are irregular cocci, typical for the genus, and are proteolytic, that is, they grow best with complex media including yeast extract, peptone, and casein using sulfur or polysulfide as electron acceptors and forming H_2S as reduced product. Neither uses hydrogen but are not inhibited by its presence. *Thermococcus alcaliphilus* cannot use casamino acids or any sugar (so far tested), whereas *Tc. fumicola* can grow on a mixture of 20 amino acids. Although final cell yields are not affected, in the presence of polysulfide, the doubling time of *Tc. alcaliphilus* was 1.3 h, whereas in its absence it was 4 h. In the absence of sulfur compounds, the final product was hydrogen. Optimum growth conditions required 0.2% yeast extract and 6 mM polysulfide or sulfur. Besides 25 mol H_2S, other products per 10^8 cells were 15 mol acetate, 3.6 mol propionate, 1.9 mol isobutyrate, traces of isovalerate and carbon dioxide and ammonium (both not quantified).

Sun-Heated Alkaline Environments

Thermotolerant Methanogens

Methanohalophilus zhilinae. Although it is only a thermotolerant archaeon (T_{opt} 45 °C), the gram staining positive, methanol and methyl amine-using, coccoid archaeon *M.* (proposed to be changed to *'Methanosalsus') zhilinae* deserves to be mentioned here as the most alkaliphilic methanogen able to grow at elevated temperatures. The type strain WeN5 was isolated from the

sediment of the alkaline natrono Bosa Lake in the Wadi Natrun area (Egypt) with a water pH of 9.7 (68). At the same time, the authors isolated four other similar alkaliphilic methanogens; however, they were rod-shaped and mesophilic with a T_{opt} of 31 and 37 °C, respectively. An additional *Mh. zhilinae*, strain Z-7,936, (91% DNA : DNA homology to the type strain) was isolated from the alkaline soda lake Magadi (Kenya) (24). It grows optimally at pH_{opt}^{RT} up to 9.5 when grown on methanol and pH 8.5 when grown on methyl amines, however, this second strain is a mesophile with a T_{opt} around 37 °C and a T_{max} below 48 °C. It is inhibited by 30 mM methyl amine and ammonium and by 1 atm of hydrogen in the gas phase. Interestingly, the thermophilic type strain is also inhibited by 1 mM sulfide when growing on methyl amines, however, most of the alkaline lakes have concentrations of sulfides below this value (5).

Anthropogenic Niches

Methanogen

'Methanothermobacter thermoflexus' and Methanobacterium thermoalkaliphilum (sic). Now Strains of *Methanothermobacter thermautotrophicus*. The most alkaliphilic methanogen able to grow optimally above 50 °C is *M. thermoflexum* (sic) (69), which is to be renamed *Mt. thermoflexum* (23) (however, this species is not yet validly renamed according to the rules). This autotrophic, formate-using thermophile was isolated from the sludge of an anaerobic digester operating at elevated temperature and using wastewater containing methacrylates. This archeaon, in the presence of 150 mg/L Na_2S, and 1–30 g/L NaCl, grows with a doubling of 3.5 hours at 55 °C and pH 7.9 to 8.2. Such doubling time is typical for thermophilic methanogens but is long compared with one of the fastgrowing *C. paradoxum*. A very similar pH range has been observed for a strain isolated from cow manure and originally described as *M. thermoalcaliphilum* (70) (pH_{opt} 7.5 to 8.5; T_{opt} 58 to 62 °C) but later identified by 16S rDNA sequence and other characteristics as a strain (biovar) of the type species of *Methanothermobacter* (basonym *Methanobacterium thermautotrophicus* with its type strain delta H also isolated from sewage sludge (71). The type species with the type strain delta H, however, has a higher T_{opt} (around 68 °C) and a lower pH_{opt} of around 7.5. The typical *Mt. thermautotrophicus* strains can be easily isolated from many different mesobiotic (including lake sediments in which bulk temperature does not exceed 20 °C) anaerobic sediments and sewage digesters all over the world. It is regarded as a truly ubiquitous microorganism. However, no other similar alkaliphilic strains have been reported, although one can speculate that similar strains are present in manure of cows in other countries.

POSSIBLE CORRELATION BETWEEN THE SHORTEST OBSERVED DOUBLING TIMES FOR A SPECIES AND THE TYPE OF HABITAT FROM WHICH THE ALKALITHERMOPHILES WERE ISOLATED

From the few presently isolated and validly described anaerobic alkalithermophiles and alkali-tolerant thermophiles, it appears that bacteria isolated from mesobiotic and more pH-neutral habitats tend to exhibit unusually short doubling times of less than 20 minutes, whereas those isolated from thermobiotic environments, that is, geothermally heated environments or from alkaline habitats exhibit usually longer doubling times above 40 minutes. Among the archaea, all alkalithermophiles and alkali-tolerant thermophiles were isolated from thermobiotic environments and all exhibit doubling times longer than one hour. As only a few species of alkalithermophiles have been isolated and described, this trend might be just anecdotal. On the other hand, it could be that the organisms living in environments with a neutral bulk pH and mesobiotic temperatures can only thrive in these environments if they are able to react quickly ("instantly") to transient alkaline pH and elevated temperatures. The transient-elevated temperatures and alkaline pH values are thought to occur mainly in microniches created by microbial metabolism as discussed in the preceding text. It is futile to discuss whether the microorganisms have adapted to such environments or whether these environments have selected these type of microorganism until many more alkalithermophiles from various environments have been isolated, characterized, and thoroughly compared.

CONCLUSION

During the last eight years, several anaerobic alkalithermophiles and alkali-tolerant microorganisms have been isolated. They belong to several physiological types and to different systematics groups. The majority of isolated strains belong to the gram-type positive bacteria with proteolytic or glycolytic metabolisms, but the present group also contains one sulfate reducer, one gram-type negative bacterium, an extreme thermophilic member of the *Thermotogales*, two hyperthermophilic archaea, and three moderate thermophilic methanogenic archaea. The highest T_{opt} (85 °C) among the anaerobic alkalithermophiles is observed for the archaeal *Tc. fumicolans* (T_{max} 103 °C; pH_{opt} 8.5; pH_{max} 9.5) and *Tc. fumicolans* (T_{max} 95 °C; $pH_{opt}^{25\,°C}$ 9.0; $pH_{max}^{25\,°C}$ 10.3). The highest pH optimum and maximum is exhibited by the gram-type positive *C. paradoxum* with a $pH_{opt}^{25\,°C}$ 10.1 (pH_{opt}^{55C} 9.3) and a $pH_{max}^{25\,°C}$ of 11.0 (pH_{max}^{55C} 10.3). The various species differ from being isolated only from one location (restricted biogeography) to being truly ubiquitous. The habitats include anthropogenically and geothermally heated environments with alkaline but also acidic pH values, and mesobiotic (bulk property) neutrophilic environments such as river and lake sediments, and animal feces. It is expected that the diversity will increase when more alkalithermophiles will be isolated through intensified studies on the ecology and diversity of these microorganisms and investigation of additional alkaline habitats.

The anaerobic alkalithermophiles described till date obviously do not represent the most alkaline nor the most thermophilic microorganisms, however, they are the most thermophilic alkaliphiles (the most alkaliphilic thermophiles). But they contain some of the fastest growing bacteria known to date such as *Tb. celere* with a doubling time of 10 minutes. The alkalithermophiles

represent an interesting but relatively little investigated group of microorganisms, which should receive much more attention in the near future.

THERMOPHILES, DIVERSITY OF

Margaret L. Rising
Anna-Louise Reysenbach
Portland State University
Portland, Oregon

Thermophiles are heat-loving organisms that thrive in naturally and artificially heated environments. For the purposes of this review, we define thermophiles as organisms capable of growing best above 45 °C, and hyperthermophiles are thermophiles that grow best above 80 °C. Thermophiles are found in all three domains of life, the *Bacteria*, *Archaea*, and *Eukarya* (1; Fig. 1). Among the

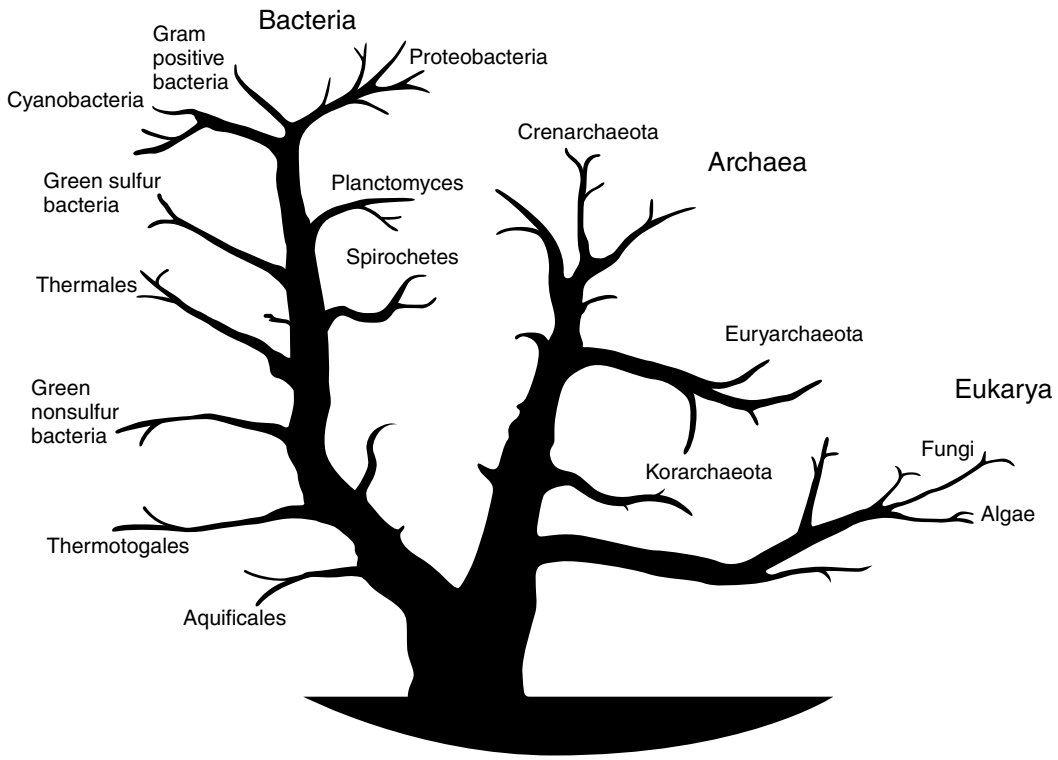

Figure 1. Stylized phylogenetic tree of all life showing the major thermophilic lineage in the three domains of life. See alrlab pdf. edu for photographs of many thermophiles.

Eukarya only a few algae and fungi are thermophilic. In contrast, thermophiles are widely distributed amongst the *Bacteria* and occupy many primary lineages in the *Archaea*. The diversity of thermophiles is reflected by their ability to grow in chemically diverse, high-temperature environments. In geothermally heated pools at Yellowstone National Park in Wyoming, U.S.A., colorful microbial mats are produced by photosynthetic thermophiles, such as *Cyanidium caldarium*, a moderately thermophilic alga, with an upper temperature limit for growth of 57 °C, and *Synechococcus*, a cyanobacterium with an upper temperature limit for growth of about 75 °C (2). In man-made, self-heating coal refuse piles, one finds *Thermoplasma acidophilum*, a cell wall-less *Archaea* that grows at temperatures from 40 to 62°C (3). Far removed from Yellowstone and coal mines, and a few thousand meters beneath the ocean's surface, hyperthermophiles, such as the archaeum *Pyrolobus*, grow at deep-sea vents at temperatures as high as 113 °C (4). These and other thermophiles share in common high temperatures for growth. In the past 20 years, the discovery of new species of thermophiles has grown exponentially and has challenged our preconceptions of the limits and origins of life.

ECOLOGICAL NICHES OF THERMOPHILES

Thermophiles are found in a wide variety of ecological niches. These include artificially heated environments, such as coal refuse piles and water from geothermal power plants (5,6). Solar-heated soils, fermenting compost piles and anaerobic sewage sludges are also good sources of thermophiles. By far, most of the thermophiles isolated are from geothermal environments, such as terrestrial hot springs, shallow marine and deep-sea vents, and deep subsurface ecosystems (7).

The ecological niches available for thermophiles in geothermally heated environments are diverse and reflect the unique physical forces at work in these environments. For instance, deep subsurface aqueous environments are heated by the Earth's core, with an average temperature increase of about 25°C per kilometer within the crust (8,9). Microbial growth in deep subsurface ecosystems is dependent upon either compacted organic material in sedimentary rock or the slow and modest energy-yielding chemical reactions that are continuously at work between the inorganic elements of rocks and minerals in the Earth's crust (9).

Deep-sea hydrothermal vents are, in part, surface expressions of hot deep subsurface environments (see HYDROTHERMAL VENTS: BIODIVERSITY IN DEEP-SEA HYDROTHERMAL VENTS and HYDROTHERMAL VENTS: PROKARYOTES IN DEEP-SEA HYDROTHERMAL VENTS). The geological forces creating deep-sea hydrothermal vents are similar for shallow marine and terrestrial vents. As a result of plate tectonics, nascent oceanic crust forms at mid-oceanic spreading centers and moves away in opposite directions until it subducts below the less dense continental crust. Generally, volcanically active regions occur along these mid-oceanic spreading centers or plate boundaries. The exceptions are hot spots, which are volcanically active regions, such as Yellowstone, Iceland and Hawaii that are far-removed from plate boundaries. These are caused by plumes of hot lava rising through the Earth's mantle. The near-surface lava at mid-oceanic spreading centers and hot spots superheats water in the Earth's crust, ultimately convectively forcing it to the surface. The reduced, hot emerging hydrothermal fluid is the culmination of a hydrological cycle that began with seawater or groundwater percolating through rocks in the Earth's crust. Before it emerges at the vent, the superheated fluid reacts with the surrounding rock, losing elements and ions, such as Mg^{2+} and SO_4, and adding minerals and gases, such as Fe^{2+}, Mn^{2+}, carbon dioxide, methane, and hydrogen sulfide. In deep-sea hydrothermal vents, when the seawater emerges, it mixes with cold oxygenated seawater, causing many of the iron-sulfur minerals to precipitate, forming a "smoky "plume characteristic of "black smoker "vents. At these depths (>2, 000 m), water can remain liquid at temperatures up to 400 °C because of the increased pressure. Just as was the case for microbial growth in the deep subsurface, energy from sunlight is not available at deep-sea vents. Microbes are therefore dependent upon the abundant supply of inorganic chemicals associated with the hydrothermal fluid. Organic carbon is also available as a result of the high productivity in these "oases "of the deep-sea. Shallow marine vents can be distinguished from deep-sea vents, as light energy from sunlight in addition to chemical energy from hydrothermal fluids is available for microbial growth in these shallower environments.

Terrestrial hot springs also occur as a result of plate tectonics. These are distinguishable from deep-sea hydrothermal vents and shallow marine vents because groundwater, and not seawater, percolates through the crust. Terrestrial thermal springs may have pH values ranging from 1 to 10, depending on the subsurface hydrological and geochemical reactions. For example, thermal fluid rich in hydrogen sulfide gas will react with water to produce sulfuric acid. These thermal springs are very acidic and, if located in limestone formations, the fluid dissolves the surrounding rock and produces the characteristic low pH mudpots. Microorganisms thrive in these acidic thermal mudpots, which may have pH values less than 4.

PHYSIOLOGICAL DIVERSITY

The metabolic and physiological diversity of thermophiles is a direct expression of their ability to inhabit the wealth of ecological niches thus far discussed. Metabolically, there are three general strategies by which microbes obtain their carbon and energy sources for growth — photoautotrophy, chemolithoautotrophy, and heterotrophy (or chemoorganotrophy) — and thermophiles employ them all. Photoautotrophs use energy from sunlight and fix carbon dioxide, chemolithoautotrophs use energy from inorganic molecules and fix carbon dioxide, and heterotrophs use organic molecules as both energy and carbon sources. In addition, some microbes are photoheterotrophs, obtaining energy from sunlight and using organic carbon molecules as a carbon source. Heterotrophs and photoautotrophs are

found in all three domains of life. Chemolithoautotrophy is restricted to the bacterial and archaeal domains.

In addition to the variety of metabolic strategies for gaining energy and organic carbon, thermophiles are physiologically adapted to environments that are extreme in more than temperature. Thermoacidophiles inhabit hot and extremely acidic environments, such as sulfur- and iron-rich terrestrial acidic hot springs and coal refuse piles. Thermoacidophiles not only tolerate extremely low pH, they require it to grow. At the other end of the pH scale, thermophilic alkalophiles that grow up to pH 10 have been isolated from some thermal environments. Many of the thermophiles are resistant to heavy metals. Some of the thermophiles from deep-sea hydrothermal vents are barophilic (piezophilic) or barotolerant, able to grow at the high pressures from which they were isolated. Additionally, they may be halophilic, specifically adapted to high saline conditions.

In summary, thermophiles are found in virtually any environment where high temperatures occur. Thermophiles are diverse, capable of growth as chemolithoautotrophs, photoautotrophs, or heterotrophs and they can occupy extremes in pH, salinity and pressure. This metabolic and physiological diversity is a reflection of the diverse environmental settings and ecological niches in which thermophiles are found.

PHOTOTROPHS

One dramatic difference between deep-sea and deep subsurface high-temperature environments and shallow marine and terrestrial hydrothermal environments is the prevalence of photosynthetic communities in the latter. Phototrophic thermophiles include members of both the eukaryal and bacterial domains. Two general mechanisms of photosynthesis are used by thermophiles, namely oxygenic and anoxygenic photosynthesis. Oxygenic photosynthesis occurs when water is the electron donor and in which the by-product of photosynthesis is oxygen. This is characteristic of thermophilic algae (*Eukarya*) and cyanobacteria (*Bacteria*). Thermophiles that use *an*oxygenic photosynthesis, in which molecules, such as hydrogen and hydrogen sulfide serve as the electron donors, and oxygen is not evolved as a by-product of photosynthesis, is restricted to several lineages within the Bacteria. The mechanisms by which these anoxygenic photoautotrophs and photoheterotrophs photosynthesize differ considerably from each other and will be discussed in the following sections.

Oxygenic Phototrophs

Within the *Eukarya*, thermophilic representatives are thus far restricted to the algae and fungi. The photosynthetic organelle in algae is the chloroplast, and based on small subunit rRNA (16S rRNA) sequence comparisons, chloroplasts are closely related to the cyanobacteria (10). Both algae and cyanobacteria use water as the source of electrons, and light energy splitting water and generating oxygen: $2H_2O + h\nu \rightarrow O_2 + 2H_2$. Oxygenic photosynthesis is characterized by two distinct photosystems — photosystem I and photosystem II — each of which absorbs sunlight at different wavelengths. Chlorophyll *a* and phycocyanin, the sunlight-absorbing pigments within cyanobacteria and eukaryotic algae, give these phototrophs their characteristic blue-green color.

Algae are very prevalent in terrestrial thermal springs at temperatures below 45 °C. They produce the very characteristic bright yellow, orange, and reddish-brown mats (such as produced by *Zygogonium*) on the edges of many thermal pools. At the higher temperatures, cyanobacteria prevail, except in acidic thermal springs, like Nymph Creek, in Yellowstone National Park. At pH less than 4.5 and temperatures between 35 and 57 °C, the single-celled alga, *Cyanidium caldarium* forms spectacular blue-green communities with the thermophilic fungus, *Dactylarium gallopava*. These communities have been likened to the symbiotic relationships that exist with lichens. *Cyanidium* has been found in many hot springs around the world, including hot springs in Japan, Costa Rica, New Zealand, and the Azores.

Thermophilic cyanobacteria are generally the dominant phototroph in near-neutral thermal springs, present up to 73 °C. Some examples of thermophilic cyanobacteria include the filamentous gliding *Oscillatoria*, the globally distributed *Mastigocladus* and the kidney-shaped rods of *Synechococcus*. *Synechococcus* cells are abundantly distributed in the top 1-mm thick photic zone of the extensive microbial mats in Yellowstone Park (11). Laboratory isolates of *Synechococcus lividus* exhibit motility in response to light intensity, but no diel shifts in vertical distribution because of light intensity have been detected in situ (11). *Synechococcus lividus* dominates Yellowstone microbial mats throughout the light-deficient winter months, possibly because the ecological role of *S. lividus* is like that of trees in a climax forest community, dominating biomass even when conditions are not optimal (11). Furthermore, cyanobacterial mats, such as those dominated by the filamentous cyanobacterium, *Phormidium*, have been used as models for studying stromatolite (laminated mineralized structures that can be biogenic in origin) formation.

Anoxygenic Phototrophs

The oxygenic phototroph *Synechococcus* occurs in close association with anoxygenic phototrophic *Bacteria*, such as the green nonsulfur bacterium, *Chloroflexus*. During anoxygenic photosynthesis, chemicals that are abundant around terrestrial and shallow marine vents, such as dissolved hydrogen sulfide $H_2S_{(}aq)$, molecular hydrogen (H_2) or organic compounds are used as electron donors and light serves as the energy source. Anoxygenic phototrophs are found in three different lineages in the bacterial tree. They differ from each other in their pigments and modes of photosynthesis. These lineages are the green nonsulfur bacteria (e.g., *Chloroflexus*), the green sulfur bacteria (e.g., *Chlorobium*) and the purple sulfur or Proteobacteria (e.g., *Chromatium*).

Although not all members of the green nonsulfur bacteria are phototrophs or thermophiles, *Chloroflexus aurantiacus* is commonly found in the lower layers of

mats containing the thermophilic oxygenic phototroph, *Synechococcus*. *Chloroflexus aurantiacus* is a filamentous, gliding bacterium that grows optimally at 55 °C, with an upper temperature limit of 65 to −70 °C (12). The long, slender filaments of *C. aurantiacus* are thought to provide stability to microbial mats. *Chloroflexus aurantiacus* is an unusual phototroph in that it exhibits considerable metabolic diversity. Under aerobic conditions and without light, *C. aurantiacus* grows chemoorganotrophically. In the presence of light, *C. aurantiacus* grows best photoheterotrophically on a wide variety of sugars, amino acids and organic acids, but can also grow photoautotrophically with hydrogen sulfide or molecular hydrogen as electron donors.

Based on 16S rRNA phylogenetic analyses, *C. aurantiacus* and its close allies form the deepest branching group of photoautotrophs (1). This phylogenetic placement of *C. aurantiacus* is of particular interest because *C. aurantiacus* converts carbon dioxide to organic carbon by the unique hydroxyproprionate pathway. Unlike the Calvin cycle and the reverse citric acid cycle, the hydroxyproprionate pathway involves the conversion of two molecules of carbon dioxide to glyoxylate. Phylogenetic analysis of conserved photosynthetic light harvesting pigments placed the green sulfur bacteria in close relationship with the green nonsulfur bacteria (13), However, based on 16S rRNA phylogenetic analysis these two groups form distinct unrelated lineages. Both of these groups have bacteriochlorophyll *c*, yet they possess different photosynthetic pathways. A common member of the green sulfur thermophiles, *Chlorobium tepedium*, can be found in high-sulfide hot springs where temperatures have cooled below 50 °C. These anoxygenic phototrophs produce S^0 as a by-product of photosynthesis, which is deposited outside the cell.

Chlorobium is often found in close association with another anoxygenic phototroph, the purple sulfur proteobacterium, *Chromatium tepedium*. These organisms form photosynthetic mats in high sulfide, near neutral pH thermal springs (temperature ~50 °C). *Chlorobium* can generally withstand higher H_2S concentrations than *Chromatium*, and the different organisms stratify within a microbial mat accordingly. Additionally, *Chromatium* is generally absent from thermal springs dominated by *Chloroflexus* because the latter is more thermotolerant. Like *Chlorobium*, *Chromatium* produces elemental sulfur during phototrophic growth on hydrogen sulfide, however, *Chromatium* deposits the sulfur within the cell.

CHEMOLITHOAUTOTROPHS

The oxygenic and anoxygenic phototrophs dominate many of the terrestrial thermal springs. However, at temperatures at which photosynthesis has not been reported and in thermal springs where the chemistry inhibits photosynthesis, chemolithoautotrophic and chemoorganotrophic thermophiles proliferate.

The abundance of inorganic electron donors and acceptors in hydrothermal vents, provides a wide range of inorganic energy sources for chemolithoautotrophic thermophiles. Many chemolithoautotrophs are facultative, using organic compounds as energy sources if they are available.

Chemolithoautotrophic *Bacteria*

By far most of the thermophiles that have been isolated from the bacterial domain, are heterotrophs. However, two deeply diverging lineages with the *Bacteria*, the *Aquificales* (14) and "*Desulfurobacteriales* " (15) are primarily chemolithoautotrophic thermophiles. The *Aquificales* obtain energy from hydrogen oxidation using the "knallgas" reaction ($H_2 + O_2 \rightarrow 2H_2O$). These organisms are all microaerophiles, as they tolerate and grow on low levels of oxygen. Many of the *Aquificales* can also use alternate electron donors (other than H_2), such as elemental sulfur and thiosulfate ($S_2O_3^{2-}$), and they can use alternate electron acceptors (instead of O_2), such as nitrate (NO_3^-).

Members of the *Aquificales* are widespread in thermal environments. They have been isolated from shallow marine vents (*Aquifex pyrophilus*), deep-sea vents ("*Perseponella*"), terrestrial thermal springs (*Calderobacterium*, *Hydrogenobacter*), and heated compost (*Hydrogenobacter*). Many of these thermophiles form visible filamentous biomass in terrestrial thermal springs, and in some cases have evaded cultivation and isolation. One such organism forms the pink filaments ("streamers") from Octopus Spring, Yellowstone National Park. After years of effort this organism was only recently isolated and named *Thermocrinis ruber*.

The story of the isolation of *T. ruber* is an example of how environmental 16S rRNA gene analysis can place as yet uncultured microbes in a phylogenetic tree, thereby providing a guide for enrichment culturing approaches. The dominant 16S rRNA gene sequence obtained from DNA extracted from the pink filament community in Octopus Spring was closely related to other members of the *Aquificales*, (16). From this information, Huber and coworkers (17) speculated that, like their close relatives, the pink filaments were hydrogen oxidizers. Indeed, they were successful in isolating *T. ruber* from Octopus Spring under growth conditions favorable to H_2 oxidizers.

Closely related to the *Aquificales*, yet a distinct lineage, is the recently isolated sulfur-reducing chemolithoautotroph, *Desulfurobacterium thermolithotrophum*. This is the first S^0-reducing chemolithoautotroph to be isolated within the domain *Bacteria* (15). For *D. thermolithotrophum*, molecular hydrogen always serves as the electron donor. The sulfur compounds used as electron acceptors include elemental sulfur, thiosulfate, and sulfite (SO_3^{2-}).

The gram-positive *Bacteria* have many representatives that are thermophilic (see following text), but few that are also chemolithoautotrophs. *Ammonifex degensii* and *Thermoterrabacterium ferrireducens* are both facultative chemolithoautotrophs, and capable of growing heterotrophically. The former is a nitrate reducer, whereas the latter reduces iron.

Within the *Proteobacteria*, *Thermothrix azorensis* is a beta proteobacterium with a physiology very reminiscent of the *Aquificales*. This thermophile is capable of growing by oxidizing compounds, such as sulfur and thiosulfate.

It is likely that as we explore diversity of more thermal environments, more chemolithotrophic *Bacteria* will be isolated. For example, the bacterial diversity reported by Hugenholtz and coworkers (18) from a single hot spring in Yellowstone National Park, Obsidian Pool, revealed 54 distinct phylotypes (16S rRNA gene sequence types), perhaps some of these lineages are also chemolithoautrophs?

Chemolithoautotrophic *Archaea*

There are two major kingdoms within the *Archaea*: the Euryarchaeota and the Crenarchaeota. A proposed third kingdom, the Korarchaeota, was proposed based on 16S rRNA sequences obtained from Obsidian Pool in Yellowstone National Park (19). Until recently, it was thought that all members of the Crenarchaeota were thermoacidophiles, requiring high temperature and low pH for growth. But low-temperature members of the Crenarchaeota have been identified in temperate regions, revealing that the Crenarchaeota are more physiologically diverse than previously thought. The Euryarchaeota include the methane-producing methanogens, salt-loving halophiles and many of the thermophilic *Archaea*. For a review on the metabolism of many of these *Archaea*, see Schonheit and Schafer, 1995 (20).

Perhaps some of the best studied chemolithoautotrophic members of the Crenarchaeaota are *Pyrodictium*, *Pyrolobus* and *Acidianus*. *Pyrodictium occultum* is a hyperthermophilic sulfur reducer that was isolated from shallow marine vents and grows optimally at 105 °C. In addition to a high optimal growth temperature, *P. occultum* exhibits an unusual morphology. The cells of *P. occultum* are disk-shaped, and they grow moldlike on sulfur crystals in a huge network of hollow, proteinaceous fibers. The sulfur reducer *Pyrolobus fumari* is best known for it high temperature growth characteristics. This hyperthermophile grows best at 106 °C (up to 113 °C) and survives autoclaving at 121 °C for one hour (4). *Pyrodictium* and *Pyrolobus* grow optimally in moderately acidic conditions (pH 5.5), whereas their relative *Acidianus brierleyi* thrives at pH of 2.0. (21). *Acidianus brierleyi* is a facultative anaerobe that grows aerobically by sulfur oxidation, producing sulfuric acid (H_2SO_4), or anaerobically by sulfur reduction coupled with hydrogen oxidation producing hydrogen sulfide (H_2S). Unlike *Acidianus*, its close relative, *Sulfolobus* is an obligate aerobe that grows by sulfur oxidation in the presence of oxygen, producing sulfuric acid. Both *Acidianus* and *Sulfolobus* can oxidize iron (Fe^{2+} to Fe^{3+}), making them good candidates for high-temperature leaching of copper and iron ores. Another member of this group, *Metallosphaera*, can oxidize sulfide ores, such as pyrite, chalcopyrite, and sphalerite, producing sulfuric acid and mobilizing heavy metals in the process (22,23).

In the Euryarchaeota, the sulfate reducer, *Archaeoglobus fulgidus* grows chemolithoautotrophically with sulfate as an electron acceptor (5), whereas *A. profundus* can only grow chemoorganotrophically with sulfate as an electron acceptor (24). *Archaeoglobus* is unusual because it also produces small amounts of methane and possesses coenzyme F_{420}. Coenzyme F_{420} is typically unique to the methanogenic Archaea. It absorbs light at 420 nm and fluoresces light blue, providing an easy method for preliminarily identifying methanogens. The presence of F_{420} in the methanogens and in *Archaeoglobus* suggests that sulfate reduction may represent a transitional metabolism in *Archaea* between sulfur respiration and methanogenesis.

Examples of thermophilic chemolithoautotrophic methanogens are *Methanococcus*, *Methanothermus*, and *Methanopyrus*. These methanogens reduce carbon dioxide and oxidize molecular hydrogen ($CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O$) to produce methane. *Methanococcus* and *Methanopyrus* have both been isolated from deep-sea vents (25,26), whereas *Methanothermus* has only been isolated from terrestrial thermal springs in Iceland (27). *Methanopyrus kandleri*, grows optimally at 98 °C and up to 110 °C (25).

In summary, the thermophilic chemolithoautotrophs described in this section illustrate only a sample of the many metabolic pathways possible within this metabolic group, and more will no doubt be discovered. Additionally, many of the same microorganisms or their close relatives can also grow chemoorganotrophically.

HETEROTROPHS

Chemolithoautotorphs, like photoautotrophs, are the basis of the carbon food chain. These organisms produce organic carbon from inorganic carbon (primarily CO_2) that is then a source of carbon for heterotrophs. Thermophilic heterotrophs can grow either aerobically or anaerobically, by respiration or by fermentation of organic compounds. Many of these thermophiles use complex organic mixtures containing peptides and sugars.

Heterotrophic *Eukarya*

Within the *Eukarya*, about 30 species of approximately 50,000 species of fungi are thermophilic heterotrophs and almost all are strict aerobes (28). With few exceptions, thermophilic fungi cannot grow anaerobically, although the sexual stage of at least one species, *Talaromyces (Penicillium) duponti*, is initiated under anaerobic conditions (28). An example of a thermophilic fungus is *Dactylaria gallopava*, mentioned previously in conjunction with *Cyanidium caldarium*, the thermoacidophilic algae that forms extensive mats at Yellowstone National Park. *Dactylaria gallopava* relies on low molecular weight organic compounds excreted by *C. caldarium* as an energy and carbon source (2).

Compost piles are an excellent source for thermophilic eukaryotes. As composts are piles of organic plant matter consisting primarily of cellulose, an important step in the degradation of the organic matter is cellulose degradation. *Chaetomium thermophile* releases simple sugars as it degrades cellulose that the noncellulolytic thermophilic heterotrophs like *Thermomyces lanuginosus* can consume. Other noncellulolytic thermophilic heterotrophs grow on xylan, which is also present in the cell wall of plants (28).

Heterotrophic *Bacteria*

Compost piles are also a source of novel thermophilic Bacteria. At temperatures of 65 to 69 °C, obligately heterotrophic bacteria, such as *Bacillus stearothermophilus*, thrive (29). The genus *Bacillus* belongs to the gram-positive *Bacteria*, a group with many heterotrophic thermophilic representatives isolated from diverse warm environments. For example, *Bacillus thermoaerophilus* was isolated from sugar beet factories (30) and *B. sporothermodurans* was obtained from milk-processing plants (31). *Clostridium thermopalmarium* (32) and *B. thermoamylovorans* (33) were isolated from palm wine, a traditional alcoholic beverage from tropical countries where palm trees are common. The heterotrophic iron reducer, *B. infernus*, was obtained from samples collected 2.7 km below the Earth's surface. *Bacillus infernus* ferments glucose or oxidizes formate or lactate when using iron (Fe^{3+}) or manganese dioxide as an electron acceptor (34). *Thermoterrabacterium ferrireducens*, another iron-reducing thermophilic gram-positive bacterium was isolated from Calcite Springs at Yellowstone National Park (35). *Moorella glycerinia* was also isolated from the same environment and is capable of growth solely on glycerol.

Whereas *Bacillus* relatives grow well within composts from 65 to 69 °C, heterotrophs, such as *Thermus thermophilus*, can thrive in composts with internal temperatures above 70 °C (36). *Thermus aquaticus*, a close relative of *T. thermophilus*, is found in geothermally heated environments throughout the world and even in hot water heaters (37). It forms filaments up to 200 μm in length (Fig. 2a). *Thermus aquaticus* may be best known as the source of *Taq* polymerase, the DNA polymerase used in the polymerase chain reaction (PCR) that has revolutionized the field of molecular biology.

Another filamentous chemoorganoheterotroph isolated from terrestrial vents is *Isosphaera pallida*, which may appear salmon-colored because of the presence of carotenoids (38). *Isosphaera pallida* is a member of the poorly studied Planctomyces group, which reproduce budding and produce stalks. The importance of this group was recently exemplified when a nonthermophilic Planctomycete was implicated in the anaerobic oxidation of ammonia via the "anammox" reaction ($NH_4^+ + NO_2^- \rightarrow N_2 + 2H_2O$) (39). One might expect to find similar unusual organisms associated with high-temperature ecosystems.

Spirochetes have also been identified in thermal environments (Fig. 2b,c) and grow anaerobically by fermentation of complex organic compounds. Microscopic examination of samples from a New Zealand thermal spring revealed that thermophilic spirochetes grew best from 45 to 50 °C (40) although they were also prevalent at 50 to 58 °C. Thermophilic spirochetes have also been obtained from Hunter Hot Spring, Oregon, U.S.A. (41) and Furnas, Azores (Aguiar and Reysenbach, unpublished results, Fig. 2b,c).

The only hyperthermophilic and heterotrophic lineage within the *Bacteria*, is the *Thermotogales*. These organisms are characterized by having a characteristic sheath, or "toga," which surrounds the cell (Fig. 2d). The genus,

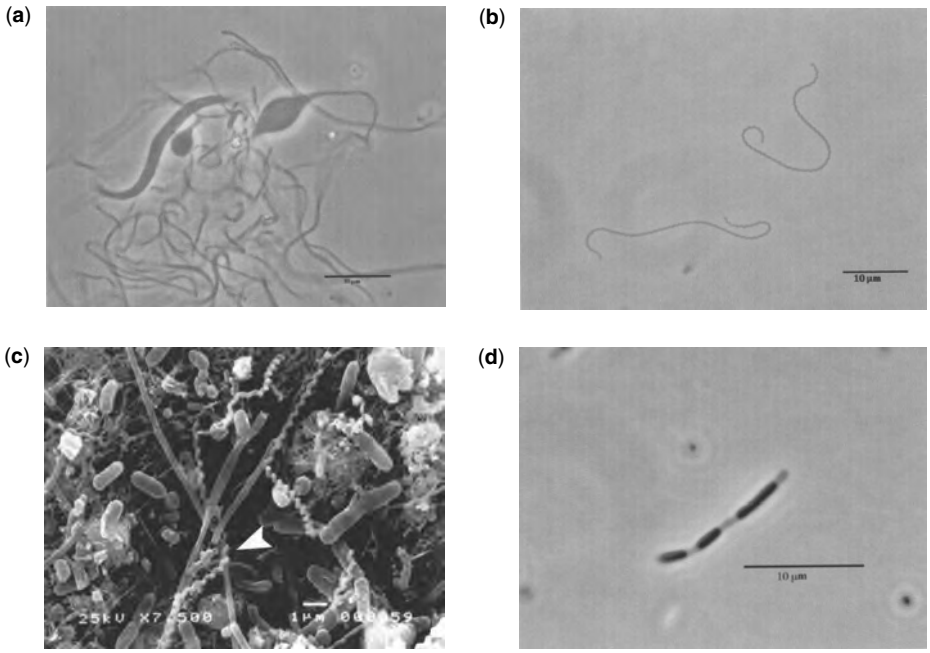

Figure 2. (**a**) A phase contrast micrograph of a filamentous *Thermus* sp. isolated from Yellowstone National Park (courtesy C. Takacs). (**b**) A phase contrast micrograph of a thermophilic spirochete isolated from Furnas, Azores, Portugal (courtesy P. Aguiar). (**c**) Scanning electron micrograph of a microbial mat community from a hot spring from Furnas, Azores, Portugal. Note the spirochete. Arrow points to a spirochete (courtesy P. Aguiar). (**d**) Phase contrast micrograph of a deep-sea hydrothermal vent Thermotogales isolate from Guaymas Basin, Mexico. Note the "toga" around the dark cells (courtesy M. Kendall). See color insert.

Thermotoga has been isolated from deep-sea vents, terrestrial vents, and oil production wellheads (see PETROLEUM RESERVOIRS, MICROBIAL DIVERSITY IN) (42–45). Depending on the species, *Thermotoga* grows best anaerobically from 65 to 80 °C. Although *Thermotoga* is a fermentative chemoorganoheterotroph, all species of *Thermotoga* grow faster when they utilize thiosulfate as a terminal electron acceptor (44). The reduction of thiosulfate produces hydrogen sulfide, (also a by-product of sulfate-reducing bacteria) a potential hazard and corrosive agent of oil pipelines (46).

Heterotrophic *Archaea*

Perhaps the best-studied hyperthermophiles are the euryarchaeal heterotrophic sulfur-reducing *Thermococcales*. Three genera are represented by this order: *Thermococcus*, *Pyrococcus*, and *Paleococcus*. More new species have been described that belong to the genus *Thermococcus* than almost any other hyperthermophilic genus, and these species are distinguished primarily by the organic compounds they are able to ferment. For example, *Thermococcus chitonophagus* uses chitin, the second most abundant natural polymer on Earth, as its sole carbon and energy source (47). Although there are thermophilic *Bacteria* that use chitin as an energy and carbon source (48), *Thermococcus chitonophagus* was the first archaeum to do so, and the first such thermophile isolated from deep-sea vents (47). Although this group is primarily marine, a few terrestrial isolates have been obtained from terrestrial hot springs in New Zealand.

Closely related to the *Thermococcales* are the methanogens. As mentioned in the preceding text, methanogens may grow chemolithoautotrophically or chemoorganoheterotrophically. The latter occurs through the reduction and oxidation of methyl-containing compounds (e.g., $4CH_3OH \rightarrow 3CH_4 + CO_2 + 2H_2O$) or through the cleavage of acetate to methane and carbon dioxide ($CH_3COO^- + H_2O \rightarrow CH_4 + HCO_3^-$). *Methanosarcina thermophila*, isolated from a 55 °C anaerobic digester, is an example of a chemoorganoheterotrophic methanogen that is capable of either reaction.

An unusual heterotroph within the Euryarchaeota is *Thermoplasma*, a cell wall-less thermoacidophile that grows best at pH 2.0. *Thermoplasma* is an aerobic chemoorganoheterotroph that can also grow by sulfur respiration, producing large amounts of hydrogen sulfide. These organisms have been found in terrestrial springs (*T. volcanium*, 49) and hot coal refuse piles (*T. acidophilum*, 3). An extreme thermoacidophile related to *Thermoplasma* is *Picrophilus oshimae*, which grows best at pH 0.7. *Picrophilus* is an obligate aerobe and chemoorganoheterotroph. Unlike *Thermoplasma*, *Picrophilus* cannot grow by sulfur respiration (50).

Among the Crenarchaeota, many of the members of the thermoacidophilic *Sulfolobales* grow only chemoorganoheterotrophically (e.g., *Sulfurisphaera ohwakuensis*, 49). Another crenarchaeal heterotroph, *Thermofilum*, grows in culture only in association with *Thermoproteus* or when supplemented with a high polar lipid fraction obtained from *Thermoproteus* (52). Both *Thermofilum* and *Thermoproteus* are moderately acidophilic, with an optimal pH of 5.0.

Like *Thermofilum*, *Pyrobaculum organotrophum* is capable of respiration using organic compounds as the electron donors, where sulfur compounds, such as elemental sulfur are the electron acceptors. A close relative, *P. aerophilum* uses nitrate or oxygen instead of sulfur compounds as the electron acceptors. *Pyrodictium abyssi*, however, ferments organic compounds, such as starch and glycogen, producing end products, such as carbon dioxide, butanol, isovalerate, acetate, and isobutyrate.

An example of a halophilic thermophile within the Euryarchaeota is *Holoarcula quadrata*, which grows best at 50 to 53 °C and requires a minimum of 3 M NaCl to grow (53). *Holoarcula* is a chemoorganoheterotroph, and it exhibits an unusual morphology of predominantly flat and square cells.

CONCLUSION

Thermophiles are found among all domains of life, and are metabolically and physiologically diverse and include photoautotrophs, chemolithoautotrophs, and chemoorganoheterotrophs. Both anoxygenic and oxygenic photosynthesis occur in terrestrial and shallow marine environments. Chemoorganoheterotrophs use carbon sources that include complex biomolecules, such as cellulose and chitin, simple sugars, such as glucose, and simple organic acids, such as acetate. Many of these heterotrophs are facultative chemolithoautotrophs, capable of using molecules, such as hydrogen, thiosulfate, pyrite and sulfur as electron donors and sulfur, thiosulfate, sulfate, sulfite, nitrate, ferric iron, and oxygen as electron acceptors.

It is generally believed that early Earth offered a hot and anoxic environment to its inhabitants, and thermophilic chemolithoautotrophs are likely to have been among the first organisms to inhabit Earth. Many of the deepest lineages in the phylogenetic tree of life are thermophiles, which suggests that perhaps they are relatives of the ancestors of early life. With such a vast array of genetic, metabolic and physiological diversity, and their biogeochemical and evolutionary significance, thermophiles are testimony to the resiliency of life and the contribution of microbes to nutrient cycling on Earth.

Some hydrocarbons have been present in the environment for a long time as a result of natural biosynthesis (1,2). Additionally, the production and use of various hydrocarbons as organic solvents is widespread in industry. Because of this widespread industrial use, the amount of solvents present in the environment has increased since the early industrial revolution. Their toxic and even carcinogenic effects make them a potential threat to human health. However, some groups of microorganisms are able to transform organic solvents, often leading to complete mineralization of these compounds (3–5). Although many microorganisms degrade organic solvents at low concentrations, various solvents can become toxic at slightly higher concentrations (6,7). Hydrophobic organic solvents are toxic to living organisms because they accumulate in cell membranes and cause disruption. The toxicity of a compound correlates with the logarithm of its octanol/water partition coefficient ($\log P_{OW}$). Substances with a log P value between 1 and 5 are, in general, toxic for whole cells. Such hydrocarbons can only be degraded at low concentrations and, consequently, stay often as persistent pollutants in the environment. Therefore, toxic

effects of hydrocarbons and other solvents on microorganisms can cause problems in bioremediation, waste gas, and wastewater treatment (8).

In addition, the toxicity of organic solvents plays not only a decisive role in environmental microbiology but also in the biotechnological production of fine chemicals (9). The use of organic solvents also has several advantages in the application of whole cell systems (10–12). Solvents can increase the available amount of poorly water-soluble substrates for the cells. When organic solvents are used as a second phase, the products of a biotransformation can be extracted continuously from the aqueous reaction system. This enables not only the reduction of inhibitory effects caused by the product but also a much easier recovery with positive effects on the costs for the downstream-processing. Solvents or structurally similar compounds are also useful as substrates for some applications. However, problems resulting from the toxicity of hydrophobic organic solvents to whole cells are still an important drawback for the application of these compounds in biocatalysis (11,13) and in environmental biotechnology in general.

In recent years, different bacterial strains that adapted to organic solvents have been isolated and characterized. These strains grow in the presence of a second phase of solvents previously believed to be lethal. For the applications mentioned in the preceding text, an understanding of the effect of hydrophobic solvents on microorganisms and the adaptation of solvent-tolerant microorganisms is of great economic importance. This entry focuses on effect of hydrophobic solvents on microorganisms and the adaptation mechanisms found in microorganisms growing in the presence of such compounds.

EFFECTS OF SOLVENTS ON MICROORGANISMS

Most microorganisms tolerate water-miscible solvents such as lower alcohol's and acids. In addition, it has been established that very lipophilic natural solvents including some hydrocarbons are not toxic for whole cells. However, many of the organic solvents used in petrochemical operations occupy a position between the water-soluble alcohol's and acids and the lipophilic compounds. Solvents of intermediate hydrophobicity, such as aromatic solvents, are very toxic to cells. These have been widely used as antimicrobial agents (14,15) and food preservatives, disinfectants, tools for the permeabilization of cells, and as narcotic agents (16–19).

The antimicrobial action of a solvent correlates with its hydrophobicity, as expressed by the logarithm of the partition coefficient of the compound in a mixture of *n*-octanol and water (log P_{ow}). Organic solvents with log P_{ow} values between 1 and 5, such as toluene, are highly toxic for microorganisms. This influence of hydrophobicity on toxicity can be found in different solvent classes, for example, aromats, alcohols, phenols, alkanes (20–24). Table 1 lists classes of solvents and their respective hydrophobicities and toxicity's, expressed in terms of their log P_{ow} values and their midpoint cytotoxicity values (LD_{50} values). It should be emphasized that the toxic effects of solvents, and their dose-response relationships,

Table 1. Hydrophobicity and Toxicity of Several Solvent Classes

Solvent Class	Compound	Log P[a]	LD_{50}[b] (mmol l^{-1})
short-chain alcohols	methanol	−0.76	501.1
	ethanol	−0.28	223.9
	1-butanol	0.9	64.5
weak acids	acetic acid	−0.23	60.0
aromatic alcohols	phenol	1.5	7.94
	4-chlorophenol	2.4	1.29
	2,4-dichlorophenol	3.2	0.144
	2,4,5-trichlorophenol	4.1	0.016
	pentachlorophenol	5.1	0.0067
Aromatic solvents	benzene	2.1	17.38
	toluene	2.6	3.58
	styrene	2.9	3.15
	ethylbenzene	3.2	0.9
	tetraline	3.9	0.75

[b] LD_{50} values measured with *Pseudomonas* cells.

are similar for a variety of microorganisms. Thus, the toxicity of hydrophobic solvents is caused by general, nonspecific effects, and no metabolic or chemical reactions are associated with the toxic effects.

It has been established that there is a systematic relationship between values of log P in the range between 1 and 5 and the partitioning of solvents in membrane buffer systems (19,23,24). The absolute values of partition coefficients are approximately eight times lower in membranes than in octanol. These can be estimated by the following equation from Sikkema and coworkers (24):

$$\log P_{M/B} = 0.97 \cdot \log P_{O/W} - 0.64$$

where M = membrane, B = Buffer, P_{ow} = octenol/water coefficient $P_{M/B}$ = membrane/buffer partition coefficient.

Hence, the log P value is a suitable parameter that describes the accumulation of these solvents in membranes. However, two aspects have to be taken into consideration. First, in addition to hydrophobicity, the molecular structure of a compound also influences its solubility in membranes. Amphipatic molecules will dissolve relatively well in membranes because their structure is similar to that of the phospholipids in the membranes. Consequently, such compounds are relatively more toxic than others with the same log P value. This explains the relatively high toxicity of aromatic structures with hydrophilic substituents, particularly phenols. Second, the composition of the membrane will also influence the partitioning of a compound into the membranes. So far, this has only been demonstrated with artificial membranes. The partition coefficient of lindane is, for instance, 50 times higher in liposomes

of dimyristoylphosphate (C14 : 0) than in liposomes of distearoylphosphatidylcholine (C18 : 0) (27). In artificial membranes, the position of a solvent partitioning into the membranes depend on the molecular structure (28). Therefore, changes in the membrane structure can affect the preference of solvents entering the membrane.

The accumulation of the solvent toluene into bacterial membranes can be made visible by electron microscopy (16,29). This demonstrates that the membrane in which the solvents accumulate is the main target of the toxic effect. This of course does not rule out additional sites of toxic action because they may be caused by the specific properties of a molecule.

Although no individual analytical technique is able to determine fully the effects of solvents on a membrane, several mechanisms of membrane toxicity have been reported.

First, the accumulation of organic solvents leads to a permeabilization of the cell membranes. In *Escherichia coli*, it was observed that potassium ions and ATP are released after treatment with phenol (30). For toluene, the leakage from the cell of macromolecules such as phospholipids, proteins, or even RNA, has been demonstrated (31,32). This permeabilization was due to a considerable damage to the cytoplasmic membrane, whereas the outer membrane was still intact (16). For artificial membranes the presence of the solvent tetraline increased proton permeability (19,24). Other studies with bacterial and artificial membranes revealed a passive flux of protons and other ions across the membrane because of the presence of solvents (19,24,33–37). This flux of ions dissipates the proton motive force (Δp), and affects both the proton gradient (ΔpH) and the electrical potential ($\Delta\psi$) (24,36).

The second mechanism of the membrane toxicity of organic solvents is to diminish the energy status of the cell. The effect of solvents on the energy transduction of membranes was tested in liposomes reconstituted with cytochrome *c* oxidase. The presence of the solvent tetraline caused decreases in the proton gradient ΔpH and the electrical potential $\Delta\psi$ of 80% and 50%, respectively (24). It has been established that the dose-response curves for a range of solvents were very similar if the dissolved membrane concentration of the solvent is considered to be the dose. Intact cells show a similar effect of solvents on ΔpH and $\Delta\psi$ (19).

The decrease of the proton motive force is not the only reason for lower energy levels of cells in the presence of organic solvents. The presence of solvents also leads to impaired ATP synthesis because of a partial inhibition of ATPase and of other proteins engaged in the energy transducing process (38,39).

Third, besides the proteins engaged in energy transduction, the accumulation of solvents into a membrane also affects the function of other proteins embedded in the membrane. In *E. coli*, toluene leads to a total inactivation of the galactose permease system (31) and in *Saccharomyces cerevisiae*, the proton-potassium translocation is blocked (35).

Fourth, the fluidity of the membrane, an important aspect of membrane structure, is affected by organic solvents (24). The effect of organic solvents on the fluidity was measured through the use of fluorescent probes. The probe 1,6-diphenyl-1,3,5 hexatriene (DPH), partitions into the hydrophobic inner parts of cell membranes, whereas a trimethylamine derivative of this compound (TMA-DPH) anchors its hydrophilic group in the headgroup region of the bilayers. Solvents partitioning into the membrane will affect the polarization of the probe located at the site entered by the solvent. Several solvents with a logPo/w between 1 and 5 affected the polarization of both probes (24). Thus, the whole membrane was fluidized. An increased fluidity of membranes results in changes in stability, structure, and interactions within the membrane (40,41).

Fifth, membrane-active compounds can affect the hydration characteristics of the membrane surface (42) and the thickness of the membrane (43). Swelling of the membrane can be investigated through the use of liposomes labeled with the fluorescent fatty acid, octadecyl rhodamine β-chloride. An expansion of the membrane will lead to a dilution of the fluorescent probe in the membrane, which can be recorded as a reduction in fluorescence self-quenching. Swelling of the membrane is monitored by plotting relative fluorescence against the amount of solvent added to the liposomes. This was tested for several solvents with logP values between 2 and 5 (24). For all solvents tested, the surface area of the membrane increase linearly up to a concentration of 0.5 μmol mg^{-1} of solvent in the membrane. At that concentration, the maximum increase in the membrane swelling was reached. This maximum level corresponds to approximately one solvent molecule per two phospholipid molecules.

It can be concluded that once a solvent has dissolved in a membrane, it will disturb the integrity of the membrane and hence its function as a barrier, as matrix for enzymes and as energy transducer. For membranes of living cells, these effects are difficult to quantify in view of the complex and heterogeneous nature of the protein-containing bilayer.

ADAPTATION OF MICROORGANISMS TO ORGANIC SOLVENTS

Despite the general toxic effects of organic solvents, some microbial strains can adapt to high concentrations of otherwise toxic organic solvents. This surprising observation was first made by Inoue and Horikoshi in 1989 for a *Pseudomonas putida* strain, IH-2000, which grows in the presence of a second phase of toluene (44,45). This strain was able to survive the presence of toluene as a second phase but was not able to metabolize the toluene. Soon afterward, other researchers confirmed this initial observation. Other *P. putida* strains were shown to grow in a two-phase solvent-water system containing toluene or other solvents. These strains were isolated on xylene, styrene, or toluene (46–49). They all were able to grow in the presence of a second phase of various solvents such as xylene, styrene, and toluene, but benzene as a second phase was not tolerated. Some of the strains were able to metabolize the solvents, others had to use alternative carbon and energy

sources. All solvent-tolerant *P. putida* strains were all isolated from a normal soil environment. Similarly, other solvent-tolerant species of *Pseudomonas* (*P. aeruginosa, P. fluorescens, P. mendocina*) were also isolated (50–54). Attempts to isolate solvent-tolerant strains from more extreme environments, such as the deep sea, resulted in the isolation of solvent-tolerant members of other genera. A *Flavobacterium* was reported to grow in the presence of a second phase of benzene (5%) (55), and apparently was even more tolerant of solvents than the strains belonging to the genus *Pseudomonas*.

Solvent-tolerant gram-positive strains have also isolated been isolated from deep-sea environments. Strains belonging to the genus *Bacillus* that survived a second phase of benzene were described (56,57). The authors attributed this remarkable property of benzene tolerance to the source from which the strains were isolated. A benzene-tolerant *Rhodococcus* strain was isolated from a contaminated site in Australia, with benzene as the growth substrate (58). More recently, it was shown that gram-positive bacteria tolerating benzene and/or toluene can also be isolated from normal soil environments.

Another way to obtain solvent-tolerant strains is to increase the resistance of nontolerant strains by mutations. Mutant strains with enhanced solvent-tolerance properties were obtained with *P. putida* PpG1 (59) and *P. aeruginosa* PAO1161 (60). *Escherichia coli* K12 could also be mutated to yield strains that are more solvent-tolerant (61).

Table 2. Strains Growing in the Presence of a Second Phase of Toxic Organic Solvents

Strain	Solvents Tolerated	Reference
Pseudomonas putida IH-2000	Heptanol, toluene	44
Pseudomonas putida Idaho	Dimethylphthalate, toluene	46
Pseudomonas aeruginosa ST-001	Heptanol, toluene	51

Source: (Modification of table presented by S. Isken and J. A. M. de Bont, *Extremophiles* **2**, 229–238 (1998)).

However, the tolerance of a particular strain to a solvent is not always tested for in a clear-cut way. The medium composition, the cultivation conditions, and the history of the inoculum have an effect on the ability of an organism to grow in the presence of a solvent. Strains that can grow in the presence of a second phase of the toxic organic solvent toluene have been compiled in Table 2. From the Table it is obvious that the potential for solvent resistance is much higher in gram-negative than in gram-positive strains. This observation is in agreement with the observation that gram-negative bacteria appear to be less sensitive to lipophilic compounds than gram-positive bacteria (26,62,63). This fact possibly may be explained by the presence of the additional outer membrane in gram-negative bacteria. Indeed, for all microbial strains tested, growth can be detected in the presence of a second phase of a solvent as long as the log P of the solvent is less a strain-dependent value (Table 3).

ADAPTATION MECHANISMS

Since the first solvent-tolerant strain was isolated, research started to uncover the mechanisms responsible for this unique ability. Already, in the first paper dealing with solvent-tolerant bacteria, changes in the membrane composition were predicted to play a crucial role in the mechanisms contributing to solvent tolerance (44). This was likely as the membrane is the main target of the toxic action of solvents. Indeed, several adaptive changes in the structure of the membrane have been observed in reaction to the accumulation of organic solvents in the membranes of microorganisms. Mechanisms involved in solvent tolerance, as considered by various researchers, are shown in Figure 1.

Adaptation on the Level of the Cytoplasmic Membrane

Adaptations on the level of the cytoplasmic membrane have often been studied with less toxic solvents such as ethanol (68,69). In the cytoplasmic membrane, changes at the level of the lipids and proteins have been observed. These adaptations reestablish the stability and fluidity of the membranes once it is disturbed by the solvents (28). In principle, several mechanisms are possible here and may vary from strain to strain. Mechanisms described so far are (*1*) the length of the fatty acid chains, (*2*) the degree of saturation of the fatty acids, (*3*) *cis*/*trans*-isomerization of unsaturated fatty acids, (*5*) composition of phospholipid headgroups, and (*5*) dynamics of the phospholipid turnover.

The organisms that exhibit the greatest resistance to alcohols, *Lacotobacillus homohiochii* and *Lactobacillus heterohichii*, react to the presence of ethanol by altering the composition of their membranes. They increase the chain length and decrease the amount of *cis*-unsaturated fatty acids in their membranes (68).

In nearly all micoorganisms, the presence of solvents causes a shift in the ratio of saturated to unsaturated fatty acids. Generally, cells react to the presence of organic solvents by increasing the amount of saturated fatty acids in the membrane (70–74). Alterations in the degree of

saturation of the fatty acids change the fluidity of the membrane and in this way compensate for the effects caused by solvents. This stabilization of the membrane fluidity is known as "homeoviscous adaptation" (75). Changes in the fatty acid composition of membrane lipids are the most important reaction of bacteria against membrane-active substances. Most bacteria synthesize fatty acids by the well-established anaerobic pathway (76) and are only able to change their membrane fluidity by de novo synthesis of membrane lipids with a different ratio of

saturated to *cis*-unsaturated fatty acids during growth. As a result, bacteria are not able to perform a postbiosynthetic modification of their membrane fluidity.

One exception to this restriction is the isomerization of *cis*- to *trans*-unsaturated fatty acids in strains of the genera *Pseudomonas* and *Vibrio* (76,77). These bacteria are able to change their membrane fluidity by isomerizing *cis*-unsaturated fatty acids to the *trans*-isomers. At least, some representatives of the genus *Pseudomonas* convert their *cis* into the corresponding *trans* unsaturated fatty acids after the addition of toxic compounds (77,78). This conversion also takes place in nongrowing cells. Furthermore, cells are still able to accumulate *trans* fatty acids when the biosynthesis of fatty acids was inhibited by cerulenin (79,80). The isomerization of the double bond is a special mechanism of this bacterium to adapt to high concentrations of toxins under conditions not allowing growth and de novo synthesis of lipids. The benefit of this reaction lies in the steric differences between *cis* and *trans*-unsaturated fatty acids. Unsaturated fatty acids in the *cis*-configuration with their bent steric structures (a nick in the acyl-chain) result in a membrane with a relatively high fluidity. In contrast, the long extended steric structure of the *trans*-configuration is able to insert into the membrane structures similar to saturated fatty acids which are also mostly in all-*trans*-conformation.

The *cis* to *trans*-isomerization is catalyzed by an energy-independent enzyme (81,82). The enzyme responsible for the *cis*/*trans*- isomerization in nonsolvent-tolerant strains has been purified (83,84). The enzyme is periplasmic and acts in vivo both on phospholipids and on free fatty acids (85). In vitro, the purified isomerase acts only on free unsaturated fatty acids (84). Holtwick and coworkers (82) obtained isomerase-negative mutants of *P. putida* P8. A DNA fragment that complemented the mutation was isolated and cloned. The DNA sequence showed no significant homologous regions when the deduced amino acid sequence was compared with other proteins. Close to the N terminus of the predicted polypeptide of the *cis*/*trans*-isomerase gene (*cti*) a cytochrome c-type heme-binding motif was found (83). As a consequence a possible mechanism of heme-catalyzed *cis*/*trans*-isomerization of unsaturated fatty acids is discussed currently.

To prove that the *cis*/*trans*-isomerization is necessary for the survival of solvent-tolerant strains, studies were performed with mutants lacking the ability to perform this isomerization (86). A transposon mutant of the solvent-tolerant *P. putida* DOT-T1 was both solvent-sensitive and unable to perform the isomerization (87). However, the *cis*/*trans*-isomerization is unlikely to be the only necessary adaptation mechanism to organic solvents because strains are known that can perform the isomerization and are still solvent-sensitive (73,87). The *cis*/*trans*-isomerization has also been reported as a response to starvation (88) and in the presence of antibiotics (89) or heavy metals (90). This indicates that the *cis*/*trans*-ratio may be part of a general stress response of microorganisms.

Apart from the fatty acid composition, the headgroups of lipids are also altered during solvent-adaptation. In solvent-tolerant *P. putida* strains the relative amount of diphosphatidylglycerol (cardiolipin) increases during the adaptation to the solvent toluene (28,87). Such a change in the headgroups had also been found in *E. coli* mutants with an increased resistance to solvents (91). *Pseudomonas putida* Idaho was shown to adapt differently. The amount of phosphatidylethanolamine increases in this solvent-tolerant strain (92). In general, the regulation of the headgroup composition is said to control the phase preference of the lipids. In this way, the effect of solvents on the fluidity, the volume, and the density of the lipids is compensated (28).

Next to changes in membrane composition, the dynamics of biosynthesis of membrane compounds may play an important role in solvent tolerance. Pinkart and White (92) demonstrated that in the solvent-tolerant strain *P. putida* Idaho the rate of phospholipid synthesis increases after exposure to xylene. The total amount of phospholipids increases in this strain. A solvent-sensitive control strain, *P. putida* MW1200, has a much lower turnover of lipids and a reduction of the phospholipid content after exposure to xylene. Therefore, it is likely that *P. putida* Idaho is better equipped to repair damaged membranes than the solvent-sensitive strain.

Apart from changes in the composition of the cytoplasmic membrane and in the dynamics of the formation of phospholipids, alterations in the protein content have been observed as a response to solvents (68,93,94). In addition, lipid soluble compounds were shown to play a role in adaptation to solvents. *Zymomonas mobilis* increases the amount of hopanoids as response to ethanol (95) and in *Staphylococcus aureus*, the tolerance to oleic acid correlates with carotenoid production (96).

Adaptation on the Level of the Outer Membrane

As mentioned earlier, gram-negative bacteria are less sensitive to solvents than gram-positive organisms. However, no differences between gram-positive and gram-negative bacteria were observed with regard to the critical concentration of molecules dissolved in the cytoplasmic membrane (63). Hence, the differences in solvent tolerance must be based on other alterations.

In contrast to the gram-positive bacteria, the gram-negative bacteria have an additional outer membrane. The outer membrane was shown to be engaged in promoting solvent tolerance. Ions, such as Mg^{2+} or Ca^{2+}, stabilize the organization of the outer membrane and contribute to a higher resistance of solvent-tolerant *Pseudomonas* strains toward toluene (28,45,48). After adaptation to toluene solvent-tolerant *P. putida* S12 cells become less hydrophobic (28). Recently, it was shown that a reduction of the cell hydrophobicity correlates with changes in the LPS content (97). Indeed, the LPS composition of solvent-tolerant *P. putida* Idaho changes as result of the presence of solvents (73).

Apart from changes in the LPS, the porins that are embedded in the outer membrane have been related with solvent tolerance. On the one hand, mutants of *P. putida* Dot-T1 lacking the porin Ompl are hypersensitive to solvents, possibly because of the missing stabilization of the envelope integrity by Ompl (87). On the other hand, the absence of the porin Ompf in *P. aeruginosa* (98) leads to a higher tolerance toward solvents. Such an increase

in solvent tolerance because of the absence of a porin was also obtained in *E. coli* (96). The authors of these studies suggested that organic solvent molecules were able to pass through the porins. Therefore, mutants lacking these porins have a higher tolerance to solvents. Later, this theory was disproved for *E. coli* (99). The organic solvent tolerance was shown to be independent of Ompf levels in the membrane. Earlier found relations between solvent sensitivity and the level of Ompf were caused by variations in transcriptional activators.

Adaptation on the Level of the Cell Wall

Bacteria with hydrophobic cell walls were shown to have a higher affinity for hydrophobic compounds (100,101). Therefore, cell wall modifications that lower the hydrophobicity of the cell may provide a higher tolerance to solvents.

Adaptation Caused by Biodegradation of Solvents

Resistance to antibiotics is often based on the degradation of these antimicrobial compounds into less or nontoxic products. Many of the toxic solvents studied up to now can be degraded by microorganisms. Therefore, tolerance could be mediated by degradation of the solvents. The benzene tolerance of *Rhodococcus* strain 33 may partly depend on this mechanism because this strain was shown to be an effective degrader of benzene (58). Because many organic solvents can be utilized as carbon source this may be the case for other strains. Additionally, biodegration was predicted to play a role in tetraline-tolerance in *E. coli* (102). However, many of the solvent-tolerant strains described so far are able to cope with a broad range of solvents up to a second phase which often cannot be biodegraded at all by these strains. *Pseudomonas putida* S12 is, for instance, tolerant for both styrene and toluene. Of these solvents, however, only styrene can be metabolized (47). Hence, degradation may mediate the resistance of some strains to specific solvents, but it cannot be the main mechanisms contributing to the tolerance to a broad range of solvents.

Adaptation Caused by Active Excretion of Solvents

Metabolism of toxicants is the only mechanism that decreases the amount of toxins in the cell or membrane actively. An alternative method is to decrease the concentration of the toxin by removing it from the cell by active excretion. Such efflux systems are well known for lipophilic cytotoxic agents, such as antibiotics (103–106). Many of the energy-driven export systems play an important role in drug resistance because they are able to pump out a wide range of compounds having no common chemical structure. The only common feature is that most of these compounds are charged amphiphilic molecules. It was shown that genes coding for the proteins engaged in such an export can be induced by structurally unrelated hydrophobic compounds (107). In several strains the adaptation to organic solvents results in an increased resistance to various chemically and structurally unrelated antibiotics (89). Therefore, research started to determine whether organic solvents can be actively excluded from a bacterial membrane. Indeed, we demonstrated that the amount of toluene accumulated in *P. putida* S12 is dependent on energy originating from the proton motive force (108,109). This strain was not able to transform the toluene. Therefore, it was concluded that the amount of toluene in the cell was kept at a relative low level by the action of an active efflux system. Since then, active efflux as a mechanism contributing solvent tolerance has also been observed in other *Pseudomonas* strains (49,87,110). The gene responsible for the export of toluene in *P. putida* S12 was identified (111) and showed homology with other well-known export systems responsible for the active efflux of antibiotics out of the cell. The homology of this gene called *srpABC* with proton-dependent efflux pumps, such as the *acrAB* operon in *E. coli*, implicates again that the solvent efflux is dependent on the proton motive force. The participation of the multidrug efflux pump AcrAB, encoded within the *acrAB* operon, in the solvent tolerance of *E. coli* was demonstrated by White and coworkers (112). Rojas and coworkers (113) demonstrated that the presence of several solvent efflux pumps can be necessary to provide efficient tolerance to toluene in *Pseudomonas* strains.

OLE OF GENERAL STRESS RESPONSE

The large number of adaptation mechanisms described in the preceding text suggest that solvent tolerance is not mediated by one mechanism only. It is likely that a combination of different mechanisms is necessary to provide solvent tolerance. A kind of cascade of fast (urgent), midterm, and long-term mechanisms are working together to reach a full adaptation to toxic solvents. This includes the presence of a general stress response system (114,115), such as the one known for heat shock, which is induced or activated by the solvents. Indeed, the induction of a large number of proteins by toxins was demonstrated in *E. coli* in the presence of pollutants (116) or the uncoupler 2,4-dinitrophenol (117) leads to the induction of 39 or 53 different proteins, respectively. When *Clostridium acetobutylicum* initiates the solvent transformation, various known heat-shock proteins are expressed (118). In *P. putida* Kt2442 the expression of approximately 100 proteins is affected by the presence of 2-chlorophenol (119).

As mentioned earlier, the adaptation to a solvent does not only enhance the resistance to other solvents (80), but also to heavy metals (90) and antibiotics (89) in the solvent-tolerant strain *P. putida* S12. Such a correlation was earlier found in *E. coli* in which the overexpression of stress-response genes enhanced tolerance to various environmental factors (120–123). The question remains whether genes, which mediate solvent resistance and whose functions are still unknown, like *osta* (124), can be embedded in the cascade system of stress response.

TOXICITY TESTING IN SOIL, USE OF MICROBIAL AND ENZYMATIC TESTS

MIKAEL PELL
LENNART TORSTENSSON
Swedish University of Agricultural Sciences
Uppsala, Sweden

The economic well-being of human society is dependent on the productivity and sustainability of arable soils. Soil is the ultimate receptor of, and the incubation chamber for, decomposing organic material and recycling nutrients back to plants, as well as detoxification of organic pollutants. Soil quality can improve or deteriorate depending on several factors. If mismanaged, the soil can work against us, for example, it can pollute the air by emissions of nitrous gases and pollute water by leaching of nitrogen and other plant nutrients or pesticides. We are becoming more aware of the frequent exposure of soils to anthropogenic substances and that there is a delicate balance between maintaining good soil quality and achieving production goals. Therefore, there is an urgent need for tools to measure toxicity in soils (Fig. 1), to interpret toxicity data, as well as to develop a strategy for evaluating soil quality (1).

Our aim is to give a short overview of the soil microbial ecosystem and some important factors pertaining to soil formation, and against this background to discuss what kind and quality of information soil tests should deliver. Examples of useful microbial and enzymatic tests are given. Finally, we discuss strategies and problems in screening and testing the effects of chemicals and heavy metals, the assessment of soil quality, and the monitoring of long-term changes in both naturally managed and polluted soils.

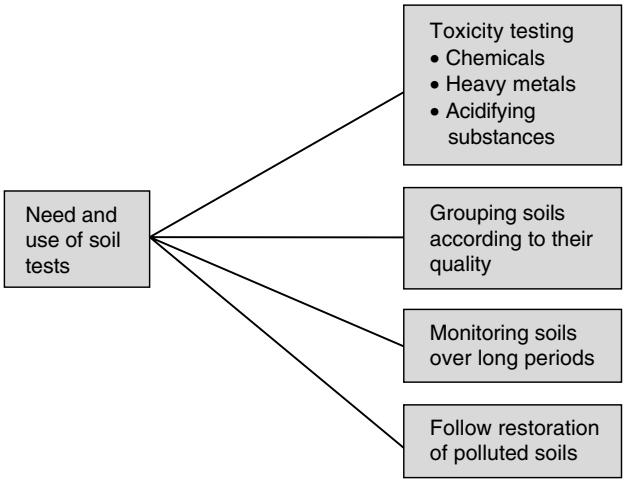

Figure 1. The need of various soil tests to be able to assess soil quality.

THE SOIL MICROBIAL ECOSYSTEM

The soil ecosystem gains most of its energy from dead organic materials, for example, plant and animal residues. During the mineralization of these residues, carbon dioxide and inorganic nutrients such as nitrate, phosphate, and sulfate are released so that plants can utilize them again. The microbial biomass itself represents a major pool of readily available nutrients, which is continuously shunted into the growth cycles of macro- and microphytes. Consequently, soils that host a high level of microbial biomass are capable not only of storing more nutrients, but also have the potential of cycling more nutrients through the ecosystem.

As microorganisms are adapted to survive under extreme conditions, they are present in soil both in large numbers and under almost all environmental conditions. Many catabolic and anabolic functions are widely distributed among soil micropopulations, and groups of taxonomically diverse organisms can therefore replace one another in the decomposition cycles. The microbial community carries out the majority of decomposition processes in soil and is stimulated by the activities of soil invertebrates, especially saprotrophs feeding on decaying organic matter and microbivores grazing the microflora. Furthermore, microorganisms are irreplaceable in the biological transformation and degradation of synthetic organic compounds and natural waste materials.

Soil microorganisms are critical in creating and maintaining good soil structure, which is important for proper soil aeration and the formation of humus and particle aggregates. Filamentous fungi and actinomycetes, in particular, entrap soil particles to form aggregates. In addition, bacteria produce extracellular metabolites, for example, polysaccharides, lipids, and proteins, which function as gums and cementing agents that stabilize the aggregates. Soil texture and structure, in combination with a variation in moisture levels, can drastically affect the aeration status, thus influencing the distribution of physiological groups in the microbial community.

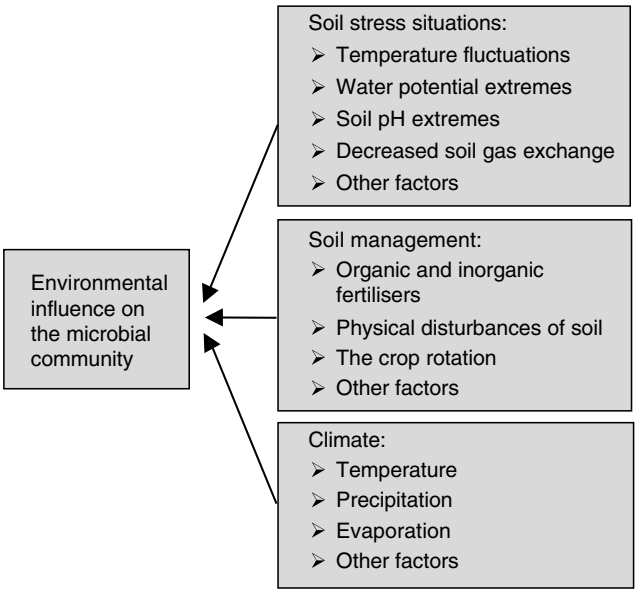

Figure 2. The environmental factors influencing soil microbial communities.

In all terrestrial ecosystems, microorganisms are more or less continuously exposed to changing environmental conditions. This means that the microbial community in soil is exposed to stress situations owing to both soil management and climatic conditions (Fig. 2).

SOIL QUALITY

In agriculture, soil quality is an integral part of agricultural sustainability, and is influenced by a number of degrading and conserving forces (2). Soil is a complex system created by a number of factors that cannot be easily influenced, such as geology, topography, and climate (Fig. 3). Soil quality is controlled by physical, chemical, and biological components. Soil quality factors that can be influenced are humus content; the number, composition, and activity of microorganisms; the degree of base saturation; nutrient status; and others. A number

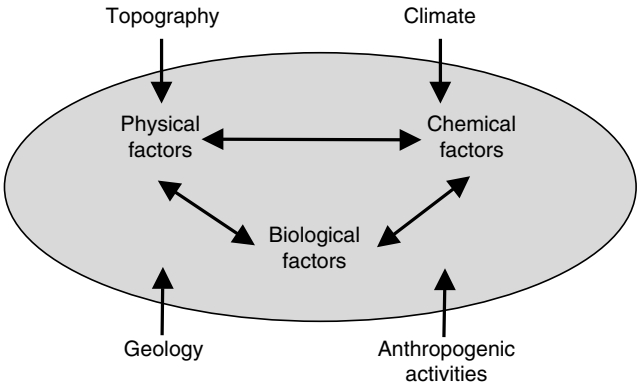

Figure 3. Soil is a complex structure created by influences of geology, topography, and climate as well as anthropogenic activities.

of short-term practices, such as soil cultivation or use of fertilizers and pesticides, are generally not included as soil quality factors. Neither are unintended deposition of chemicals, heavy metals, or acidifying substances considered soil quality factors. Many attempts have been made to define soil quality (3–5). All definitions have in common the capacity of a soil to function effectively both at present and in the future. As suggested by Doran and Parkin (3), soil quality can be defined as "the capacity of a soil to function within ecosystem boundaries to sustain biological productivity, maintain environmental quality, and promote plant and animal health." Such a definition implies that good soil quality is relative, and must be individually defined for each soil ecosystem (see SOIL QUALITY: THE ROLE OF MICROORGANISMS, this Encyclopedia).

SOIL TEST DATA — A COMPREHENSIVE PICTURE

With the development of new methods for assessing soil biomass and microbial or enzymatic activity, it is important to have a clear idea of what kind of information the test should deliver. It is important to consider whether to choose a test for the evaluation of a soil property or to test the effect of a specific substance. Furthermore, when interpreting data the basic test design, that is, the possibilities and limits of the test, must be considered. This work would be simplified if apparently different tests and test data could be treated in a common frame, that is, to use the same basic concept of kinetics. The kinetic discussion in the following text refers to tests of potential activities, that is, tests performed under optimized environmental conditions so that only the amounts of organisms and enzymes are rate limiting.

In its simplest form, a quantitative soil test assay uses the assumption that no product is present at time zero. After a certain time of incubation the first and only sample is withdrawn for analysis of the product. A constant product formation rate must be assumed to allow calculation of a process rate from such limited data. A more accurate way is to also establish the initial concentration of the product. Even if in most cases the product formation rate of some tests is constant, the above test strategy has some uncertainty in the rate and, hence, should be viewed as semiquantitative information. The uncertainty will increase not only with time of incubation, but also when an unknown substance to be tested is added. A better experimental design is to take a reasonable number of samples during the test so that a straight-line relation can be established by linear regression. Moreover, many samples give more accurate data, that is, random errors in sampling and analysis cancel each other. The linear product formation can be described by the following general formula:

$$p = p_0 + Et \tag{1}$$

where p and p_0 are the amounts of product at time t and $t = 0$, respectively, and E is the enzyme activity (Fig. 4a). When referring to the enzyme activity of a specific microbial process showing no growth during the test, E can be replaced by, for example, K, a rate constant for potential microbial activity (Fig. 4b).

The complexity increases when nonlinear test data are generated because nonlinear processes, by necessity, demand a larger number of sampling points to establish the shape of the curve. Several means of linearization of such data have been proposed. Perhaps the most common way is to make only a very short incubation and to subjectively fit a straight line to the nonlinear data. A biased estimate will probably be achieved in this way. As a nonlinear product formation rate is most likely owing to de novo synthesis of enzymes, with or without cell growth, the use of antibiotics with inhibitory effect on protein synthesis has been proposed to maintain linear rates.

Another strategy is to analyze the phenomenon as a nonlinear process. Such a strategy generates more information of the process tested for. In most test situations enzyme activity, as well as growth of microorganisms, must be considered. These two properties are described in the formula

$$p = p_0 + \frac{r}{\mu}\left(e^{\mu t} - 1\right) \tag{2}$$

where r is the initial microbial activity and μ the specific growth rate (6). Thus, by assuming a constant amount of enzymes without cell growth (i.e., zero-order kinetics with respect to cell growth), a constant product formation rate (K), as discussed earlier, will explain the straight-line result of a test (Fig. 4b). Assuming a substrate saturated enzyme system with cell growth (i.e., first-order kinetics with respect to cell growth), both the initial rate of product formation (r) and specific rate of cell growth (μ) will explain the nonlinear curve of some tests (Fig. 4c).

For general soil processes such as respiration, it is not likely that all microorganisms react to a substrate in the same way. It has been suggested that mineralization of glucose is performed by two main groups of microorganisms. The first group grows exponentially as a result of substrate addition, whereas the other group increases its respiration activity to a higher rate without multiplication. In a further modification of formula (2), the activity of the nongrowing group, denoted K, was introduced (7), resulting in the new formula:

$$p = p_0 + \frac{r}{\mu}\left(e^{\mu t} - 1\right) + Kt \tag{3}$$

By applying this formula (Fig. 4d), a deeper understanding of underlying structures in the soil ecosystem can be achieved (8).

From the preceding discussion it is evident that results from different tests permit different degrees of interpretation and understanding. Many enzymatic tests used today are simplifications chosen to get rapid and inexpensive tests. One reason for this is that authorities and the chemical industry have urged the development of these kinds of tests. Another reason is that the awareness of the enormous task ahead with so many untested chemicals necessitates the use of simple tests. On the other hand, the consequence of using such simple tests might be that important pieces of information are overlooked. Thus, a contradiction can be seen between using soil tests as research tools or as practical environmental indicators.

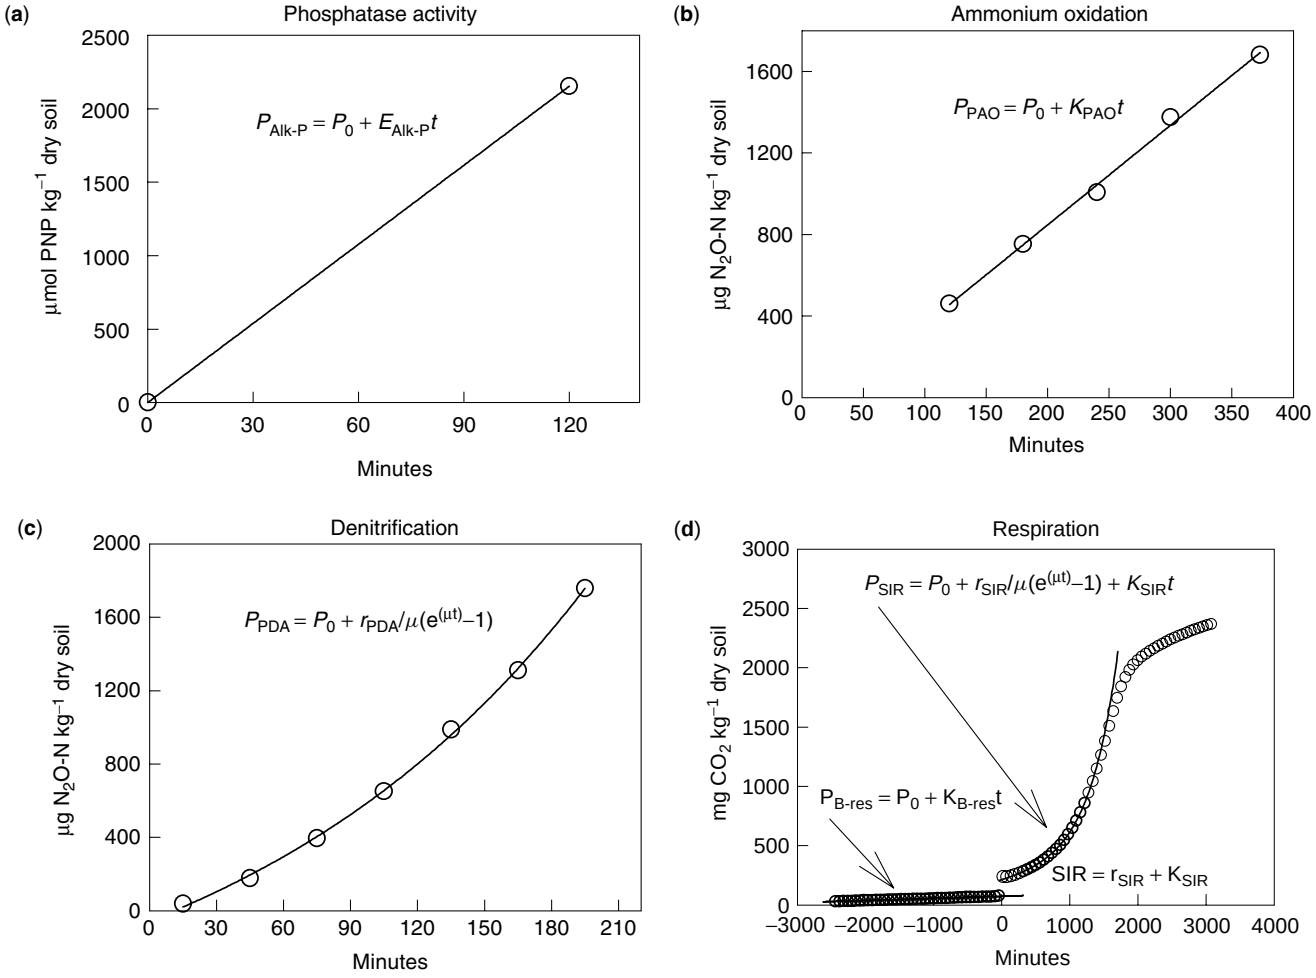

Figure 4. Examples of microbiological test data and a kinetic approach to evaluating product formation rates: (**a**) rate of phosphatase activity (P_{Alk-P}), (**b**) potential NH_4^+ oxidation rate (P_{PAO}), (**c**) potential denitrification rate (P_{PDA}), and (**d**) substrate induced respiration rate (P_{SIR}) and basal respiration rate (P_{B-res}). Gray circles are data not included in the regression analysis.

The conclusion is, however, that both types are needed and their development must go hand in hand.

MICROBIAL AND ENZYMATIC TESTS

Commonly, microbial soil tests are grouped into biomass estimations, activity measurements, and assays of soil enzymes. The distinction between activity and enzymatic assays is not straightforward as several enzymes may simultaneously be located intracellularly, on cell surfaces, and also be actively exuded as free enzymes into the bulk soil. In addition, "dead" or dormant cells can be regarded as being in between these two states. Another common practice is to relate tests to the general biogeochemical cycles of carbon, nitrogen, phosphorus, and sulfur. To be more precise, we have chosen to classify the tests according to different functional levels within ecosystems: (*1*) basic microbial soil functions (biomass and processes performed by virtually all groups of microbes), (*2*) specific microbial soil functions (performed by a more or less well-defined group of microbes), and (*3*) general microbial growth. A review of some important tests that are commonly used for assessing the effects on the soil ecosystem is given later. Several manuals with detailed information on soil test performance (9–11) and soil toxicity testing (9,12) have been produced.

Basic Microbial Soil Functions

Biomass. (see BIOMASS: SOIL MICROBIAL BIOMASS, this Encyclopedia) The level of total soil biomass has often been regarded as a fertility indicator as a microbial biomass is correlated with nutrient turnover. Moreover, a high biomass contains a reserve of valuable nutrients. Historically, the total biomass of soil microorganisms has been determined by viable plate counts or direct counts by microscopy. The former method seriously underestimates the biomass whereas the latter is tedious and time consuming. By combining the microscopic technique with immunological techniques or molecular genetic probing techniques, specific groups of soil bacteria can be enumerated. Also, various techniques for indirect estimation of the microbial biomass have been developed,

of which the chloroform fumigation–extraction (CFE) techniques of biomass carbon, nitrogen, or phosphorus are the most widely used (13–16). Another method for indirect measurement of biomass is the substrate-induced respiration (SIR) technique (16,17). After a period of 7 to 10 days of preincubation the soil sample is amended with glucose in surplus. To ensure no nutrient limitation, ammonium and phosphate can also be added. Immediately after substrate addition, the respiration pattern is recorded for at least 8 hours. The maximum response in CO_2 production or O_2 consumption before start of cell growth is proportional to the amount of biomass. Several techniques exist for the determination of carbon dioxide produced, such as titration, gas chromatography, or infrared gas analysis. One convenient respirometer to use is a Respicond III (Nordgren Innovations AB, Umeå, Sweden). It is based on the capture of carbon hydroxide in potassium hydroxide and measurement of the resulting decrease in conductivity of the KOH solution. The respirometer can measure the respiration of 96 soil samples two times every hour. A computer program allows the calculation of SIR. In addition, data can be exported to a computer program capable of nonlinear regression analysis. By fitting data to formula (3) above, the total biomass can be split into the amount of growing (r) and nongrowing (K) bacteria, respectively.

Basal Respiration. Soil respiration is the degradation of organic forms of carbon. For organisms to access the carbon, several enzyme systems must be involved, resulting in the release of various nutrients bound in the organic matter. Thus, the ultimate products of respiration, or carbon mineralization, are carbon dioxide, water, and various nutrients. Owing to competition for energy among fast-growing microorganisms, the most available carbon fractions, such as simple sugars and amino acids, will be degraded first, leaving the more recalcitrant structures of hemicellulose and lignin to slow-growing organisms. In an undisturbed soil, respiration is dominated by the degradation of more complex forms of carbon and is often referred to as basal respiration. The simplest way to measure basal respiration is to preincubate a soil sample to allow the initial flush of carbon dioxide caused by sample manipulation to level off. Thereafter, carbon dioxide production is measured in a closed system by absorption of carbon dioxide in an alkaline KOH solution. By titration, the remaining potassium hydroxide can be determined and the amount of carbon dioxide produced can be calculated. By using the respirometer described earlier, basal respiration can conveniently be monitored during a 48-hour period before the glucose addition for determination of SIR. The respirometer method gives very accurate estimates as many data points per assay are generated.

Nitrogen Mineralization. Nitrogen mineralization is the process during which organic bound nitrogen is enzymatically degraded to the mineral form ammonium ion (18). In soil, the process is performed by many diverse bacteria, both aerobic and anaerobic. Thus, the mineralization process is more or less independent of the oxygen status. To degrade organic macromolecules, microorganisms have to excrete extracellular enzymes, many of which are unspecific. Owing to the importance of nitrogen in crop production, many methods have been proposed to estimate the nitrogen mineralization capacity. One technique is to make a standardized aerobic incubation of a soil sample over several weeks or months. During the incubation period, nitrogen that is soluble in water is leached, either at the end or repeatedly at specified intervals. Alternatively, many replicates are started and destructive extractions with a KCl solution are made. The leachates/extracts are analyzed for ammonium and nitrate, and eventually nitrite. This technique estimates net mineralization because virtually all microbial nitrogen transformation processes might occur during the incubation. Moreover, if the effect of a test substance is to be evaluated, it is impossible to determine which group of organisms involved in nitrogen transformation are affected. Another commonly used technique to measure nitrogen mineralization capacity is the slurry assay (19) performed under anaerobic conditions with water as the only additive. The incubation period is 7 to 14 days. The advantage of an anaerobic slurry assay is that problems with determination and maintenance of an optimum soil water content is avoided. Substrate limitations because of restricted diffusion are also minimized. Moreover, nitrification is inhibited and assimilation is retarded by the anaerobiosis, as well as by uncontrolled losses of gaseous nitrogen. Thus, only ammonium has to be analyzed. Ammonium can effectively be analyzed by the indophenol blue method on a spectrophotometer provided with a flow cuvette system. The net mineralization capacity is calculated as the difference in ammonium content at the start and end of incubation.

Specific Microbial Soil Functions

Nitrification. Autotrophic nitrification is the two-step process by which ammonia is first oxidized to nitrite and then further to nitrate (20). In this aerobic process nitrifying bacteria gain energy for growth and reducing capacity to fix carbon dioxide. Nitrification ability is restricted to only a few bacterial species, all within the family *Nitrobacteriaceae*. Owing to their complicated metabolic machinery, nitrifying bacteria are sensitive to various environmental disturbances and thus can be used as organisms indicative of low levels of stress. Another reason for using nitrification in a test system is its important role in the biogeochemical cycle of nitrogen. Two basic nitrification assays are used: (*1*) assessing only the first step by analysis of nitrite after a short incubation period and (*2*) assessing the full nitrification pathway by analysis of ammonium and/or nitrate after a longer incubation period. The former assay has become increasingly popular because of its rapidity and simplicity (21). In the assay a soil slurry is generated by adding an optimum concentration of ammonium dissolved in a buffer (pH 7.2). The second step in the nitrification pathway is blocked with chlorate. The product, nitrite, can easily be analyzed colorimetrically. To increase the analysis capacity, the use of an automated

spectrophotometer technique is recommended. As NH_4^+ oxidizing bacteria have long generation times (>10 hours), the rate of product formation will be constant when short incubation periods are used. This means that data can be evaluated by linear regression. The NH_4^+ oxidation test is now in its final revision in becoming an ISO standard (ISO DIS 15685).

Denitrification. Biological denitrification is the process by which nitrogenous oxides, mainly nitrate and nitrite, are reduced to the nitrogen gases nitric oxide, nitrous oxide, and anitogen (20). Most denitrifiers prefer oxygen as the terminal electron acceptor and therefore reduce nitrogenous oxides only under anaerobic conditions. The complex pathway of denitrification is not fully understood, but is thought to consist of more than 26 genes and to be regulated both at the enzyme and gene levels by a number of environmental factors. Moreover, the steps in the denitrifying pathway have different sensitivities to various kinds of disturbances. Denitrification is a functional trait found within many taxonomical and physiological groups of bacteria. The genera *Pseudomonas*, *Alcaligenes*, and *Bacillus* are thought to be the most frequently found denitrifiers in soil. However, the list of denitrifiers is increasing with the introduction of molecular biology techniques for identification and determination of taxonomic relationships. Thus, denitrifiers can be viewed as representatives of a broad range of soil microbial populations. Denitrification is not just a process where nitrogen is lost to the atmosphere but can also indicate easily available organic carbon, as most denitrifiers are organotrophic and mineralize organic matter both under aerobic and anaerobic conditions. A common way to characterize denitrification in soil is to determine the potential denitrifying activity (PDA). In this method a soil slurry is incubated anaerobically with additions of an optimum amount of nitrate and an easily available carbon and energy source, such as glucose (22). At the start of the incubation, acetylene is added to block the last step in the denitrification pathway, the reduction of nitrous oxide to nitrogen. The accumulated product, nitrous oxide, is then analyzed on a gas chromatograph (GC) equipped with an electron capture detector (ECD). In this assay, problems with substrate diffusion have been eliminated and thus only the amounts of denitrifying enzymes will be rate limiting. The use of chloramphenicol (CAP) has been suggested to lock the enzyme concentration at its initial test concentration. The result will be a prolonged initial phase of linear product formation. Unfortunately, CAP seems to affect not only the synthesis but also the activity of denitrification enzymes (22,23). Recently, it has been demonstrated that it might be possible to use low concentrations of CAP ($<0.1\ g\,L^{-1}$) without negative effects (24), however, we recommend omitting CAP. The resulting nonlinear data can be evaluated by fitting data to formula (2). A manifold system for changing gases in the assay vessels improves the method. Such systems are not commercially available and must therefore be constructed in the laboratory.

Nitrogen Fixation. Diazotrophy, that is, the capacity to biologically reduce atmospheric dinitrogen gas into ammonia and further incorporate the nitrogen into cell biomass, is restricted to bacteria (20,25). Nitrogen-fixing bacteria are a diverse group of prokaryotes. Some of these bacteria are members of the bacterial family *Rhizobiaceae* and fix nitrogen in root nodules in a symbiotic relation with legumes. A second large group of nitrogen fixers are organotrophic and heterotrophic bacteria in the soil ecosystem. A third group, originally classified as algae, are the photosynthetic cyanobacteria (blue green algae). The actual fixation is performed by the oxygen-sensitive nitrogenase enzyme system. This system is complex and is under the control of at least 21 different genes which are regulated both on enzyme and gene level by a number of environmental factors such as ammonium, nitrate, and oxygen (see NITROGEN FIXATION IN SOILS — FREE-LIVING MICROBES, this Encyclopedia). Owing to both the economical and ecological importance of nitrogen fixers, many methods have been proposed to monitor their activities. The most commonly used technique, the C_2H_2 reduction technique, takes into account the higher affinity with the nitrogenase to acetylene than with the normal substrate nitrogen (26). When acetylene is reduced by the nitrogenase the end product ethylene is formed. As ethylene can be produced by other soil organisms, the endogenous production must be estimated by the CO blockage method to get an accurate estimate of nitrogenase activity (27). In the assay of heterotrophic N_2 fixation, a soil sample is preincubated with glucose for 48 hours, after which the sample is placed in a gastight chamber and injected with acetylene (28). After 24 to 48 hours the concentration of ethylene is analyzed on a GC equipped with a flame ionization detector (FID). Assuming a linear product formation, the rate of C_2H_2 reduction is calculated. For the determination of cyanobacterial nitrogen fixation, a moistened soil sample is incubated under permanent light for two to four months (29). During the light incubation period, ethylene production is assayed at regular intervals by placing the sample in a gastight chamber, which is injected with acetylene. Soil is incubated for one to four hours before C_2H_4 concentration is analyzed. The result is reported as the mean value of ethylene formed at each determination. The reproducibility of both the heterotrophic and the cyanobacterial nitrogen fixation methods is not very high, as both methods depend on a period of enrichment of the bacteria before the actual activity assay is performed.

Phosphatase Activity. (see SOIL ENZYMES, this Encyclopedia) Depending on the organic matter content, the total amount of organically bound phosphorus in soil varies from a little more than zero up to nearly 90% of the total soil P fraction. As phosphorus is an essential nutrient, not only for plants but also for all living organisms, a deficit of free mineral phosphate is the normal status of the soil ecosystem. Moreover, the deficiency is amplified by the formation of insoluble P complexes owing to pH and the mineral content of metals such as iron, aluminum, and calcium. The mineralization of phosphorus by phosphatases is therefore probably rate limiting for the activity of many soil organisms. Phosphatases are a group of enzymes of plant root and bacterial origin that hydrolyze esters and anhydrides of phosphoric acids. Even if microbial phosphatases

dominate in soil, they cannot be attributed to specific groups of bacteria. Phosphatases occur intracellularly in the periplasmic space of gram-negative bacteria, adsorbed to cell surfaces or as extracellular enzymes adsorbed to humic or mineral surfaces. Groups of phosphatases found in soil are phosphomonoesterases, phosphodiesterases, phosphotriesterases, and polyphosphatases, of which the activity of the three latter groups is rarely assayed. A parallel to the nitrogen mineralization assay would be just to analyze the content of phosphate after a mineralization period of naturally occurring or added phosphate esters. Owing to the influence of assimilation processes and the occurrence of more or less firmly chemically precipitated phosphate in soil, this technique is unreliable. The most widely used phosphatase assay is that of acidic or alkaline phosphomonoesterases (30). There are strong indications that acidic phosphatases are largely extracellular. Alkaline phosphatases are known to occur at high levels in the periplasmic space but can also be stabilized outside the cell. The phosphomonoesterase activity is determined as the release of *p*-nitrophenol after the addition of a buffered (pH 6.5 or 11) solution of the artificial substrate *p*-nitrophenyl phosphate. *p*-Nitrophenol is a yellow colored product that can be analyzed colorimetrically. As the substrate is added in excess to form a soil slurry, the product formation will be dependent on the amount of active enzymes. Assuming no product at the start, the rate is calculated as the increase in product after one hour of incubation. To estimate the basic phosphatase activity the soil should be preincubated at constant moisture for at least six weeks prior to the test.

Other Enzymes. The metabolism of living cells involves a vast number of different enzymes. Some are strictly intracellular whereas others are exposed on the outer cell surface or even exported to the environment. The role of excreted enzymes is to hydrolyze substances that are too large to be taken up and transported through the cell membrane. Other exoenzymes are involved in the detoxification of chemicals harmful to the cell. The mineralizations of carbon, nitrogen, phosphorus, and sulfur are complex processes each involving many different enzymes, both general and binding specific. Methods have been developed for measuring the activity of more than 50 soil enzymes (31). Usually, the enzyme assays are carried out by adding to a soil sample a solution with an optimum concentration of a specific substrate and then carrying out an incubation for 1 to 24 hours. As temperature, pH, and other environmental conditions are also optimized, it is the potential activity that is measured. Some commonly assayed exoenzyme activities of the carbon metabolism are: amylase and cellulase; nitrogen metabolism: proteinase, peptidase, and urease; and sulfur metabolism: sulfatase. A group of enzymes involved in internal redox reactions of the cell are the dehydrogenases. As these are general and ubiquitous enzymes, they are thought to be good indicators of the overall metabolic status of the microbial system. Most often enzyme assays are carried out using an artificial substrate that becomes colored when the target group is cleaved off, or the product can be colored by a developing procedure. The process can thus be measured with a spectrophotometer.

By setting up a system capable of monitoring many enzymes, an entire enzyme profile of a soil sample can be determined. Likewise, by modifying the SIR method to involve respiration with not only glucose but also a larger set of carbon sources, a substrate profile can be generated. A simple system for establishing substrate profiles is the Biolog system (Biolog, Inc., Hayward, California). The system consists of a 96-well microtiter plate containing different sole carbon sources and nutrients, and a control. Microbial utilization of the substrate leads to formation of colored products. The substrate utilization pattern can be read in a microtiter-plate reader. Enzyme or substrate profiles can be used to follow changes in the metabolic diversity of a soil ecosystem.

Microbial Growth

The ability to grow and divide is a fundamental property of the cell. This process involves enzymes for generating energy and building blocks for the new cells, as well as enzymes for duplicating the genetic pool. This is a complex process susceptible to various disturbances. Unfortunately, techniques to follow microbial multiplication in soil, such as counting bacteria by culture-dependent methods or by microscopic techniques, are too insensitive to give reliable results. However, by combining methods for measurement of product formation with kinetic theories, bacterial growth can be calculated. Data from SIR and PDA have successfully been used for estimation of the specific growth of both aerobic bacteria (7,8) and denitrifying bacteria (22), using glucose as the carbon and energy source. Moreover, the specific growth rate is a sensitive indicator of toxicity, for example, of silver (32). Advantages of this approach are that no separate assays need to be performed, and growth rates can be derived from ordinary SIR and PDA assays, thus making such assays cost-effective.

SCREENING AND TESTING OF CHEMICALS AND METALS

In addition to the approximately 100,000 chemicals used currently in society, a substantial number of new chemicals are introduced every year. The effects of most of these chemicals on the soil ecosystem are not known. The addition of any potentially toxic compound to a soil ecosystem may be a serious threat to microbial functions and hence to the sustainability of the soil. Ideally, it would be possible to screen many chemicals, heavy metals or complex substances to differentiate between those that are harmful and those that are not. In a second step, acceptable values for doses or concentrations to the soil ecosystem should be determined in dose-response tests. In all soil toxicity testing the selection and handling of the soils to be used as standard soils is crucial for the outcome of the tests.

Standard Soils

The properties of a soil influence the bioavailability of chemicals, thus leading to varying degrees of bioaccumulation, degradability and toxicity in different types of soil.

Several ideas have been presented to deal with the problem of determining acceptable concentrations of bioavailable chemicals in soils. One obvious way is to use a wide range of soils representing different properties. Soils ranging from low to high levels of organic material, clay to sand ratios, and pH values are generally chosen. Sometimes only soils representing the two ends of the spectrum with respect to each variable are tested to generate information on worst-case situations. Another strategy is to identify a set of soils representing the most common types within a specific region. However, with the latter strategy only the most common situations can be simulated, and no information on the boundaries for risks or use will be achieved. Another weakness of this strategy is that transport of soils may alter their properties, and hence lower the quality and reliability of the test results. A third strategy is to specify general criteria for the types of soil to be used in testing. The Organization of Economic Cooperation and Development (OECD) agreed on a type of soil for testing the side effects of pesticides on soil microflora (33) and that any soil/sediment fulfilling specified criteria could be used. The criteria include specified ranges in pH, organic content, sand content and that a certain fraction of the total organic content is microbial biomass, to ensure sufficient biological activity. If soil criteria are set correctly, it should be possible to find suitable soils within a convenient distance from the test laboratory.

To be able to conduct a large number of tests with both reliable and reproducible results, proper handling of the soil is important. As the soil microbial environment constantly changes during the season, one strategy is to collect a large batch of soil to be used for a period of a year. The soil batch should be homogenized by mixing and sieving the fresh soil before further storage. If the soils are collected under wet conditions, it might be necessary to allow them to dry gently to about 50 to 60% of their water holding capacity. This is best done under a constant temperature of $+4\,^{\circ}C$. Many protocols also stipulate soil storage at this temperature. As many microoorganisms are active even at low temperatures, changes in microbial populations and organic matter content will gradually occur during storage. Therefore, the best method of conserving a soil is to freeze it at $-20\,^{\circ}C$ (34), at least for soils from the temperate part of the world.

Screening of Chemicals

For rapid screening of a high number of substances, high-capacity microbiological assays must be used. The SIR and PAO are two such tests. In addition, they represent microbial indicators of low and high sensitivity, respectively, and so complement one another. Numerous tests and procedures have been used for screening purposes. In the screening procedure, one or a few concentrations of the test substance are added in a series of assays. Typically the highest dose chosen is 10 to 100 times higher than the expected field rate or soil contamination level, to ensure that substances also with low toxic effects are identified. Given later are some examples of the screening of pesticides, heavy metals, and sewage sludge.

The acute toxicities of 54 pesticides on nitrification and denitrification in soil were surveyed in a screening test by assessing effects on PAO, PDA, and μ_{PDA} (35). The results revealed that 35% of the substances tested had a significant effect on PAO, 23% on PDA, and 26% on μ_{PDA}. For nitrification, all observed effects were inhibitory, whereas for denitrification both stimulatory and inhibitory effects were observed.

The effects of a large number of pesticides, for example, fumigants, herbicides, and insecticides, on various microbial and enzymatic activities in soil were tested (36–38). The microbial activities tested were ammonification, nitrification, denitrification, and sulfur oxidation. The enzyme activities tested were amylase, dehydrogenase, invertase, nitrogenase, phosphatase, and urease. The results showed that most pesticides had a significant effect on most of the activities tested. However, the recovery of these processes was rapid and the authors concluded that soil microbes can tolerate chemicals used for control of soil pests.

The effect of 16 heavy metals at four rates was tested on 16 microbial indicators (39). The enzymes involved in carbon-cycling were the least affected, whereas various enzyme activities related to cycling of nitrogen, phosphorus, and sulfur showed a considerable decrease in activity. Arylsulfatase and phosphatase were the most sensitive enzymes.

The effect of sewage sludge on PDA and acidic phosphatase activity in soil was tested using sludge amounts comparable with normal field applications. Three different sludges influenced PDA differently at increasing rates, from inhibition through no effect to stimulation (Fig. 5). The same sludges all stimulated phosphatase activity at higher application rates.

Dose-Response Testing

The effects of various substances on specific processes in soil can be quantified by assessing the effect concentration (EC). The concentration required to cause an inhibition of 50% is thus designated EC_{50}, whereas the highest dose causing no effect is designated no effect concentration (NOEC). Many similar terms have been used in various contexts for expressing dose effects (Table 1). Various mathematical models have also been suggested to describe data and to calculate cardinal effect concentrations. Both sigmoidal dose-response curve models (40) and Michelis-Menten kinetic models (41,42) have been used. Our experience is that if a sufficient number of concentrations are used, ranging from concentrations with no effect to concentrations causing inhibition, semilogarithmic models for the effect range can be used to calculate various EC values as well as the NOEC. Because often too few concentrations are tested, making it difficult to use mathematical models to calculate EC values, the highest concentration tested showing no effect is used as the NOEC value.

In Fig. 6 the results of a dose-response test to assess the effect of the organic solvent toluene on PDA is shown. In similar dose-response tests, the effects of the fungicide mancozeb was tested on PAO and PDA (35), and the effects of Cr(VI) were tested on seven microbial indicators (42). In all three studies it was concluded that denitrification is a sensitive test.

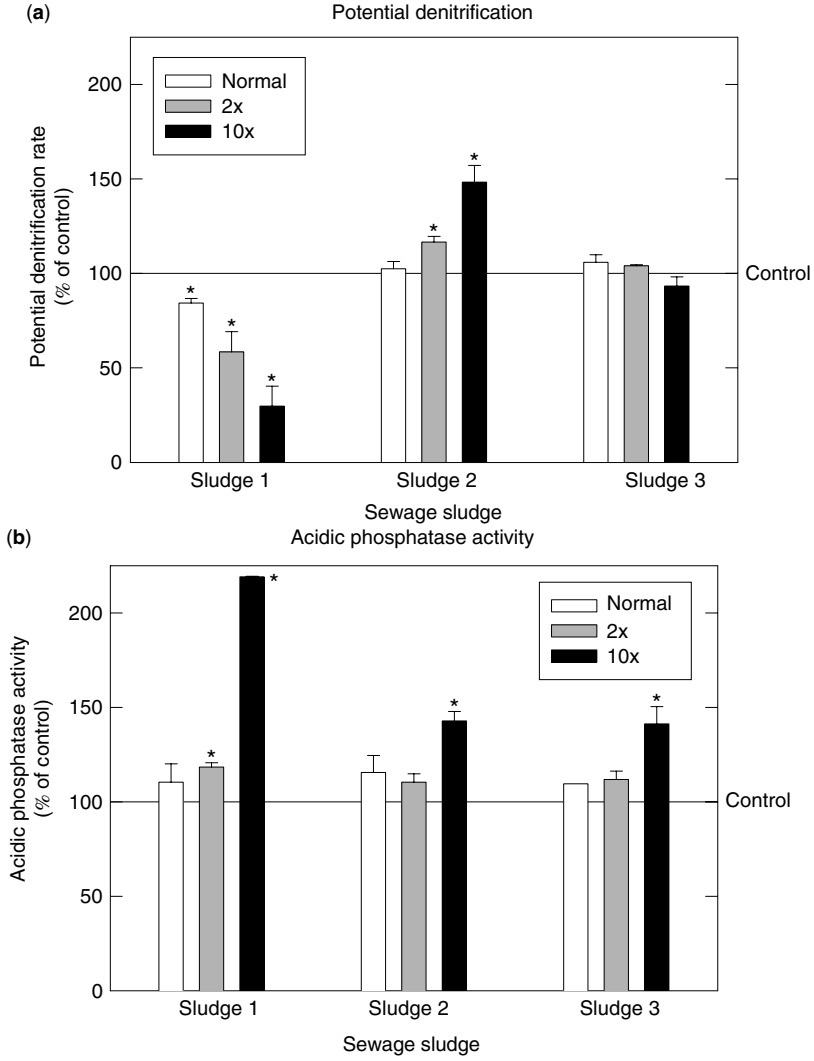

Figure 5. Effect of the addition of three different sewage sludges, at three rates each, on potential denitrification and phosphatase activity in soil (normal rate 4 ton ha^{-1} yr^{-1}, double rate, and 10 times the normal rate). Asterisks indicate significant differences ($p < 0.05$) to control.

Table 1. Commonly Used Definitions and Abbreviations in Expressing Results of Soil Microbial Toxicity Results

Abbreviation	Definition
BEC	Bound Effect Concentration. The effect of the biologically available amount of a chemical or metal.
NOEC	No Observed Effect Concentration. The highest test concentration at which the substance has no observed effect on the test species.
NEC	No Effect Concentration.
PNEC	Predicted No Effect Concentration. Environmental concentration that is regarded as a level below which the balance of probability is that an unacceptable effect will not occur.
PEC	Predicted Environmental Concentration. Estimated environmental concentration based on either measured or calculated data.
LOEC	Lowest Observed Effect Concentration. The lowest test concentration at which a chemical is observed to have a "statistically significant" effect on test organisms.
LEC	Lowest Effect Concentration.
EC_X	Effective Concentration. The concentration which affects X% of a test population after a specified exposure time. The EC_{50} usually relates to effects other than lethality in 50% of the test organisms. The effect concentration may refer to other percentages such as 10%, 90%, e.g., EC_{10} and EC_{90}, etc.

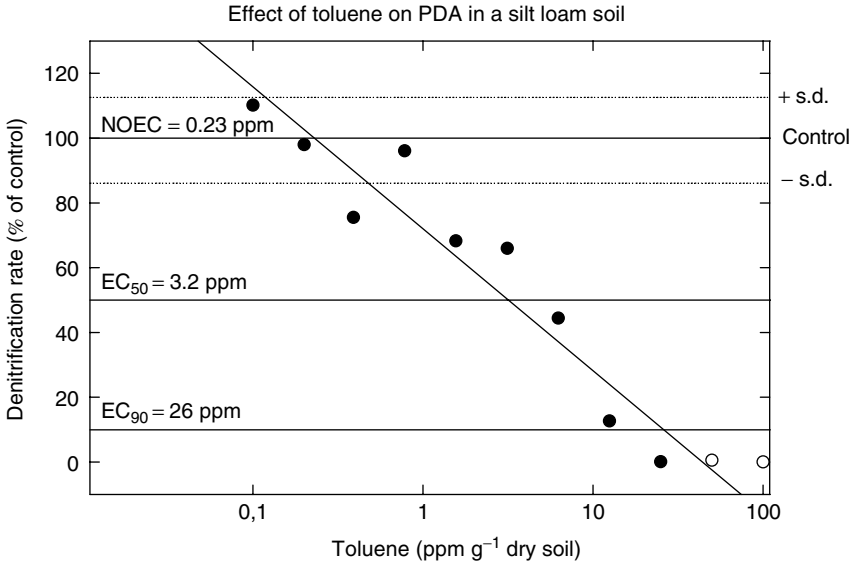

Figure 6. Relative rates of potential denitrification activity (PDA) in soil at different concentrations of toluene. Horizontal lines are mean value ± standard deviation of the control without toluene ($n = 3$). Solid symbols are rates included in the linear regression line from which the dose-response calculations of NOEC, EC_{50}, and EC_{90} were made.

Some Considerations

The data for toxicity evaluations used by environmental protection agencies and authorities to prepare guidelines are based on results derived from a wide variety of laboratory test methods and investigations of field trials or polluted areas. In addition, data are scarce for many chemicals. Reviews of data for pesticides (43) and heavy metals (44,45) have been presented. A consequence of the lack of a standardized test system is that the reliability of the database for different substances varies widely, and hence the quality of the guidelines.

INTERNATIONAL GUIDELINES

The OECD has acted to standardize test protocols and laboratory standards for investigation and evaluation of chemicals. They have published the "OECD Guidelines for Testing of Chemicals" (46) and "Principles of Good Laboratory Practice-GLP" (47). Two guidelines for toxicity testing in soil have been approved: (*1*) Soil Microorganisms, Nitrogen Transformation Test (TG 216, Original Guideline, adapted 21st January 2000), and (*2*) Soil Microorganisms, Carbon Transformation Test (TG 217, Original Guideline, adapted 21st January 2000).

In the OECD nitrogen transformation test, soil is amended with powdered plant meal and either treated with the test substance or left untreated (control). A minimum of two test concentrations is recommended. At the start and after a period of incubation, samples of treated and control soils are extracted with an appropriate solvent, and the quantities of nitrate in the extracts are determined. The rate of nitrate formation in treated samples is compared with the rate in the controls, and the percentage deviation of the treated from the control is calculated. In the carbon transformation test, soil is either treated with the test substance or left untreated (control). After incubation and sampling at the same time intervals as for the nitrogen transformation test, samples of treated and control soils are mixed with glucose, and SIR are measured. Respiration rates are expressed as carbon dioxide released or oxygen consumed. Results from both the nitrogen and carbon transformation tests, with multiple concentrations, are analyzed using a regression model, and the EC_X values with 95% confidence limit are calculated, that is, EC_{50}, EC_{25}, and/or EC_{10}.

Both OECD tests are tests on net soil processes, so include a multitude of microbial transformation processes. Therefore, the test cannot be viewed as very sensitive. If on the other hand, a negative effect is detected then the test substance can be expected to have a serious negative impact on the microbial soil community.

In many countries, national soil toxicity test guidelines similar to those described in the preceding text have been issued, for example, by the U.S. Environmental Protection Agency (U.S.EPA) and the German Biologische Bundesanstalt (BBA). Also, international organizations such as the European and Mediterranean Plant Protection Organization (EPPO) are developing guidelines for the environmental risk assessment of plant protection products (48,49). Another international organization, the International Organization for Standardization (ISO), is acting on standardization of test routines and has also issued standards for soil tests (50,51).

It can be concluded that despite the imminent danger of chemicals to our environment, surprisingly few international test guidelines have been approved. The reason for this is probably conflicting aims of testing between a multitude of potential users. Moreover, the time from proposing a test until its becoming accepted means that the development of new tests is far behind the research front in soil microbiology.

TESTING EFFECTS ON SOIL QUALITY

Taking a soil sample to the laboratory for testing effects of specific substances is relatively easy, but the natural soil ecosystem is exceedingly complex (Fig. 3). To use a soil in an effective but also sustainable way, we must

have an understanding of the ecosystem from which it is possible to establish criteria for normal levels and ranges of microbial activities. Not until such baseline knowledge has been established will it be possible to tell if a soil system is affected by an anthropogenic chemical. In the present situation our task is to collect and systematize information from essential soil indicators, and from this growing database try to describe and understand intrinsic relations in the soil system. This must be done for a range of both undisturbed as well as polluted systems. Two important prerequisites for the success of such a work are good soil sampling design and proper sample handling (2,34).

Integrated Functional Structures Evaluation

The interactions between, and within, the physical, chemical, and biological compartments of the soil ecosystem are numerous. Therefore, a description of the soil and its various functions unavoidably generates large amounts of data. To be able to handle and interpret such large data sets, methods to simplify and sort out the important signals must be used. One approach is multivariate data analysis (52), for example, principal components analysis (PCA) or factor analysis (FA). Such methods can be viewed as variable reduction techniques that facilitate interpretation and understanding of complex relations (53).

PCA has been used for grouping soils into fertility classes based on their characteristics (54), and for determining factors controlling aerobic nitrogen mineralization in different soils (55). By use of PCA, changes were revealed in microbial community patterns 20 years after addition of heavy-metal contaminated sewage sludge (56). Changes in the phospholipid fatty acid composition of bacterial cell membranes and metabolic fingerprints determined by the Biolog system indicated similar effects of the heavy metals. On the other hand, observed changes in seven microbial indicators could not be related to any effect of several heavy metals and xenobiotics in sewage sludge that had been applied for 16 years (57).

The relations of 29 different biological, chemical, and physical variables in two sets of soil data, also representing two scales, was explored by use of PCA (58). The first set consisted of samples taken in a single arable field whereas the second set consisted of bulk soil samples from 26 very diverse agricultural fields scattered all over Sweden. The main conclusion was that despite the very large difference in scales, the data sets displayed more similarities than dissimilarities regarding functional structures. Three main variable groups were found in both data sets. In the first group, organic matter variables were tightly clustered together. The second group consisted of pH dependent variables, whereas the third group consisted of various heterotrophic microbial activities.

MONITORING LONG-TERM CHANGES IN SOIL QUALITY

Another use of microbial soil tests is to monitor changes in soil over the long term. The aim of a monitoring program is to collect information over a long enough period to be able to detect when drastic changes occur or, when progress in reclamation or remediation has been made. The political willingness to undertake the long-term costs for starting and running a monitoring program must be well anchored. Therefore, in reality the number of soil samples as well as the number of indicators must be kept at a minimum. However, too few variables do not generate enough information. Also, a monitor program must have a readiness to respond to unseen future demands.

Soil Indicators of Minimum Data Sets

The use of minimum data sets (MDS) has been proposed to describe soil quality. The indicators included in an MDS should relate to functions such as productivity, water regulation, the soil as an environmental filter, and higher animal health. In addition to several physical and chemical variables, the following biological indicators have been proposed as part of an MDS: microbial biomass (carbon and nitrogen), potential mineralizable nitrogen and soil respiration (5,59). All three variables can indicate the nutrient status and thus crop productivity of the soil. The nitrogen-supplying capacity of a soil is a good predictor of yields within arable systems. In addition, the three microbial variables may indicate the potential for degradation of anthropogenic substances. An MDS including only three biological properties, though manageable, is probably insufficient to define the soil-microbial ecosystem. To increase the information the additional microbial variables PAO and PDA have been suggested (2). As opposed to the other biological variables, PAO is not directly coupled to organic matter and is also sensitive to environmental stress. Apart from being dependent on high-quality organic matter, PDA probes the response of microbes to anaerobic conditions such as created by soil compaction.

Near-Infrared Reflectance (NIR)

Near-infrared reflectance (NIR) spectroscopy has been successfully used to analyze a wide variety of organic products. As NIR offers a high-speed, low-cost, method as well as being a nondestructive analysis, its use has spread to a wide area of applications. When used for analysis of low organic matter soils, a close correlation of NIR spectra with total carbon and total nitrogen have been found (60). NIR together with multivariate regression has also been used to model both basal respiration and SIR in forest soils (61). In our own work, NIR spectra modeled by PCA showed close correlations not only with organic carbon, magnesium and pH but also with acidic phosphatase activity and PDA. Moreover, NIR has been demonstrated to predict crop uptake of nitrogen (62). It is not likely that NIR directly measures biological activities, but rather gives an integrated index through its correlation with soil properties that can be measured by NIR.

NIR seems to be a suitable method for presurveying potential locations for a soil-monitoring network. On the basis of the results, a stratified sampling design can be worked out. NIR should also be included in the actual analysis program because it is able to capture, directly or indirectly, important signals from the biological, physical, as well as chemical compartments of soil.

Monitoring Programs

A national benchmark program was established in Canada with 23 sites to monitor changes in agricultural soil quality resulting from land use and management practice (63). Besides collecting extended baseline data sets of various soil properties, the program includes collection of continuous monitoring data at intervals ranging from daily to every 5 or 10 years, depending on their sensitivity. In France, a similar program has been set up with 11 sites (64). The objective of the program is to detect early changes in soil quality and to identify their causes. Neither of these programs includes biological soil indicators, which is probably due to lack of a standardized methodology combined with the perception that biological soil indicators are unpredictable. However, the importance of including microbiological soil indicators in soil monitoring has been stressed (2). The German Special Working Group on "Basic Information for Soil Conservation" proposed the following microbial indicators to be analyzed in a system of permanent soil monitoring sites: microbial biomass, basal respiration, and the enzyme activity of protease, catalase, glucosidase, and arginine ammonification. In a project commissioned by the Swedish Environmental Protection Agency, the inclusion of microbial indicators in a future Swedish soil-monitoring program is recommended (2).

IMPORTANT REMARKS ON SOIL TESTING

A strategy for soil testing is that the test criteria used should guarantee the protection of the structure and function of the soil ecosystem (65). Ideally, adequate data for the effects of a toxic compound should be obtained in the ecosystem of concern. As not all organisms and functions in an ecosystem can be tested against all possible compounds and combinations, extrapolations are often made from simple laboratory tests to the ecosystem. Moreover, in addition to the vast number of nontested substances, a great number of methodological problems and difficulties in interpretation of data remain to be dealt with. Not until many of these problems have been solved can an overall strategy for soil toxicity testing and soil quality testing be laid out. Some important problems and suggested strategies to overcome them are considered in the following.

Problems

Choice of Test Soil. Different physicochemical soil conditions change the bioavailability of compounds. For example, the availability and toxicity of most metals increase with reduced pH and organic matter content, whereas for selected metals, for example, Mo, the solubility decreases with decreasing pH. This means that physical and chemical data for substances to be tested are important when choosing a soil for an individual test program. If physicochemical data are not available, soils with "extreme" characteristics, for instance, low and high pH, are the best choice. The test results form a reasonable basis for determining if a compound constitutes no risk or requires further testing.

Combination of Tests. The sensitivity of different tests, that is, end points, is not the same for all organisms and compounds. Depending on the end point chosen, more sensitive parameters, and hence lower effect-levels, may be neglected. It is not obvious whether sensitive tests or tests with a coarse resolution are the best general choice. The best strategy is to combine several methods, for example, respiration or biomass, and nitrification tests.

Addition of Test Substance. The common practice of using carrier solvents or the addition of soluble salts, often just before the start of the test, may lead to a greater bioavailability of the pollutants in laboratory experiments than in the field situation. Under field conditions, part of the pollutant becomes not only sorbed and unavailable, but may also be transformed to other forms. In laboratory studies, after mixing the dissolved chemical into the soil, the solvent is allowed to evaporate before start of the assay. This procedure is questionable because many organic solvents themselves have been proven to affect the microorganisms and their activity. Alternatively, the test substance can first be mixed into an inert carrier such as sand and then blended with the soil. A third way is to use an ultrasonic bath to dissolve and distribute as much as possible in an aqueous suspension. Eventually, mild leaching with water should be included to rid the soil of water-soluble remains immediately after adding the test substance. In subsequent dose-response tests, a leached and unleached soil should be tested in parallel.

Test Level. Laboratory-derived NOEC and LOEC values do not necessarily represent "true" no-effect concentration (NEC) or lowest effect concentration (LEC) values (Table 1). An alternative approach for the future, as pointed out by Hoekstra and van Ewijk (66), is the use of bound effect concentrations (BEC). Furthermore, it is difficult to assess if protection of the functioning of an ecosystem is required that all species are protected, or if some loss is accepted. Structure and function of an ecosystem are often uncoupled and thus toxicity data for single species cannot be used to predict safe levels for ecosystems with a great level of safety. Thus, the obvious strategy must be to test at the level of ecosystem, community, or population, rather than at the level of species or individual, although the recent rapid development in molecular biology allows for such studies.

Evaluation and Interpretation. The normal situation today is that toxic compounds are discharged or present in the environment in mixtures. Therefore, more attention must be paid to interactive or synergistic effects among compounds. The strategy must be, in addition to making field observations, to design laboratory tests to study some commonly found mixtures. Microbial tests might even be used instead of some of the very complicated and expensive chemical analyses of organic environmental chemicals.

In soil toxicity testing, sometimes the tested chemical is observed to have a stimulation effect on microorganisms. Stimulatory effects are a difficult phenomenon to deal with, as stimulation does not always mean a positive effect, but can be a stress response of the microorganisms.

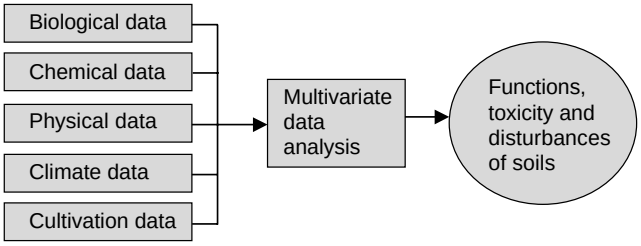

Figure 7. Strategy for integrated evaluation of data leading to a picture of the function of the soil or an indication of the potential outcome of disturbances in the soil.

Another explanation of stimulatory effects is that resistant organotrophic bacteria proliferate on the biomass of the organisms killed by the compound. Therefore, one must be cautious when such observations are made, and not automatically interpret increased levels of microbial activity as benign. Instead, stimulatory effect should stimulate further investigation on possible negative effects.

Loss or lowering of a microbial activity can be temporary and does not necessarily mean that the genetic base of the microbial community has been lost or diminished greatly. However, some genetic capacities will undoubtedly be lost owing to anthropogenic activities. The consequences of such losses are difficult to foresee, the only thing known is that there is no way back. Thus, future recommendations for toxicity testing in soil must include genetic diversity testing as an integral part of a test system.

Soil Quality Testing. It is obvious that no single measurement of a soil factor, whether it be biological, chemical, or physical, will give a comprehensive picture of the quality of a specific soil (1). Because of the complexity of the soil (Fig. 3), evaluation of a single parameter provides only a small part of the answer as to whether the soil has a low or high quality status. Therefore, a strategy for integrated evaluation of a soil quality is needed. A number of indicators that reflect biological, chemical and physical components of a soil would be used in such a strategy. Climatic conditions as well as data concerning cultivation measures, previous and present, would also be included. Appropriate statistical tools are needed to evaluate the complex data sets associated with these variables. Principal component analysis (PCA), a multivariate statistical analysis, is such a tool (Fig. 7).

CONCLUSION

The vast number of chemicals used in society today urge for simple and rapid tests to assess toxic effects on the soil ecosystem. Several microbial methods for soil toxicity testing and soil quality testing exist today. Surprisingly, few of these tests have, though, reached the level of becoming international standards. By using such tests for screening purposes and dose-response testing it is possible to identify chemicals, and concentrations of these chemicals, that could be allowed without seriously threatening the productivity and sustainable use of soils.

A general conclusion, however, is that we have a long way to go before acceptable safety levels can be defined for our soil ecosystems. Much work remains before we will be able to detect and understand the meaning of anthropogenically induced changes in microbial functions. At present, not even generally accepted simple test programs for microbial soil toxicity exist.

TOXICITY TESTING IN WASTEWATER TREATMENT PLANTS USING MICROORGANISMS

GABRIEL BITTON
Department of Environmental Engineering Sciences
University of Florida
Gainesville, Florida

INTRODUCTION

Process waters released by industry must be treated in a wastewater treatment prior to discharge into receiving waters. Traditionally, discharge limits were focused on biochemical oxygen demand (BOD) and suspended solids concentrations. Nowadays, there is a great concern over the impact of toxic industrial pollutants on wastewater treatment processes and on receiving waters. To avoid damage to the environment, two approaches can be taken to control industrial discharges (1):

1. Biomonitoring of the mixing zone where the effluent mixes with the recipient water. Biological surveys or biosurveys can be used to assess the impact of toxic chemicals on the resident aquatic communities and require the use of a reference site. These surveys are, however, expensive, and the results obtained are difficult to interpret. Some believe that they have a limited value as regards the evaluation of the impact of effluent discharges (2).
2. Another approach is the use of whole effluent toxicity (WET). The advantages of toxicity testing of complex effluents are (1):

- There may be numerous toxicants in complex effluents. Even sophisticated chemical analyses detect only a fraction of these chemicals.
- Toxicity assays give an indication of the deleterious effects of chemicals and encompass antagonistic or synergistic interactions between chemicals.
- Toxicity testing aided by fractionation can help identify the toxic chemical within the complex effluent.

There are regulations concerning the discharge of effluents into receiving waters in many industrialized countries such as the United States, the United Kingdom, France, Japan, and Germany (3). For example, in the United States, effluent discharge to surface waters is enforced under the National Pollutant Discharge Elimination System (NPDES) of the Clean Water Act and is administered by the U.S. Environmental Protection Agency (EPA), which may delegate its authority to state agencies. Under the NPDES process, permits are issued to dischargers, who must comply with the industry sector minimum standards. NPDES sets two types of performance criteria (3,4): (*1*) *Technology-based criteria*, which deal with the ability of a wastewater treatment plant to remove specific pollutants; (*2*) *Water quality-based criteria*, which specify that a wastewater treatment plant must not discharge effluents "in toxic amounts" into receiving waters. Toxicity must be reduced sufficiently to a level that is not deleterious to the biota in the receiving water.

The main criteria for an ideal toxicity test are ecological relevance, reproducibility, rapidity, simplicity, and low cost. However, no test fulfills all of these criteria. For example, microcosms are ecologically relevant but do not have a good reproducibility or low cost. It is thus recommended to use a battery of tests that covers several trophic levels. For example, in Germany, an effluent biotesting battery includes a fish test, a 24-hour *Daphnia* test, an algal assay using *Scenedesmus subspicatus*, and a bioluminescence inhibition assay using a marine bacterium (1).

The goals of toxicity testing in wastewater treatment plants are:

1. to test any deleterious effect toxic chemicals in wastewater may have on the wastewater microorganisms, leading to a reduction in treatment efficiency. These screening tests should also be useful for indicating the source of the toxicants entering the wastewater treatment plant.
2. to assess from a toxicity standpoint the removal of organic and inorganic toxicants following their passage through a wastewater treatment plant.
3. to assess the toxicity of effluents and their impact on receiving waters.
4. if the effluents are toxic, there may be a need to perform a toxicity reduction evaluation (TRE) to identify the problem toxic chemical(s).

The most common test organisms used in biological monitoring are fathead minnow (*Pimephales promelas*) and daphnid (*Daphnia magna, Ceriodaphnia dubia*) toxicity tests. We will, however, focus on microbial- and enzyme-based toxicity tests and examine their applications to wastewater treatment.

SURVEY OF MICROBIOTESTS FOR MONITORING TOXICITY IN WASTEWATER TREATMENT PLANTS

Microbiotests, also called microscale toxicity tests, are based on the inhibition of the activity of enzymes, bacteria, algae, fungi, and protozoa (5–10). The microbiotests (microbe- and enzyme-based tests) most suitable for toxicity testing in wastewater treatment plants are shown in Figures 1 and 2. These tests are simple, rapid, and relatively inexpensive; require low sample volume; can be miniaturized; and can be made portable for field applications. The advantages of microbiotests are further displayed in Table 1 (7). We now describe these toxicity tests and discuss their application to municipal and industrial wastewater treatment plants.

Enzyme Assays

Enzymes serve as catalysts of biological reactions in animal, plant, and microbial cells. Toxicity tests based on the

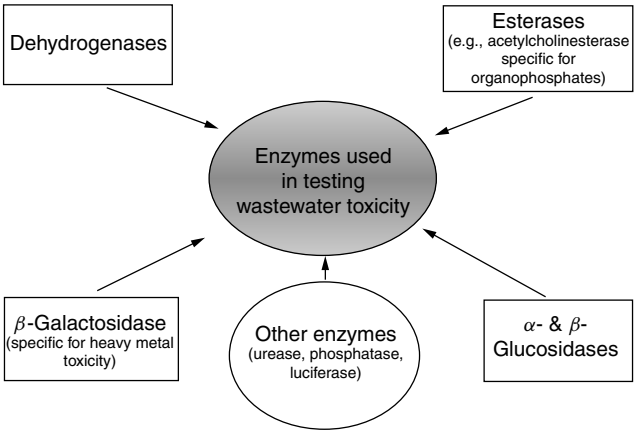

Figure 1. Enzymatic tests used in the determination of wastewater toxicity.

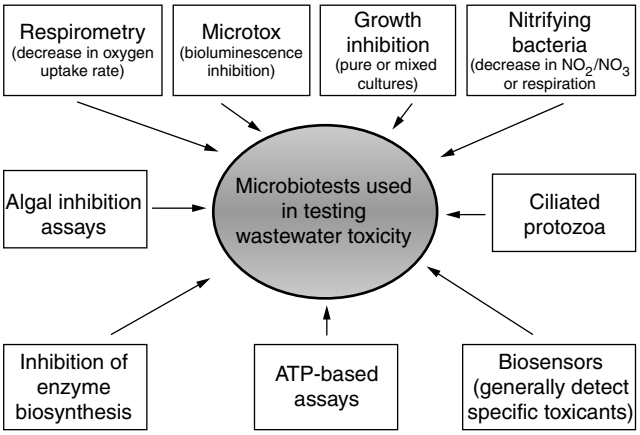

Figure 2. Microbiotests used in the determination of wastewater toxicity.

Table 1. Some Features of Microbiotests

Feature	Explanatory Remark
Inexpensive *or* cost efficient	Cost is test-dependent and can vary from a few dollars to several hundred dollars in Canadian currency
Generally not labor-intensive	As opposed to steps involved in undertaking fish bioassays, for example
High sample throughput potential	When automation technology can be applied
Cultures easily maintained or maintenance free	Freeze-drying technology can be applied
Modest laboratory and incubation space requirement	As opposed to a specialized laboratory essential for fish bioassays, for example
Insignificant post-experimental chores	Owing to disposable plastic ware, which is recycled instead of having to be washed for reuse, as in the case of large experimental vessels
Low sample volume requirements	Often, a few milliliters suffice to initiate tests instead of liters
Sensitive/rapid responses to toxicants	Short life cycles of microorganisms enable end point measurements after just minutes or several hours of exposure to toxic chemicals
Precise/reproducible responses	High number of assayed organisms, increased number of replicates, and error-free robotic technology are contributors to this feature
Surrogate testing potential	Microbiotests are adequate substitutes for macrobiotests in some cases
Portability	Cases where microbiotests are conveniently amenable to being applied in the field

inhibition of the activity of a wide range of enzymes have been suggested for assessing chemical toxicity in aquatic environments, including wastewater treatment plants. The enzymes include dehydrogenases, ATPases, esterases (particularly acetylcholinesterase), phosphatases, urease, luciferase, β-galactosidase, protease, amylase, and α- and β-glucosidase (11,12). Some of these enzymes are specific to particular toxicants. Hence, acetylcholinesterase is specifically inhibited by organophosphates and carbamate pesticides and has been used to monitor surface waters for these chemicals. β-galactosidase and urease are relatively insensitive to organic toxicants and respond mostly to heavy metals (19,21).

Dehydrogenases have been frequently utilized as target enzymes in toxicity testing in wastewater treatment plants. These enzymes are assayed by using specific oxidoreduction dyes such as triphenyl tetrazolium chloride (TTC), 2-(*p*-iodophenyl)-3-(*p*-nitrophenyl)-5-phenyltetrazolium chloride (INT), nitroblue tetrazolium (NBT), 3-4,5-dimethyl thiazole-2-yl 2,5-diphenyl tetrazolium bromide (MTT), or resazurin (11). These oxidoreduction dyes are routinely used to determine microbial activity in surface waters, soils, sediments, and other environmental samples. Lehnard (13) was one of the first to demonstrate the usefulness of dehydrogenase activity (DHA) as a basis for assessing the effect of toxicants on biological treatment of wastewater. An INT reduction assay was used to measure the activity of filamentous bacteria in activated sludge following exposure to chlorine and hydrogen peroxide (14,15) (see FILAMENTOUS BULKING IN ACTIVATED SLUDGE, CONTROL OF and ACTIVATED SLUDGE — FOAMING). Botsford (16) proposed a toxicity test based on the inhibition of the reduction of MTT by *Rhizobium meliloti* used as the indicator organism. A resazurin reduction assay was considered for measuring mercury toxicity in activated sludge (17). DHA-based toxicity tests are often well correlated with those based on oxygen uptake in wastewater systems.

In vivo microbial enzyme activity has been measured in the flow stream of bioreactors containing a fixed bed of immobilized microorganisms. The test water is pumped through the bioreactor, and enzyme activity is determined by injecting a synthetic substrate through the reactor (12,18). This semi–on-line system should be potentially useful for the determination of toxicant impact on microorganisms in water and wastewater treatment plants.

Several enzymes (α-glucosidase, phosphatase, acetylcholinesterase, β-galactosidase, urease) were screened for their sensitivity to heavy metals and organic toxicants. β-galactosidase and urease were found to be the most sensitive to heavy metals but were not affected by organic toxicants. This led to the idea of developing microbial kits for the specific detection of heavy metal toxicity. A urease toxicity assay (UTA) was developed and was found to be quite sensitive to metals (19) but did not respond to organic toxicants. However, this test performed poorly as regards wastewater effluents. Since ammonia is the end product of urease activity, the high levels of ammonia in wastewater and other environmental samples interfere with the assay. An attempt was made to immobilize urease to avoid the ammonia interference. However, immobilized urease generally is less sensitive to metals than free urease (19).

A crucial finding was the selective response of β-galactosidase activity to toxic chemicals. This enzyme was relatively insensitive to organic toxicants while being sensitive to cationic metals (20) and provided the basis for the development of a toxicity test that is selective

for heavy metals. Subsequently, two kits, MetPAD™ (21) and MetPLATE™ (22), were developed for assessing metal toxicity in environmental samples. Both toxicity test kits are based on the specific inhibition of the activity of β-galactosidase in an *E. coli* strain by heavy metals. MetPAD™ is a semiquantitative test with the enzyme assay performed on a supplied pad, whereas MetPLATE™ is a quantitative test, allowing EC_{50} determination in a 96-well microtitration plate. These tests were used to determine metal toxicity in surface waters, wastewater effluents, landfill leachates, ashes, soils, sediments, biosolids, and metal-hyperaccumulating plants (23). Heavy metal toxicity of wastewater effluents was assessed using MetPAD™ assays. Five of eight samples displayed toxicity related to heavy metals, which were also detected with chemical analysis (21). Sample toxicity was removed following passage through a cation exchange resin, confirming that the test was indeed specific for heavy metals (24). MetPLATE™ was also useful in detecting metal toxicity in industrial effluents (22).

Microbial Assays

Microtox

Microtox is based on the inhibition of a bioluminescent marine bacterium, *Vibrio fischeri* (formerly known as *Photobacterium phosphoreum*) by toxic chemicals (25–27). Microtox is a 5- to 15-minute bacterial test that can be extended to 60 minutes. It has been used to test the toxicity of thousands of pure chemicals as well as complex domestic wastewater effluents, industrial effluents, fossil fuel process water, surface waters, stormwater, groundwater, and solids which include among others, soils, biosolids, solid wastes, and sediments. It has also been used to test the interactions between chemicals. Several countries (e.g., Canada, France, Germany, Italy, Mexico, Spain, Sweden, the United States) have adopted Microtox for screening toxicity of environmental samples, including wastewater effluents. Comparative studies of Microtox with other toxicity tests (fathead minnow, rainbow trout, daphnids) showed a correlation coefficient r varying from 0.4 to more than 0.9 (27). Conflicting results were obtained when comparisons were made to examine the relationship between toxicity data obtained through Microtox and *Ceriodaphnia dubia* tests. Some reported that *C. dubia* was much more sensitive than Microtox to wastewater effluent toxicity (28,29), whereas others (30–32) suggest that Microtox can serve as a surrogate test for the determination of wastewater toxicity. Sherry and coworkers (33) used a battery of toxicity tests to assess the acute and chronic effects of refinery effluents. Only Microtox and a submitochondrial particle test detected acute toxicity in these refinery. Others have found that Microtox was much less sensitive to a refinery effluent than rat liver mitochondria (34). Microtox was also used to evaluate the toxicity of effluents from the textile, chemical, pharmaceutical, tank cleaning, forest products, food production, and olive oil industries (35–37). Brown and coworkers (38) used a luminescence-based *Ps. fluorescens* assay (*lux* gene introduced into *Ps. fluorescens 10586s/pUCD607*) to monitor the toxicity of a paper mill effluent. The toxicity test based on bioluminescence inhibition was more sensitive than a test based on the respiration of the same bacterial strain (39,40). In a limited number of tests, this bacterium was found to be more sensitive to Cd than Microtox. Inhibition of other bioluminescent bacterial species (*Vibrio harveyi, Photobacterium leiognathi*) was used as an end point in testing industrial wastewater (41).

There have been several developments concerning the use of bioluminescence inhibition or induction as the end point. Mutatox® is a genotoxicity assay based on the induction of bioluminescence in the marine bacterium *Photobacterium leignathi* in response to the presence of DNA-damaging agents (42,43). Another development is the 22-h Microtox chronic toxicity test (44), which is based on growth inhibition of *Vibrio fisheri*. Following testing of 14 wastewater treatment plant effluents, Sweet and coworkers (45) reported a good correlation between chronic Microtox and *Ceriodaphnia dubia* bioassays.

ATP-Based Assays

ATP is the primary high-energy molecule that is formed following catabolic reactions such as oxidative phosphorylation in heterotrophs, photophosphorylation in phototrophs, or oxidation of inorganic chemicals by chemotrophs. It is a good indicator of viability of microbial, plant, and animal cells. ATP assay is relatively simple and consists of measuring light emission, using a luminometer, following reaction of cell ATP with firefly luciferin. The reaction is catalyzed by the luciferase enzyme (11). ATP assays have been used to measure live biomass in environmental samples and in engineered systems such as water and wastewater treatment plants. Some 30 years ago, investigators considered ATP assays for assessing the operating conditions in wastewater treatment plants (46–48), and this has led to their use in toxicity testing. Thus, an ATP-based toxicity assay is quite useful in monitoring the impact of industrial discharges on wastewater treatment plants. Bitton and Koopman (11) suggested the necessity to monitor the potential effect of toxicants on the firefly luciferase itself. This has led to the development of the ATP-TOX system, which is a 5-hour toxicity test that is based on inhibition of both ATP (growth inhibition) and the enzyme luciferase that drives the production of bioluminescence in some marine bacteria such as *Vibrio fisheri* (49,50). Several bacterial strains were examined for their sensitivity to toxicants. *E. coli* PQ37 was found to be the best suited for the ATP-TOX system. This test was found to be about as sensitive to metals as Microtox but was clearly less sensitive to organic toxicants. The test detected toxicity in field samples of river water and sediments in Canada (51,52), but no studies are available on its application to wastewater samples.

Growth Inhibition Assays

Assays based on growth inhibition have long been used by microbiologists to assess the sensitivity of

microorganisms to antibiotics. Growth inhibition assays are quite appropriate for determining the impact of industrial discharges on pure bacterial cultures (e.g., *Pseudomonas fluorescens*) or mixed cultures of wastewater microorganisms. These assays consist of measuring the changes in microbial numbers caused by the presence of a given toxicant generally within a 24-hour incubation period. These changes are often measured with a spectrophotometer or by measuring ATP as performed in the ATP-TOX assay discussed earlier (50). Recently, a 22-hour Microtox assay based on the growth inhibition of *Vibrio fisheri* was proposed as a chronic toxicity test (44). The 96-hour algal toxicity test is also considered a chronic toxicity test (see algal assays section).

Assays Based on De Novo Enzyme Biosynthesis in Bacteria

Toxic chemicals can also decrease the de novo biosynthesis of inducible enzymes in bacteria. A commercial toxicity assay, based on the inhibitory effect of chemicals on β-galactosidase biosynthesis, has been developed and marketed as Toxi-Chromotest (53). This test was successfully applied to wastewater treatment plants and revealed a decrease in toxicity in a large plant in Jacksonville, Florida (54). It was, however, less sensitive than assays with *Daphnia pulex, Ceriodaphnia dubia*, and Microtox (54,55). A monitoring program for nuclear and hydroelectric facilities in Ontario, Canada, has shown the low sensitivity of Toxi-Chromotest, which displayed a poor correlation with the *D. magna* acute test (56).

The effect of toxicants on the de novo biosynthesis of other inducible enzymes (tryptophanase in *E. coli* and α-glucosidase in *Bacillus licheniformis*) was also investigated (57,58).

Bacterial Biosensors

Another advantage of using bacteria as test microorganisms in toxicity monitoring is their amenability to genetic manipulations, which would allow their use for targeting specific toxic chemicals. The construction of a bacterial biosensor involves the inclusion of both sensing and reporter elements. There is a wide variety of sensing elements that detect different classes of toxicants or stresses. The most convenient reporter system used in bacterial biosensors are the *lux* genes from *Vibrio fischeri* (59). The *lux* system contains seven genes, five of which are generally used in the reporter system. *Lux A* and *lux B* code for the enzyme luciferase, whereas *lux C, D*, and *E* code for an aldehyde (60).

Target compounds detected by bacterial biosensors include heavy metals (61–64) and hydrophobic organic compounds (65,66). Bacterial biosensors using *Alcaligenes eutrophus* and designed to specifically detect the bioavailability of individual or mixtures of heavy metals contain a reporter gene (*luxCDABE*) under the control of genes involved in bacterial resistance to metals (61,62). An *E. coli arsB: luxAB* luciferase gene fusion strain has been used for the specific detection of arsenic and responded to the presence of chromated copper arsenate traditionally used for wood preservation. This biosensor had a detection limit of 10 μg/L arsenic (67).

Others have constructed *E. coli*–based biosensors, which are less specific but are able to detect different categories of stresses, including heat shock, oxidative (peroxide and oxygen radicals), or DNA-damaging stresses (68,69). The use of a panel of five of such *E. coli* constructs showed oxidative (oxygen radicals) and DNA-damaging stresses in industrial wastewater (59).

Nitrifying Bacteria

In the nitrogen cycle, nitrification probably is the process most sensitive to the deleterious effect of toxicants. Nitrification is driven by chemoautotrophic bacteria such as *Nitrosomonas*, which oxidizes NH_4 to NO_2, and *Nitrobacter*, which oxidizes NO_2 to NO_3. Both bacteria are sensitive to a wide range of chemicals but, although *Nitrosomonas* is more sensitive to toxicants than *Nitrobacter*, the latter was the most used in toxicity testing. Toxicity tests are needed to monitor the risk of nitrification inhibition in wastewater treatment plants in order to meet standards for ammonia discharge (see ACTIVATED SLUDGE — MICROBIOLOGY OF NITROGEN REMOVAL). These tests are based on measuring the rate of formation of NO_2 and/or NO_3, NH_4 removal rate, or respiration inhibition.

Gernaey and coworkers (70) used a rapid (14-minute) test based on respiration inhibition of a nitrifying sludge culture. The test was quite sensitive to organic toxicants (EC_{50} of 2.67 mg/L for phenol and 0.51 mg/L for 3,5-dichlorophenol) but not as sensitive to metals (EC_{50} of 173 mg/L for Cu^{2+} and 8.3 mg/L for Cd^{2+}). Due to its relatively short response time, this method is amenable to on-line operation in a treatment plant. Others have considered fixed-film nitrifying bioreactors to measure respiration inhibition by toxicants (71). Hayes and coworkers (72) developed Amtox^{TM}, an on-line monitor based on inhibition of cultures of nitrifying bacteria immobilized in a polyvinyl alcohol (PVA) matrix. The bacterial monitor is preceded by a carbon removal stage. Amtox^{TM} was used in a large wastewater treatment plant and revealed low chronic inhibition followed by peaks of acute inhibition caused by the incoming wastewater.

Nitrobacter was also used in the toxicity identification evaluation (TIE) of wastewater from a forest product processing industry. Resin acids and unsaturated fatty acids were shown to be responsible for the observed toxicity (73).

Algal Toxicity Assays

Algal assays are generally conducted as flask or 96-well microplate assays. Comparative studies have shown that the results obtained with both systems are comparable. Microplate-based toxicity tests using microalgae (e.g., *Selenastrum, Chlamydomonas, Scenedesmus, Chlorella, Anabaena*) as test organisms have been proposed as cost-effective and relatively simple assays for toxicity testing (74,75). These tests generally are based on inhibition of algal growth or ATP content and sometimes inhibition of esterase activity (76). The tests can be carried out with

unialgal cultures or with a battery of algal cultures to obtain more ecotoxicological information (32,77). To avoid culture maintenance, some have proposed to cryopreserve the algal cells (78). An Algaltoxkit is now being marketed to facilitate the use of algal assays by wastewater treatment plants operators and others interested in environmental monitoring for toxic substances. The kit is also based on inhibition of algal growth, as measured spectrophotometrically at 670 nm. The algal seed is provided as cells immobilized in alginate, which eliminate the need to maintain algal cultures in the laboratory (79,80).

Algal tests have been recommended as standard procedures for determining the toxicity of environmental samples in several countries. They also have been used for the determination of toxicity in domestic and industrial wastewaters (32,80–83) and sanitary landfill leachates (84). Algal toxicity assays are discussed in more details by Blaise (this encyclopedia).

Ciliated Protozoa

Ciliated protozoa are unicellular protista that are widely distributed in the environment and play a crucial role in ecological food chains. They serve as a link between the microbial and the zooplankton communities. Ciliates found in activated sludge plants (see PROTOZOA IN ACTIVATED SLUDGE) are quite sensitive to metals such as Cd, Cu, and Hg (85). Protozoan grazing on bacteria (i.e., bacterivory) is an important process implicated in the treatment of domestic wastewater. Such grazing has been shown to be significantly reduced in the presence of toxicants (e.g., heavy metals). For example, *Aspidisca costata* grazing on bacteria in activated sludge is reduced in the presence of cadmium (86). The wide distribution of protozoa and their significant role in food chains make them desirable test organisms to be used in toxicity testing in the environment. The ciliate genera most used in toxicity tests are *Tetrahymena, Paramecium, Colpidium, Colpoda*, and *Euplotes*, and the general parameters selected most to evaluate the response of ciliates to toxicants are growth inhibition, survival, respiration, ingestion rates, and chemoattraction inhibition tests (87). A relatively recent toxicity test is based on measuring the impact of toxicants on the rate of ingestion of fluorescent latex microspheres by ciliates (88). However, this test necessitates the use of relatively expensive beads and a fluorescent microscope. Another rapid test is the inhibition of the chemotactic response of ciliates to yeast extract, which serves as an attractant. This test helped evaluate the toxicity of an effluent from the metal-plating industry but did not perform as well with a paper mill effluent because the ciliates were found to be attracted to it (89,90).

Ciliates are ecologically important organisms, and their response to toxicants in complex effluents deserve to be evaluated in a battery of toxicity tests. However, there is a need for standardized procedures regarding their use as test organisms in toxicity testing.

Respirometry

The rate of oxygen uptake by microorganisms is a useful parameter used to measure the acute effect of toxic chemicals and other insults to microorganisms (91). The earliest approach for measuring respiration rates in wastewater is via manometry (e.g., Warburg-type manometer). Electrolytic respirometers avoid, however, the drawbacks of manometers (e.g., oxygen limitation) by including reoxygenation by electrolysis. Dissolved oxygen can also be directly measured via titrimetric methods, oxygen electrodes that are sometimes incorporated in flow-through devices, or electrodes incorporating immobilized microorganisms. Biosensors using pure microbial cultures (e.g., *Bacillus subtilis, Clostridium butyricum, Trichosporon cutaneum*) or mixtures of activated sludge microorganisms have all been considered for biochemical oxygen demand (BOD) estimation in wastewater.

Toxicity tests based on respiration inhibition generally are carried out over time periods ranging from minutes to days in the presence of substrates such as wastewater, synthetic wastewater, or pure organic compounds (e.g., glucose, amino acids). The test biological component can be a pure culture of bacteria or mixed cultures as found in wastewater and activated sludge. Mixed cultures are used in the BOD inhibition method. The method varies according to the type of information needed to be drawn from the respiration inhibition test. On-line measurement of oxygen uptake can be useful for detecting toxic shocks in activated sludge systems (92). Rodtox (Rapid Oxygen Demand and TOXicity), an on-line device that measures the endogenous and exogenous respiration rate of microorganisms in an activated sludge sample taken from the plant under investigation, was useful in pinpointing the source of toxic input to the Antwerp, Belgium, wastewater treatment plant (93).

CONCLUSION

Microorganisms are suitable alternate or complementary tools for carrying out toxicity testing in environmental samples. They offer numerous advantages (see Table 1) that make them attractive for toxicity assessment in wastewater and effluents from municipal and industrial treatment plants. We have seen that several approaches have been taken to achieve this goal. The nine types of microbiotests described in this review can give a reasonable account of the impact of toxic chemicals on wastewater treatment plants and receiving waters. Biosensors are not "typical" toxicity tests but include a biological component that indicates the presence of a given toxicant in the sample. Enzymes, especially the dehydrogenases, have also been considered in assessing wastewater toxicity. Some of the enzymes respond to selective categories of toxicants. An example is the inhibition of β-galactosidase activity in MetPAD/MetPLATE kits that selectively detect heavy metal toxicity.

A useful application of microbiotests is their use in toxicity identification evaluation (TIE) and toxicity reduction evaluation (TRE) proposed by the U.S. EPA (94,95). TIE and TRE entail a series of tests that determine the source of effluent toxicity, the specific causative toxicant(s), and the effectiveness of pollution control measures to reduce effluent toxicity. These fractionation schemes generate more than 50 fractions per sample, which can be conveniently and rapidly tested using microbiotests.

A battery-of-tests approach has been suggested because no single microbiotest can detect all the categories of environmental toxicants with equal sensitivity. Some of the microbial toxicity tests (e.g., Microtox, Toxi-Chromotest, MetPAD/MetPLATE) are now commercially available and are utilized in wastewater treatments facilities by environmental toxicologists.

Animal and Natural Resources Institute,
Beltsville, Maryland

Infection with the protozoan parasite *Toxoplasma gondii* is one of the most common parasitic infections afflicting man and other warm-blooded animals (1). It has been found worldwide from Alaska to Australia. Nearly one-third of humanity has been exposed to this parasite (1). In most adults, it does not cause serious illness, but it can cause blindness and mental retardation in congenitally infected children and devastating disease in those with depressed immunity. It is a common cause of abortion in goats and sheep.

CLASSIFICATION

T. gondii is a coccidian parasite with cats as the definitive host, and warm-blooded animals as intermediate hosts (2). It is among the most important of parasites of animals. It belongs to:

Phylum: Apicomplexa; Levine, 1970
Class: Sporozoasida; Leukart, 1879
Subclass: Coccidiasina; Leukart, 1879
Order: Eimeriorina; Leger, 1911
Family: Toxoplasmatidae, Biocca, 1956

There is only one species of *Toxoplasma*, *T. gondii*.

Coccidia, in general, have complicated life cycles. Most coccidia are host-specific, and transmitted by a fecal-oral cycle. *Toxoplasma gondii* has adapted transmission by a fecal-oral cycle, by carnivorism, and transplacentally (1,2).

STRUCTURE AND LIFE CYCLE

The name *Toxoplasma* (toxon = arc, plasma = form) is derived from the crescent shape of the tachyzoite stage (Fig. 1). There are three infectious stages of *T. gondii* namely, the tachyzoites (in groups), the bradyzoites (in tissue cysts), and the sporozoites (in oocysts).

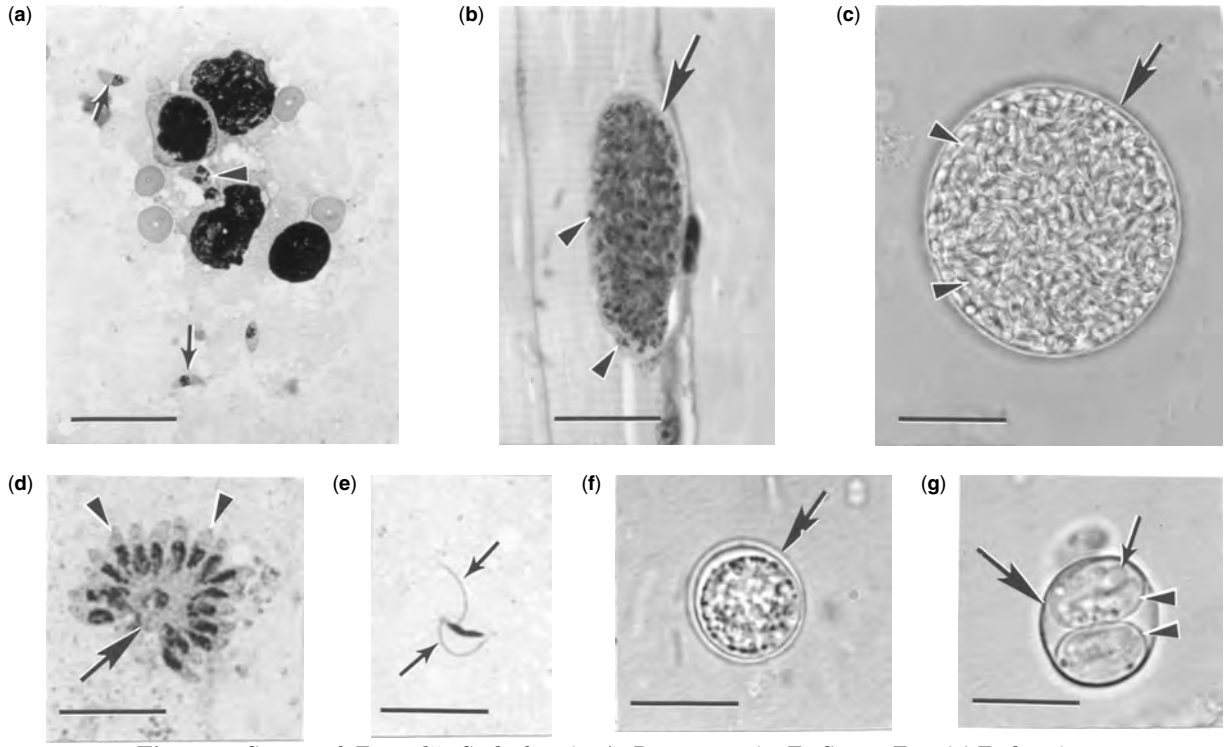

Figure 1. Stages of *T. gondii*. Scale bar in A–D = 20 μm, in E–G = 10 Fm. (**a**) Tachyzoites in impression smear of lung. Note crescent-shaped individual tachyzoites (arrows) dividing tachyzoites (arrowheads) compared with size of host red blood cells and leukocytes. Giema stain. (**b**) Tissue cysts in section of muscle. The tissue cyst wall is very thin (arrow) and encloses many tiny bradyzoites (arrowheads). Hematoxylin and eosin stain. (**c**) Tissue cyst separated from host tissue by homogenization of infected brain. Note tissue cyst wall (arrow) and hundreds of bradyzoites (arrowheads). Unstained. (**d**) Schizont (arrow) with several merozoites (arrowheads) separating from the main mass. Impression smear of infected cat intestine. Giemsa stain. (**e.**) A male gamete with two flagella (arrows). Impression smear of infected cat intestine. Giemsa stain. (**f**) Unsporulated oocyst in fecal float of cat feces. Unstained. Note double-layered oocyst wall (arrow) enclosing a central undivided mass. (**g**) Sporulated oocyst with a thin oocyst wall (large arrow), 2 sporocysts (arrowheads). Each sporocyst has four sporozoites (small arrow) that are not in complete focus. Unstained.

The tachyzoite is often crescent-shaped and is approximately the size (2×6 μm) of a red blood cell (Fig. 1a). Its anterior end is pointed and its posterior end is round. It has a pellicle (outer covering), several organelles including subpellicular microtubules, mitochondrium, endoplasmic reticulum, a Golgi apparatus, apicoplast, ribosomes, rough-surfaced endoplasmic reticulum, a micropore, and a well-defined nucleus. The nucleus is usually situated toward the posterior end or in the central area of the cell.

The tachyzoite enters the host cell by active penetration of the host cell membrane and can tilt, extend, and retract as it searches for a host cell. After entering the host cell, the tachyzoite becomes ovoid in shape and becomes surrounded by a parasitophorous vacuole. *Toxoplasma gondii* in a parasitophorous vacuole is protected from the defense mechanisms of the host. The tachyzoite multiplies asexually within the host cell by repeated divisions in which two progeny form within the parent parasite, consuming it (Fig. 1a). Tachyzoites continue to divide until the host cell is filled with parasites.

After a few divisions, *T. gondii* form another stage called *tissue cysts*. Tissue cysts grow and remain intracellular. Tissue cysts vary in size from 5 to 70 μm (Figs. 1b,c). Although tissue cysts may develop in visceral organs, including lungs, liver, and kidneys, they are more prevalent in muscular and neural tissues (Fig. 1b), including the brain (Fig. 1c), eye, skeletal, and cardiac muscle. Intact tissue cysts probably do not cause any harm and can persist during the life of the host.

The tissue cyst wall is elastic, thin (<0.5 μm), and may enclose hundreds of the crescent-shaped slender *T. gondii* stage known as *bradyzoites* (Fig. 1c). The bradyzoites are approximately 7×1.5 μm. Bradyzoites differ structurally only slightly from tachyzoites. They have a nucleus situated toward the posterior end, whereas the nucleus in tachyzoites is more centrally located. Bradyzoites are more slender than tachyzoites and less susceptible to destruction by proteolytic enzymes.

All coccidian parasites have a resistant stage in their life cycle, called *oocyst*. Oocysts of *T. gondii* are formed only in cats, not only domestic cats, but probably all members of the Felidae (Fig. 2). Cats shed oocysts after ingesting any of the three infectious stages of *T. gondii*, namely, tachyzoites, bradyzoites, and sporozoites (3–5). Prepatent periods (time to the shedding of oocysts after initial infection) and frequency of oocyst shedding vary according to the stage of the *T. gondii* ingested. Prepatent periods are three to ten days after ingesting tissue cysts and 21 days or more after ingesting tachyzoites or oocysts (3–5). Less than 50% of cats shed oocysts after ingesting tachyzoites or oocysts, whereas nearly all cats shed oocysts after ingesting tissue cysts (4).

After the ingestion of tissue cysts by cats, the tissue cyst wall is dissolved by the proteolytic enzymes in the stomach and small intestine. The released bradyzoites penetrate the epithelial cells of the small intestine and initiate the development of numerous generations of asexual and sexual cycles of *T. gondii* (3). *Toxoplasma gondii* multiplies profusely in intestinal epithelial cells of cats (entero-epithelial cycle) and these stages are known as *schizonts* (Fig. 1d). Organisms (merozoites) released from schizonts form male and female gametes. The male gamete has two flagella (Fig. 1e) and it swims to and enters the female gamete. After the female gamete is fertilized by the male gamete (Fig. 1e), oocyst wall formation begins around the fertilized gamete. When oocysts are mature, they are discharged into the intestinal lumen by the rupture of intestinal epithelial cells.

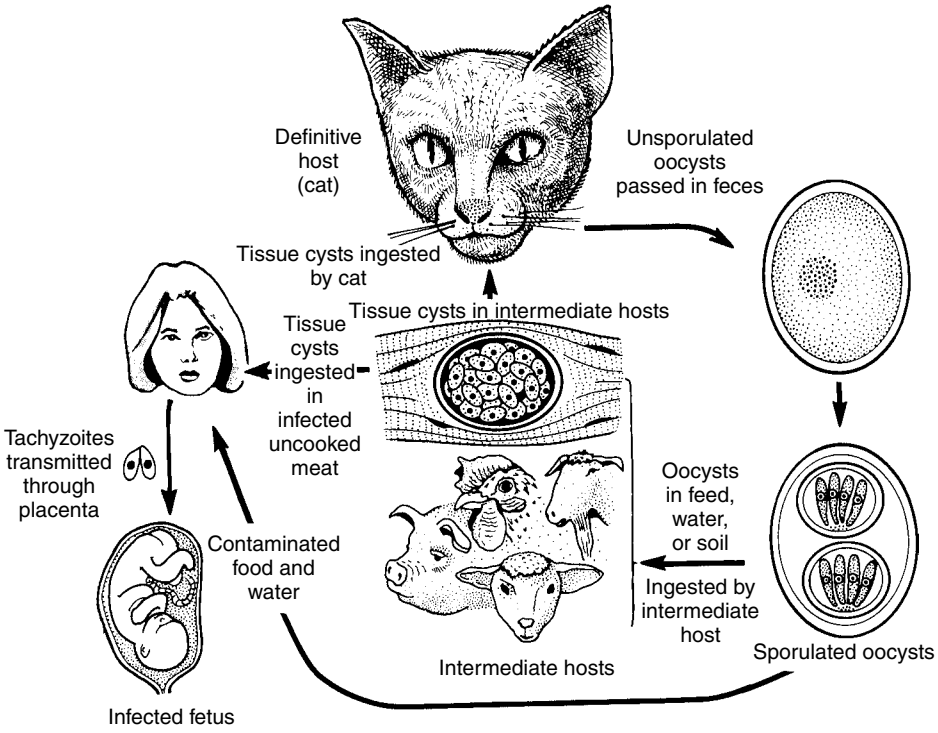

Figure 2. Life cycle of *T. gondii*.

In freshly passed feces, oocysts are unsporulated (noninfective). Unsporulated oocysts are subspherical to spherical and are 10×12 μm in diameter (Fig. 1f). They sporulate (become infectious) outside the cat within one to five days, depending on aeration and temperature. Sporulated oocysts contain two ellipsoidal sporocysts (Fig. 1g). Each sporocyst contains four sporozoites. The sporozoites are 2×6 to 8 μm in size.

As the entero-epithelial cycle progresses, bradyzoites penetrate the lamina propria of the feline intestine and multiply as tachyzoites. Within a few hours after the infection of cats, *T. gondii* may disseminate to extraintestinal tissues. *Toxoplasma gondii* persists in intestinal and extraintestinal tissues of cats for at least several months, and possibly for the entire lifespan of the cat.

CULTIVATION, MOLECULAR BIOLOGY, AND GENETICS

Toxoplasma gondii has not been grown in cellfree media. It can be cultivated in laboratory animals, chick embryos, and cell cultures. Mice, hamsters, guinea pigs, and rabbits are all susceptible, but mice are generally used as hosts because they are more susceptible than the others and are not naturally infected when raised in the laboratory on commercial dry food that is free of cat feces.

Toxoplasma gondii tachyzoites will multiply in many cell lines in cell culture. Although most strains of *T. gondii* can develop tissue cysts in cell cultures, the yield is lower than that produced by infection in mice. Feline entero-epithelial stages of *T. gondii* have not yet been cultivated in vitro. Oocysts can be obtained by feeding tissue cysts from infected mice to *T. gondii*–free cats.

The *T. gondii* nucleus is haploid except for the zygote, in the intestine of the cat (6). Sporozoites result from a miotic division followed by mitotic divisions, and genetic segregation seems to follow classical Mendelian laws. The total haploid genome contains approximately 8×10^7 base pairs. There is also a 36- kb circular mitochondrial DNA. Nine chromosomes have been identified by pulsed field gel electrophoresis. Unlike many other microorganisms, *T. gondii* is very stable with very little mutation. Although minor differences exit among different isolates of *T. gondii* so far analyzed, at present there is no definitive way to classify or type the different isolates of *T. gondii* because they are all morphologically identical and all cross-react immunologically. On the basis of antigens, isoenzymes, antigens, and DNA characteristics, all *T. gondii* isolates can be broadly grouped into three types (types I,II,III) (7–10). Although type I strains have been isolated from patients with symptoms, a definitive association of virulence with the type has not been established. Variations among the three types are being recognized (11).

HOST–PARASITE RELATIONSHIP

Toxoplasma gondii can multiply in virtually any cell in the body. How *T. gondii* is destroyed in immune cells is not completely known (12). All extracellular forms of the parasite are directly affected by antibodies, but intracellular forms are not. It is believed that cellular factors, including lymphocytes and lymphokines, are more important than humoral factors in the immune-mediated destruction of *T. gondii* (12).

Immunity does not eradicate infection. *Toxoplasma gondii* tissue cysts persist several years after acute infection. The fate of tissue cysts is not fully known. Whether bradyzoites can form new tissue cysts directly, without transforming into tachyzoites, is not known. It has been proposed that tissue cysts may at times rupture during the life of the host. The released bradyzoites may be destroyed by the host's immune responses. The reaction may cause local necrosis accompanied by inflammation. Hypersensitivity plays a major role in such reactions (12). After such events, inflammation usually again subsides with no local renewed multiplication of *T. gondii* in the tissue, although occasionally there may be a formation of new tissue cysts.

In immunosuppressed patients, such as those given large doses of immunosuppressive agents in preparation for organ transplants and in those with AIDS, rupture of a tissue cyst may result in the transformation of bradyzoites into tachyzoites and renewed multiplication. The immunosuppressed host may die from toxoplasmosis unless treated. It is not known how corticosteroids cause relapse, but it is unlikely that they directly cause rupture of the tissue cysts.

Pathogenicity of *T. gondii* is determined by the virulence of the strain and the susceptibility of the host species. Strains of *T. gondii* may vary in their pathogenicity in a given host. Certain strains of mice are more susceptible than others and the severity of infection in individual mice within the same strain may vary. Certain species are genetically resistant to clinical toxoplasmosis. For example, adult rats do not become ill, whereas young rats can die of toxoplasmosis. Mice of any age are susceptible to clinical *T. gondii* infection. Adult dogs, like adult rats, are resistant, whereas puppies are fully susceptible to clinical toxoplasmosis. Cattle and horses are among the hosts more resistant to clinical toxoplasmosis, whereas certain marsupials and New World monkeys are the most susceptible to *T. gondii* infection (1). Nothing is known concerning genetically determined susceptibility to clinical toxoplasmosis in higher mammals, including humans.

INFECTIONS IN HUMANS

Toxoplasma gondii infection is widespread among humans and its prevalence varies widely from place to place. In the United States and the United Kingdom, it is estimated that about 16 to 40% of people are infected, whereas in Central and South America and continental Europe, estimates of infection range from 50 to 80% (1). Most infections in humans are asymptomatic, but at times, the parasite can produce devastating disease. Infection may be congenitally or postnatally acquired. Congenital infection occurs only when a woman becomes infected during pregnancy, and the severity of the disease may depend on the stage of pregnancy when the woman becomes infected. Infections

acquired during the first trimester are more severe than those acquired in the second and third trimester (13,14). Although the mother rarely has symptoms of infection, she does have a temporary parasitemia. Focal lesions develop in the placenta and the fetus may become infected. At first, there is a generalized infection in the fetus. Later, infection is cleared from the visceral tissues and may localize in the central nervous system. A wide spectrum of clinical diseases occurs in congenitally infected children (13). Mild disease may consist of slightly diminished vision, whereas severely diseased children may have the full tetrad of signs: retinochoroiditis (inflammation of inner layers of eye), hydrocephalus (big head), convulsions, and intracerebral calcification. Of these, hydrocephalus is the least common but most dramatic lesion of toxoplasmosis. By far the most common sequel of congenital toxoplasmosis is ocular disease (13,14).

The socio-economic impact of toxoplasmosis in humans suffering and the cost of the care of sick children, especially those with mental retardation and blindness, are enormous (15,16). The testing of all pregnant women for *T. gondii* infection is compulsory in some European countries including France and Austria. The cost benefits of such mass screening are being debated in many other countries (14).

Postnatally acquired infection may be localized or generalized. Oocyst-transmitted infections may be more severe than tissue cyst–induced infections (1,17–21). Enlarged lymph nodes are the most frequently observed clinical form of toxoplasmosis in humans (Table 1). Lymphadenopathy may be associated with fever, fatigue, muscle pain, sore throat, and headache. Although the condition may be benign, its diagnosis is vital in pregnant women because of the risk to the fetus. In a British Columbia outbreak, of 100 people who were diagnosed with acute infection, 51 had lymphadenopathy and 20 had retinitis (18,19).

Table 1. Frequency of Symptoms in People with Postnatally Acquired Toxoplasmosis

	Patients with Symptoms (%)	
Symptoms	Atlanta Outbreak[a] (35 Patients)	Panama Outbreak[b] (35 Patients)
Fever	94	90
Lymphadenopathy	88	77
Headache	88	77
Myalgia	63	68
Stiff neck	57	55
Anorexia	57	NR[c]
Sore throat	46	NR
Arthralgia	26	29
Rash	23	0
Confusion	20	NR
Earache	17	NR
Nausea	17	36
Eye pain	14	26
Abdominal pain	11	55

[a] From Teutsch et al., (20).
[b] From Benenson et al., (17).
[c] Not reported.

Encephalitis is the most important manifestation of toxoplasmosis in immunosuppressed patients because it causes the most severe damage to the patient (1). Infection may occur in any organ. Patients may have headache, disorientation, drowsiness, hemiparesis, reflex changes, and convulsions, and many become comatose. Encephalitis caused by *T. gondii* is now recognized with great frequency in patients treated with immunosuppressive agents.

Toxoplasmosis ranks high on the list of diseases that lead to the death of the patients with acquired immunodeficiency syndrome (AIDS); approximately 10% of AIDS patients in the United States and up to 30% in Europe are estimated to die from toxoplasmosis (22) Although in AIDS patients, any organ may be involved, including the testis, dermis, and the spinal cord, infection of the brain is most frequently reported. Most AIDS patients suffering from toxoplasmosis have bilateral, severe, and persistent headache that responds poorly to analgesics. As the disease progresses, the headache may give way to a condition characterized by confusion, lethargy, ataxia, and coma. The predominant lesion in the brain is necrosis, especially of the thalamus (23).

INFECTION IN ANIMALS OTHER THAN HUMANS

Toxoplasma gondii is capable of causing severe disease in animals other than humans (1). Toxoplasmosis causes great losses in sheep and goats. *Toxoplasma gondii* may cause embryonic death and resorption, fetal death and mummification, abortion, stillbirth, and neonatal death in these animals. Disease is more severe in goats than in sheep. Outbreaks of toxoplasmosis in pigs have been reported from several countries, especially Japan. Mortality in young pigs is more common than mortality in adult pigs. Pneumonia, myocarditis, encephalitis, and placental necrosis have been reported to occur in infected pigs. Sporadic and widespread outbreaks of toxoplasmosis occur in rabbits, mink, birds, and other domesticated and wild animals.

DIAGNOSIS

Diagnosis is made by biological, serological, or histological methods or by some combination of these. Clinical signs of toxoplasmosis are nonspecific and are not sufficiently characteristic for a definite diagnosis. Toxoplasmosis, in fact, mimics several other infectious diseases.

Detection of *T. gondii* antibody in patients may aid diagnosis. There are numerous serological procedures available for the detection of humoral antibodies; these include the Sabin-Feldman dye test, the indirect hemagglutination assay, the indirect fluorescent antibody assay (IFA), the direct agglutination test, the latex agglutination test, the enzymelinked immunoabsorbent assay (ELISA), and the immunoabsorbent agglutination assay test (IAAT). The IFA, IAAT, and ELISA have been modified to detect IgM antibodies (2,14). The IgM antibodies appear sooner after infection than the IgG antibodies, and the IgM antibodies disappear faster than IgG antibodies after recovery (14).

The finding of antibodies to *T. gondii* in one serum sample only establishes that the host had been infected at some time in the past. It is best to collect two samples from the same individual, the second sample two to four weeks after the first. A 16-fold higher antibody titer in the second sample indicates an acute infection. A high antibody titer sometimes persists for months after the infection. A rise may not be associated with clinical symptoms for, as indicated earlier, most infections in humans are asymptomatic. The fact that titers persist in infected people after clinical recovery complicates the interpretation of the results of the serological tests. Establishing the recency of infection in pregnancy is of clinical importance with respect to medical intervention to minimize damage to the fetus, and there is not a single test that can achieve this at the present.

Toxoplasma gondii can be isolated from patients by inoculation of laboratory animals and tissue cultures with secretions, excretions, body fluids, tissues taken by biopsy and tissues with macroscopic lesions, taken postmortem. Using such specimens, one may not only attempt isolation of *T. gondii*, but may search for *T. gondii* microscopically or for toxoplasmal DNA by the use of the polymerase chain reaction (24).

As just noted, diagnosis can be made by finding *T. gondii* in the host tissue removed by biopsy or at necropsy. A rapid diagnosis may be made by the microscopic examination of the impression smears of lesions. After drying for 10 to 30 minutes, the smears are fixed in methyl alcohol and stained with one of the Romanowsky strains, the Giemsa stain being very satisfactory. Well preserved *T. gondii* are crescent-shaped (Fig. 1a). In the sections, the tachyzoites usually appear round to oval. Electron microscopy can aid diagnosis. Tachyzoites of *T. gondii* are always located in vacuoles. Tissue cysts are usually spherical, lack septa, and the cyst wall can be stained with a silver stain. The bradyzoites are strongly periodic acid Schiff (PAS) positive. The immunohistochemical staining of parasites with *T. gondii* antiserum can aid in diagnosis.

TREATMENT

Sulfadiazine and pyrimethamine (Daraprim) are two drugs widely used for the therapy of toxoplasmosis (25). Although these drugs have a beneficial action when given in the acute stage of the disease process, when there is active multiplication of the parasite, they usually will not eradicate infection. It is believed that these drugs have little effect on subclinical infections, but the growth of tissue cysts in mice has been restrained with sulfonamides.

Certain other drugs, diaminodiphenylsulfone, atovaquone, spiramycin, and clindamycin are also used to meet toxoplasmosis in difficult cases.

EPIDEMIOLOGY

As noted earlier, toxoplasmosis may be acquired by the ingestion of oocysts or by the ingestion of tissue-inhabiting stages of the parasite. The contamination of the environment by oocysts is widespread because oocysts are shed by cats, not only the domestic cat, but by other members of the Felidae as well (1,2). Domestic cats are probably the major source of contamination because oocyst formation is greatest in the domestic cats, and they are extremely common. Widespread natural infection of the environment is possible because a cat may excrete millions of oocysts after ingesting as few as one bradyzoite or one tissue cyst and many tissue cysts maybe present in one infected mouse (3,26). Sporulated oocysts survive for long periods under most ordinary environmental conditions. They can survive in moist soil, for example, for months and even years (1). Oocysts in soil do not always stay there because invertebrates such as flies, cockroaches, dung beetles, and earthworms can mechanically spread these oocysts and even carry them onto food.

Although a few cats may be shedding *T. gondii* oocysts at any given time (as few as 1%), the enormous numbers shed and their resistance to destruction assures widespread contamination. Under experimental conditions, infected cats can shed oocysts after reinoculation with tissue cysts (27). If this occurs in nature, it would greatly facilitate the spread of oocyst. Congenital infection can also occur in cats, and congenitally infected kittens can excrete oocysts, providing another source of oocysts for contamination. Infection rates in cats are determined by the rate of infection in the local avian and rodent population because cats are thought to become infected by eating these animals. The more oocysts in the environment, the more likely prey animals would be infected, and this in turn would increase the infection rate in cats.

Infection in humans is probably most often the result of the ingestion of tissue cysts contained in undercooked meat (1, 28, 29). Infection by *T. gondii* is common in many animals used for food including sheep, pigs, and rabbits. Prevalence is very high (80%) in bears in the United States. Infection in cattle is less prevalent than is infection in sheep or pigs. *Toxoplasma gondii* in tissue cysts survive in animals used for food for years.

Cultural habits of people may affect the acquisition of *T. gondii* infection. For example, in France, the prevalence of antibody to *T. gondii* is very high in humans. Although 84% of pregnant women in Paris have antibodies to *T. gondii*, only 32% in New York City and 22% in London have such antibodies (1). The high incidence of *T. gondii* infection in humans in France appears to be related, in part, to the French habit of eating some of their meat raw. In contrast, the high prevalence of *T. gondii* infection in Central and South America probably is a result of the high levels of contamination of the environment by oocysts (1). However, it should be noted that the relative frequency of the acquisition of toxoplasmosis from eating raw meat and that caused by the ingestion of food contaminated by oocysts from cat feces is very difficult to determine and as a result, statements on the subject are at best controversial.

There is little, if any, danger of *T. gondii* infection by drinking cow's milk and, in any case, cows milk is generally pasteurized or even boiled, but drinking goat's milk without boiling it has led to infection (1). Raw hens' eggs, although an important source of *Salmonella* infection, are extremely unlikely to transmit *T. gondii* infection.

Transmission by sexual activity, including kissing, is probably rare and epidemiologically unimportant (1).

Transmission may occur through blood transfusions and organ transplants. Of these means, transmission by transplantation is most important. Toxoplasmosis may actually arise in two ways in people undergoing transplantation, namely, from the implantation of an organ or bone marrow of an infected donor into a nonimmune immunocompromised recipient and from the induction of disease in an immunocompromised, latently infected recipient. The tissue cysts in the transplacental tissue or in the latently infected are probably the source of the infection. In both cases, the cytotoxic and immunosuppressive therapy given to the recipient is the cause of the induction of the active infection and the disease (1,12).

Reservoirs and Detection of *T. gondii* in the Environment

As mentioned earlier, humans become infected by ingesting tissue cysts in undercooked or uncooked meat or by ingesting food and water contaminated with oocysts from infected cat feces. There are no tests at the present time to determine the source of infection in a given person. All the evidence is based on epidemiological surveys. For example, in certain areas of Brazil, approximately 60% of the six- to eight-year-old children have antibodies to *T. gondii* linked to the ingestion of oocysts from the environment heavily contaminated with *T. gondii* oocysts (30). Oocysts of *T. gondii* survive even in harsh environments for months. Infection in aquatic mammals indicates contamination and survival of the oocysts in seawater (31). The largest outbreak of clinical toxoplasmosis in humans was epidemiologically linked to the drinking of water from a municipal water reservoir in British Columbia, Canada (32). This water reservoir was thought to be contaminated with *T. gondii* oocysts excreted by cougars (*Felis concolor*) (33,34).

Oocysts can be detected by an examination of cat feces. Concentration methods (e.g., flotation in high-density sucrose solution) are often used because the number of *Toxoplasma gondii* oocysts in cat feces may be too few to be detected by a direct smear (Fig. 3). For definitive identification, *T. gondii* oocysts should be sporulated and then bioassayed in mice to distinguish them from other related coccidians (1).

For epidemiological surveys, detection of *T. gondii* oocysts in cat feces is not very practical; at any given time, only 1% of cats are found shedding oocysts because oocysts are shed for only a short period (one to two weeks) in the life of the cat (1). Determining serological prevalence is a better measure of exposure of cats to *T. gondii* infection than detection of oocysts. It is a fair assumption that cats that are seropositive have already shed *T. gondii* oocysts. In an epidemiological survey on *T. gondii* infection on pig farms, *T. gondii* oocysts were detected in only 5 of 274 (1.8%) samples of cat feces, 2 of 491 (0.4%) samples of feed, and 1 of 79 (1.3%) samples of soil on some farms; 267 of 391 (68.3%) cats had antibodies to *T. gondii* (35).

Although *T. gondii* has been isolated from soil, there is no simple method for use on an epidemiological scale.

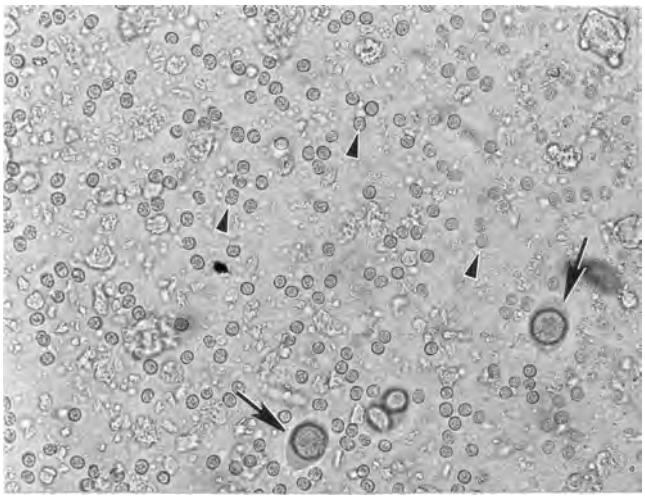

Figure 3. *Toxoplasma gondii* oocysts in sugar fecal float of an infected cat. Note many spherical *T. gondii* oocysts (arrowheads). Also note oocysts of *Isospora felis* (arrows), which are often present in cat feces. *Isospora felis* is the most common coccidium of cats. Its oocysts are about four times the size of *T. gondii* oocysts and they are often in a different focus than *T. gondii* oocysts.

Bioassay of soil samples in pigs and chickens may be more useful than the direct determination of oocysts in soil; pigs can be infected by feeding on as few as one oocyst (36). In a study of feral chickens, *T. gondii* was isolated from 54% of 50 chickens by bioassay in mice (37). Because feral chickens on small farms feed on the ground, finding *T. gondii* in chickens is a good indicator of infection in the environment. Although attempts to recover *T. gondii* oocysts from water samples in the British Columbia outbreak were unsuccessful, methods to detect oocysts were reported (32). At present, there are no commercial reagents available to detect *T. gondii* oocysts in the environment.

As stated earlier, among food animals, infection is more prevalent in sheep, goats, pigs, and rabbits than in cattle, horses, and water buffaloes (1). Virtually, all edible portions of an animal can harbor viable *T. gondii*. In one study, viable *T. gondii* was isolated from 17% of 1,000 adult pigs (sows) from a slaughter plant in Iowa (38). *Toxoplasma gondii* infection is also prevalent in game animals. Among wild game, *T. gondii* infection is most prevalent in black bears and in white-tailed deer. Approximately 80% of the black bears are infected in the United States (39), and about 60% of the raccoons have antibodies to *T. gondii* (35,39). As raccoons and bears scavenge for their food, infection in these animals is a good indicator of the prevalence of *T. gondii* in the environment.

The number of *T. gondii* in meat from food animals is very low. It is estimated that as few as one tissue cyst may be present in 100 grams of meat. Therefore, without using a concentration method, it is not practical to detect this low level of *T. gondii* infection. Therefore, digestion of meat samples in trypsin or pepsin is used to concentrate the *T. gondii* in meat (40). Digestion in trypsin and pepsin ruptures the *T. gondii* tissue cyst wall releasing hundreds of bradyzoites. The bradyzoites survive in the digests for several hours. Even in the digested samples, only a few

T. gondii are present and their identification by direct microscopic examination is not practical. Therefore, the digested material is bioassayed in mice (40). The mice inoculated with digested material have to be kept for six to eight weeks before *T. gondii* infection can be detected reliably; this procedure is not practical for mass scale samples. The detection of *T. gondii* DNA in meat samples by PCR has been reported (41) but there are no data on specificity and sensitivity of this method to detect *T. gondii* in meat samples. A highly sensitive method using a real-time PCR and fluorogenic probe was found to detect *T. gondii* DNA from as few as four bradyzoites (42). This method is now being tested to detect *T. gondii* in meat samples obtained from slaughtered animals.

PREVENTION AND CONTROL

To prevent infection of human beings by *T. gondii*, the hands of people handling meat should be washed thoroughly with soap and water before they go to other tasks (1,29). All cutting boards, sink tops, knives, and other materials coming in contact with uncooked meat should be washed with soap and water also. Washing is effective because the stages of *T. gondii* in meat are killed by the contact with soap and water (1).

Organisms of *T. gondii* in meat can be killed by exposure to extreme cold or heat. Heating the meat throughout to 67 °C kills the tissue cysts in it (43). *Toxoplasma gondii* in meat is killed by cooling to −13 °C (44). *Toxoplasma* in tissue cysts is also killed by exposure to 0.5 kilorads of gamma irradiation (45). Meat of any animal should be cooked to 67 °C before consumption, and tasting meat while cooking or while seasoning should be avoided. Pregnant women, especially, should avoid contact with cats, soil, and raw meat. Pet cats should be fed only dry, canned, or cooked food. The cat litter box should be emptied everyday, preferably not by a pregnant woman. Gloves should be worn while gardening. Vegetables should be washed thoroughly before eating because they may have been contaminated with cat feces. Expectant mothers should be aware of the dangers of toxoplasmosis (46). At present, there is no vaccine to prevent toxoplasmosis in humans.

CONCLUSION

Infection by the protozoan parasite *T. gondii* is widely prevalent in humans and animals. Although it causes asymptomatic infection in immunocompetent adults, *T. gondii* can cause devastating disease in congenitally infected children and those with depressed immunity. To prevent human infection, all meat should be cooked well before consumption and gloves should be worn while gardening to prevent exposure to soil contaminated with *T. gondii* oocysts excreted in cat feces.

MICROBES AND THE ATMOSPHERE

When we consider interactions between the atmosphere and microorganisms, we tend to think about atmospheric effects on microorganisms, particularly with the distinction of aerobes versus anaerobes. Alternatively, perhaps, we think on the geological timescale about evolution of cyanobacteria and creation of an aerobic Earth. We tend not to think about the critical role of ongoing microbial activities in controlling the day-to-day composition of the atmosphere. Current microbial activities have limited impact on the bulk composition of the atmosphere: the 99.96% of the atmosphere that is N_2, O_2, or argon. However, the last 0.04% of the atmosphere, the "trace gases" are absolutely critical to the atmosphere's chemistry and radiation balance.

With the exception of the inert gases (helium, argon, etc.) and some halogenated gases, such as chlorofluorocarbons (CFCs), all the trace gases are produced by and/or consumed by the biota, many by microorganisms in both marine and terrestrial ecosystems (Fig. 1). For many of these gases, microbial processes function as the major sources to the atmosphere. For some of the gases, microorganisms act as important sinks as well. Thus, to understand the dynamics of the Earth's atmosphere and global biogeochemical cycles fully, it is necessary to have an understanding of the microbial processes that control atmospheric gases. In the remainder of this entry, I will give a very brief overview of atmospheric chemistry, and then discuss the primary groups of gases, their budgets in the atmosphere, the organisms responsible for their production or consumption, the mechanisms by which they are produced, and aspects of the microbial ecology that control the process dynamics.

ATMOSPHERIC CHEMISTRY

The atmospheric concentrations and roles of trace gases are described in Table 1. Atmospheric chemistry differs dramatically between the lower atmosphere (troposphere) and the upper atmosphere (stratosphere). In the troposphere, atmospheric chemistry is dominated by oxidation reactions carried out largely through the action of hydroxyl radical (OH•). Hydroxyl radical acts as the atmosphere's general cleaning agent. For example, it reacts with CH_4, other hydrocarbons, CO, and even some halocarbons, oxidizing them to carbon dioxide (1). SO_2 is oxidized to SO_4^{2-}, whereas NO and NO_2 are oxidized to NO_3^-. Through their reaction with OH•, trace gases may affect the dynamics of other gases even though they may not react directly with each other. For example, it is thought that the increase in CH_4 leads to a reduction in OH•, and thereby to an increase in the lifetime of other gases in the atmosphere (2). Tropospheric oxidation chemistry is also important in the production and destruction of tropospheric ozone and in the production of smog.

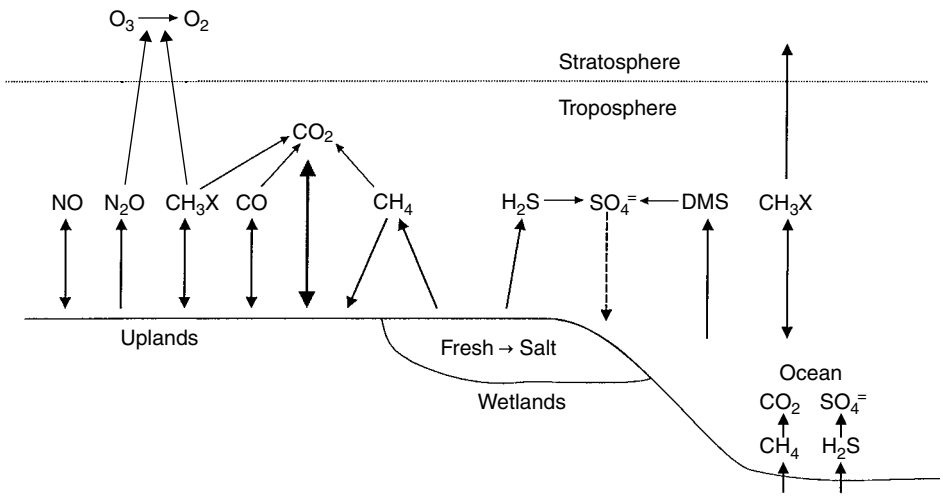

Figure 1. Overview of global trace gas dynamics.

Table 1. Characteristics of Important Atmospheric Trace Gases (Data from Refs. 2 and 3)

Compound	Current Concentration	Rate of Increase	Atmospheric Lifetime	Global Warming potential[a]	Other Effects
CO_2	370 ppm	0.4%	~100 years	1 (by definition)	
CH_4	1.8 ppm	0.6%	12 years	56	Oxidation chem.
CO	50 to 150 ppm		1 to 4 months	No direct	Oxidation chem.
CFC-11	0.27 ppb	0%	50 years	4,900 direct, net ca. 2,000	Strong ozone depleter
CH_3Cl	0.6 ppb	~0	1.5 years		Weak ozone depleter
CH_3Br	0.012 ppb	~0	1.3 year		Weak ozone depleter
N_2O	320 ppb	0.8 ppm/year	120 years	280	Ozone depleter
NO/NO_x	Variable		1 to 10 days		Oxidation chem.
Dimethyl sulfide	6 to 200 pg/L		Hours to days		Cloud formation
H_2S			Hours to days		Cloud formation

[a] 20-Year time horizon.

In the stratosphere, atmospheric chemistry is dominated by photochemical reactions, made possibly by high-energy ultraviolet (UV) radiation. The availability of UV allows the breakdown of chemicals that are inert in the troposphere. For example, N_2O is resistant to attack by OH•, but can react with an energized oxygen atom, $O(^1D)$, that is produced when ozone (O_3) is cleaved by UV. The product of N_2O breakdown reaction is two NO molecules. CFCs are also inert in the troposphere, but can be cleaved either directly by UV or through reaction with $O(^1D)$. The breakdown of CFCs in the stratosphere produces chlorine and ClO radicals. Chlorine catalyzes ozone destruction through the following reaction sequence:

$$Cl + O_3 \longrightarrow ClO + O_2$$

$$O_3 \longrightarrow O + O_2$$

$$ClO + O \longrightarrow Cl + O_2$$

$$\text{Net: } 2O_3 \longrightarrow 3O_2$$

Thus chlorine is regenerated through the reaction cycle and can cause the destruction of hundreds or thousands of ozone molecules before being "quenched" by reaction with another free radical. NO acts through a similar reaction pathway in which NO and NO_2 replace chlorine and ClO.

Many trace gases absorb infrared radiation emitted by the Earth, trapping it in the atmosphere and thereby contributing to the "greenhouse effect." The natural greenhouse effect is enough to warm the Earth by roughly 33 °C (1). Most of this is caused by water vapor and clouds, which are short-lived and variable. The long-lived trace gases, on the other hand, contribute more than 8 W/m^2 to the atmosphere (enough to cause several degrees of warming). This is an increase of 2.45 W/m^2 from preindustrial levels, and if the increase in tropospheric ozone is included, this total increase is closer to 3 W/m^2 (4). This extra energy input to the lower atmosphere is known as radiative forcing. The climate system responds to this forcing in multiple ways, including simply warming up, and through evaporating water, thus increasing humidity and rainfall. Whereas many trace gases impose a direct, positive radiative forcing on the atmosphere, some gases can have an indirect negative forcing as well. This occurs through two mechanisms. The first is through catalyzing ozone depletion. Ozone is a strong greenhouse gas, and so the gases that catalyze its destruction reduce radiative forcing (4). If the reduction in ozone is great enough, a gas may have a net cooling effect on the atmosphere (e.g., CCl_4 and some brominated compounds). The second mechanism for indirect negative radiative forcing is through stimulating cloud production. Clouds are reflective (they have a high albedo) and so they reduce energy inputs to the Earth's surface, thus cooling it. Sulfur gases, in particular are important in this. They are oxidized to SO_4^{2-}, which forms particles that act as cloud condensation nuclei (CCN). The radiative forcing caused by sulfate aerosol stimulation of cloud production is estimated currently at around -0.5 to -0.8 W/m^2 (5). The role of trace gases in atmospheric oxidation chemistry interacts with their role in radiative forcing. The overall radiative forcing caused by a greenhouse gas increases with its lifetime in the atmosphere. Therefore, if a gas reacts with OH•, it will increase the atmospheric lifetimes of other gases, and thereby increase their contribution to the overall greenhouse effect. Reducing OH• will also reduce the rate at which sulfur gases are oxidized to SO_4^{2-}, reducing the supply of CCN, also possibly increasing global warming.

CARBON DIOXIDE

The main role of carbon dioxide in the atmosphere is as a greenhouse gas. Whereas carbon dioxide is a much weaker absorber of IR radiation than most of the other gases on a molecule-by-molecule basis, it is present in much greater concentrations. Thus, carbon dioxide accounts for around 60% of the total radiative forcing caused by trace gases (4).

The biology of carbon dioxide is fundamentally different from that of other trace gases, because it is central to the metabolism of just about every living organism on Earth. It is produced by almost all heterotrophs (from bacteria to animals) as the final product of catabolism. There are only a few fermentative bacteria that do not produce carbon dioxide (e.g., lactic acid bacteria, which produce lactic acid as a sole product). It is consumed by every autotroph. Of the carbon dioxide consumed from the atmosphere, about 60% is accounted for by marine algae, whereas the remainder goes into terrestrial plants (1).

Nonphotosynthetic autotrophs are insignificant players in the carbon dioxide cycle. Because carbon dioxide is cycled by such a wide variety of organisms, and because so many specific processes are involved in its production, there is little point in even attempting to discuss the specifics of the microbiology that control its dynamics in the atmosphere.

METHANE

Importance

Methane has several important roles in the atmosphere. First, it is a greenhouse gas. It is roughly 20 to 60 times as powerful as carbon dioxide (depending on the time interval considered; 2). Beyond that, however, CH_4 is important in atmospheric oxidation chemistry. Methane is an important sink for OH•. Increasing CH_4 is thought to be partly responsible for reducing atmospheric OH• concentrations (2). Methane is also reasonably stable in the troposphere (lifetime of 12 years), and thus some fraction diffuses up into the stratosphere. When it is oxidized photochemically in the stratosphere, it produces H_2O. This is one of the few sources of stratospheric water vapor, which is required for the formation of polar stratospheric clouds: a central component in ozone depletion and the formation of the ozone hole (2). Thus, CH_4 is indirectly involved in ozone depletion.

Budget

Methane is increasing in the atmosphere at an average rate of 0.6% per year, though the rate decreased somewhat during the early 1990s (2). This small net increase, however, results from the difference in large production and consumption fluxes. The current budget estimates for CH_4 are presented in Table 2. The total estimated emission of CH_4 to the atmosphere is roughly 400 Tg CH_4-C/year. Of this only 120 Tg CH_4-C/year (29%) is thought to be from entirely natural sources (mostly wetlands). The remainder comes from various anthropogenic sources, of which 60% is still microbially produced (e.g., methanogenesis in rice paddies and cattle).

The bulk of atmospheric CH_4 is consumed by photochemical oxidation. Only about 20 to 25 Tg CH_4-C/year of atmospheric CH_4 is consumed by microorganisms (6% of total consumption), mostly by soil bacteria (Table 2). However, this is only a fraction of the total CH_4 that is consumed by microorganisms. A significant amount of the CH_4 produced in sediments and soils is consumed before it ever reaches the atmosphere. The total, gross amount of CH_4 that is actually produced on Earth is probably closer to 900 Tg CH_4-C/year, compared to the actual emissions of 400 Tg CH_4-C/year (6). Total consumption is 520 Tg CH_4-C/year or roughly 60% of the CH_4 produced on Earth. Thus the greatest importance of methane oxidizers is to prevent CH_4 emissions, rather than to consume atmospheric CH_4.

Table 2. Sources and Sinks of CH_4 (Data from Ref. 2)

Source	Estimated Flux (Tg C/year)	Sink	Estimated Flux (Tg C/year)
		Microbial	
Natural wetlands	86	Microbial consumption in soil	22.5
Rice paddies	45		
Landfills/ sewage	67.5		
Ruminant animals	64		
Termites	15		
Marine	3.75		
Freshwater	7.5		
		Nonmicrobial	
Geological	7.5	Oxidation by OH•	334
Fossil fuel related	75	Reaction in stratosphere	30
Biomass burning	30		
Total sources	401	Total sinks	386
		Atmospheric increase	22.5

Organisms and Physiology

Production. Methane is produced predominantly by a group of anaerobic archaea, known as the methanogens (7). These organisms form several closely related branches within the Euryarchaeota. Methane is produced by two dominant pathways.

$$CO_2 + H_2 \longrightarrow CH_4 \text{ (CO_2 reduction)}$$

$$CH_3COOH \longrightarrow CH_4 + CO_2 \text{ (acetate fermentation)}$$

Some methanogens can use other C-1 compounds, such as methanol, methylamine, and formate. However, these pathways are not dominant in nature. The pathway of carbon dioxide reduction begins with the reduction and condensation of carbon dioxide with methanofuran (MFR) to produce formyl-MFR. The pathway then proceeds through a cycle that involves a number of other specific coenzymes. The final step (cleavage of methyl-co-M), in which CH_4 is released, also restarts the cycle by activating carbon dioxide (7). The other pathways of methanogenesis feed into this cyclic pathway by reacting with co-M to form methyl-co-M.

There are organisms other than the true methanogens that produce CH_4, but these are generally considered to be "minimethane producers" because they produce CH_4 as a minor side product of their normal metabolism, rather than as a primary metabolic pathway. These organisms have been studied very poorly, and the full biochemistry involved is not clear (7). They are not thought to be important in global CH_4 cycling.

It is important to note that because methanogens only act on simple compounds, they rely on an extensive food web to supply them with substrates. Polymeric material, such as proteins, cellulose, chitin, and other

compounds, must first be depolymerized to produce soluble monomers. These are then fermented by a wide suite of bacteria to produce H_2, CO_2, and acetate, which the actual methanogens act on. In a number of cases, the fermenters and the methanogens live in very close association. As the free energy available from fermentation is only negative when H_2 concentrations are very low, any build up of H_2 can cause fermentation to shut down (8). By living in close association with fermenters, therefore, methanogens maintain their substrate supply.

Consumption. The bulk of CH_4 consumption is thought to be carried out by the methanotrophs, a group of gram-negative aerobic bacteria (9). There are two primary groups (Types I and II) that are distinguished primarily by the structure of their internal membrane structures. Both types use the same basic pathway of CH_4 oxidation. The first, key enzyme in the pathway is methane monooxygenase (MMO), which converts CH_4 to CH_3OH. There are two forms of this enzyme: a soluble form and a membrane-bound form, known as particulate MMO or pMMO. pMMO is found in all methanotrophs, whereas only a small number of species are known to make the soluble form (9). pMMO appears to be evolutionarily closely related to ammonia monooxygenase, which is found in nitrifiers (10). Methane and ammonia are very similar in size, shape, and structure, and as a result, both enzymes can oxidize both substrates, though each is more selective for its "proper" substrate (11). In methanotrophs, carbon is assimilated from formaldehyde, though there are two distinct pathways that do this. Both of these pathways involve condensing formaldehyde with more complex carbon compounds. Type I methanotrophs generally use the ribulose monophosphate cycle in which formaldehyde is combined with ribulose-5-phosphate. Type-II methanotrophs generally use the serine cycle, in which formaldehyde reacts with tetrahydrofolate to form methylene tetrahydrofolate, which then reacts with glycine to form serine.

Whereas methanotrophs have appeared to be the dominant consumers of atmospheric CH_4 in nature, some other organisms have some ability to oxidize CH_4 as well. Predominant among them are the ammonia oxidizers. Their ability to oxidize CH_4 results from the similarity between CH_4 and NH_3 mentioned earlier. Several studies (12) have suggested that nitrifiers may be important CH_4 consumers in some ecosystems, but the significance of this process is not known.

In marine sediments, where large amounts of CH_4 are produced and consumed, most of the consumption appears to be carried out under anaerobic conditions by a process known as sulfate-dependent methane oxidation. The organisms responsible for the process are not well known, but the process appears to require syntrophy between methane-oxidizing archaea and sulfate-reducing bacteria (13). The specific organisms responsible for the methane oxidation have not been isolated.

Ecology

Production. There are several levels of control over CH_4 production. The first level is redox, and it acts largely as an on/off switch. Methane is produced under only anaerobic conditions (generally redox < -100 mV). Thus, it occurs at high rates only in flooded ecosystems (e.g., wetlands, sediments, animal guts, and a few other situations such as landfills). Draining a wetland rapidly shuts off CH_4 production. Furthermore, the addition of any alternate electron acceptor that will raise the Eh of the system can also shut down CH_4 production. Methane production is commonly limited by high concentrations of SO_4^{2-} such as occur in marine sediments, salt marshes, and even freshwater wetlands experiencing SO_4^{2-} deposition (14). In freshwater wetlands, NO_3^- inputs will reduce methanogenesis.

The effect of environmental controls on CH_4 production can be complicated, and it is often difficult to evaluate where in the whole fermentative pathway they act. For example, in a study of methane production in peats from northern Canada, Valentine and coworkers (15) ascribed temperature effects to the fermentation process but pH effects directly to the methanogens. Some studies have found extraordinarily strong temperature responses for CH_4 production with Q_{10} values greater than 20 (16). This too is likely to reflect responses at multiple stages in the food web, as low temperature inhibits H_2 production, shuts down carbon dioxide reduction, and forces shifts in the specific methanogenic pathways involved. Thus the overall temperature effect may result from multiplicative responses of each group of organisms rather than just the effect on any one.

After redox, the most important control on CH_4 production is substrate quantity. Whereas H_2 and acetate availability directly limit the rate of methanogenesis, their availability is controlled entirely through the fermentative food web, and so the availability of substrate to methanogens is ultimately controlled by the quality of organic substrates entering the soil or sediment. High-quality inputs are decomposed more rapidly and so provide a greater supply of substrates to the methanogens. Because of the importance of the quality of substrates entering an ecosystem, the nature of the plant community is an important factor in controlling CH_4 production rates in terrestrial ecosystems.

Consumption. Methane consumption behaves quite differently in saturated environments (wetlands, sediments), where there is a local source of high concentrations of CH_4, than in unsaturated environments (soils), where the only source of CH_4 is the atmosphere. In saturated terrestrial systems, the primary control on the rate of CH_4 consumption is the availability of O_2. In sediments and saturated soils, methanotrophs tend to occur at very high densities at the anaerobic–aerobic interface (17). In unsaturated systems, because the atmosphere is the source of CH_4 gas, diffusion is the primary control on the rate of CH_4 consumption (18). Thus, soil structure and moisture are the critical controls on consumption, that is, the porosity and their portions that are filled with water.

In upland, unsaturated systems, methane consumption appears to be sensitive to many chemical and physical perturbations. Factors that have been observed to inhibit consumption include plowing, compacting, fertilizing, and

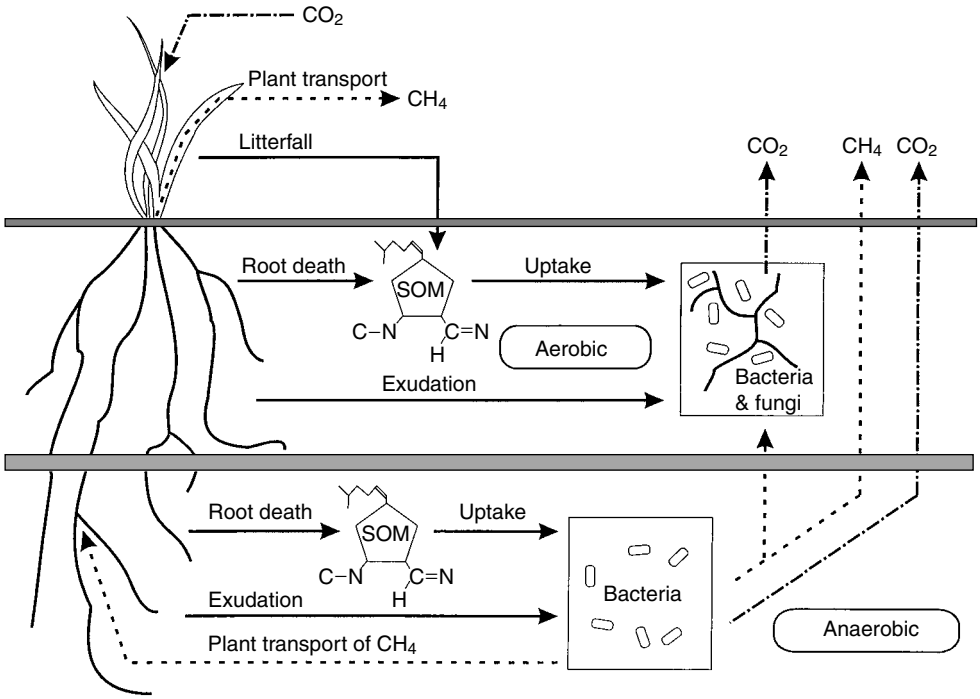

Figure 2. Carbon fluxes in a wetland ecosystem (from 24).

adding salts (19,20). Many physical disturbances may reduce porosity and thus the ability of CH_4 to diffuse into the soil. Nitrogen additions, on the other hand, appear to inhibit CH_4 consumption primarily by competitive inhibition at the enzyme level, as CH_4 and NH_3 are very similar in size and structure (19). The specific mechanisms of some of the other factors are not well understood.

Control on Overall Flux. The actual rate of net CH_4 efflux from a system depends on the balance of CH_4 production and consumption. In nonvegetated sites, this is controlled primarily by the rate of CH_4 production in the anaerobic zone and the diffusion rate of that CH_4 through the aerobic zone where it is consumed. In vegetated systems, the pattern of control is more complex (Fig. 2) because plants dominate CH_4 dynamics. Not only do they supply the carbon and the energy for CH_4 production, but the supply of carbon can also control O_2 consumption and hence the extent of anaerobiosis in the soil. Additionally, wetland plant roots contain aerenchyma, which are air-filled passages within the roots that provide O_2 for root metabolism. Aerenchyma transport O_2 into the soil, producing an aerobic zone around each root, which can allow extensive rhizosphere CH_4 consumption. Aerenchyma also allow CH_4 to diffuse from the deep soil to the atmosphere and avoid the CH_4 consuming zone entirely. Plant transport is typically the dominant efflux mechanism in vegetated wetland systems, though the ability of wetland plants to transport CH_4 varies greatly. Thus, whereas CH_4 flux correlates well with total plant productivity at the global scale (21), at the plot scale, total flux may have little to do with the rate of CH_4 production and may be dominated by the ability of the plants present to transport CH_4 out of the soil (22). The balance of efflux versus consumption varies tremendously among systems, with consumption ranging from as low as 10 to 15% of produced CH_4 in some systems to greater than 90% in others (23).

CARBON MONOXIDE

Importance

Carbon monoxide is one of the most important and complex of the biogenic trace gases (2). It is the most important trace gas in terms of controlling atmospheric oxidation chemistry, as reaction with CO is the major sink for OH• (CO consumes about six times as much OH• as CH_4). Whereas CO is itself not a greenhouse gas because it is too short lived, it has strong indirect effects on the greenhouse effect through its reactivity. For example, it has been estimated that 10 to 37% of the increase in atmospheric CH_4 concentrations has been caused by reduced consumption because of increased competition with CO for OH• (25). Finally, tropospheric CO is strongly involved in tropospheric production of O_3, which is a greenhouse gas (4), but which can also be toxic.

Budget

Carbon monoxide, perhaps surprisingly, cycles through the atmosphere in quantities larger than any trace gas other than carbon dioxide (800 to 1,200 Tg CO-C/year). However, its turnover time is rapid (100 days) and so its average concentration is low; roughly 100 ppb. Because of its rapid turnover and low concentration, the budget for CO has large uncertainties. The major source is the oxidation of organic chemicals (including CH_4) in the atmosphere,

Table 3. Sources and Sinks for CO (Data from Refs. 2 and 26)

Source	Estimated Flux (Tg C/year)	Sink	Estimated Flux (Tg C/year)
	Biotic		
Terrestrial	26 to 69	Soil uptake	6.5 to 270
Oceanic	8.6 to 86		
	Abiotic		
Technological	130 to 240	Reaction with OH•	600 to 1,115
Biomass burning	130 to 300	Stratospheric loss	~43
Atmospheric oxidation	260 to 690		
Total sources	**780 to 1,160**	**Total sinks**	**900 to 1,300**

and much of this results from anthropogenic activity, including industry and biomass burning (Table 3). There are direct microbial sources, but they are rather minimal in the global budget. The largest sink is the chemical reaction with hydroxyl radical in the atmosphere, which accounts for 80% or more of the total sink. Soil microbes are smaller sinks, and estimates of their importance vary greatly. Prather and coworkers (2) in the Intergovernmental Panel of Climate Change 1994 assessment estimated microbial consumption of between 110 and 275 Tg CO-C/year; more recent studies on the other hand, argue that the number may be only in the range of 7 to 20 Tg CO-C/year (26).

Organisms and Physiology

The biological processes affecting CO dynamics are poorly understood. CO is produced as part of organic matter breakdown, apparently by a wide range of organisms. Potter and coworkers (26) simply model it as a fixed proportion of total decomposition. Microbial consumption of CO occurs by a variety of processes, with oxidation to carbon dioxide being the dominant one. CO can also be reduced to CH_4 under anaerobic conditions, but diffusion into saturated systems limits the activity of the anaerobic pathway. Aerobic organisms that can consume CO include carboxydotrophs, methanotrophs, ammonia oxidizers, and some fungi. In the case of carboxydotrophs, they can actually grow on CO and rely on a CO dehydrogenase enzyme that oxidizes CO to CO_2. Methanotrophs and ammonia oxidizers oxidize CO as a side reaction of methane/ammonia monooxygenase.

Ecology

CO production by microbes appears to be controlled by the same suite of factors that control overall microbial activity, as would be expected for a process that appears to be a side reaction. Thus, organic matter content, temperature, and moisture all appear to be important factors (26). The most general control on consumption of atmospheric CO by microorganisms is simply diffusion of the gas to the microbes (26). Any factor that controls diffusion kinetics becomes a control on CO consumption by soils. The dominant such factors are soil texture (porosity) and water content. This is similar to the controls on CH_4 consumption, except that while CH_4 is generally consumed in deeper soils (20 to 50 cm), CO oxidation appears to occur in the surface horizon (27). Thus the key control is diffusion into the immediate surface soil rather than through the soil profile. Consumption rates are greatest in moist soils with adequate porosity and are lower in soils that have a heavy texture or are saturated. Thus, consumption in aquatic, wetland, and tundra systems is limited. Moist, but drained upland soils (forests, grasslands, and agricultural soils) of the tropics are the dominant sinks for CO (26). The secondary controls will depend on which specific groups of microbes are responsible for the activity, and are not well understood.

HALOGENATED HYDROCARBONS

Importance and Budget

Halogenated compounds (chlorocarbons and bromocarbons) are important in the atmosphere (Table 1). They are all strong infrared absorbers and so can act as greenhouse gases with direct global warming potentials that are typically several thousand times that of carbon dioxide (Table 1). They are also involved in ozone depletion as their photochemical breakdown in the stratosphere releases chlorine and bromine radicals that catalyze ozone destruction. Thus, the net effect of these gases on global warming is less than their innate IR absorption would suggest. In fact, brominated compounds, which are potent catalysts of O_3 breakdown (4), act to cool the atmosphere.

The atmospheric effects of the different chlorocarbons vary with their chemical structure. An important distinction is whether the carbons are completely halogenated (e.g., CFCs) or contain hydrogen (including hydrochlorofluorocarbons; HCFCs). CFCs are very inert chemically; they do not react well with OH•, and so have very long lifetimes in the troposphere. They are only active in photochemical reactions, in which high-energy UV can split off the halogens (2). Thus, they become reactive in the stratosphere, where the generation of halogen radicals catalyzes O_3 destruction. The HCFCs, on the other hand, are much more susceptible to chemical reaction with OH•, and thus more likely to be consumed in the troposphere. Thus, while they do contribute to ozone depletion, they are much less effective than the CFCs. Early workers assumed that halocarbon cycling through the atmosphere was almost entirely dominated by anthropogenic emissions and chemical consumption. More recent work, however, has shown that microorganisms are involved in both the production and consumption of halogenated compounds (2,28,29).

Organisms, Physiology, and Ecology

Microorganisms appear to be responsible for producing substantial amounts of several halogenated methane derivatives, particularly CH_3I, CH_3Br, and CH_3Cl, though compounds with multiple halogens are not unknown (2). Natural sources of some of these compounds are

substantially larger than the anthropogenic sources for most of these gases. For example, despite recent concern about the use of methyl bromide as an agricultural fumigant, natural sources of this gas are an order of magnitude greater than the total anthropogenic sources (0.3 Tg versus 0.05 Tg; 30). The same pattern appears to be true for CH_3Cl as well.

The main organisms responsible for the halocarbon production appear to be marine algae, though terrestrial fungi are also capable of producing halocarbons (30). The biochemistry involved in halomethane production is unclear. There are several possible pathways involved in the production of these compounds, but there is strong evidence that at least some large fraction is the result of biosynthesis, rather than from untargeted side reactions. For example, algae are known to contain iodoperoxidases, and a methyltransferase has also been identified that methylates Cl ions (30). The reason why microorganisms produce these compounds remains unclear.

It is not surprising that, since microorganisms are capable of producing halocarbons, they are also capable of consuming them. There has been relatively little research on microbial consumption of halocarbons, but clear evidence exists that it does occur (28). For example as much as one-third of the methyl bromide that is applied to soil as a fumigant may be oxidized in situ (31). Atmospheric methyl bromide is also consumed in soils through microbial activity, and the measured rates are enough to account for 25% of the total global consumption of CH_3Br (28). The organisms involved may be methanotrophs or nitrifiers, as both methane and ammonia monooxygenase are capable of oxidizing CH_3Br. Organisms that are capable of consuming CH_3Br also appear able to consume other methyl halides (29). As for the other atmospheric gases, the primary control on the consumption of halocarbons is diffusion into the soil. Thus, soil structure and moisture content are the critical variables.

NITROGEN GASES: NITROUS OXIDE AND NITRIC OXIDE

Importance

There are two nitrogen-containing gases that are produced by microbial processes: nitrous oxide (N_2O) and nitric oxide (NO). These gases can both be produced by several processes. Essentially all microbial processes that involve oxidizing or reducing nitrogen have the potential to produce one or both gases, though for most processes they are minor side products. The dominant sources of both N_2O and NO are nitrification and denitrification. As both gases are produced in the same pathways, they will be discussed together.

N_2O is a long-lived species in the atmosphere, with an average turnover time of 160 years (Table 1). It is stable in the troposphere, and its primary pathway for destruction is through reaction with $O(^1D)$ in the stratosphere (2). As a result of its lifetime and chemistry, N_2O is a powerful greenhouse gas (a global warming potential 280 times that of CO_2), and it is directly involved in ozone depletion.

NO, on the other hand behaves very differently in the atmosphere. NO is extremely reactive chemically, and so its lifetime in the atmosphere is short, ranging from less than 1 day up to several days (Table 1; 2). It is strongly involved in atmospheric reactions, including the production and destruction of tropospheric ozone. At low concentrations, NO catalyzes O_3 removal, whereas at high concentrations (as occurs in polluted air), NO catalyzes O_3 production (1). Because of its short lifetime, the role of NO in atmospheric processes tends to be local to regional, rather than global.

Budgets

The "likely" values of N_2O and NO fluxes are shown in Tables 4 and 5, respectively. The best-known value in the N_2O budget is its rate of atmospheric increase (3.9 Tg/year) as this can be measured reasonably accurately. There is substantial error in all the other terms, particularly the source estimates, because these are extrapolated from a limited set of field measurements. Several points, though are clear: the major sources to the atmosphere are the oceans, tropical forests, and agriculture. Whereas nitrification accounts for a substantial proportion of the total N_2O emitted (particularly in drier biomes), denitrification accounts for the bulk of emitted N_2O. The only substantial sink for N_2O is reaction in the stratosphere. The budget for NO is less well known, because it has a short lifetime in the atmosphere. However, the largest source is combustion, particularly of fossil fuels (24 Tg N/year). Soil emissions are the second largest source, with estimates ranging from 12 to 20 Tg N/year. The main source of NO is nitrification. In soils that become wet enough to stimulate denitrification, NO diffusion out of the soil is reduced and NO is more likely to be consumed

Table 4. Sources and Sinks of N_2O (Data from Ref. 2)

Source	Estimated Flux (Tg N/year)	Sink	Estimated Flux (Tg N/year)
	Microbial		
Oceans	1 to 5	Soil consumption	Low
Temperate forest	0.1 to 2.0		
Temperate grassland	0.5 to 2.0		
Tropical forest	2.2 to 3.7		
Tropical savanna	0.5 to 2.0		
Crop agriculture	1.8 to 5.3		
Feed lots	0.2 to 0.5		
	Nonmicrobial		
Industrial	0.7 to 1.8	Stratospheric reaction	9 to 16
Biomass burning	0.2 to 1.0		
Total sources	**10 to 17**	**Total sinks**	**9 to 16**
		Atmospheric increase	**3.1 to 4.7**

Table 5. Sources and Sinks of NO (Data from Refs. 2 and 32)

Source	Estimated Flux (Tg N/year)	Sink	Estimated Flux (Tg N/year)
	Microbial		
Temperate forest	0.1		
Temperate grassland	0.6		
Tropical forest	2.6		
Savanna	7.7

Crop agriculture	7.2		
	Nonmicrobial		
Fossil fuel combustion	24	Atmospheric oxidation	24 to 64
Biomass burning	8		
Lighting	5		
Total production	**57**.2	**Total sinks**	**24 to 64**

before it escapes. The vast bulk of the NO emitted to the atmosphere is consumed by reaction with OH• and O_3 in the troposphere.

Organisms and Physiology

Nitrification. In nitrification, NO and N_2O are produced by NH_4^+ oxidizers. These are a moderately diverse group of obligately aerobic, chemoautotrophic bacteria. Whereas most genera are found in the β-proteobacteria, some lineages are found in the χ-proteobacteria (33). Despite this, the biochemistry and enzymology of nitrification are quite similar in both sets of lineages (34). Ammonia is oxidized by the enzyme ammonia monooxygenase to produce hydroxylamine. Hydroxylamine is then oxidized to NO_2^-. Nitrous oxide is produced by ammonia oxidizers reducing NO_2^- to N_2O. Nitrite reduction is linked to NH_3 oxidation and occurs predominantly under low O_2 conditions (35). Nitrite reduction and N_2O production appears to be a minor side reaction in most natural ecosystems (accounting for a few percent of the NH_4^+ oxidized), but in sewage treatment systems and some other specialized circumstances it may account for a significant fraction of the total products (36).

Denitrification. Denitrification is broadly distributed across the bacteria (37). Almost all known denitrifiers are aerobic bacteria that switch to denitrification when O_2 becomes limiting. Most denitrifiers are chemoheterotrophs and use organic carbon as an electron donor, with representative organisms covering most branches of the Proteobacteria, as well as some gram-positives, such as several species of *Bacillus*, and even some archaea. Denitrification is not, however, limited to the heterotrophs, as there are known denitrifiers among the sulfur oxidizers (e.g., *Thiobacillus denitrificans*), which uses reduced sulfur as an electron donor. This broad distribution of denitrification is likely because in most cases, it is a "backup" physiology that uses most of the same enzymatic machinery as aerobic respiration and only diverts electron flow at the terminal stage to NO_3^- (or other nitrogen oxides) instead of O_2 (37). Denitrification follows a multistep pathway in which NO_3^- is successively reduced to NO_2^-, NO (this functions as an intermediate, but its exact chemical status is unclear), N_2O, and finally to N_2. Most denitrifiers can carry out all the steps in the process, though there are many isolates that do not have (or have lost) nitrous oxide reductase (38).

Ecology

Controls on nitrogen-containing trace gas production by microbes have commonly been described by the "leaky pipe" analogy of Firestone and Davidson (39). The controls can be separated into those that control the overall rate of nitrification or dentrification (flow through the pipe) and those that control the fraction of product released as NO or N_2O (size of the leaks).

The two most general controls on both nitrification and denitrification are O_2 and nitrogen availability. Ultimately, low nitrogen availability (as NH_4^+) limits nitrification, and thus the supply of NO_3^- to denitrifiers as well (unless NO_3^- is transported in). Oxygen, on the other hand, acts as an on/off switch for both processes. Nitrification requires O_2 for ammonia monooxygenase, whereas denitrification is repressed by O_2.

Nitrification. Because of their great demand for NH_4^+ (they require it for both energy and biomass production), nitrifiers compete poorly against other microorganisms for NH_4^+. Thus, nitrification is invariably low in environments that are poor in available NH_4^+. In terrestrial systems, nitrification is generally rapid in agricultural soils and in many tropical soils. Tropical soils are often phosphorus limited, and so nitrogen is often present in excess. Grasslands sometimes have substantial rates of nitrification, whereas temperate and high-latitude forests are often nitrogen limited and so have low nitrification rates. In many aquatic systems nitrification occurs, even when NH_4^+ is dilute. The supply of carbon is often so limited that nitrifiers are able to compete for the available NH_4^+.

Nitrifiers are able to exist and function under many circumstances that would appear to be difficult for them, as long as adequate NH_4^+ is available. Thus in most NH_4^+-rich environments, NO_3^- dominates the inorganic nitrogen pools even if other factors might appear to be unfavorable for nitrification. One such factor is low pH. Low pH often leads to reduced nitrification rates, and many workers have concluded that nitrifiers are intolerant of low pH. This conclusion comes from both pure culture studies, where it has been very difficult to isolate acid tolerant nitrifiers, and field studies where nitrification is often observed to be limited in low pH environments. However, low pH environments are typically low in available NH_4^+, and thus would be expected to have low nitrification rates. If NH_4^+ levels are increased in such ecosystems, such

as occurred when a watershed was clear-cut at Hubbard Brook, New Hampshire, nitrification rates were very high, despite very low soil pH (40). Removing plants increased available NH_4^+ levels to the point that nitrifiers could compete. It is likely that part of the effect of pH is because nitrifiers act on NH_3, rather than NH_4^+, and at low pH the equilibrium is strongly to the side of NH_4^+ and so NH_3 is likely to be in particularly low supply.

Another factor that has often been discussed as a possible control on nitrification in terrestrial systems is toxic effects of specific plant chemicals, a phenomenon known as allelopathy (41). However, most of the effects of plant chemicals can be explained by changes in nitrogen mineralization and the supply of NH_4^+ to nitrifiers (42). Given recent results, it seems likely that specific toxicity of plant chemicals to nitrifiers is uncommon (43).

In nitrification, O_2 is the critical factor that controls the amount of nitrified nitrogen that is released as NO or N_2O. Since the trace gases are produced by NO_2^- reduction, this happens more rapidly when O_2 is limiting. However, because the process is aerobic, as O_2 drops so does the overall rate of nitrification. Thus, there is an optimum level of O_2 for producing trace gases that balances the rate of the process with the fraction of side products. This optimum has been found to be around 1% O_2 (44).

Denitrification. The primary control on denitrification is O_2 availability, as the process only occurs under anaerobic conditions (though one organism has been isolated that can denitrify aerobically-*Thiosphora pantotropha*; 45). Once conditions have become anaerobic, NO_3^- availability is generally the most important factor limiting denitrification rates, though carbon availability has been shown to limit rates in some circumstances. Denitrification functions rather differently from many other anaerobic processes because the organisms involved (facultative anaerobes) can live aerobically and denitrification can occur at relatively high redox potentials. Thus, denitrification can switch on rapidly when conditions become anaerobic. There is no need for an extended period of anaerobiosis for developing a substantial population of denitrifiers. Additionally, denitrification can occur in anaerobic microsites in an otherwise aerobic environment (46). So in a soil environment, denitrification usually occurs in pulses following rain events, when soil aggregates and organic matter fragments become wet enough to develop anaerobic microsites. In one classic study, Parkin (47) subdivided a soil core into progressively smaller components and showed that 85% of the total denitrification activity was associated with one small fragment of decaying plant material (Fig. 3). There are ecosystems where carbon and NO_3^- are more continuously available, where denitrification may function as more of a bulk process. One such important system is aquatic sediments where there is a constant downward diffusion of NO_3^- into the anaerobic zone. Another type of system is riparian areas along streams. In riparian zones, groundwater carries NO_3^- back to the soil surface in an area where high water contents induce anaerobiosis and root and litter inputs provide large amounts of available carbon (48). Riparian areas can therefore be very important as buffer zones to reduce NO_3^- runoff from agricultural lands. On the other hand, this same process may release a lot of N_2O to the atmosphere.

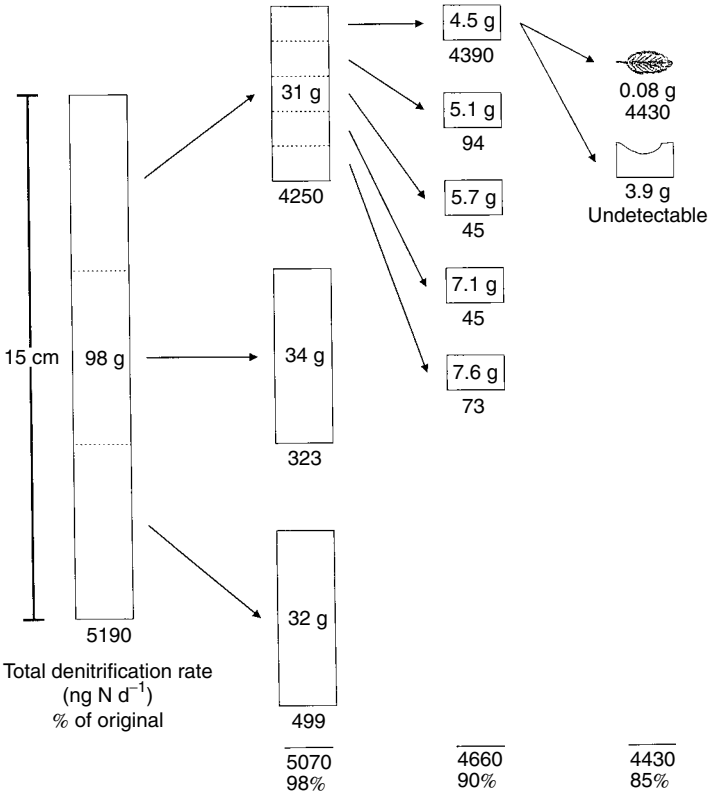

Figure 3. Microsite nature of denitrification. A single soil core was progressively subdivided into smaller and smaller components. The numbers at the bottom of the columns are the sum of the amounts of denitrification measured in each component and the rate percentage measured on the intact core. Ultimately 85% of the total denitrification in the core was associated with a single piece of decomposing plant material (from 47).

The controls on the proportion of NO and N_2O that are released as side products in denitrification are complex. In general, whereas N_2O can be the dominant product, NO rarely accounts for more than a few percent of the total product mix. As for nitrification, O_2 is an important factor in controlling the product mix. As O_2 increases, the fraction of products that remains in a more oxidized form (NO and N_2O) increases. However, as O_2 increases, the rate of denitrification decreases, producing an optimum where decreasing rates of denitrification balance the increasing fraction of product as NO or N_2O. Coincidentally, this balance is at roughly 1% O_2 (49). The balance of NO_3 and carbon availability is also important in controlling NO and N_2O production. When carbon is more available than NO_3^-, the NO_3^- will tend to be used "efficiently," that is, completely reduced to N_2. However, when NO_3^- is present in abundance, it is used less efficiently and more is released as N_2O and NO (39). A final factor that controls the proportion of N_2O released is pH. Nitrous oxide reduction is inhibited at low pH (38), and so N_2O can become the only significant product of denitrification.

SULFUR GASES

Importance and Budget

Both inorganic and organic sulfur gases are important in sulfur cycling and atmospheric chemistry. These gases are produced by different organisms under different conditions and in different ecosystems. The total emissions of sulfur gases to the atmosphere are shown in Table 6. The single largest source of sulfur to the atmosphere is industrial SO_2, but marine emissions of organic sulfur compounds, particularly dimethyl sulfide (DMS) are probably second in importance. All of the sulfur gases that are emitted to the atmosphere react with hydroxyl radicals and other oxidants to produce SO_2 and ultimately SO_4^{2-}. This is the dominant pathway for consumption of atmospheric sulfur gases (1); there are no significant microbial sinks for any of the sulfur gases.

Organic Sulfur Gases

The major organic S gas that is emitted to the atmosphere is DMS. The primary atmospheric source of DMS is marine algae, though smaller amounts are also produced by higher plants (such as *Spartina* spp.). It is produced as an enzymatic cleavage product of dimethylsulfonium propionate (DMSP). DMSP appears to serve primarily as an osmoregulatory agent in most of the major groups of marine algae. The major producers appear to be dinoflagellates, but other algae, including Chlorophyta, Rhodophyta, Phaeophyta, and others, also produce DMSP (3). DMSP is also produced by marine Cyanobacteria. The conversion of DMSP to DMS is accelerated by bacterial breakdown of senescent algae or by grazing. These various processes that cause release

Table 6. Sources for Sulfur Gases (Data from Refs. 3 and 50). Essentially all S gases are oxidized in the atmosphere

Biotic Source	Estimated Flux (Tg S/year)	Abiotic Source	Estimated Flux (Tg S/year)
		DMS	
Oceans	20	Biomass burning	??
Salt marshes	0.6		
Swamps	0.8		
Soil and plants	0.2 to 4.0		
		Other organic gases	
Oceans	0.7 to 1.7	Biomass burning	0 to 1

		SO_2	
		Biomass burning	2.5
		Volcanoes	8
		Industry	67
Total biotic sources	43 to 104	Total abiotic sources	77.5
Total atmospheric oxidation		120.5 to 181.5	

of DMS can produce concentrations in surface seawater of up to several hundred nanograms per liter. This creates a strong DMS source to the atmosphere.

There is the potential for a strong negative feedback between DMS production and local climate: elevated temperatures increase DMS production and emission, which in turn increases cloud formation, reducing temperatures (1). However, increased cloudiness will also reduce light levels, reducing phytoplankton growth and DMS production, in turn producing a negative feedback on cloudiness. These feedbacks may produce a complex regulation between local marine climate and phytoplankton growth and DMS production. The full extent to which to this potential feedback loop actually functions, however, remains nuclear (51).

Other organic sulfur gases are released to the atmosphere, including dimethyl disulfide, carbon disulfide, and carbonyl sulfide. These gases together account for only around 9 Tg S, or about 10%, of total global S emissions to the atmosphere (3). These gases are produced by a variety of mechanisms, including as simple byproducts of the microbial decomposition of sulfur-containing organic molecules.

Hydrogen Sulfide

The second major source of sulfur to the atmosphere is H_2S. H_2S is produced under anaerobic conditions by dissimilatory reduction of sulfur. This process is a form of anaerobic respiration in which sulfur compounds are used as terminal electron acceptors. This process is carried out by a diverse group of strictly anaerobic bacteria, including members of the archaea, the gram-positive bacteria (genus *Desulfotomaculum*), and the gram-negative bacteria (52). These organisms have been divided into several major groups based on their physiologies. One fundamental distinction among the organisms is whether they are capable of reducing SO_4^{2-} to H_2S, or whether they can only reduce elemental sulfur (e.g., *Desulfuromonas*). Among sulfate reducers, there is a large group of bacteria that use acetate as their primary carbon source (including *Desulfobacter, Desulfosarcina*, etc.).

Sulfur reduction only occurs in low redox environments, such as under constantly flooded conditions, and where SO_4^{2-} or elemental sulfur concentrations are high. As the process is carried out by heterotrophs, organic carbon must be available. The most widespread environment where these conditions occur is marine sediments. Sulfur reduction may dominate the biogeochemistry that occurs in these sediments. However, sediments are not a large source of H_2S to the atmosphere, because much of the H_2S that is produced is oxidized in the aerobic surface sediments or in the water column, and more may precipitate out as pyrite or other metal sulfides. The largest actual biogenic sources of H_2S to the atmosphere are terrestrial (3). In terrestrial ecosystems highly reducing conditions exist close enough to the atmosphere that a substantial portion of the H_2S produced is released to the atmosphere. Salt marshes, in particular, are hot spots of H_2S emissions, because of the large inputs of SO_4^{2-} into a saturated environment. However, the small area of salt marshes globally reduces their importance in the overall global H_2S cycle.

Whereas microbes are not largely involved in removing sulfur gases from the atmosphere, H_2S consumption by autotrophic sulfur oxidizers is critical in limiting the amount of sulfur gases that are emitted to the atmosphere in the first place. In marine sediments and salt marshes, a large amount of energy is recycled through the oxidation/reduction cycle of H_2S/SO_4^{2-} and the rates of H_2S oxidation are very high. The role of sulfur oxidizers is thus analogous to the importance of methanotrophs in the global CH_4 cycle: neither group consumes a large fraction of the gases that make it into the atmosphere but both groups are critical to limiting what makes it into the atmosphere in the first place.

CONCLUSION

Microorganisms (including archaea, bacteria, fungi, and algae) are central to controlling the chemically and radiatively active components of the atmosphere, the trace gases, as shown here. The organisms involved in trace gas dynamics are diverse, and the processes involved are complex. Whereas many environmental and biotic factors interact in controlling trace gas dynamics, this entry has focused on single-factor controls. In fact, many of these factors can interact with each other to produce behaviors that are more complex than would be expected from single-factor analysis (53). Additionally, the specific composition of the microbial communities (rather than just the presence of a functional group such as methanotrophs) may affect the rates and controls of trace gas fluxes (54). Whereas we have an adequate understanding of the large-scale biogeochemistry of most trace gases, our understanding of the microbiology and microbial ecology controlling them is still somewhat limited.

TRACERS IN GROUNDWATER: USE OF MICROORGANISMS AND MICROSPHERES

RONALD W. HARVEY
U.S. Geological Survey
Boulder, Colorado

HAUKE HARMS
Swiss Federal Institute of Technology
Lausanne, Switzerland

Microorganisms have been deliberately injected into groundwater environments for well over a hundred years. Reasons for the additions include increasing oil recovery from less permeable zones, increasing rates of organic contaminant biodegradation, a better understanding of the hydrologic properties of aquifers, particularly those characterized by a high degree of physical heterogeneity, a better understanding of the factors controlling the transport and (or) survival of pathogenic, genetically engineered, or other nonindigenous microorganisms in groundwater systems, and assessments of the vulnerability of an aquifer to microbial (pathogen) contamination. This chapter will focus on addition and recovery studies in which microorganisms are used as tracers in order to gain information about subsurface microbial transport behavior, biorestoration potential, geohydrology, or vulnerability to microbial contamination of groundwater systems. Because of the importance of microbial-sized microspheres to the overall understanding of subsurface microbial attachment and transport behavior and of the hydrologic properties of different types of aquifers, the uses of microspheres as microbial-sized tracers are also discussed.

HISTORY OF MICROBIAL TRACERS IN GROUNDWATER

The first published studies involving the use of microorganisms as tracers in injection and recovery studies of

groundwater systems occurred in the latter part of the 19th century. In the earliest studies, pigment-producing bacteria were used to delineate flow paths in karst and fractured-rock aquifers (1,2). During the following century, other types of microorganisms were employed, including enteric viruses, bacteriophages, yeast, and protozoa. However, the use of human and animal viruses as tracers in groundwater studies has been limited because of safety and water quality considerations. There are a number of reviews focusing on the use of microorganisms as groundwater tracers. The interested reader is referred to Keswick and coworkers (3) and Gerba (4) for brief descriptions of microbial tracer studies conducted before 1981, to Harvey (5) for a history of microbial tracers up to 1997, to Hötzl and coworkers (6) for descriptions of studies in which microbial tracers are used in a number of geohydrologic studies involving granular and karstic aquifers, and to Rossi and coworkers (7) for a discussion of the use of viruses in groundwater studies.

Bacteriophages

Following their first use as a surface water tracer as described by Wimpenny and coworkers in 1972 (8), bacteriophages (bacteria-specific viruses), often referred to simply as *phages*, were employed widely as tracers in groundwater applications. A modest number of phage tracer experiments involving groundwater systems were conducted in the 1970s and 1980s. Most notable were transport studies involving the use of an Aerobacter aerogenes phage (9), phage T4 in a gravel aquifer in New Zealand (10), three unspecified phages, having *Escherichia coli* K12, *Serratia marcescens* and *Enterobacter cloacae* as their respective hosts, in a chalk aquifer in the United Kingdom (11,12), phages f2 and P22H5 in a karst aquifer in Greece (13), and MS2 in a sandy aquifer in Arizona (14). A protocol for using phages as groundwater tracers in granular aquifers is depicted in Figure 1.

Many of the bacteriophages commonly used as tracers in groundwater applications are coliphages, that is, they have *E. coli* as their host. Although there are many RNA- and DNA- containing coliphages (15), only a few (e.g., MS2, T4, T7, ϕX174, and f2) were used in tracer applications involving subsurface media. In addition to the aforementioned list of coliphage tracers, it is noted that the popular tracer phage, PRD1, which can also infect a strain of *E. coli*, has *Salmonella typhimurium* as its primary host. Numerous injection and recovery studies were conducted in the 1990s that involved comparing coliphage and conservative solute tracers in a variety of groundwater environments. The tracer test sites included sandy aquifers in Cape Cod, Massachusetts (16–18), and Ontario (19), highly fractured till in Ontario (20), fractured saprolyte in Tennessee (21), a floodplain aquifer in Montana (22), an alluvial aquifer in New Zealand (23,24), and a dune recharge site in the Netherlands (25). In addition to their widespread use with conservative tracers in injection and recovery experiments, coliphages are often used as indicators or tracers of fecal contamination in groundwater environments, including recent groundwater studies in the United States (26,27), Spain (28), Finland (29), and Israel (30). As noted by Edberg and coworkers (31) and Leclerc and coworkers (32), there are a number of problems associated with the uses of coliphages as tracers of groundwater contamination and the future of such uses remains unclear. A major problem is the lack of a strong relationship between bacteriophage recovery from groundwater and enteric gastroenteritis outbreaks attributed specifically to enteric viruses. A detailed discussion of the use of coliphages as indicators of human enteric viruses in groundwater is provided by Snowdon and Cliver (15).

Recently, various marine phages have been used with conservative solutes as groundwater tracers to understand better the geohydrology in karst (7), heterogeneous (periglacial) granular (7,33), and fractured-granite (33) aquifers in Switzerland. Unlike coliphages and phages of other bacterial inhabitants of mammalian intestinal tracts, marine phages are not a regulatory or water quality concern because their hosts are harmless. Also, the background concentration of marine phages in freshwater aquifers should be zero, even in groundwater contaminated by domestic or agriculture wastes. Comparisons of the transport characteristics of different marine phages with coliphages, indicate that at least one marine phage, H40, may have superior transport characteristics to the coliphage MS2 (33). Recent genetic studies show that marine phages are closely related to coliphages, although their life histories can be quite different (34). Although marine phages have not been widely used as groundwater tracers outside Switzerland, the authors anticipate that their use in injection and recovery experiments will spread. Conversely, phages commonly associated with contaminated freshwater environments were used to trace septic tank contamination in the Florida Keys into the marine environment (35).

All tracer experiments employing phages have the drawback that the standard plaque assays do not account for the total mass of the phage in the sample. This is because the phages are subject to an inactivation rate (rate of loss of host infectivity). Although the inactivation rate often is described as a simple function of temperature, there is increasing evidence that inactivation is more complicated and in some cases, loss of infectivity in groundwater systems may be poorly calculated by mean groundwater temperature. This is because the inactivation rates are subject to change, depending on whether the phage is attached to surfaces or unattached. Also, the intersurface forces that come into play when phages interact with solution-solid and water-air interfaces can cause inactivation. One method of assessing the true mass movement of phages in the aquifer involves radiolabeling the protein capsid with S^{35} or genetic material therein with P^{32} (17,18). However, the hazards and regulatory issues involving the use of radiolabeled phages restrict its use to a small number of controlled groundwater study sites.

Bacteria

The choice of bacteria in the first (nineteenth century) injection and recovery microbial tracer studies was made primarily because of their ease of detection in collected groundwater samples, rather than their transport or survival characteristics. The fact that the bacteria

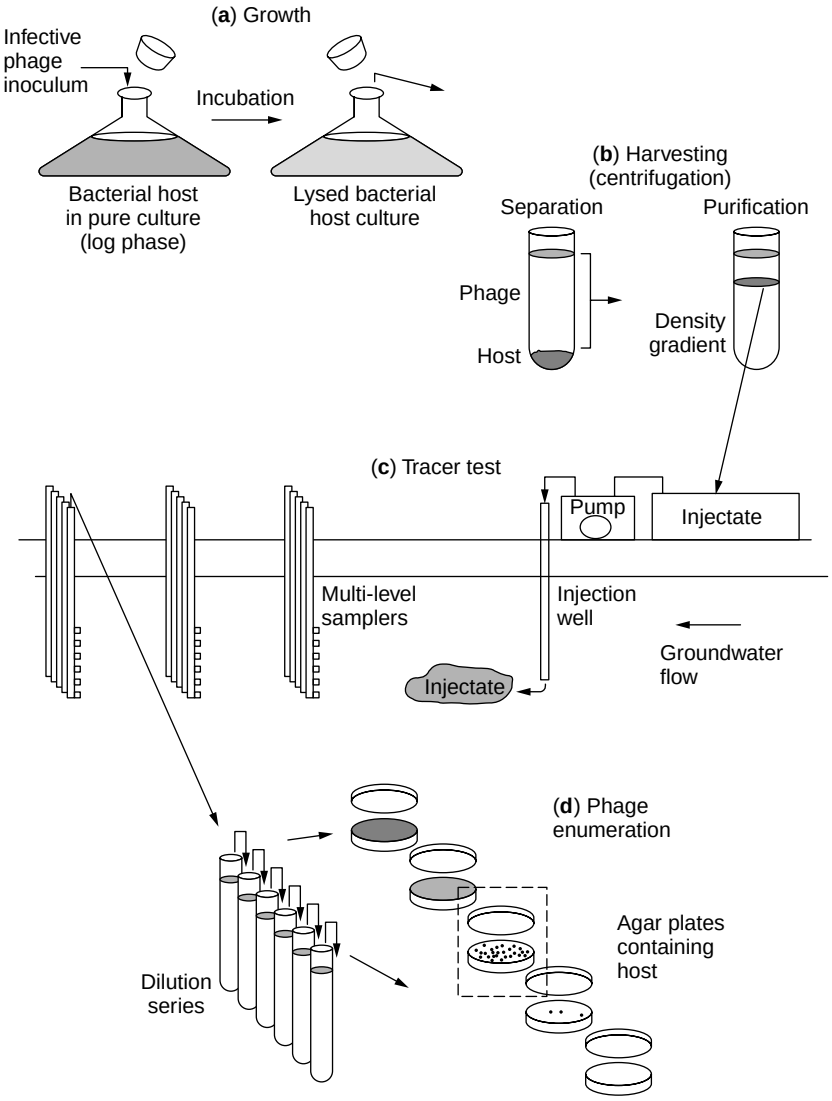

Figure 1. Protocol for the use of bacteria-specific viruses (bacteriophages) as tracers in injection and recovery tests in granular aquifer sediments: (**a**) Growth involves infecting the host bacterium during log phase growth in nutrient broth. (**b**) Purification of the phage involves initial separation of host cell debris from the new phage by centrifugation, followed by density gradient centrifugation of the supernatant. (**c**) Natural-gradient transport study involves a pulse injection of the purified phage and a conservative solute tracer upgradient from an array of multilevel samplers that are in rows perpendicular to the direction of groundwater flow. (**d**) Enumeration of phages in groundwater samples involves a dilution series and enumerating plaques (clearing zones) in agar plates containing a cloudy suspension of the bacterial host.

employed in the early studies formed brightly colored (red or yellow) colonies on solid media greatly facilitated differentiation of the tracer bacterium from the indigenous bacteria in the aquifer. There was a dearth of similar injection and recovery experiments through the first seven decades of the twentieth century, although a number of microbial tracer studies focused on tracking bacterial indicators of fecal contamination downgradient from known sources (36,37). Such studies provide very limited information about subsurface microbial transport because of difficulties in defining the source. A notable exception involved a bacterial tracer study in which known quantities of specific pigment-producing bacteria, including *S. marcescens*, were introduced into an Alaskan aquifer and tracked downgradient (38).

A resurgence in injection and recovery tests involving bacterial tracers occurred in the 1970s and 1980s. A number of bacterial tracer studies published during that period employed antibiotic resistance as a mechanism to facilitate differentiation of the bacteria of interest from other bacteria in groundwater samples (39,40). More definitive labeling of bacteria with a DNA-specific fluorescent (fluorochrome) stain, that is, DAPI (4′,6-diamidino-2-phenylindole) (41) and a radioisotope (P^{32}) (42) facilitated bacterial tracer experiments in the late 1980s. Other fluorochromes possessing a variety of wavelengths of excitation and emission are available for labeling bacteria and were considered in tracer applications. However, unlike DAPI, (43,44), several of the more common fluorochromes, that is, ethidium bromide (2,7-diamino-10-ethyl-9-phenyl-phenanthridinium bromide), acridine orange (3,6-bis(dimethylamino)acridinium chloride), and Hoechst 33258 (2′-(4-hydroxylphenyl)-5-(4-methyl-1-piperazinyl)-2,5′-bi-1-H-benzimidazole) can alter the attachment behavior of bacteria in porous media (44), thus limiting their use in groundwater tracer applications.

In the 1990s, microbial tracer studies involved tracking nalidixic acid-resistant (45) and antibiotic-resistant (46) *E. coli* and antibiotic-resistant *Pseudomonas fluorescens* (47) through the subsurface. Also, the first bacterial tracer tests were conducted in which bacteria

that were labeled with a stable isotope (C^{13}) (48) and a vital fluorescent stain, 5-(and 6-)-carboxyfluorescein diacetate, succinimidyl ester (CFDA/SE) (49), were injected into a sandy aquifer in Virginia. Also, a bacterial tracer was developed based on the ability of some naturally occurring and engineered bacteria to facilitate the formation of ice in small water droplets at approximately 5 °C (50). One such ice nucleation active (INA) bacterium, *Pseudomonas syringae*, was employed as a readily identifiable bacterial tracer in a tracer experiment involving a shale-saprolyte aquifer in Tennessee (21). A discussion of methods to label bacteria apriori for subsequent groundwater tracer studies is provided by Harvey and Harms (51) and Deflaun and coworkers (52). Colwell and coworkers (53) discuss the advantages of using a cyanobacterium as an easily quantified particulate tracer in the terrestrial subsurface. Beeman and Suflita (54) describe the use, as tracers, of sulfate-reducing bacteria serendipitously present in drilling muds to help assess to what degree subsurface core sample are compromised by the inadvertent introduction of non-indigenous microorganisms through drilling and recovery operations.

Yeast and Protozoa

Uses of yeasts and protozoa in groundwater tracer applications have been limited. The large size of yeasts and protozoa may preclude their use in many aquifer studies because of problems relating to correspondingly high sedimentation (settling) rates. Although the first use of eukaryotic microorganisms as tracers in groundwater studies is not clear, Reichert (55) mentions the use of "yeast bacteria" in aquifer tracer studies conducted in the early 1900s. In 1975 and 1976, hydrologic studies were conducted in Texas in which 3 μm Baker's yeast (*Saccharomyces cerevisiae*) were employed as particulate groundwater tracers along with conservative halide (chloride, bromide, and iodide) tracers. The purpose was to delineate secondary permeability features within a heterogeneous granular aquifer interdispersed with clay and partly cemented with calcium carbonate (56). Baker's yeast had the advantages of being easily obtainable in large (kg) quantities and being easily identified and counted. The first use of a protozoan tracer in an injection and recovery experiment occurred in 1991. In order to better understand the transport behavior of groundwater protists, the nanoflagellate, *Spumella guttula* (Kent) was isolated from a sandy aquifer in Massachusetts, grown up in liquid media, labeled with the vital stain hydroethidine, and injected back into the aquifer along with bromide (57). A subsequent experiment was conducted in 1994, in which *S. guttula* was grown in aquifer sediments under low pH and carbon conditions, labeled with DAPI, and again injected into the aquifer with a conservative tracer. Although the smaller (2 to 3 μm), porous-media-grown nanoflagellates were advected through the sandy sediments (58), their delicate nature and the difficulties in obtaining large numbers limit their usefulness as groundwater tracers.

Microspheres and Spores

Well-characterized, microbial-sized microspheres (minute beads consisting of organic polymers) were first employed as particulate surrogates for microbial groundwater tracers starting in the 1980s. In 1986, bacteria-sized (0.2, 0.5, 0.6, 0.7, 0.9, 1.4 μm) microspheres that differed in surface properties were injected into and recovered from a sandy aquifer in Cape Cod, Massachusetts to gain information about the physicochemical controls of subsurface microbial transport (Table 1; 41). Microspheres

Table 1. Use of Microbial-Sized Microsphere Tracers in Granular Aquifers (in Progress)

Factor aquifer	Microsphere	Size μm	Test		RF[b] %	RF[c]	Ref.

[f] Range of values correspond to the three different depths, that is, 8.8, 9.0, and 9.5 m below land surface.

in the 0.8, 1.2, and 2.1 μm size class were also injected into and recovered from a fractured-granite aquifer at the Chalk River site in Ontario (42). A number of injection and recovery experiments employing virus-, bacteria-, and (or) protist-sized microspheres in a variety of geohydrologic environments were conducted in the 1990s. These tests included injections of both bacteria-sized (0.7 μm) (16,59) and protozoa-sized (57) (2 to 6 μm) microspheres at the Cape Cod site, bacteria-sized (0.2 to 1.0 μm) microspheres in a fractured-rock sites in Northern California and New Hampshire (60), bacteria-sized microspheres in marine sediments (61), virus-sized (100 nm) microspheres in a weathered shale saprolyte in Tennessee (21), and protist-sized (2, 5, and 15 μm) microspheres in a heterogeneous granular aquifer in Idaho (62).

Microbial-sized microspheres sometimes are injected into the subsurface to determine the degree by which the aquifer material, subsequently recovered from the same site, has been compromised by drilling and recovery activities. This microsphere tracer application involves determination of the number of log unit reductions between the abundance of microspheres added to the drilling fluid or borehole and the microsphere abundance in the recovered core material. Examples of this use of microspheres as subsurface tracers for quality-control purposes include studies involving deep aquifer sediments in South Carolina (63) and subsurface sediment and basalt in Idaho (64).

Various types of spores have been used as particulate tracers in groundwater systems. Many of these studies involved *Lycopodium clavatum* (clubmoss) spores that are typically approximately 30 μm and are stained apriori for easy identification in groundwater samples. The first published use of *L. clavatum* spores as groundwater tracers occurred in 1926 (65). However, stained spores of *L. clavatum* have largely been restricted to hydrologic studies involving karst aquifers (66,67). This is because the relatively large sizes of *L. clavatum* spores render them a less attractive choice in many fractured-rock and granular aquifers. Kass and Reichert (68) describe methodologies for using spores as groundwater tracers, including preparation, sampling, and quantification. Endospores of the bacterium, *Bacillus subtilis* were used in several injection and recovery studies involving heterogeneous granular aquifers in New Zealand (24). The small (<1 μm) size and high resistance to environmental conditions make bacterial endospores better candidates as groundwater tracers in many granular and fractured groundwater systems.

HYDROLOGIC STUDIES

The search for definitive, quantifiable particulate tracers to understand better the hydrology of different types of aquifers provided the impetus for the first uses of microorganisms as groundwater tracers. It should be noted that particulate and solute tracers can exhibit very different transport behaviors in the same aquifer. Many of the hydrologic studies employing microbial tracers that were conducted during the last few decades used both particulate and conservative solutes. In the process of assessing and comparing the breakthrough curves of both microbial and solute tracers, important information has been acquired, not only about the hydrology of aquifers, but about how microorganisms being transported through different groundwater environments are affected by chemical and physical heterogeneities.

Table 2 lists the retardation factors (ratio of the velocity of the microorganisms to that of the conservative tracers) for microbes being advected downgradient in injection and recovery tests. Results are compared for a number of different types of subsurface media. The retardation of microorganisms relative to a conservative tracer is a very complex phenomenon, but is strongly affected by the degrees of physical and chemical heterogeneity. In fractured media, the peak concentration of microorganisms appearing downgradient often significantly precedes that of a conservative tracer. For example, it is reported that the velocities associated with peak concentrations of microbial tracers exceeded those of a conservative tracer by two or more factors of ten in aquifers characterized by high heterogeneity and fracture-flow, that is, weathered-shale saprolyte (21) or clay-rich till (69). This leads to calculated retardation factors for microorganisms that are substantially less than one. The specific mechanism for apparently faster transport of the peak concentrations of microorganisms relative to those of conservative tracers remains unclear, although volume/pore-size exclusion of the microorganisms, hydrodynamic retardation of the conservative solute, and immobilization of the trailing microbes can contribute to this phenomenon. Studies performed in highly heterogeneous granular aquifers in New Zealand and Switzerland indicate that the appearance of the peak abundance of microbial tracers can substantially precede that of conservative tracers, although substantially less so than in aquifers dominated by fracture flow.

A number of studies involving relatively homogeneous well-sorted granular media in Massachusetts suggest that the transport of viral-, bacterial-, and protozoan-tracers can often occur concomitantly with that of the conservative tracer (16,41,59,71), that is, the retardation factor is unity. This suggests that the microbial and conservative tracers are taking the same flow paths and accessing the same pore volumes. Studies involving karstic aquifers indicate that peak concentrations of microbial tracers and conservative solutes can also appear coincidently (6,7). However, such observations involving karst undoubtedly depend on the physical nature of the aquifer. Finally, substantial retardation of microorganisms advecting through granular media may be expected under conditions of unsaturated flow (72). This is because microorganisms, unlike conservative solutes, become trapped at air-water interfaces that move much more slowly than the bulk flow of water.

Microspheres were extensively used, in lieu of and in addition to microbial tracers, to gain information concerning the hydrology of different types of aquifers. Data concerning selected studies involving the injection and recovery of microbial-sized microsphere tracers that have resulted in information about how microorganisms move through granular aquifers are summarized in Table 1. Results of these studies indicate the roles of

Table 2. Retardation in Transport of Microorganisms Relative to Conservative Solutes for In situ Tracer Experiments Involving Different Types of Subsurface Media

Media Type	Microorganism(s)		Test		RF[a]	Ref.

heterogeneity in aquifer structure, of microbial size, and of microbial surface charge upon the retardation and relative breakthrough/immobilization of microorganisms, as they are advected downgradient. Microspheres with similar surface chemistries and buoyant densities, but different sizes, were important in determining the effect of microbial size during transport through granular (41) and highly fractured (60,73) aquifers. Microspheres were also useful in determining the suitability of applying the clean-bed colloid-filtration theory (74) in multi component models describing microbial transport in a well-sorted sandy aquifer (41,71) and in determining whether or not 2 to 15 μm sized bacteria-containing encapsulations could be efficiently dispersed in a heterogeneous granular aquifer (41).

PUBLIC HEALTH STUDIES

In the United States, subsurface transport of pathogens continues to be responsible for a majority of the outbreaks of waterborne disease. The interested reader is referred to Macler and Merkle (75) for discussions of what is currently known about groundwater pathogens and their control. Valuable information was gathered about how pathogens behave in the subsurface by using microbial tracers, including the use of nonpathogenic surrogates in groundwater injection and recovery experiments. More specifically, microbial tracers have been useful tools for delineating the likelihood of pathogen transport pathways from known sources of subsurface microbial contamination and have provided a better delineation of how pathogens move in different types of media. Microbial tracer information has been valuable to regulators, environmental engineers, public health officials, and environmental microbiologists.

Future experiments should focus on the use of tracer microorganisms to assess the vulnerability of various aquifers to microbial contamination. Of particular concern is microbial contamination resulting from ongoing and planned aquifer storage and recovery, deep well injection of treated domestic wastewater, artificial recharge, bank filtration, and deployment of decentralized waster water treatment systems (e.g., septic tanks). The utility of a microbial tracer for aquifer vulnerability studies depend, in part, on how well the tracer represents the survival and transport characteristics of the pathogens of concern in groundwater. Macler and Merkle (75) list the contaminant groundwater viruses of concern as Coxsackie, Echo, Norwalk, Hepatitis A & E, Rota, Enteric adeno, Calici, and Astro viruses. They also list the bacterial pathogens of concern as *E. coli*, *Salmonella* spp., *Shigella* spp., *Campylobacter jejuni*, *Yersinia* spp., *Legionella* spp., *Vibrio cholera* and the protozoan pathogens as the obligate parasites *Cryptosporidium parvum* and *Giardia lamblia*. However, it would be difficult, at best, to find a microbial tracer that represents the transport and survival of more than a few of the aforementioned pathogens.

Phages have often been the microbial tracer of choice, largely because they are harmless, easy to assay

using standard plaque assays, and exhibit good survival characteristics (3). Phages are found in a number of habitats, including marine and freshwater environments, wastewater, soils, plants, animals, and food (7). It is clear that phages are an important and frequently abundant component of a number of aquatic ecosystems (76,77). For some marine systems, phage abundances can be as high as 10^7to10^8 per mL (78). However, phage tracers can be differentiated easily from the often abundant indigenous phages in aqueous systems because of their high degree of host specificity, often involving a single bacterial host. Their small size (10 to 200 nm) also contributes to their suitability as a tracer because it results in negligible settling, good penetration into smaller porosity, and a low propensity for clogging of granular media. Although a number of phages, particularly coliphages, were used as tracer viruses in public health studies, a number of recent studies focused specifically on PRD1 and (or) MS2. Schijven (79,80) describes the extensive series of experiments and modeling efforts concerning the use of PRD1 and MS2 to assess the efficacy of groundwater environments in the Netherlands to remove harmful viruses. Unfortunately, important questions remain about how well PRD1 and MS2 represent the pathogenic viruses of interest in groundwater applications. At the time of this writing, detailed in situ studies were yet to be conducted to determine the suitability of many other phages as groundwater tracers or as surrogates for other viruses.

BIOAUGMENTATION/BIORESTORATION STUDIES

Recently, experiments were conducted in which microorganisms were added to subsurface media and used as tracers to gain useful information for the growing field of in situ bioremediation. Bioaugmentation involves the addition to the contaminated subsurface of specialized or genetically engineered microorganisms (GEMs) to affect a measurable degree of biodegradation. The majority of studies supporting bioaugmentation involved laboratory microcosms. This is, in part, because regulatory concerns have restricted the uses of GEMs in the field. However, critical information needed to predict the potential of GEMs to disperse and survive in contaminated subsurface environments must come from in situ experiments. This is because many of the complex and interrelated processes operative on the field-scale are not represented well in lab-scale studies. One of the first microbial "tracer" applications in support of future biorestoration procedures involved the injection of *Pseudomonas* sp. strain B13, a 3-chlorobenzoate metabolizing bacterium, into the aquifer in Cape Cod, MA. The bacterium was subsequently recovered from aquifer sediments 14 months later (81) suggesting that the survival time in an aquifer for a nonindigenous, genetically altered bacterium may be long enough to enhance aquifer remediation, at least under some circumstances. Although 3-chlorobenzoate was not present around the zone of injection, the genes required to affect degradation of that compound served as a key to its identification and quantification in aquifer samples. In a subsequent in situ bioremediation study, the bacterium *Pseudomonas stutzeri* strain KC that degrades carbon tetrachloride (CT) under denitrifying conditions was injected into a granular, CT- and nitrate-contaminated aquifer in Michigan (82). The bacterium not only served as its own microbial tracer, based on its DNA sequences and tendency to form distinctive "fried-egg" shaped colonies on solid media, it substantively enhanced the degradation of CT within the aquifer.

Another "tracer" application of bacteria for contaminated subsurface environments involves the use of specific GEMs as "sentinels" or indicators of whether or not specific contaminants are present and how the contaminants are distributed. One study involved a controlled, intermediate-scale field release of a bioluminescent bacterium *P. fluorescens* Hk44 in a vadose zone contaminated with polyaromatic hydrocarbons (PAHs). The bacterium harbored an introduced lux gene fused with a naphthalene-degradative pathway, allowing the bacterium to bioluminesce in the presence of naphthalene (83). The bioluminescence at depth then was measured by employing fiber-optic-based biosensor devices. The use of lux-based bioreporter bacteria such as *P. fluorescens* Hk44 as tracers for subsurface contaminants is a promising new tool in aquifer biorestoration.

Another recent subsurface bioaugmentation study involving the addition of a GEM included the addition to atrazine-contaminated soil of killed, stabilized *E. coli* genetically engineered to overproduce atrazine chlorohydrolase (84). Results supported the tractability for using bacteria engineered with "overexpressing" catabolic genes to increase significantly in situ biodegradation rates. However, many technical problems regarding the use of GEMs in subsurface bioaugmentation lie ahead. Recently, the field-usage of GEMs was permitted at a number of locations. Consequently, future additions of GEMs to contaminated aquifers and vadose zones are likely to be forthcoming in order to gain more information about the feasibility of using different recombinant bacteria to enhance biodegradation in a variety of subsurface environments. In these types of experiments, the GEMs can serve both as microbial tracers, because their engineered DNA sequences can be traced in space and time, and as agents of bioremediation.

CONCLUSION

In conclusion, microorganisms and microbial-sized microspheres are used as tracers in groundwater-related studies in many ways. The first injection and recovery studies in which microorganisms were used to delineate groundwater flow in karst have evolved into much more complex experiments involving both conservative and particulate tracers and well-instrumented sites in many different geohydrologic environments. The use of more sophisticated labeling methods, such as the use of recombinant DNA, is allowing for more efficient differentiation and quantification of microorganisms introduced into freshwater aquifers. In turn, the increasing number and technical sophistication of injection and recovery studies employing microbial tracers will further enhance our knowledge of groundwater systems, particularly karstic, fractured rock, and heterogeneous granular aquifers, and of the potential

fate of pathogens in different types of groundwater environments. Studies that employ microorganisms as tracers also facilitate new bioaugmentation technologies that will be used in future aquifer restoration projects.

In most environments, more than 99% of the prokaryotic microorganisms (generically referred to as *bacteria*) observed under a microscope are unculturable, yet they represent considerable genetic diversity, as determined by molecular techniques (1,2). Given that most of earth's inhabitable environments are permanently cold [$<20\,^{\circ}C$; $<5\,^{\circ}C$ in the volumetrically dominant ocean (3)], a significant fraction of the unculturable microbial life is likely to be cold-adapted — uniquely evolved to exploit the resources present in their vast and chemically diverse aquatic and terrestrial environments. In fact, native consortia of cold-adapted bacteria often catalyze reactions at rates comparable to their mesophilic counterparts inhabiting warmer climes (4). Knowledge of the genetics and physiology of isolates in culture and biogeochemical information on native consortia in cold environments indicate that the probability of these diverse uncultured microorganisms expressing novel processes or products of biotechnological interest is high. This article provides a review and prospectus of molecular-genetic technologies, catalytic proteins or enzymes, and bioremediation strategies as they pertain to the biotechnological application of cold-adapted microorganisms.

Although the terms "psychrophilic" (cold-loving) and "psychrotolerant" (cold-tolerant, also synonymous with "psychrotrophic") have been used in the microbiological literature for decades to describe varying degrees of cold adaptation (3), their specific meanings in research articles are often unclear or misunderstood. Here we refer to those microorganisms capable of growth at temperatures below $15\,^{\circ}C$ (the lower threshold for mesophiles) as "cold-adapted." Cold-adapted thus includes bacteria that require low temperatures ($\leq 15\,^{\circ}C$) for optimum growth, originally defined by Morita (3) as psychrophiles, and those that prefer warmer temperatures (usually $>20^{\circ}C$) but can still grow slowly at temperatures as low as $0\,^{\circ}C$, which are considered psychrotolerant. For catalytic proteins and their functions at low temperatures, we use the term "cold-active," regardless of the thermal class of the enzyme-producing organism.

UNDERLYING PRINCIPLES AND MOLECULAR GENETIC TECHNOLOGIES

Recombinant Gene Cloning

Bacteria have evolved a variety of strategies at the molecular level to adapt to cold temperatures (5,6). Structural changes in cellular membranes that allow maintenance of membrane fluidity and permeability, for example, have long been understood to play a crucial role in growth at low temperatures (7). Structural changes in proteins that allow enzymatic activity in the cold, and thus low-temperature biotechnology applications of the proteins, are the subjects of intensive investigation. An ability to explore such adaptations at both the molecular and organismal level is expanding rapidly as powerful new tools have become available. The new field of proteomics, taking advantage of two-dimensional gel electrophoresis (8), can give insight into gene regulation and optimum expression conditions for cold-active enzymes. The still rapidly developing technology of recombinant gene cloning, however, has already played an important role in understanding the structure-function relationships of bacterial enzymes and in enhancing the production of commercially important enzymes for the food, detergent, and pharmaceutical industries (9). In fact, more than 50% of the industrially important enzymes are produced from recombinant expression systems (10).

Typical gene cloning techniques begin with the generation of random or specific DNA fragments from the organism (or environmental DNA sample) under study, followed by the joining (ligation) of these fragments to a DNA-containing vector (such as a plasmid or virus). The vector, complete with its foreign DNA, is replicated in great quantity after introduction into a suitable host (typically *Escherichia coli*). The DNA fragments of interest are then selected by methods depending on the genetic system used and the desired gene product. Screening methods can include activity assays, when the host system has also allowed for efficient transcription and translation of the gene, or approaches that begin with reisolation of the DNA and analysis of its size and sequence.

Recombinant DNA technology thus not only gains access to the direct nucleotide sequence of the gene of interest, but also potentially yields the gene product in large quantities. For proteins encoded by cloned genes to make up 10 to 50% of the total protein produced by the host *E. coli* cells is not uncommon (11). Furthermore, the expression of genes from the uncultivated vast

majority of microorganisms is absolutely dependent on recombinant DNA technology and identification of suitable expression systems. Examples of success with this approach for uncultivated cold-adapted microorganisms are already evident: recombinant technology has allowed for the cold-active DNA polymerase from the uncultivated psychrophilic archaeon, *Cenarchaeum symbiosum*, to be cloned, sequenced, and expressed in *E. coli* using genomic DNA prepared from a sample of marine sponge tissue (12).

In many cases, however, researchers have experienced difficulties expressing recombinant catalytic proteins derived from extremophiles (whether cold- or heat-loving) in mesophilic hosts such as *E. coli*. These enzymes may require conditions for activity and stability that are not conducive to growth of a mesophilic host. Relatively few genes from cold-adapted organisms have been expressed successfully in *E. coli*; gene expression is normally achieved in large quantities only when *E. coli* is grown at suboptimum temperatures (13–15). Discovery of a host expression system using a cold-adapted bacterium, in which the growth rate of the host at lower temperatures is higher than that of *E. coli*, is expected to enhance the ability to express cold-active enzymes efficiently. Developing a cold-active expression system should also circumvent the problem of expressed proteins becoming insoluble in the host cell because of suboptimum temperature, and thus interfering with efficient protein expression.

Genetic Compatability

Given the highly developed genetic systems in mesophiles and relative lack of comparable systems in cold-adapted bacteria, fundamental genetic compatibility between the two thermal classes of microorganisms has been instrumental to successful genetic engineering in low-temperature applications. Such compatability has been demonstrated by the successful exchange of whole plasmids, implying shared translational functions and regulatory motifs (16). For example, antibiotic resistance has been conferred from *E. coli* to Antarctic psychrotolerant bacteria, *Moraxella* spp. (17), and the capacity to degrade toluene, from a mesophilic strain of *Pseudomonas putida* to a psychrotolerant strain of the same species (18). The latter example emphasizes the potential of genetic engineering for enhancing bioremediative processes in natural cold environments (16). Indeed, known plasmids commonly encode catabolic functions that include the degradation of environmental contaminants such as naphthalene, chlorobiphenyl, and chlorobenzoate in addition to toluene (19). Plasmids can also be designed to encode multiple degradative steps that otherwise would require complex bacterial communities. For example, a *P. putida* strain (with unspecified thermal characteristics) was designed for the degradation of polyhalogenated compounds to nontoxic products that otherwise required both aerobic and anaerobic bacterial populations (20). The mere physiological capability thus engineered, however, does not necessarily result in expression in situ, nor can the designed bacterium be assumed to compete successfully with the natural flora.

Plasmid transfer may also occur in the opposite direction, from cold-adapted microorganisms to mesophiles. For example, a nonconjugative plasmid encoding resistance to chromium and ampicillin was transferred by electroporation and transformation from a psychrotolerant, cryptoendolithic Antarctic bacterium into other cryptoendolithic bacteria and *E. coli*, with successful conferral of resistance (21). A shuttle vector has recently been constructed from plasmids of the Antarctic bacterium *Psychrobacter* sp. and *E. coli* that allows genetic manipulation in both organisms (22). Taken together, these findings suggest the ready potential to express recently discovered novel plasmids, predominantly of unknown function, from cold marine environments (23,24). That the replicative burden of carrying such plasmids is maintained in a large percentage of the in situ population (24 to 28% in the study cited) implies a selective advantage associated with each plasmid, perhaps pertinent to biotechnologically useful chemical processes in these environments. Some studies suggest that the frequency of catabolic plasmids within a population increases with the degree of pollution (19), implying mechanisms for in situ and interspecific transfer at cold temperatures and an innate bioremediative capacity (25–29). Some of these plasmids have broad host-range replicons (30), suggesting a potential promiscuity of interest both to biotechnological and environmental applications. Concomitant with such benefits, however, are the implied risks of unintentional transfer of introduced plasmids into the community at large, with unknown and unpredictable consequences (31–33).

The fundamental genetic compatibility of cold-adapted organisms with mesophiles has also been emphasized by recent analyses of cold-shock responses in both groups. Cold shock refers to the synthesis of a novel suite of more than a dozen proteins in response to a rapid decline in temperature (34). Regulation of cold-shock genes at the transcriptional level (35) may be of particular interest from the perspective of genetic engineering. Numerous experiments involving mesophiles (*E. coli*), psychrotolerant bacteria (*Lactococcus lactis* MG1,363, *Yersinia enterocolitica*) and a psychrophile (*Colwellia maris* ABE-1) have indicated enhanced transcription of cold-shock genes during temperature downshift (36–42). Particular advances in understanding such cold-shock regulation have emerged through recent research on the psychrophile *C. maris* ABE-1 and its two genes for the enzyme isocitrate dehydrogenase, one of which is preferentially expressed at low temperatures. This low-temperature gene appears to be controlled transcriptionally with a cold-inducible promoter (a specialized DNA sequence preceding the gene and required for transcription) and a transcription silencer (regulating the promoter activity) (42). Deletion of the promoter prevents low temperature-dependent expression, whereas deletion of the silencer results in 20-fold overexpression of the gene at low temperature.

Fusion of a promoterless gene of biotechnological interest to a cold-inducible promoter should allow preferential expression of that gene with lowered temperature. This type of expression has been demonstrated in *E. coli* using a promoterless, non-cold-shock gene for chloramphenicol acetyltransferase (36). In an environmental or industrial

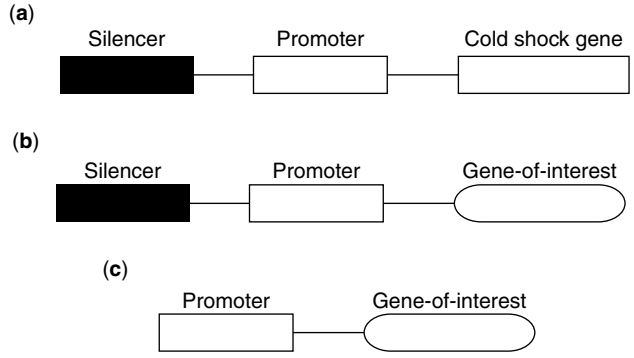

Figure 1. Schematic depiction of the potential exploitation of (**a**) cold-shock regulation, such as in *C. maris* ABE-1 (42), for (**b**) preferential expression of a gene of interest at low temperature or (**c**) mass production of the desired gene product at low temperature.

setting, this approach could provide a means to switch engineered genes — and with them, associated metabolic processes — on or off as a function of temperature. Deletion of a silencer, such as that in *C. maris* ABE-1, also suggests a simple mechanism to overexpress a given gene product specifically at low temperature (Fig. 1). Because the cold-shock response to decreases in temperature is relative to the normal growth temperature of the organism, exploitation of cold-shock genes could proceed at a variety of low temperatures by selecting an organism with the appropriate thermal characteristics. Because proper gene expression involves other factors, including structural stabilization of DNA and RNA and perhaps specialized RNA polymerases that may require additional regulatory components, such manipulation of intrinsic regulatory mechanisms may be more likely to succeed than de novo engineering.

Further advances in understanding and manipulating gene expression in cold-adapted bacteria can be expected with the establishment of appropriate genetic systems. Development of the psychrotolerant *Photobacterium profundum* strain SS9 system, which includes conjugal transfer of broad host-range plasmids and transposon mutagenesis (43), is encouraging. The linked goals of elucidating genetic regulation in psychrophiles and enhancing biotechnological exploitation of them should be facilitated further by completion of the first whole-genome sequences for psychrophilic microorganisms, anticipated for the Archaeon *Methanogenium frigidum* (44) and the Bacterium *Colwellia psychroerythraea* 34 H (45,46).

Viruses as Genetic Tools

Although viruses, specifically bacteriophage, are a common genetic tool for the manipulation of mesophilic bacteria, their use with cold-adapted microorganisms for biotechnological purposes represents a new field of endeavor. The potential for developing a low-temperature viral transduction system to facilitate genetic engineering work with psychrophiles (5,16) is supported by the number of viruses already isolated for cold-adapted bacteria, predominantly relevant to the food industry (47–53). Given high concentrations of viruses in the vast and cold ocean (54), appropriate phage-host systems may be much more abundant than realized. The typical specificity of a virus for a host species or strain (55) and the growing evidence for transduction in the natural environment (56–61) together suggest that targeted modification of a bacterial species may eventually be possible by in situ transduction (see Fig. 2). Viruses in nature are likely to influence bacterial community diversity and dynamics: they may select against dominant species, increase or decrease growth rate depending on the type of viral infection (62,63), regenerate nutrients through lysis to support growth of unsusceptible bacteria (64), and help maintain disadvantageous phenotypes in a population despite selective pressure (59). These properties, along with the specificity of viruses, may prove useful tools for stimulation or inhibition of select members of indigenous communities (Fig. 2) — a bioremediative strategy that may be more promising than the introduction of cultured organisms (65,66) discussed later.

Shortly after the discovery of bacterial viruses, d'Herelle proposed their use in the treatment of pathogenic bacterial infection (67), an idea subsequently elaborated in Sinclair Lewis's famous novel *Arrowsmith* (68). The discovery of antibiotics distracted researchers from further pursuit of this concept, but the growing specter of antibiotic resistance has renewed interest in the possibility. A number of characteristics of viral infection, including the viral replicative ability and specificity, make phage therapy attractive if sometimes problematic (69). Broad-scope antibiotics select resistant bacteria regardless of species; moreover, such resistance is frequently transferable. Resistance to a lytic phage, on the other hand, although likely to develop, will be restricted to the host species and has a reasonable probability of selecting for less virulent pathogens by selecting

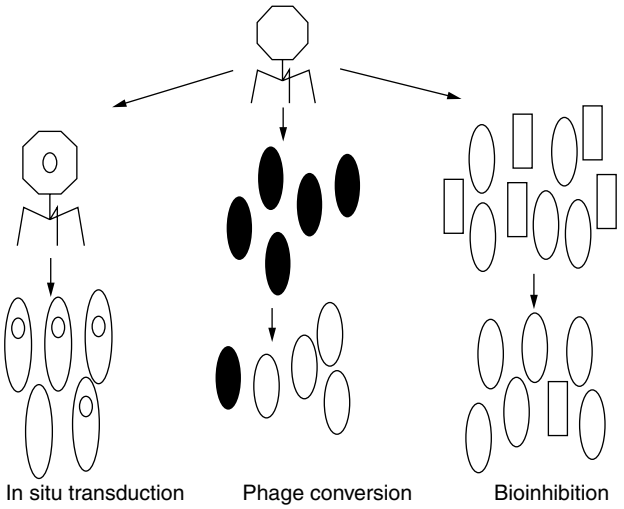

Figure 2. Potential exploitation of viruses for environmental bioremediation: transfer of foreign DNA (interior circles) encoding desired trait to select bacteria (ovals) in a natural community (in situ transduction); display of altered phenotype by infected bacteria (phage conversion); or shift in community structure from the natural dominant to desired bioremediator (bioinhibition).

against expression of antigenic surface receptors (70–72). Low-temperature phage therapy could be particularly practicable for applications in aquaculture, agriculture, and food storage. One study to consider such applications demonstrated that viruses could increase the shelf life of milk products an additional week at 7 °C by extending the lag phase of cold-adapted bacterial contaminants (53). The isolation of viruses specific to bacteria causing fish and meat spoilage (48,52) suggests additional applications of such an approach. Some bacterial pathogens or food-spoilers are psychrotolerant (*Listeria monocytogenes*) or psychrophilic (*Clostridium gasigenes*) (73) and could be controlled or attenuated by similar means. Numerous cold-adapted bacteria are known pathogens of fish (74) or fish eggs (75) and can cause serious fish diseases such as cold-water vibriosis (76). Antibiotic treatment in such cases is unsatisfying because of the likely development of resistance, whereas vaccination may injure fish, making alternative treatment possibilities desirable.

Other applications of cold-active viruses will involve their own genetic potential, because their encoded proteins and enzymes are also likely to be cold-active. Useful viral genes may be easier to find and express than their bacterial counterparts: viral genomes are much smaller than bacterial genomes; viruses replicating within a host may result in a high copy number (burst size); and the phenomenon of phage conversion may transform the bacterial phenotype to reflect viral genes (Fig. 2). For example, studies of viruses infecting bacteria that produce exopolysaccharides indicate that the viruses may encode the polysaccharase activity (77), the expression of which facilitates the spread of the virus through the biofilm. An analogous but cold-active enzyme could be employed to degrade or control biofilm formation in low-temperature industrial processes.

COLD-ACTIVE ENZYMES

For bacteria to grow in the cold, they must possess enzymes capable of catalyzing chemical reactions with high specific activity at low temperatures. Such enzymes generally have higher specific activities (in the range of 0 to 30 °C), lower temperature optima for activity (45), and greater lability at warmer temperatures than enzymes derived from mesophilic or thermophilic organisms (78,79). The realization that cold-active enzymes offer novel tools for biotechnological purposes (6) has sparked interest and increasing research in such promising areas as the expression and structural features of cold-active enzymes, especially as such knowledge can be applied to goal-oriented enzyme engineering.

Early approaches to enzyme research involved growing the enzyme-producing wild strain to sufficient cell density, obtaining an extract with the desired enzyme activity, purifying the native enzyme to homogeneity, and determining the amino acid composition and sequence (left pathway in Fig. 3). Note that the primary sequence of a cold-active enzyme was only determined in this way relatively recently (80). From the amino acid sequence, the nucleotide sequence of the gene encoding the enzyme

[b] Crystalline structure also now available (see Table 2).

can then be predicted. Determining the entire amino acid sequence of a protein is a substantial and not always straightforward process; determining the amino acid sequence from the encoding gene sequence instead is far easier (11). The development of recombinant techniques has made the latter approach feasible in many cases (right pathway in Fig. 3), obviating many of the problems associated with earlier biochemical approaches to the study of enzyme structure and function. The databases building from each approach, biochemical and genetic, now serve the other to maximize the research effort (cross pathways in Fig. 3).

Although the number of genes for cold-active proteins cloned and sequenced is relatively small compared with those of mesophilic and thermostable counterparts, it is growing rapidly (Table 1). Only very recently have researchers attained direct structural determinations of protein crystals for cold-active enzymes (Table 2), held by many to be the best approach to investigate the structure–function relationships of an enzyme. In the meantime, much of the research on structural aspects of cold-active enzymes has been the result of computer-based predictions of protein folding (homology models) based on gene sequences and the known three-dimensional structures of homologous enzymes optimized to warmer temperatures. Although this modeling approach is widely accepted, it can give only limited information critically dependent on the accuracy of computer programs (81). Often activity in the cold is due to unique structural modifications that simply cannot be predicted from gene-homology models. As

more structures for cold-active enzymes are solved, direct comparisons to homologous proteins optimized to warmer temperatures may yield a better understanding of the structure–function relationships that allow for activity in the cold.

Molecular Features Allowing for Cold Activity

Understanding molecular features that confer activity in the cold contributes to effective engineering and use of biotechnologically relevant enzymes. Molecular adaptations to temperature have been deduced largely from comparisons of mesophilic and highly thermostable enzymes. Although the active sites and overall three-dimensional structure of homologous enzymes tend to be conserved, a general relationship between overall enzyme flexibility, stability, and specific activity appears to exist.

For example, enzymes derived from thermophilic organisms have displayed high stability under conditions that denature mesophilic enzymes, but relatively low specific activity at moderate temperatures (118,119). This enhanced stability has been attributed to the relatively rigid, less flexible structure of thermostable enzymes. The most frequently observed features thought to contribute to this structural rigidity include:

1. increases in the number of salt-bridges;
2. increases in hydrophobic residues;
3. increases in ionic interactions and hydrogen bonding; and
4. reductions in the active site of the enzyme (120,121).

Cold-active enzymes, as inferred from high specific activities and thermolabilities, appear to be characterized by an increased flexibility of the overall polypeptide chain, enabling greater accessibility to the active site and helping to counteract the effects of low temperature (122). The recent availability of structural determinations of cold-active enzymes has enabled researchers to directly test the hypothesis that cold-active enzymes have a more flexible structure than their warmer counterparts. Preliminary trends to explain cold activity include:

1. decreased number of salt-bridges;
2. more polar and fewer hydrophobic residues;
3. fewer hydrogen bonds, aromatic interactions, and ion pairs; and
4. extended surface loops (79,123,124).

At first glance, the structural features conferring flexibility in cold-active enzymes appear to oppose those rendering enhancing stability in thermostable enzymes. An in-depth look at available gene sequences and protein structures, however, suggests that the relationship between stability, activity, and flexibility is more complex. When a small number of amino acids were introduced into a wild-type structure (via site-directed or random mutagenesis) in some recent studies (91,125), the thermostability and catalytic activity of the cold-active enzymes were both enhanced. Enzyme adaptation to temperature will not be summarized easily by a continuum of amino acid substitutions affecting overall structural flexibility along a temperature spectrum; cooperative local effects are likely to prove critical.

The first suggestion of the important role of local flexibility in cold activity came from comparative investigations of the crystalline structures of a cold-active salmon trypsin and a mesophilic bovine trypsin (126). The reduced stability of the cold-active trypsin appeared to derive from weakened interactions between local domains (regions) of the molecule, not differences in overall flexibility between the two structures. These weaker interdomain interactions were suggested to ease motion during catalysis, thus explaining increased catalytic efficiency of the cold-active trypsin. In a comparative study of the crystalline structure of cold-active citrate synthetase and a thermostable homolog (81), greater differences in flexibility between the large and small domains of the cold-active enzyme were considered to lead to greater relative movement and thus activity in the cold. Although maximal flexibility in domains directly involved in the catalytic reaction (the active sites) appears critical to cold activity, rigidity in areas not directly involved in catalysis is also important (127), as exemplified by thermal unfolding studies of cold-active and mesophilic phosphoglycerate kinases (128), in which the stability of a presumed noncatalytic domain actually exceeded that of the corresponding domain in the mesophilic homolog. Thus, activity in the cold may be a result of local flexibility and relative interdomain movement in enzymes, as opposed to overall flexibility.

Protein Engineering

Despite advances in deducing possible molecular adaptations from the first structures for cold-active enzymes, little progress has been made in determining specific mechanisms affecting enzyme activity. Often structures available for comparison are derived from divergent organisms that, as a result of genetic drift and differential selective pressures, may contain numerous amino acid differences not related to cold activity (129). Simply comparing the gene sequences of cold-active enzymes to existing structures of homologous enzymes is not intuitively satisfying and can be misleading. Alteration of the amino acid

sequence of a protein of interest in a controlled and documentable manner, known as protein engineering, has thus emerged as a useful tool for examining structure–function relationships.

Protein engineering can be achieved either through rational protein design using site-directed mutagenesis or through random mutagenesis, which includes directed evolutionary approaches. In site-directed mutagenesis, prior knowledge of enzyme structure is needed to make rational mutations in the encoding gene. Mutations can be in the form of replacement, deletion or insertion of one or more nucleotides into the gene sequence. Directed evolution, on the other hand, does not require that mutations be targeted; mutations are introduced randomly throughout the protein via sequential rounds of mutagenesis each followed by selective screening. Selecting for only adaptive mutations decreases the interference of neutral evolution. Directed evolution has been used in a variety of studies to generate specific enzymatic properties while simultaneously determining the mutations that led to them (125).

In addition to elucidating structure–function relationships, the application of protein engineering technologies to modify enzyme structures and give enhanced properties for biotechnological purposes appears to have unlimited potential. These methods have already been successful in engineering cold-active enzymes, in which both stability and activity were improved simultaneously (91,125). Such properties can be beneficial economically in industrial processing, resulting in higher rates of reaction with less enzyme loss because of denaturation. Also, enzyme immobilization is widely used in industrial applications to stabilize and retain enzyme activity (130,131). These benefits must be balanced, however, against diffusional limitations and decreased specific activity of some enzymes when immobilized to a surface because of limited accessibility of the active site (132). Given recently obtained knowledge of the importance of interdomain movement for cold activity in enzymes, protein engineering can now be used to substitute specific amino acids in the remaining stable regions known to bind preferentially to the support matrix. This approach should enable enzyme immobilization although allowing the catalytic domain to retain flexibility and remain exposed in solution, perhaps enhancing catalytic activity. In many cases, industrial processes target the production of artificial compounds using heat or other nonenzymatic means to generate them. Protein engineering may aid in the development of enzymes with novel catalytic properties that could replace or improve the efficiency of rates of production of such compounds.

Applications of Cold-Active Enzymes

Enzymes are ideally suited to catalyze the production or breakdown of specific compounds, both because of their high substrate specificity and greater ease of control, relative to an introduced organism, for example. Enzymes from extremophiles already play a significant role in a variety of applications — the annual market for thermostable enzymes is $250 million U.S. dollars (133). Although the economical value of cold-active enzymes has yet to be realized, the potential for use of their novel properties in a variety of applications is great. Growing interest in cold-active enzyme catalysis is evident through the establishment of such projects as "COLDZYME" in the European Union, aimed at coordinating research efforts to better understand the molecular basis of cold-activity in proteins and their potential biotechnological uses. Some of these applications are outlined later.

Food Industry. Enzymes have been involved in the preparation of foods for recorded history. Traditionally, cold-active enzymes have been associated negatively with food spoilage. The beneficial applications, however, that take advantage of their high catalytic activity at low temperatures and ease of inactivation are numerous. Cold-active β-galactosidases that work optimally at neutral pH can be used in milk to degrade lactose rapidly at cold temperatures, enhancing the digestibility and sweetness but minimizing the growth of contaminants (5), whereas β-galactosidases optimized to more acidic pH can be used to degrade lactose in acid-whey, a product of cottage cheese manufacture. The increased sweetness and fermentability of the resulting breakdown products, glucose and galactose, expand the potential to reuse whey as a sweetener for beverages, syrups, and so on., thus decreasing the demand for sweeteners while mitigating the cost of waste treatment (134). Cold-active lipases and proteases can be used to accelerate the ripening of cheese at low temperatures, whereas proteases may act as efficient meat tenderizers. In the juice industry, pectinases may be used to enhance juice yield and clarification, subsequently inactivated by a relatively small increase in temperature, resulting in a less "cooked" taste for the juices. In baking, enzymes such as amylases, proteases, and xylanases may be used to reduce the dough fermentation time by acting directly on starch, gluten, and hemicellulases (133). Although generally regarded as having hydrolytic properties, these enzymes can catalyze reverse reactions under certain conditions, thus synthesizing organic compounds (9). Cold-active enzymes may prove very lucrative in such processes because the amount of energy required to drive the reverse reaction of a cold-active enzyme will be relatively low as a result of their inherently low activation energies. Furthermore, cold-active enzymes may even replace some chemical preservatives in foods by acting to disrupt microbial cells, deplete metabolites, or degrade enzymes needed for contaminant growth (135,136). Although they are not technically enzymes, ice-nucleating proteins expressed by a number of cold-active bacterial species can serve as a template to trigger ice-crystal formation at subzero temperatures (-2 to $-5\,^{\circ}$C) at which water would otherwise remain liquid and supercooled. These proteins could be used to improve ice-cream manufacture, and freeze-texturing or freeze-drying of foods at relatively warm temperatures, thus decreasing energy consumption (137).

Detergent Industry. Hydrolytic enzymes such as proteases, lipases, α-amylases, and cellulases already comprise significant ingredients in many common detergents; the uses of proteases in laundry detergents accounts for approximately 25% of the global sale of enzymes (9). The benefits of using cold-active enzymes as detergent additives, thus allowing sufficient hydrolysis to take place at

cold temperatures, include reductions in energy consumption and the fabric degradation characteristic of warm- and hot-water washing. Along with energy constraints, the increasing use of synthetic fibers, which can only tolerate moderate wash temperatures, is also increasing the demand for cold-water washing. Other more specific uses of cold-active enzymes can also be projected. For example, cellulases can increase the softness of cotton garments that become frayed over time. Use of a cold-active enzyme for this purpose is particularly attractive because the enzyme could be inactivated during the wash cycle by a small increase in temperature so as to halt further degradation of the fabric (133).

Molecular Biology. Many of the enzymes presently used in molecular biotechnology were developed to work at moderate temperatures to facilitate research with *E. coli* cells and tissue cultures. Recent interest in working with and expressing components of cold-active systems in a variety of molecular applications creates the need for enzymes with higher activities at lower temperatures (see Table 3). The radioactive end-labeling of nucleic acids by T4 polynucleotide kinase, for example, is a useful tool in determining the structure of nucleic acids. Before kinase can act, however, removal of the existing phosphates at the 5′ termini of oligonucleotides must be completed by alkaline phosphatase (APase), whose activity must then be eliminated. Use of a cold-active APase would aid in this process (138) because of its thermolability at relatively moderate temperatures that do not affect nucleic acids. Presently, commercially available DNA ligases have poor activity below 15 °C, which results in long incubation times at these temperatures, thus increasing the risk of residual nuclease activity degrading the DNA and interfering with the ligation reaction. The application of a cold-active ligase would result in shorter incubation times, helping to alleviate nuclease degradation of DNA (106). Other enzymes directly involved with molecular processes such as a cold-active restriction endonuclease (139) and a DNA polymerase (12) also demonstrate great potential as tools for molecular research and biotechnology.

BIOREMEDIATION

As the global human population has grown, dependence on hydrocarbons for heating and transportation, on yields of large-scale agriculture boosted by the use of pesticides and herbicides, and on large-scale industrial processes to provide goods deemed essential or desirable has also increased. The scale of these activities and limited attention to containment have resulted in widespread pollution by a variety of chemicals. Although many of these compounds and their congeners may occur naturally, human exploitation and manipulation of such resources, even with the best of intentions, has resulted in amplification of chemical concentrations well above natural background levels, in some cases representing serious threats to ecosystem and human health. These problems are accentuated in polar environments, because many chemicals produced and released at low latitudes are transported by planetary circulation systems (atmospheric and oceanic) and deposited in cold high-latitude regions that otherwise would be pristine (140–146). Developing applications of cold-adapted microorganisms (or cold-active enzymes) to bioremediation, defined as the use of organisms (through their degradative enzymes) to remove hazardous pollutants from the environment (147),

Table 3. Examples of Demonstrated and Proposed Applications[a] of Cold-Active Heat-Labile Enzymes to Genetic Engineering

Enzyme	Application	Publication Date (Reference)
Alkaline phosphatase	Radioactive end-labeling of nucleic acids: enzyme rapidly inactivated with heat, allowing its removal for subsequent reaction steps	1984 (138)
DNA polymerase	DNA synthesis: DNA amplified enzymatically at cold temperatures	1997 (12)
Restriction endonucleases	Sequence-specific cleavage of DNA, including possible new specificity with blunt or single-stranded ends: enzyme activated at low temperatures, then inactivated by heating	1997 (139)
DNA ligase	DNA recombination: enzyme activated at low temperatures nonpermissive to competing nucleases, then inactivated by warmer temperatures still below that of DNA denaturation	2000 (106)
Reverse transcriptase	Reverse transcription of RNA into DNA: enzyme activated at low temperatures nonpermissive to competing nucleases could make RT-PCR more quantitative and possibly more economical	(proposed here)
Essential enzymes	Heat-controlled inactivation of organisms: deliberate design of strains with essential but heat-labile enzymes could allow more efficient exploitation of the organism and protection if inadvertently released	(proposed here)

[a] Ordered by publication date to underscore newness of the field.

thus emerges as an important endeavor in the broader field of environmental biotechnology. The concept of bioremediation currently includes both the manipulation of environmental conditions to enhance native microbial activities (biostimulation) and the addition of laboratory-cultured organisms with demonstrated and sometimes unique degradative abilities (bioaugmentation). Recent findings from both laboratory and field studies (addressed later) reveal the potential of cold-adapted microorganisms and their enzymes to provide solutions to the bioremediation of organic contaminants — hydrocarbons, substituted hydrocarbons, and other xenobiotics — present in cold environments.

Hydrocarbon Degradation

While some hydrocarbon compounds represent a direct threat to human and ecosystem health as a result of leaking underground storage tanks, oil spills, and chronic smaller-scale spills at transfer stations, many microorganisms have the ability to utilize hydrocarbons as sources of energy for metabolism and growth. The biodegradation of naturally occurring aliphatic (open-chained) hydrocarbons is almost exclusively an oxidative process, beginning with the addition of oxygen to the first or second carbon in the molecule, as mediated by the enzyme monoxygenase (148). The final product is acetyl CoA, which shunts into the citric acid cycle, the common central pathway for respiration in aerobic organisms. Unsaturated aliphatic hydrocarbons, characterized by a terminal double bond that is susceptible to anoxic decomposition, may also be oxidized by sulfate-reducing and other anaerobic bacteria.

Aromatic hydrocarbons (benzene-ring derivatives) comprise one of the most common classes of organic contaminants in sediments; many of these compounds, especially the polycyclic (multi-ringed) aromatic hydrocarbons or PAHs, are known carcinogens (149,150). Their strong hydrophobicity explains not only their sorption to sediment particles and organic materials, and thus concentration in freshwater and marine sediments, but also why such hydrocarbons tend to bioaccumulate in organisms, thus toxifying aquatic food webs. Many aromatic hydrocarbons can be degraded microbially under aerobic or anaerobic conditions, whereas PAHs with four or more fused rings are believed to be largely recalcitrant to biodegradation. Although microorganisms are generally understood to derive nutrition from materials in solution, direct action on particle-sorbed PAHs has been implicated (151). Biosurfactants and bioemulsifiers may play an important role in increasing the bioavailability, and thus biodegradability, of these strongly hydrophobic compounds (152–154).

Bioremediation in the Cold. Numerous studies on the potential for biological remediation of hydrocarbon contamination in cold environments have led to the conclusion that an indigenous fraction of hydrocarbon-degrading bacteria, present in virtually all environments, rapidly becomes enriched when a pollution event occurs. The hydrocarbon-degrading fraction of the population may be as small as 0.1% in pristine environments, yet constitute up to 100% of viable organisms in contaminated environments (155). Factors determining this enrichment effect, and thus the rate and extent of hydrocarbon degradation, include temperature, nutrient concentrations, aeration, bioavailability of the pollutant, and history of contamination of the site. The overall amount of hydrocarbons subject to indigenous microbial action after a spill depends on abiotic processes that contribute immediately to hydrocarbon losses from the system. The most volatile compounds are lost through evaporation, whereas other constituents of hydrocarbon mixtures may be transformed by photo-oxidation. Contamination can also be removed physically through wind, waves, and currents; numerous studies have reported that up to 30% of hydrocarbons are lost shortly after they enter an environment (156).

The specific effects of low temperature on the rate and extent of microbial degradation of hydrocarbons thus take both biological and nonbiological forms. Rates of microbially mediated processes are often observed to reduce by a factor of two for every 10 °C reduction in temperature (157,158), a phenomenon commonly known as the Q_{10} effect. Low temperatures make the target compounds more viscous, reduce evaporation of toxic short-chain alkanes, and increase water solubility (159), affecting the extent of abiotic loss and the degree to which a hydrocarbon mixture is available to microorganisms for degradation. The combined effects serve to delay the onset of hydrocarbon degradation.

Despite these commonly cited negative effects of low temperature, the indigenous genetic potential for hydrocarbon biodegradation in a variety of cold environments remains clear (Table 4), spurring continued interest in the potential for in situ attenuation and mineralization of contamination in cold climes. For example, of 135 psychrotolerant strains of bacteria isolated from pristine and contaminated sites all over Canada, including soils, sediments, lake water, seawater, and groundwater, most of the isolates were able to mineralize toluene, naphthalene, dodecane, and hexadecane at 5 °C (160). In the wake of the *Exxon Valdez* oil spill in Alaska, the genotype of the culturable hydrocarbon-degrading population was observed to change over time and reflect the hydrocarbon mixture to which it was exposed (161). In fact, the natural attenuation of many types of hydrocarbons has been demonstrated in cold environments, but over extended periods of time (162–164). Evaluations must be made on a case-by-case basis (147), but natural attenuation or in situ bioremediation may be most appropriate for spills in areas posing less immediate threats to ecosystem or human health.

Biostimulation. To enhance the rate of hydrocarbon degradation in situ at low temperatures, the addition of either oleophilic (oil-loving) or water-soluble fertilizers (biostimulation) has been a common and effective approach (Table 5). The most publicized in situ tests of biostimulation occurred after the *Exxon Valdez* oil spill in Alaska, where seawater temperatures fall between 10 and 17 °C. Improvements in the aesthetics of contaminated beaches, and increased rates of hydrocarbon

Table 4. Examples of the Degradation of Organic Pollutants at Low Temperatures by Cultured Microorganisms

Environmental Sources	Temperatures) (°C)	Organisms	Findings	Reference
Antarctic soil	−3.2, 3.1, 25, 37	Variety of isolates	Hydrocarbon-degrading strains isolated, need for adaptation to target compound if environment pristine recognized	165
Antarctic soil	16	*Rhodococcus* spp.	Psychrotolerant strains isolated from contaminated soil, able to degrade alkanes (hexane through eicosane)	166
Sub-Arctic coastline	10 to 17	Variety of isolates	Numerous plasmid-containing strains isolated, able to mineralize alkanes and aromatic hydrocarbons; composition of contaminants reflected in population genotype	161
Sub-Arctic and Arctic soil and sediment, sea-, fresh- and groundwater	5, 23	Variety of isolates	135 psychrotolerant strains isolated, most able to mineralize toluene, napthalene, dodecane, hexadecane; potentially novel pathways for toluene degradation, possible gene for degrading short and longer chain alkanes	160
Sub-Arctic coastline	5, 25	*Pseudomonas* spp.	Three plasmid-containing strains isolated, able to degrade alkanes (C_5-C_{12}), toluene and napthalene; both *nah* and *alk* plasmids carried by given strain	167

Table 5. Examples of Hydrocarbon Degradation at Low Temperatures by Native Microbial Consortia, With or Without Addition of Chemicals (Biostimulation)

Source or Type of Compounds	Environment	Temperatures (°C)	Findings	Reference
Arabian Light crude oil	Sub-Antarctic coastline	1 to 8	Degradation in winter low, due to effects of cold and initial state of native microbial consortia	164
Arabian Light diesel oil	Antarctic sea ice	−1.4 to −1.7	Degradation potential enhanced by addition of nutrients, number of hydrocarbon-degrading bacteria increased dramatically	172
Prudhoe Bay crude oil	Sub-Arctic coastline	10 to 17	Degradation enhanced by addition of oleophilic fertilizers, nutrients (inopol EAP22); number of hydrocarbon-degrading bacteria increased	168,169,173
JP-5 jet fuel, toluene	Arctic aquifer	4 to 6	Mineralization at low temperatures similar to mesophilic rate at 20 °C	162
JP-5, gasoline, diesel fuel	Arctic soils	∼10	Degradation enhanced by addition of lowest level of nutrients (N:P of 100 : 45)	174
Petroleum hydrocarbons, dodecane, phenanthrene	Arctic tundra	7, 15, 22	Mineralization substantial at 7 °C, not inhibited by heavy metals or high hydrocarbon concentrations, enhanced by nutrient additions and by inocula of indigenous or nonindigenous oil-degrading bacteria (see also Table 6)	171
Diesel oil	Alpine soils	10, 25	Degradation enhanced by addition of fertilizers	175

mineralization (complete degradation to carbon dioxide) compared with untreated plots, were reported (168–170) (note that distinguishing biological degradation from physical removal was not trivial and was later questioned (65)). From a study of Arctic permafrost, in which microbial communities were observed to degrade hydrocarbons actively at 4 to 7 °C, the availability of adequate nutrients was essential to obtaining appreciable rates of hydrocarbon degradation (171).

Bioaugmentation. The approach of adding microorganisms or groups of microorganisms with demonstrated biodegradative abilities (bioaugmentation; Table 6) has also been used in an attempt to improve both the rate and extent of hydrocarbon degradation. While several tests have been performed (65,149,176,177), few have yielded anything beyond a short-term increase in degradative activity or end-products significantly different from those generated by native organisms (171). Among the suspected shortcomings of this approach are the preferential use of other compounds by the added organisms and unsuccessful resource competition with native microorganisms. Bioaugmentation may be worth pursuing in particularly harsh or cold environments, where

Table 6. Examples of Hydrocarbon Degradation at Low Temperatures by Native Microbial Consortia, With or Without Addition of Microorganisms (Bioaugmentation)

Source or Type of Compounds	Environment	Temperatures (°C)	Findings	Reference
Alkanes, phenanthrene	Antarctic coastline	10, 25	Degradation of n-alkanes and phenanthrene with inocula from contaminated lake and beach sand	179
Diesel fuel, n-alkanes	Sub-Arctic soil	0, 5, 25	Mineralization of diesel fuel greater at 5 °C with inoculum of *Rhodococcus* sp. strain Q15	180
Diesel oil	Alpine soils	10	Degradation enhanced slightly with inoculum of cold-adapted bacteria, enhanced more by nutrient addition	176
Weathered diesel oil	Alpine soils	10, 25	Degradation inhibited by nutrient addition with inoculum, highly stimulated by nutrients without inoculum	177
Diesel oil	Alpine soils	10	Degradation temporarily enhanced by inoculum of oil-degrading bacteria, greatest effect with native consortium alone and fertilizer added	178

reduction in the lag time to biodegradation may be of greater importance than rate of removal (178).

Pollution History and Microbial Adaptation. The negative effects of cold temperature may also be overridden by pollution history as a factor in determining the rate and extent of hydrocarbon biodegradation, underscoring the importance of indigenous microbial adaptations to chronic pollution. For example, a lake subjected to chronic contamination had indigenous microorganisms that were able to degrade hydrocarbons at very low temperatures (0 °C), whereas organisms from pristine sites were unable to utilize hydrocarbons at that temperature (181). Other studies have also documented this phenomenon (160,179), including a case in which soils were challenged and rechallenged with the herbicide Napropamide (an aliphatic amide; see more on substituted hydrocarbons later). The time to 50% disappearance of the initial dose was observed after 25, 45, and 75 days at 25, 15 and 5 °C, respectively. After the second challenge, the degradation rate was at least five times more rapid, even at the lowest temperature tested (50% disappearance observed after 4, 7, and 15 days at 25, 15 and 5 °C, respectively). Given a high degree of adaptability when challenged with organic pollutants, diverse natural degradative abilities, and biostimulation as an effective strategy for enhancing in situ rates of degradation, efforts to harness cold-adapted microorganisms and native microbial consortia in the remediation of low temperature environments may prove both efficient and cost-effective. Because as much as 30% of initial contamination can remain in the form of asphalts (hydrocarbon residue) after microbial degradation has run its natural course, the challenge is to fine-tune existing methods and develop new strategies that foster breakdown of even the most recalcitrant materials currently released into the enivronment or produced by long-term weathering.

Degradation of Substituted Hydrocarbon and Other Xenobiotic Compounds

In addition to fuel and heating oils, the more complex or substituted (halogenated, alkylated, brominated) aliphatic and aromatic hydrocarbons, (which are used for such purposes as pesticides, herbicides, industrial solvents, wood preservatives, and dielectric fluids), represent large classes of environmental pollutants. Although more than a thousand of these types of xenobiotic compounds are produced and used widely for pest control and various industrial processes, relatively few studies document their degradation in low temperature environments (Table 7). Microorganisms known to degrade these compounds at moderate temperatures are diverse; some can utilize them as both carbon and energy sources and some can mineralize them to carbon dioxide and water. The typical first step in the degradation of a variety of chlorinated (halogenated) aliphatic and unsaturated hydrocarbons is reductive dechlorination under anoxic conditions, although aerobic degradation of some halogenated aliphatic compounds is known to be mediated by methanotrophic and ammonia-oxidizing bacteria.

Low temperature research on the microbial degradation of substituted hydrocarbons and other xenobiotics has taken pathways similar to those for fuel and heating oils (e.g., effects of biostimulation, importance of adaptation time), but with a difference in focus on the basis of the anaerobic steps often involved (Table 7). The need for anaerobic conditions has thus spurred studies of the effects of alternative electron acceptors, in which such "nutrients" become the test stimulant, and gradients in environmental temperatures. A range of both electron acceptors and temperatures occur in the sediments in which many of these hydrophobic pollutants accumulate.

For example, in studies of the degradation of polychlorinated biphenyl compounds (PCBs) in Hudson River sediments in winter, significant PCB removal occurred at

Table 7. Examples of the Degradation of Substituted Hydrocarbons and Other Xenobiotics at Low Temperatures by Native Microbial Consortia or Mixed Cultures

Source or Type of Compounds	Environment	Temperatures (°C)	Findings	Reference
Polychlorinated biphenyls (PCB)	Temperate sediment	4	Greater than 50% loss of Aroclor 1,242 after five months	182
	Temperate sediment	4–66	Best PCB dechlorination rates between 12 and 34 °C, little to no loss at 4 °C.	183
	Arctic soil	7, 37, 50	Greater PCB removal by cold-adapted (compared to mesophilic) bacteria at low temperature	184
Polychlorinated pesticide (DDE)	Temperate sediments	10	Dechlorination under sulfidogenic and methanogenic marine conditions	185
Trichloroethane	Temperate groundwater	10	Degradation by mixed cultures of methane-oxidizing bacteria in presence of methane	186
Trichloroethylene	Temperate groundwater	10, 12, 24	Degradation by ammonia-oxidizers, more effective than by methanotrophs	157
Chlorobenzene, tetrachlorethylene	Temperate groundwater	4, 10, 20	Degradation more effective by native consortia than with inoculum[a]	187
Chlorophenol	Temperate groundwater	4–17	Degradation rates high, over 99.9% removed at lower temperatures	188
Brominated phenols	Sub-Arctic sediments	4	Degradation of phenols and benzoic acid under sulfidogenic, methanogenic, and iron-reducing estuarine conditions	189
Phenol	Industrial wastewater	10	Degradation rate at low temperature 15–40% of mesophilic rate; useful in cold regions where temperatures fluctuate	190
Ethylene glycol, propylene glycol	Temperate soil	−2 to 25	Degradation at all temperatures with no lag time	191
Aliphatic herbicide Napropamide	Temperate soil	5, 15, 25	Degradation rate dependent on microbial adaptation, adapted consortia suitable for bioaugmentation[a]	192

[a]See Table 6 for other examples of bioaugmentation.

4 °C in the upper 15 cm of the sediment, but no loss was detected in the lower horizons after a 5-month study (182). Lower chlorinated compounds were observed to degrade in the shallower aerobic layers of the upper sediment, whereas the more highly chlorinated biphenyl and chlorinated aliphatic compounds were degraded mainly under reducing conditions deeper in the sediment (187). In a year-long study of the degradation of a tetrachlorobiphenyl over a range of temperatures (4 to 66 °C), seven different reaction pathways were observed, each dependent on the temperature of incubation (183). In the case of brominated phenols, enrichments with the electron acceptors required to fuel iron-reducing, sulfate-reducing or methanogenic microorganisms (Fe(III), SO_4^{2-} or HCO_3), obtained from cold (4 °C) marine and estuarine habitats, indicated a hierarchy of degradation rates in reverse order, with methanogenic conditions providing the highest debromination rates (189); removal of bromobenzoate, but not bromophenol, isomers required a significant adaptation period. Clearly, the actions of multiple and diverse native microbial consortia may be required under equally diverse in situ conditions to remove some xenobiotics effectively.

When a xenobiotic compound of known human health hazard (192) proves particularly recalcitrant in situ, as observed for chlorophenols (CPs) in cold groundwater aquifers (the temperature of the average North American aquifers is 10 to 13 °C), or is only partially degraded, leaving toxic intermediates behind, as observed for the solvent trichloroethylene (TCE), more aggressive engineering strategies may be in order. Ex situ treatments in the form of aerobic, fluidized bed reactors have been shown effective at removing >99.9% of total CPs from groundwater at temperatures as low as 4 °C (188). Although TCE is known to be degraded by methanotrophs aerobically (and anaerobically by reductive dechlorination), laboratory biostimulation with ammonium has been shown to be effective at reducing contamination with TCE at 12 °C, suggesting that field biostimulation with ammonium, an inexpensive and nontoxic chemical, may be an important remediation technique for TCE-contaminated aquifers. Nevertheless, observations of toxic intermediates persisting in studies of TCE degradation (186) suggest that TCE-degrading microorganisms may be prime targets for genetic engineering to overcome the toxic-intermediate

bottleneck and position them for use in ex situ reactors to achieve complete TCE degradation.

Finally, studies of the deicing-fluids used routinely in the winter to control ice formation on the wings of aircraft (191) reveal both the power of native cold-adapted microbial consortia as bioremediators in spite of the potentially constraining effects, biological and abiotic, of very cold temperatures on contaminant degradation. The principal organic constituents of these deicing fluids are ethylene, propylene, and diethylene glycols; they are sprayed on the aircraft before departure and thus wash off the runway onto surrounding soils. These glycol products, whether presented singly or in mixtures, have been shown to be mineralized to carbon dioxide in these soils when incubated at temperatures as low as $-2\,^{\circ}C$ (191). No adaptation period was required: biological transformation of the test chemicals began immediately after addition to the soil and regardless of exposure to very high concentrations. Rates of degradation ranged from 2.3–4.5 to 19–27 to 66–93 mg kg^{-1} soil day^{-1} at -2, 8 and 25 °C, respectively, translating to Q_{10} values well in excess of the expected value of two, if biological reactivity were the primary limiting factor. The suggestion that even mild warming significantly increases the bioavailability of these energy-rich compounds (a form of biostimulation) on top of the typical increase in biological reactivity portends well for positive seasonal trends in the degradation of such compounds by native microbial consortia, without aggressive treatment of the contaminated environment.

SOME FUTURE APPLICATIONS OF COLD-ADAPTED MICROORGANISMS

Fatty Acids for Aquaculture and Medicine

As part of their strategies to maintain membrane fluidity at low temperatures, many cold-adapted microorganisms produce a diversity of polyunsaturated fatty acids (PUFA) (193,194). Some PUFAs, particularly eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), are important supplements in aquaculture feeds (194). They are also essential elements in the human diet, required for retinal and neurological development in infants and helpful in treatment of rheumatoid arthritis, ulcerative colitis, skin lesions, psoriasis, coronary artery disease and some cancers (195). Use of genetic engineering tools to achieve overexpression of PUFA production for fish or human consumption represents a potential biotechnological application of cold-adapted microorganisms. Studies of both PUFA production and the genetic regulation of the process in the psychrotolerant *P. profundum* strain SS9 (43) demonstrate the potential.

Enzymes for Agriculture

Studies with cyanobacteria have indicated that transfer of the gene encoding a fatty acid desaturase enhances the ability of the transgenic organism to tolerate low temperatures, without effecting its photosynthetic activity (196,197). Potentially, such manipulation could be used to stabilize the thylakoid membranes (loci for photosynthetic activity) of commercial plants at cold temperatures. To our knowledge, a cold-active desaturase enzyme has not yet been identified, but the recent isolation of psychrophilic polar oscillatorians provides an excellent opportunity to search for one specifically compatible with cyanobacteria (198).

Degradative Pathways for Detoxification

Studies with some xenobiotic compounds have indicated that microbial degradation of the parent compound leads to more toxic and lethal intermediate compounds. Elucidation of these pathways, and how they may change with temperature, is needed to design organisms capable of degrading toxic intermediates to benign forms in low-temperature applications. Temperature-dependence of degradation pathways has already been observed for a tetrachlorobiphenyl compound, with each of seven different dechlorination pathways being favored by a given temperature (183). Meanwhile, the use of genetic engineering to achieve removal of toxic intermediates has been validated for mesophilic conditions. The presence of a genetically engineered strain of a *Pseudomonas* sp., designed to degrade mixtures of chloro- and methyl-aromatics toxic to other organisms, enabled a functional laboratory-scale sewage treatment plant; in its absence, all protists and metazoans were killed by the xenobiotics and culturable bacteria were reduced by three orders of magnitude (199).

Reporter Genes for Bioremediation

Some compounds or microbial processes of bioremediative interest are not amenable to widespread analysis in cold (or warm) environments because of detection procedures and costs. Genes with expression products that can be readily assayed have been engineered to serve as affordable "reporters" for other genes and products more difficult to measure. Typically, the gene of interest is fused with promoterless versions of a reporter gene, such that expression of the latter allows a quantitative measure of the linked expression of the former. Common reporter systems include *lacZ* gene fusions, in which β-galactosidase activity is assayed, and *lux* gene fusions, in which bioluminescence is assayed. For example, environmental concentrations of naphthalene and salicylate can be quantified quickly and inexpensively by measuring the expression of associated degradative genes with a *lux* fusion in specially designed bacteria (200). *Lux* reporters have also been used to monitor genetically engineered bacteria in field-release studies (201). For cold-specific applications, a more promising development may be that of an ice-nucleation (*lnaZ*) reporter system using the relevant gene encoded on a plasmid of broad host range from the psychrotolerant plant pathogen, *Pseudomonas syringae* (202). Assaying ice-nucleation is easy and metabolically inexpensive (203). The *lnaZ* system is also reported to be 2 to 3 orders of magnitude more sensitive than *lux*-based systems and 5 to 6 orders of magnitude more sensitive than *lacZ*-based systems (202). The combination of high sensitivity and low metabolic cost recommends the *lnaZ* reporter system for monitoring oligotrophic (nutrient-poor) environments,

measuring contaminants at low concentrations, and evaluating targeted processes in the cold. Analogously, specific cold-active enzymes, or cold-inducible promoters, could also be developed into bioreporter systems to study processes at cold temperatures in the laboratory or the environment.

Genetic Engineering for Metal Remediation

Although progress in understanding and harnessing microbial capabilities for degrading organic contaminants in cold environments is central to bioremediation, heavy metal contamination represents an additional and substantial societal challenge. The availability of cold-adapted microorganisms naturally or genetically engineered for metal remediation could be useful in detoxifying the greater than three trillion liters of radioactively contaminated (inherently cold) groundwater in North America (204). Exploitation of *Deinococcaceae* for this purpose appears promising. The *Deinococcaceae* in general have an incomparable ability to withstand and correct DNA damage, most famously due to radiation exposure (205), but the exemplar of the family, *Deinococcus radiodurans*, also tolerates exposure to heavy metals, actively reducing Fe(III), Cr(VI), U(VI) and Tc(VII) (206). *Deinococcus radiodurans* R1 has also proven readily amenable to genetic manipulation by transformation, which, along with its resilience to toxic metals and radiation, and the availability of a complete genome sequence (207), makes it an ideal candidate for genetically engineered metal remediation (204). Other work indicates that the expression systems pioneered in *D. radiodurans* can be used in its thermophilic relative, *Deinococcus geothermalis* (208). The promise of cold-adapted *Deinococcaceae*, perhaps with a similar genetic pliability, stems from a recent report that gene sequences most closely related to *D. geothermalis* have been found in Antarctic snow, where general microbial activity was detected at subzero temperatures (209). A cold-adapted *Deinococcus* would be an obvious candidate not only for heavy metal remediation but also for exploitation in outer space or on other planets, although the practicalities and philosophical implications of the latter are staggering.

CONCLUSION

The widespread availability of cold-adapted microorganisms in vast portions of the global environment stands in contrast to the limited attention given to their fundamental features and capabilities. Biotechnological interests provide a strong impetus to change this situation. Fundamental research, however, has informed such interests and even generated them. With expanding molecular-genetic and protein engineering methodologies, it will continue to do so. Solid progress in the linked exploration of fundamental and biotechnological aspects of cold-adapted microorganisms can be expected in the realms of enzyme production and environmental bioremediation, due in large part to supporting knowledge and databases in these fields of endeavor at warmer temperatures and to significant starts at cold temperatures. The future lies in creative applications of cold-specific genetic systems, especially viral-bacterial systems, in the exploration of genome-based information, and in pure discovery, as the vast numbers of uncultivated cold-adapted microorganisms and their metabolic capabilities come into view.

USE OF MICROSCOPIC ALGAE IN TOXICITY TESTING

CHRISTIAN BLAISE
Environment Canada
Montréal, Canada

Microalgae comprise a crucial component of the aquatic food web owing to their oxygen production and because they constitute a vital food source for other trophic levels. Their ubiquity in all water bodies ensures energy flow in the food chain and hence the stability and well-being of aquatic ecosystems. This in turn sustains other terrestrial and avian life-forms that are (in)directly dependent on healthy aqueous environments for their survival (Fig. 1). In short, microalgae are essential to support all life-forms on our planet including mankind. As contaminant-mediated phytotoxicity, through diverse anthropogenic activities, can harm or kill phytoplankton and ultimately disrupt the functional and structural homeostasis of species living in aquatic habitats, it is important for environmental agencies to apply tools and strategies that will enable proper assessment of toxicity stresses imposed on phototrophic organisms.

After about more than three decades of work by scientists to address the various issues of ecotoxicity,

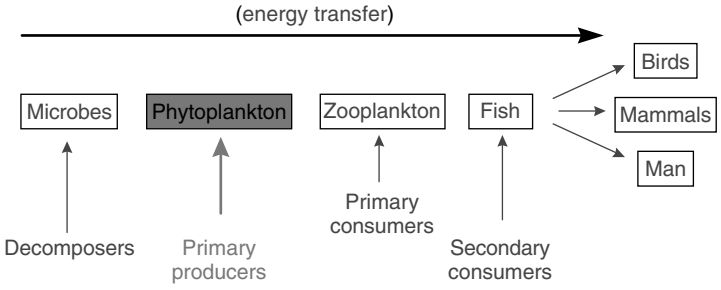

Figure 1. Hierarchy of trophic chains. See color insert.

it is now well recognized that microalgae are useful indicators of environmental quality, particularly because they have been shown to be sensitive to a wide spectrum of both inorganic (1–3) and organic (4,5) pollutants, as well as to complex environmental samples (e.g., toxic industrial effluents and contaminated sediments) containing mixtures of these (6). Because of other attractive features of microalgae as discussed later in this review article, simple (early warning) laboratory-based screening procedures have been developed that provide relevant information for sound environmental decision-taking with respect to pollutional events detected by microalgae as well as by other types of bioindicators.

The field of biological testing with microalgae continues to grow as new technologies and knowledge pave the way for breakthroughs yielding innovative tools and/or improvements for continuing environmental appraisal. In a historical context, it has gone from initial enrichment studies (e.g., determining the fertility potential of water bodies), to toxicity studies (e.g., establishing the toxic potential of contaminants) and to interaction/uptake studies (e.g., metabolic influence of microalgae on the genotoxic potency of industrial effluents). Examples of how microalgae have been profitably used in this evolving field will be presented herein with emphasis being placed on the more simple techniques available for conducting laboratory phototrophic bioassays. Recent developments related to (*1*) the incorporation of phytotoxicity tests within a bioassay battery approach, (*2*) direct sediment toxicity assessment with microalgae, and (*3*) eliminating the need for continuous laboratory cultivation of microalgae by preserving cells in a protective matrix will also be highlighted.

Finally, the reader must be reminded that the field of phototrophic ecotoxicology is very broad, and that even this review on laboratory-based studies only presents an overview, which is far from being exhaustive. Another important complementary domain concerns the strategies and approaches employed to study the ecotoxicity of natural algal communities. As it is beyond the scope of this paper, interested readers are encouraged to consult specific papers on this topic (7–10).

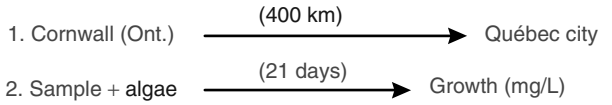
EUTROPHICATION STUDIES

Whereas toxicity tests with microalgae are the focus of this chapter, it is nevertheless important to bring to the reader's attention that they evolved from techniques employed in earlier eutrophication studies undertaken during the 1970s (11–13). As an example, Keighan (12) collected samples of surface waters from the mouth of the major tributaries discharging to the St-Lawrence River between the city of Cornwall (Ontario) and Quebec City (Quebec), spanning some 400 km of river, to determine the degree to which they could contribute to the fertility potential of this major waterway (Fig. 2). In this biological test, 40 mL of each sample were placed in 125 mL Erlenmeyer flasks to which was added a standardized inoculum of microalgal cells (1,000 cells/mL of sample). After an incubation time of 21 days, algal growth in each flask was first estimated by enumerating cells with an electronic particle counter. Afterward, growth was finally reported in mg (dry weight)/L with a predetermined conversion factor linking cell counts with dry weight measurements. With this simple test based on algal growth potential (AGP) of surface water samples, tributaries could be categorized in terms of their eutrophication potential by comparing their specific AGP to a three-class water quality index (Fig. 2). This would in turn trigger decision making so that corrective actions might be taken to protect the aquatic environment from auxinic pollutants (e.g., nitrogen- and phosphorus-containing fertilizers used in agriculture) known to stimulate phytoplankton growth. Although the data are not shown in this article, Keighan (12) used the same biotesting approach to characterize the enrichment level of 36 major industrial effluents discharging to the same portion of the St-Lawrence River, in which he demonstrated AGPs ranging from 1.7 to 183 mg (dry weight)/L.

TOXICITY STUDIES

Chronic and Acute Exposure Tests

As mentioned in the preceding section, toxicity assays with microalgae evolved from the earlier eutrophication studies flask tests. Chronic exposure tests of 21 days (12), 7 to 8 days (14) or 4 days (1), all seeking to measure algal growth inhibition resulting from chemical insult, were first developed and applied. Eventually, chronic tests were standardized at an exposure time of three days by standardization organizations, such as the Organization of Economic Development and Cooperation (OECD) and the International Standards Organization (ISO), as experience and new knowledge demonstrated that no loss of microalgal sensitivity toward contaminants occurred with this shorter exposure time. Three-day chronic tests also have the advantage of eliminating or alleviating potential problems or interferences resulting from more prolonged times of exposure (e.g., pH shifts, carbon dioxide depletion, contaminant bio- or phototransformation, algal adaptation), which can alter toxicity responses and thus confound experimental results and complicate interpretation (15). Whereas chronic exposure tests clearly outrank tests of shorter duration in numbers, acute exposure tests of only several hours have also been developed with the intent of rapidly measuring phototrophic responses to toxicant



Major tributaries	Growth potential (mg/L)	Water quality index
6 rivers	2.9–4.9	< 5 = good
12 rivers	5.5–9.9	5–10 = doubtful
15 rivers	10.7–47.7	> 10 = deteriorated

Figure 2. Enrichment level characterization of the St-Lawrence River (12). See color insert.

challenges (16–19). Because of their sensitivity, acute procedures employing motility inhibition (16) or enzyme inhibition (17) parameters as assessment end points can prove particularly useful to detect quick changes that toxic chemicals can exert on primary producers.

Experimental Testing Conditions and Toxic Effects Measurements

Undertaking toxicity tests with microalgae is relatively uncomplicated and simply requires a basic set of experimental conditions to be met (Fig. 3). An inoculum is obviously necessary, which will vary according to the intended test exposure period. Physiologically active (logarithmic phase) cells are employed for testing and inoculum size is selected such that algae will continue to be in an active state of growth at the end of the exposure period. For example, an 8-day exposure assay might call for an algal inoculum of 1,000 cells/mL to be introduced into test flasks, as this will yield sufficient cell numbers ($>10^6$ per mL in control flasks) at the end of the test to measure a growth inhibition effect resulting from the toxicity of the sample under investigation (14). For example, if the average growth in control flasks and test flasks is determined to be 2×10^6 cells/mL and 1×10^6 cells/mL, respectively, after 8 days, it will be evidently clear that a 50% growth inhibition effect has resulted owing to sample toxicity. In contrast, an acute exposure assay of only four hours based on detecting a biochemical change such as intracellular ATP (adenosine triphosphate) demands a much more important inoculum to start off with, because an inoculum of 1,000 cells/mL is well below the detection limit of ATP measurement (20). Hence, 10^6 cells/mL might be a more appropriate starting inoculum in this instance, as it will not only guarantee measurement of the ATP content of control algae, but also that of sample-exposed algae, which may display a reduction of ATP owing, once again, to toxic effects. A defined algal growth medium (AGM), composed of macro- and micronutrients is also called for to promote adequate growth of algal cultures maintained in the laboratory (13). It should be noted that medium composition is important as it has been shown to influence toxicity results (21).

In chronic toxicity tests based on growth inhibition end points, spiking all experimental flasks with a specific concentration of AGM is essential, as it ensures that algae will reach a specific biomass at the end of test exposure (e.g., 2×10^6 cells/mL for control algae after 8 days). If algae in sample-exposed flasks do not attain a similar growth yield, the experimenter can then be certain that reduced growth results from sample toxicity and not from a dearth of nutrients. A specific light source (e.g., cool-white fluorescent lighting with quantal flux between 60 and 100 $\mu E\,m^{-2}\,s^{-1}$) and incubation temperature (e.g., $24 \pm 2\,^{\circ}C$ for some green algae) will complete the essential requirements for optimum cell division. Depending on the testing procedure, a photoperiod (e.g., a 16-hour light period followed by an 8-hour dark period) may be called for, as can (manual or programmed) shaking or nonshaking of experimental vessels during the exposure period. Modern algal toxicity tests are now generally performed under continuous illumination (i.e., without a photoperiod), as this favors faster cell division in view of the fact that (shorter) 3-day chronic tests are now recommended. It also ensures asynchronous growth (algal cells are not at the same cell cycle stage at the same time and therefore do not divide in synchrony), which more closely mimics environmental situations.

- Inoculum:	Exposure	Cells/mL
	8d	1,000
	3d	10,000
	4h	10^6
- Defined growth medium (Macro- and micro-nutrients)[a]		
- Illumination ($\mu E.m^{-2}.s^{-1}$)[b]		
- Temperature ($24 \pm 2°C$)		
- Photoperiod: + (synchronous growth)		
– (asynchronous growth)		
- Agitation (+/–)

Figure 3. Basic experimental conditions for undertaking toxicity tests with algae. See color insert.

Microalgal Test Species

Several species of algae can be called upon for the conduct of toxicity tests and include representatives of freshwater chlorophytes (green algae), xanthophytes (yellow-brown algae) and cyanophytes (blue-green algae) (4,15). Of these three groups, chlorophytes including the genera *Selenastrum*, *Chlorella*, *Scenedesmus*, *Chlamydomonas*, and *Monoraphidium* have been extensively used and, in particular, the green alga *Selenastrum capricornutum* (Prinz) has been frequently employed in biological testing, particularly in North America. Its popularity is attributable to its attractive characteristics (unicellular, nonmotile, nonpolymorphic, nonagglomerating), which make it easily enumerable in the laboratory with the help of electronic particle counters. Further incentives for the use of this alga include its recognized sensitivity to heavy metals (18,22), organic contaminants (4,22) and complex samples, which may contain mixtures of these (6,23,24), and to the fact that it is a representative bioindicator because it is found in both oligotrophic and eutrophic aquatic systems. As can be seen from Figure 4, *S. capricornutum* is a crescent-shaped unicellular alga, whose dimensions vary between 3 and 5 microns (width) and 10 to 15 microns (length). Studies undertaken with this chlorophyte surpass those reported with all other microalgae to the point where it could certainly merit to be acknowledged as the "*Escherichia coli* of phytotoxicity testing". It is also known as *Pseudokirchneriella subcapitata*, particularly in Europe, whereas the name *S. capricornutum* is more prevalent in North America. Although the material presented herein focuses primarily on work performed with this particular alga because of the author's personal experience, it should be noted that similar studies can clearly be undertaken with other unicellular algae as well. Unlike their freshwater counterparts, phytotoxicity tests conducted with marine unialgal species are scarce. Several species of

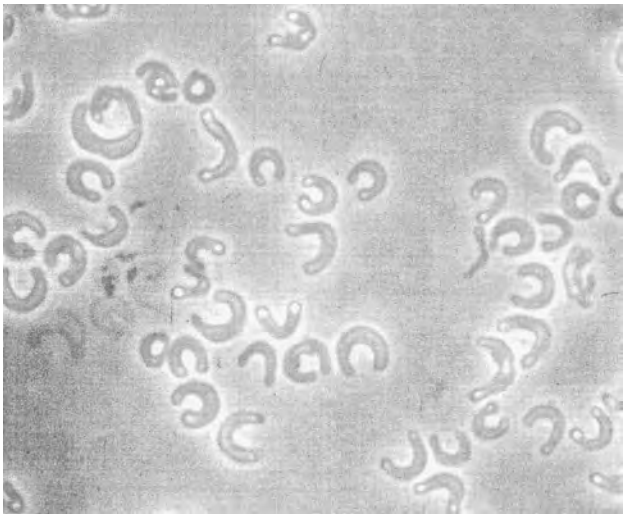

Figure 4. The freshwater chlorophyte, *S. capricornutum*, seen under phase contrast microscopy at a magnification of 400*x*. See color insert.

marine diatoms, however, have been appraised in short-term exposure tests to screen for toxic effects of metals, organics, or surface seawater samples (17,25).

Quantifying Algal Toxicity of Liquid Samples

Determining the sample concentration at which a 50% effect occurs in relation to control algae is a typical way of reporting toxicity when conducting microalgal toxicity tests. Table 1 gives an example of actual data generated in our laboratory with the heavy metal Zn^{2+}. Here, growth inhibition is termed the *assessment end point* and the 72h-IC50 (the sample concentration causing a 50% reduction in the growth of the algal population following a 72-hour exposure period) is termed the *measurement end point*. Essentially, algal cells in each experimental container (or microplate well, as discussed in the following text) are first enumerated with the help of an electronic particle counter. Next, the mean cell yield of control algae and of sample-exposed algae are determined at the end of exposure from which growth inhibition percentages can be calculated for each sample test concentration. Percentage inhibition values (*y*-axis) and sample concentration values (*x*-axis) can then be plotted graphically and a line of best fit drawn around the data points (Fig. 5). Finally, another line (. . .) is drawn perpendicularly from the 50% inhibition point on the *y*-axis to the regression line and again perpendicularly downwards until it meets the *x*-axis. This point of encounter will identify the 72h-IC50 for Zn^{2+}. Computer software is available, of course, to reduce and plot phytotoxicity data, as well as to determine appropriate measurement end point values (26).

Miniaturization of Unialgal Toxicity Tests

Whereas the initially developed algal toxicity assays conducted with glass (Erlenmeyer) flasks in the late 1970s are scientifically sound, they suffer from the fact that they are labor-intensive and do not lend themselves to a high capacity for sample throughput. This dearth in cost-effectiveness sparked a genuine desire in several research groups to find more practical alternatives for phytotoxicity testing. As a result, 96-well polystyrene

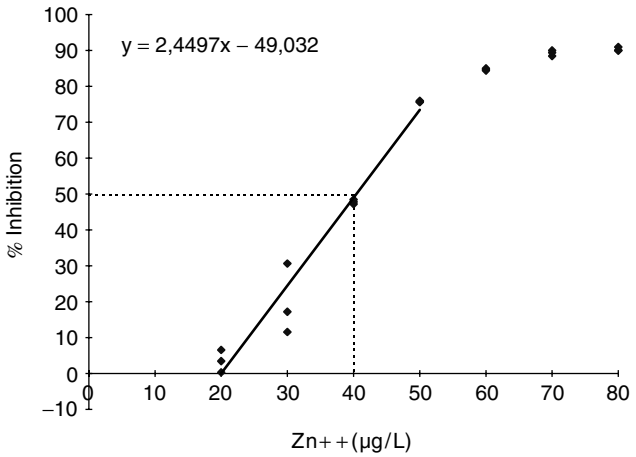

Figure 5. Concentration-response curve indicating percentage growth inhibition of *S. Capricornutum* after a 72-hour exposure to a range of Zn^{2+} concentrations. Here, the 50% effect concentration or IC50 = 40 µg/L of Zn^{2+}. See color insert.

microtitration plates (or "microplates") — for which varied applications began in the field of clinical microbiology (27) — were soon discovered, tested, validated and employed by environmental research groups for the conduct of algal bioassays (15). Microplate-based tests confer many advantages for undertaking biological tests with a variety of microorganisms, among which are small sample volume requirement, elimination of postexperimental washing of glassware and automation potential for test initiation (23). Whereas experimental configurations for algal microplate assays can be varied, they are usually tailored to meet specific testing objectives (e.g., acute or chronic testing with one or more species) or to offset potential interferences (e.g., toxicant volatility). As as example, Figure 6 displays a typical experimental disposition that was initially used to evaluate the phytotoxicity of herbicides (22) and which is now recommended by Environment Canada to perform standardized toxicity testing with *S. capricornutum* (26). As a phenomenon commonly associated with 96-well microtitration plates is the so-called "edge effect," whereby the evaporation rate of the circumferential wells tends to be greater than that of the centrally located wells, experimental dispositions tend to exclude peripheral wells from testing because they increase variability among replicates. Hence, for chronic tests of one day or more, experimental designs are usually built around the 60 internal wells, as seen in Figure 6. Whereas peripheral wells are not directly employed for testing, they are nevertheless always filled with water to increase humidity inside the microplate and, in this sense, they contribute positively to the overall experimental protocol.

Because the use of microplate tests — with a few notable exceptions — essentially came after that of the earlier flask tests, some researchers felt it important to demonstrate that microplate phytotoxicity assays did indeed reproduce the results of their glassware counterparts. Displaying agreement between the two methodologies would indicate microassay reliability and obviously enhance microtesting acceptance by the scientific community. In this perspective, several studies were undertaken to establish interprocedural compatibility. These comparative investigations conducted with varied liquid samples (metals, herbicides, phenol, effluents) essentially pointed out that microplate and flask methodologies gave concordant results insofar as generation of phytotoxicity data with microalgae is concerned. Each of these studies also presented evidence that microplate tests are reliable because of their repeatability and reproducibility (15).

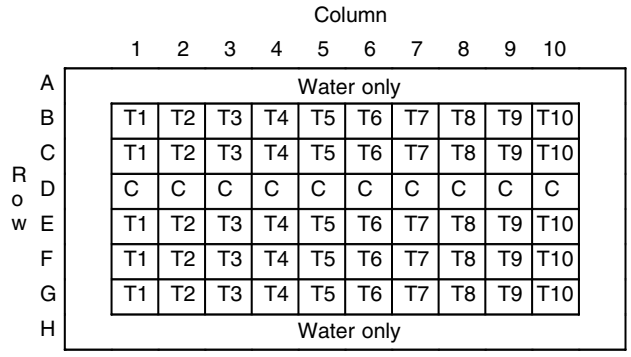

Figure 6. A typical microplate experimental configuration for toxicity testing. There are five replicates per concentration with T1 and T10 being the highest and the lowest concentrations, respectively. There are 10 centrally located control (C) wells (22).

Applications with Algal Toxicity Tests

Two examples of toxicity testing applications with microalgae are given so readers can appreciate their usefulness in contributing to the knowledge base of contaminant-related toxic effects. In a first study (6), the toxicity responses of *S. capricornutum* were appraised following an 8-day exposure to 46 effluent samples of the Pulp and Paper sector — a major industrial force in the province of Quebec, Canada (Fig. 7). Chronic 8-day IC50 values were first determined for each of the effluents, whose wastewater treatment was either absent or present based on primary, primary and secondary, and the Best Practicable Technology (BPT) installations. The BPT mill was the only one, at the time, exemplifying optimum treatment capabilities for this industrial sector. Individual 8-day-IC50s were then transformed into toxic units (TU), summed up for each of the effluent treatment categories and an average TU value calculated for each (see Fig. 7). Results show that the algal bioassay yielded responses that were able to readily discriminate effluent toxicity on the basis of treatment application. Phytotoxicity test results also demonstrate the efficiency of combined primary and secondary treatment coupled to BPT capacity in markedly reducing the toxic potential of these liquid wastes, which were at the time unquestionably toxic toward primary producers.

In a second study aimed at improving understanding of the potential impact of acute chemical exposure on microalgae, *S. capricornutum* was exposed for four hours to selected chemicals, after which (control and chemical-exposed) algal cells were removed from their contaminated medium and allowed to grow in normal algal growth medium for 96 hours (18). Significant growth inhibition in relation to controls resulting after 96 hours would thus indicate a toxic effect that had manifested itself during the initial four-hour exposure. This microplate-based *exposure-recovery* assay was able to identify chemicals posing low acute exposure risk to algae. Furthermore,

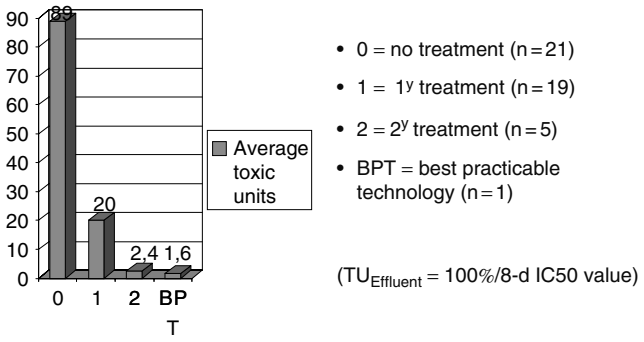

Figure 7. Toxicity responses of *S. capriconutum* exposed to pulp and paper effluents having different waste treatment facilities (6). See color insert.

Table 2. Time-Related Phytotoxicity Effects of Chemicals Based on Four Hours Acute (*A*) and 96 Hours Chronic (*C*) responses of *S. capricornutum* (18)

Chemical	4h-IC50 (*A*) (mg/L)	96h-IC50 (*C*) (mg/L)	*A*/*C*[a]
DCP[b]	112	102	1.1
Hg^{2+}	0.05	0.02	2.5
Cu^{2+}	0.14	0.05	2.8
Zn^{2+}	8.0	0.05	160
TB[c]	>100	0.102	>980

[a] Acute to chronic ratio.
[b] Dichlorophenol.
[c] Tebuthiuron.

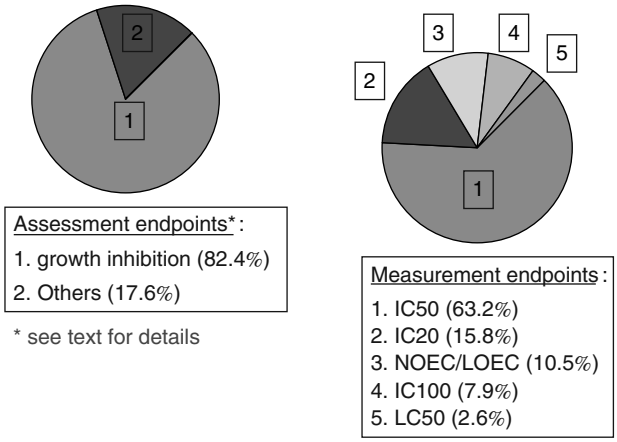

Figure 8. Endpoints for testing liquids with microplate-based phytotoxicity procedures. See color insert.

when comparing Acute (4h-exposure/96h-recovery IC50s) to Chronic (96h-IC50s) end point values, A/C ratios could identify those chemicals capable of rapid (DCP, Hg^{2+}, Cu^{2+}) and less rapid (Zn^{2+}, TB) phytotoxic effects (Table 2). DCP (dichlorophenol), for example, is a fast-acting chemical in terms of phytotoxicity, as it yields similar acute and chronic IC50s. In contrast, TB (tebuthiuron), an efficient substituted-urea class herbicide, is nontoxic to *S. capricornutum* after four hours of exposure, but very toxic after 96 hours of exposure. Clearly, combining results of time-related phytotoxicity data can give valuable insights into chemical mechanisms of toxicity and prove useful in the area of contaminant risk assessment.

End Points Measured and Types of Samples Evaluated

End points determined after testing aqueous samples with microplate-based phytotoxicity procedures are varied but some are clearly favored over others (Fig. 8). For example, intracellular ATP, esterase activity and motility have thus far been sparingly employed to report assessment end points, but growth inhibition (determined by cell counts, ATP, absorbance, fluorescence, and visual observation) has distinctly been the most popular choice. In terms of measurement end points, IC50s have been most frequently determined, but IC20s, IC100s, and NOECs/LOECs have also been computed (15).

Types of liquid media assessed with phytotoxicity tests are quite varied, as recalled in Table 3. Microalgal assays are essentially applicable to any sample that is in liquid form or "liquefiable," such as a sediment sample from which an extract would first be prepared or a hydrophobic compound, which may also require the use of a solvent carrier to insure adequate dissolution during test exposure. In such cases, the experimenter must verify that the solvent concentration employed is not phytotoxic per se and that sample/solvent interactions will also not be at play to affect the toxicity results. Whereas small-scale biological tests undertaken at all

Table 3. Examples of Liquid Test Samples Assessed with Phytotoxicity Tests and Corresponding End Points Determined

Medium Investigated	Assessment End Point and Reference (in Parentheses)
Contaminants	
Metals in solution	ATP energy loss (18); growth inhibition (28)
Organics in solution	Visual reporting of the lowest sample concentration indicating total growth inhibition at end of exposure (4); cell growth recovery (18); esterase inhibition (17)
Herbicides	Growth inhibition (22,29); cell mortality by flow cytometry measurement (30)
Complex Samples	
Oil dispersants	Growth inhibition (31)
Organic extracts	Absorbance as indicator of biomass inhibition (32)
Groundwater	Absorbance as indicator of biomass inhibition (33)
Surface waters	Esterase inhibition (19); absorbance as indicator of biomass inhibition (33)
Effluents	Growth inhibition (23); fluorescence as indicator of biomass inhibition (34); growth inhibition (24)
Solid waste leachates	Growth inhibition (35,36)
Sediment elutriates	^{14}C uptake inhibition (37)
Sediment pore waters	Growth inhibition (38)

levels of biological organization (e.g., tests with microbes, algae, microinvertebrates, fish) have thus far focused on assessing the toxic potential of liquids, some microbial assays have recently been developed to specifically address the toxicity of solid media, such as whole sediments. One such assay, conducted with microalgae, is described further on.

INTERACTION STUDIES

A third and more recent area of investigation involving microalgae was born when pioneering research groups demonstrated that vegetal systems could detoxify (39), activate (40,41), or bioaccumulate (39,42) genotoxicants. Such contaminants expressly exert their aggression toward the hereditary material of cells (i.e., DNA) and potential consequences both at the cellular (e.g., DNA damage, mutations, chromosomal breakage) and organismic/population (e.g., decreased reproductive capacity, developmental disruption, cancer formation) levels can be far-reaching.

The influence that microalgal metabolism can have on the genotoxic status of complex industrial effluents is illustrated in Table 4. In this study (43), a specific biomass of *S. capricornutum* was allowed to interact with the effluent samples for four hours. After this period, the genotoxic status of each effluent, from which the algae have first been removed by centrifugation, was determined with the SOS Chromotest (a genotoxicity screening assay). Four-hour postexposure genotoxic activity of each effluent was then compared with that determined prior to algal interaction to determine whether detoxication, activation and/or uptake has occurred.

Results of these algal exposure experiments revealed a variety of interactive patterns, as seen in Table 4, ranging from no effect (effluent samples 1 and 2) to de-activation (effluent sample 3), activation (effluent samples 6 and 7) and uptake (effluent sample 9). This particular study, including others in this (still) fledgling field of phytotoxicology, demonstrates that the fate of genotoxicants in mixtures, such as complex effluents or surface waters contaminated with these, is difficult to predict and that phytoplankton may play an important role in altering the potency of such contaminants released to aquatic systems. Microalgae therefore comprise an important "metabolic reservoir", because of their ubiquity, capable of intimate links with discharged xenobiotics. Further investigations on the chemical biotransformation and/or bioaccumulation properties of microalgae to more fully understand environmental risk appear justified (44).

PHYTOTOXICITY TESTING WITHIN AN INTEGRATED BATTERY OF BIOLOGICAL TESTS TO ASSESS THE POTENTIAL HAZARD OF INDUSTRIAL EFFLUENTS

Because toxic effects of chemicals can affect different trophic levels with varying intensity, it is now recognized that relevant batteries of bioassays should be employed for comprehensive appraisal of the hazards represented by specific contaminants and complex point source discharges (24). One example of an integrated bioassay battery approach developed to serve the purposes of environmental management is the Potential Ecotoxic Effects Probe (PEEP) index which enables the assessment and comparison of the toxic potential of industrial effluents (45).

This effluent assessment index relies on the use of an appropriate suite of multitrophic bioassays (decomposers, primary producers, and consumers) allowing the measurement of various types (acute, chronic) and levels (lethal, sublethal) of toxicity. At the time of its conception, this index integrated the results of selected small-scale screening bioassays (*Vibrio fischeri* Microtox^R test, *S. capricornutum* growth inhibition microtest, *Ceriodaphnia dubia* lethality, and reproduction inhibition tests, *E. coli* genotoxicity SOS Chromotest), and took

Table 4. Influence of Microalgal Metabolism on the Genotoxic Status of Complex Industrial Effluents (Adapted from Harwood et al., 1989) (43)

Source	Genotoxic Activity[a] Before and After a Four-Hour Interaction with Algae		Genotoxic Activity[a] of Algal Extracts After their Interaction with Effluent Samples	Remarks
	Before	After		
Sample 1: Organic chemical manufacturing effluent	−	−	−	No influence of algal metabolism
Sample 2: Organic chemical manufacturing effluent	+	+	−	No influence of algal metabolism
Sample 3: Pulp and Paper effluent	++	+	−	Decrease in genotoxicity owing to algal metabolism
Sample 6: Organic chemical manufacturing effluent	+	++	−	Increase in genotoxicity owing to algal metabolism
Sample 7: Inorganic chemical manufacturing effluent	−	+	−	Increase in genotoxicity owing to algal metabolism
Sample 9: Organic chemical manufacturing effluent	+	+	+	Uptake by algae of genotoxic components from effluent

[a] Genotoxic activity was quantified with the SOS Chromotest detection system (43).

into account the persistence of toxicity (meaning that biotests were performed on an effluent *before* and *after* a 5-day biodegradability procedure), (multi)specificity of toxic impact (number of bioindicators affected by an effluent), as well as toxic loading (effluent flow in m^3/h). The resulting PEEP index number is reflected by a $\log_{10}$ value that can normally vary from 0 to 10. The structure of the mathematical formula generating PEEP values is simple and "user-friendly" in that it can accommodate any number and type of bioassays to fit particular needs (Fig. 9a).

The PEEP formula can best be understood by means of an example showing actual toxicity data generated with an effluent sample collected in 1991 from a Pulp and Paper mill located in the province of Quebec, Canada. Measurement end point effluent concentration data calculated in % v/v are first transformed into toxic units (Fig. 9b). These values are informative per se in terms of the toxicity characteristics of the effluent under investigation. For example, it is clear that this wastewater sample is highly phytotoxic (183.8 toxic units observed following microalgal testing of the neat effluent sample), but that most of this toxicity is not persistent (5.7 toxic units remaining after the effluent sample has been subjected to a biodegradability procedure). It also illustrates the fact that effluent toxicity is trophic-level dependent and that bioassays should be conducted with different organisms to properly circumscribe the full hazard potential that complex discharges can represent with respect to aquatic biota. Interested readers are urged to consult the original PEEP article (45) for details on various conceptual aspects and further information on the significance of bioassay data generated with this managerial tool, which are outside the scope of the present article. Once toxic units are calculated for all bioassays, they are integrated in the *toxic print* portion of the PEEP formula, which is multiplied by effluent *flow* datum ($Q = 3,213$ m^3/h). The product of *toxic print* and *flow* yields the *toxic load* of the effluent. The resulting PEEP index value of 5.8 is then simply the $\log_{10}$ of the calculated effluent sample *toxic load*. The value of "1," inserted into the PEEP formula just ahead of the *toxic print*, insures that the inferior scale of the PEEP index will commence at "0" for effluents that are nontoxic (i.e., those in which toxicity responses are absent for all of the bioassays and which yield a $T_i$value $= 0$).

This approach has the advantage of combining information on (*1*) the biodegradability/persistence of effluent toxicity (indicative of its possible fate in receiving waters), (*2*) the trophic levels targeted by effluent toxicity (indicative of the ecological scope of impact), and on (*3*) the flow characteristics of the effluent (indicative of toxic loading released to the environment). The integration of these concepts into a PEEP scale or index is innovative in that it brings together factors of relevant ecotoxicological importance into a simple, practical and useful management tool that identifies the hazardous potential of industrial effluents via a bioanalytical screening strategy. Its effectiveness in predicting the overall hazard potential of wastewaters was revealed for 77 priority effluents investigated under the first two St-Lawrence Action Plans (46). In quantifying the toxicity of industrial discharges, the PEEP index unambiguously points a finger at the most problematic ones requiring priority attention in terms of cleanup action, such that environmental protection effectiveness can be achieved. It is evident by observing the range of PEEP values determined for the industrial effluents studied that some effluents are irrefutably more noxious than others (Fig. 10). As with other scales that reduce complex information into single synthetic values (e.g., species diversity indices in ecology, Richter scale for earthquakes), the effluent PEEP index produces values that can be easily understood by environmental managers, industrialists and the general public. In light of the specific

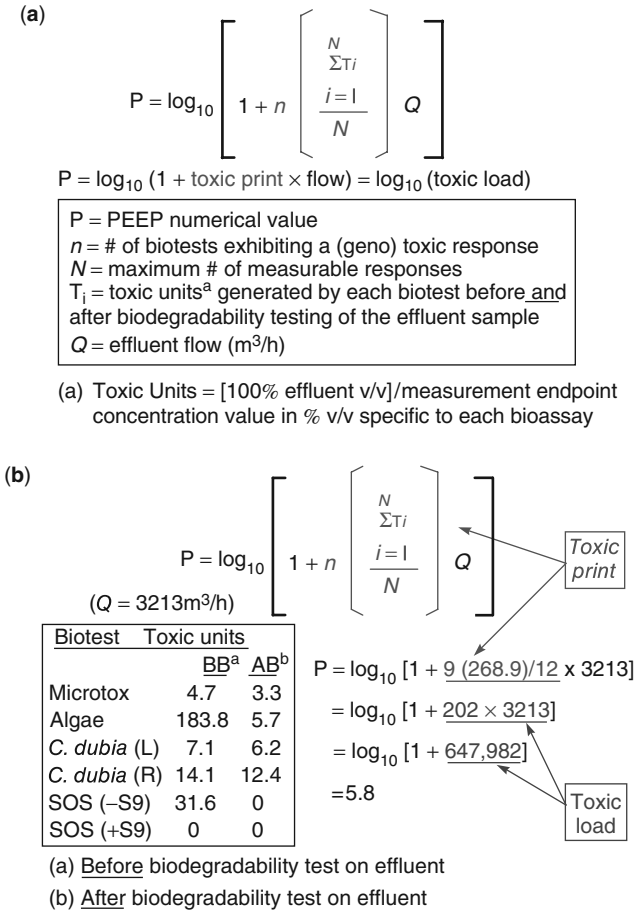

Figure 9. (**a**) PEEP index formula and (**b**) PEEP index calculation for actual toxicity data obtained for a Pulp and Paper effluent. See color insert.

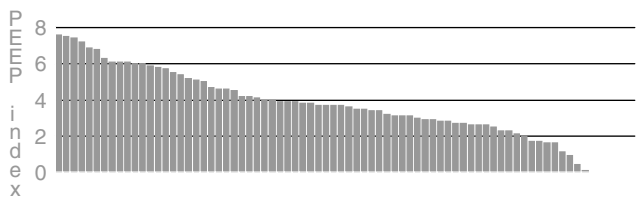

Figure 10. PEEP values for 77 Canadian-based effluents investigated under two St-Lawrence River Action Plans (1988 to 1998). See color insert.

focus of this article, it must be emphasized once again that incorporating a microalgal biotest within an integrated strategy such as the PEEP index is essential to appraise the degree of hazard that point source discharges can represent with respect to primary producers.

TESTING SOLID MEDIA: AN ALGAL SOLID PHASE ASSAY (ASPA) TO ASSESS FRESHWATER SEDIMENT TOXICITY

Because microalgae and other organisms can be adversely affected by toxicity resulting from sediment resuspension owing to both natural (e.g., flood scouring) and man-made activities (e.g., dredging, open water deposition), direct contact microassays that can react to both readily soluble contaminants and to those either adsorbed or absorbed are important to develop and apply. Whereas there are numerous microbiotests to assess liquid media (38,47), few are presently adapted to properly measure the toxic potential of solid media and there is clearly a gap to fill in this respect in terms of microscale bioassay development. Presently available direct contact tests are mostly conducted with bacteria (48–52), although a new algal solid phase assay (ASPA), has recently been developed with the green alga *S. capricornutum* to evaluate the degree of toxicity of freshwater sediments (53). In this assay, the capacity of cell esterases to cleave the (nonpolar) stain fluorescein diacetate (FDA) and liberate fluorescein, a polar and fluorescent by-product, is the criterion that allows us to determine the extent to which algae have been intoxicated after a 24-hour exposure to serial dilutions of test sediment. As illustrated in Figure 11, algal cells insulted by direct contact with sediment contaminants will be less fluorescent than normal cells either because loss of esterase activity will have transformed less FDA into fluorescein (F) and/or because any produced fluorescein will tend to leak out of algal cells owing to damaged membranes that make cells more porous. After an exposure period of algae with test sediment conducted in tubes under defined conditions (Fig. 12), individual cell fluorescence (measured from a total of 2000 cellular events in each experimental test tube) can then be precisely quantified with the help of a flow cytometer, an instrument that measures specific optical properties of cells in motion.

The resulting toxicity end point (IC50) relates to both esterase inhibition and cell membrane integrity. In applying ASPA on a series of naturally contaminated sediments sampled from various locations in the Québec portion of the St-Lawrence River, the assay was able to correctly discriminate sediments on the basis of their contamination level (53). As an example, Table 5 illustrates this by showing that ASPA toxicity responses spanned more than two orders of magnitude (i.e., IC50 of sample 4/IC50 of sample 1 = >10/0.056 = >179) after assessment of four representative sediment samples. Validation studies by generating data with additional sediments are continuing for ASPA. Whereas cost considerations clearly inhibited large application of flow cytometry in the 1980s for environmental R&D, increasing

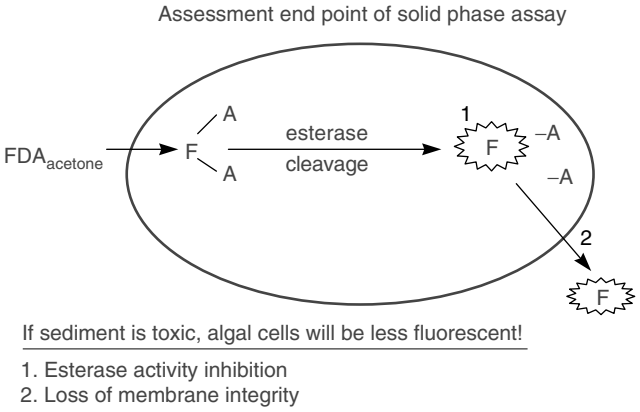

Figure 11. Principle of the algal solid phase assay (ASPA): see text for details. See color insert.

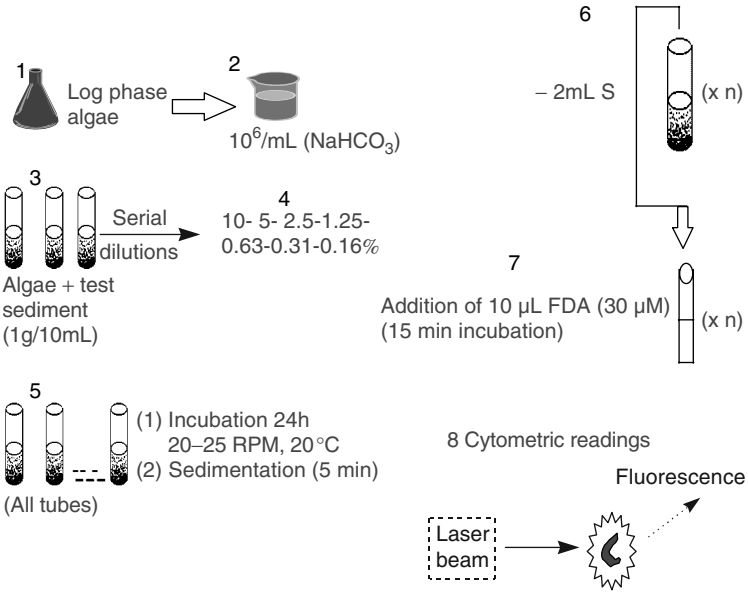

Figure 12. Algal solid phase assay: a culture of exponentially growing (log phase) algae (1) are used to prepare an algal concentration of 10^6 cells/mL in $NaHCO_3$ (2); test sediment tubes contain a starting concentration of 10% test sediment (3) from which additional serial dilutions are prepared (4); all tubes are stoppered with Parafilm and exposed under specified conditions (5); a 2-mL volume of supernatant (containing essentially postexposure algae) is withdrawn from each tube (6) and dispensed into a smaller tube compatible for flow cytometry measurements; to check for esterase activity, an FDA solution is micropipetted into each small tube and allowed a 15-minute interaction time with algae (7); FDA-induced fluorescence, indicative of cell viability, is then quantified by flow cytometry (8). See color insert.

Table 5. Algal Solid Phase Assay (ASPA) Responses to Four Sediment Samples (53)

Sample Origin	IC50 (% Wet Weight)	Confidence Intervals (95%)
Ile aux Corbeaux	0.056	0.019 to 0.10
Montréal harbor	0.24	0.097 to 0.57
Hamilton harbor	1.66	1.42 to 4.41
Lake St-François	>10	>10

demand for this versatile technology, coupled with contemporary commercialization of more cost-effective and compact (portable) flow cytometers, should stimulate the use of ASPA-like procedures by interested laboratories for a variety of environmental studies.

PRESERVING MICROALGAE FOR BIOLOGICAL TESTING

As a final section to this review on phytotoxicity testing, it is of interest to mention the advantages that readily available biological reagents can confer to the field of small-scale toxicology. Eliminating the need, therefore, for continuous culturing of indicator organisms employed for undertaking biological tests is an attractive venture, as it markedly reduces labor and increases cost-effectiveness for laboratories involved in toxicity studies. Lyophilization of luminescent bacteria (54) and the use of cryptobiotic (dormant) stages of microinvertebrates (55) are two outstanding examples of the ways in which toxicity testing can be made more user-friendly by precluding the need for constant maintenance of laboratory cultures. Microalgae have also inspired a significant amount of research in the quest for an appropriate storage technique, which would make these cells culture-free (e.g., agar preservation and cryopreservation). Immobilization of exponentially growing microalgae in an alginate bead matrix has, in particular, shown promise as an effective means of preserving cells for prolonged periods (56). More recently, a validation study aimed at standardizing an alginate-immobilized microalgal reagent with *S. capricornutum* confirmed that cells retained full viability for several months and that comparative toxicity testing with laboratory-cultured algae of the same species yielded concordant results (28). The major steps involved in the immobilization and de-immobilization of *S. capricornutum* are schematized in Figure 13. Perhaps not readily evident to the reader is that alginate-immobilized algae can be rapidly de-immobilized in 30 minutes, after which they are immediately available as inoculum for initiating toxicity testing. Immobilization of microalgal cells is an interesting breakthrough that further facilitates and enhances the use of phytotoxicity testing for assessment of xenobiotics (28,56–58).

CONCLUSION

Initially used as eutrophication indicators, microalgae are also now being employed for toxicity and interaction studies, as this review has shown. Simple algal bioassays, thanks to ingenuity, miniaturization and new instrumental technologies, can be profitably applied to enhance our knowledge of the ecotoxicity of environmental contaminants. In this respect, they have been (and continue to be) invaluable for screening, ranking and prioritizing the potential hazards of chemicals and varied complex media, alone and/or as key adjuncts to batteries of bioassays undertaken at different trophic levels. Phytotoxicity testing is an essential cog of the various tools and strategies (e.g., other bioassays, chemical analysis, field surveys), which collectively contribute to ecotoxicological knowledge to ensure rational decision making. In this sense, it is unquestionable that phytotoxicity data, generated with microalgae as bioindicators, will continue to serve the interests of aquatic environmental programs worldwide.

UV DISINFECTION — THEORY TO PRACTICE

James P. Malley, Jr.
University of New Hampshire
Durham, New Hampshire

Ultraviolet (UV) light is electromagnetic energy that is located in the electromagnetic spectrum at wavelengths between those of X-rays and visible light. UV is further broken down into UV-A, UV-B, UV-C, and vacuum UV. These types of light reside from about 40 to 400 nm in wavelength. The UV light effective in inactivating bacteria and virus resides in the UV-B and UV-C ranges of the spectrum (200 to 310 nm). Maximum effectiveness for inactivation of most bacteria and virus species occurs around 265 nm.

It is a fundamental premise of photochemistry that reactions cannot occur if the reactant species does not absorb energy in the spectral range of the incident light. Therefore, for UV to be an effective disinfectant some critical biochemical moiety of the given organism must absorb energy in the appropriate range. The photochemical interactions between UV light and living organisms, termed *photobiology*, was well explained by considering the adsorption spectra of DNA DNA, and thus living cells, such as *Escherichia coli*, adsorb significant amounts of light energy in the range of 200 to 300 nm with a peak around 260 to 265 nm. Further investigation indicated that thymine bases on the nucleic acids (DNA and RNA) were particularly reactive to UV light and would form dimers (thymine = thymine double bonds). These dimers then chemically inhibit transcription and replication of nucleic acids thus rendering the organism sterile. Once

the organism is sterile it cannot cause infection — thus effective disinfection has occurred.

It has been found that many organisms are capable of repairing the thymine dimers and restoring the original nucleic acid structures using enzymes. This repair is termed *photoreactivation* if it occurs in the presence of light or *dark repair* if light is absent. As a result of this repair phenomenon, the strategy in UV disinfection has been to provide a high enough dosage that enough nucleic acid damage occurs to prevent effective repair.

This classical explanation of the germicidal mechanisms of UV irradiation holds extremely well in cases where continuous wave, monochromatic, moderate to low energy UV light is used — which has been the standard case for the past 30 years. More recently however, continuous or pulsed wave, polychromatic, high intensity UV lamp technologies have been developed and applied to water and wastewater treatment. Continuous wave, medium pressure mercury vapor lamps are becoming increasingly popular in higher flow water and wastewater applications owing to overall cost savings. Pulsed UV technology, which relies upon a high energy xenon arc (or flash) lamp has shown promising results in recent drinking water treatment research at the bench, pilot, and full-scale. Medium pressure lamps emit significant amounts of energy at 222.5, 253.7, 265, and 296.5 nm (with lower emissions at several other wavelengths in the germicidal range). Pulsed UV lamps emit high-energy bursts (pulses) of polychromatic light in the range of 185 to 800 nm.

It is theorized that these higher intensity, polychromatic emissions may do significantly more biochemical damage (similar to that of ionizing radiation) to not only nucleic acids but also to cellular proteins and enzymes. Related work suggests that these high-intensity sources may enhance the formation of secondary radical reactions giving rise to germicidal chemical species, such as hydroxyl radicals, ozone, or hydrogen peroxide.

Biological techniques intrinsically allow accounting for the most factors that influence UV dose. These tests are usually performed in the same water that is treated by an on-line UV system or proposed system so that the water matrix effects are inherent in the test results. However, laboratory irradiation of cultures is independent of hydrodynamic effects, such as short circuiting or dispersion that can be present in flowing systems. Bioassay procedures examine a microorganism's response when exposed to a specific UV dose, known as the organism's *UV susceptibility*. For most microorganisms, there exists a first order relationship between UV dose and log inactivation.

One particular bioassay method used in the wastewater industry, NSF 55, uses *Bacillus subtilis* spores. Under controlled laboratory conditions, early experiments showed that a 4 log inactivation of spores was achieved at a UV dose of about 31 mW s/cm^2. Because drinking water applications will likely require a slightly higher UV dose, obtaining a sufficiently large initial population of spores to measure substantial inactivation is a problem. For this reason, other organisms that are more resistant to UV may be required to measure these higher UV doses. One such organism is MS-2 Coliphage, which is an F-specific single-stranded RNA virus. MS-2 is about 20 nm in diameter and can be used as a viral surrogate.

Organic matter typically found in colored surface water supplies will exert a UV absorbance at 254 nm (A/L) of between 0.100 and 0.800 cm^{-1} ($\alpha = 0.23$ to 1.84). Treated surface waters and typical groundwaters have significantly lower absorbances, generally ranging from 0.005 to 0.500 cm^{-1} ($\alpha = 0.01$ to 0.12).

Waters with lower absorbance will traditionally require less UV energy to achieve the same disinfection as waters with high absorbance. In a flowing system, UV dose is inversely proportional to system throughput. For a given UV system, water with lower energy requirements can increase throughput proportionally over water that requires more UV energy. As a general rule, when the value of α for a given water matrix exceeds 0.43 ($A/L > 0.187$ cm^{-1} or $\%T < 65\%$) pretreatment to reduce UV interference (or attenuation) will be required to insure successful UV disinfection.

The negative impacts on UV disinfection effectiveness of turbidity (particles or suspended solids) in the water quality matrix is also well documented. Unfortunately, measurement of UV absorbance (or $\%T$) does not always account for the turbidity effects. Turbidity causing particles or suspended solids can increase UV absorbance but often it has a minimal effect on absorbance measurements or α. Nevertheless, turbidity can still reduce disinfection effectiveness by shielding microorganisms from the UV. Therefore, it is also wise to measure turbidity when assessing water quality matrix effects on UV disinfection. In most cases, if the turbidity is maintained below 1 NTU the effects on UV disinfection efficiency will be minimal. To maintain low turbidities, surface waters will require filtration and some groundwaters will require iron and/or manganese pretreatments that include filtration.

BACKGROUND

Conventional UV disinfection is a physical disinfection process that uses commercially available lamps, which emit UV light in the wavelengths of 200 to 300 nm. These so-called, *germicidal wavelengths*, cause damage to DNA and RNA by dimerizing bases, such as thymine and uracil. The damaged nucleic acids prevent replication thus rendering the potential pathogen sterile and unable to cause infection. UV disinfection has had widespread use in the wastewater treatment field throughout North America. However, it has long been believed that UV was incapable at inactivating protozoan cysts or oocysts, such as *Giardia lamblia* cysts and *Cryptosporidium parvum* oocysts at cost effective dosages (1,2). Recent findings in North America that conventional, continuous wave UV disinfection can inactivate *C. parvum* as well as many other human pathogens of concern in drinking water at cost effective dosages has spurred tremendous excitement and research throughout the United States and Canada.

Pending regulations, focus on simultaneously protecting the public health from microbial risks such as those

from *Giardia*, *Cryptosporidium* and viruses and the potential chemical health risks from disinfection by-products has posed a difficult problem for the drinking water industry. In the United States negotiations are underway between all stakeholders to adopt the Stage 2 Microbial and Disinfection By-Product regulations. Concerns exist that if tighter *Cryptosporidium* inactivation requirements are imposed then drinking water systems will need to shift to more costly technologies, such as long ozonation $C \times T$ times or membrane filtration. In addition, if disinfection by-product (DBP) regulations for bromate or individual brominated organics are imposed then ozone may not be an optimal solution. The potential that UV disinfection processes could be used to inactivate microbes of concern while reducing or as a minimum not adding to DBP formation has caused many drinking water organizations to focus on bench, pilot, and full-scale research for applying UV to surface drinking water disinfection requirements.

EFFECTIVENESS OF UV DISINFECTION

Drinking water disinfection requirements have been driven in recent years by concerns about the risks from *G. lamblia, C. parvum*, and human enteric viruses. In the United States, the 1986 Surface Water Treatment Rule (SWTR) mandated a 3-log removal/inactivation of *Giardia* and a 4-log removal/inactivation of viruses. More recently, the Interim Enhanced SWTR added a 2-log removal of *Cryptosporidium* through optimized filtration requirement. Figure 1 shows the effectiveness of UV for inactivation of *C. parvum* oocysts and *Giardia* cysts. These data reflect the recent understanding that UV effectiveness for inactivating protozoan cysts or oocysts must be evaluated using animal infectivity or cell tissue culture methods (3). The *Cryptosporidium* data show that a UV dose of 10 mJ/cm^2 inactivated up to 4-log of oocysts in most cases. Finch and Belosevic (4) observed a tailing effect in their results but concluded that a UV dose of 10 mJ/cm^2 would reliably achieve a 2-log inactivation. By contrast older literature suggested that doses of hundreds or thousands of mJ/cm^2 would be required to inactivate protozoan cysts (2). It is also interesting to note that the *Cryptosporidium* data based on animal infectivity generated by Bukhari and coworkers (3) and by Finch and Belosevic (4) corresponds well with the *Cryptosporidium* data based on cell tissue culture generated by Linden and Sobsey (5) and Mofidi and coworkers (6).

The *Giardia* data suggest that greater than 2-log inactivation of cysts can be achieved at a dose of 10 mJ/cm^2. Finch and Belosevic (4) working with *G. muris* cysts noted a tailing effect, which was not observed by Linden and Sobsey (5) who were using *G. lamblia* cysts. In either case, the data sets both demonstrate that a UV dose of 10 mJ/cm^2 or less will effectively inactivate at least 2-log of *Giardia* cysts.

The effectiveness of UV for inactivating virus is well documented but it is important to note that there is a wide variety of virus strains that may be of concern in drinking water and their relative susceptibility to UV can vary widely. Table 1 summarizes the effects of UV on the major virus strains currently of interest to the drinking water industry. These data are compiled from work done by the authors on a variety of water qualities and data available in the current literature. These data suggest that Adenovirus, a double stranded (DS) DNA virus, may be the most resistant to UV inactivation. This finding would be consistent with earlier reports that Adenovirus has the capability to enzymatically repair damage to the DNA. Aside from Adenovirus data, which is currently undergoing further study and verification, it has been generally accepted that the surrogate MS-2 phage is a conservative indicator of human enteric virus inactivation by UV. As a result, it has been proposed by USEPA that a UV dose of 40 mJ/cm^2 would be granted a 2-log virus

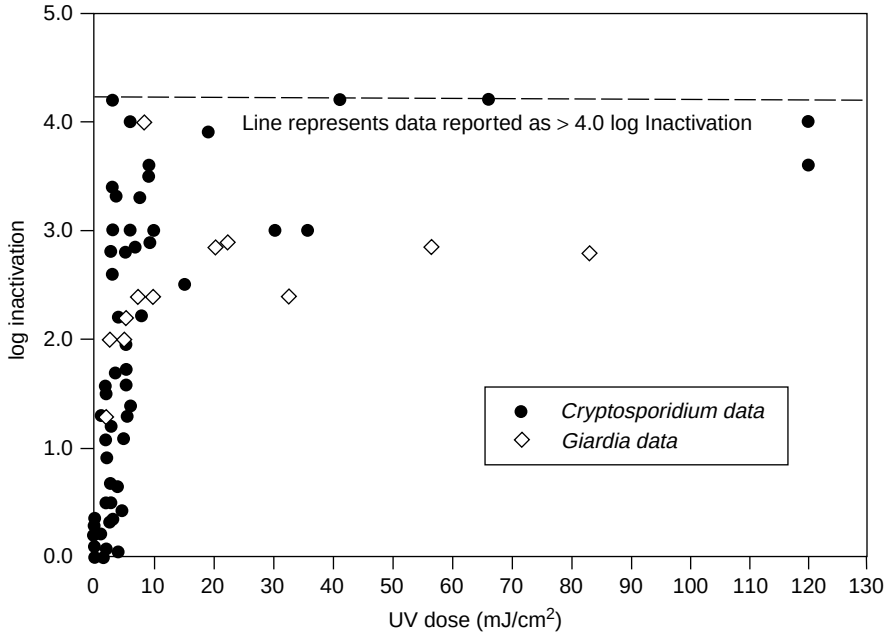

Figure 1. UV dose-response data for *C. parvum* oocysts in filtered surface water samples. Data reported by: Bukhari and coworkers (3), Finch and Belosevic (4), Linden and Sobsey (5), and Mofidi and coworkers (6).

Table 1. UV Effectiveness for Virus Inactivation

Virus	UV Dose (mJ/cm^2) for Inactivation of			Reference
	2-log	3-log	4-log	
Adenovirus 40	59	90	121	7
Adenovirus 41	50	80	—	7
Coxsackievirus B5	14	21	—	8
Hepatitis A HM-175	45	11–13	16–22	3
Poliovirus Type 1	8–11	15–19	23–29	3
Reovirus Type 1	36	—	—	9
Rotavirus WA	25–32	35–46	50–70	3
Rotavirus SA-11	19	25	36	10
Surrogate: MS-2	25–39	38–63	50–93	3

inactivation credit. If future work supports the Adenovirus data then the UV dose for 2-log credit would likely be increased to about 60 mJ/cm^2.

FACTORS EFFECTING UV SYSTEM PERFORMANCE

Water quality conditions can effect all disinfection processes. In the case of UV these effects are broken into direct effects and indirect effects. Direct effects include water quality constituents that attenuate or block UV light and thus reduce the moles of photons of UV light, which reach the nucleic acid of the target pathogen. Indirect effects are water quality conditions which can effect lamp performance, foul UV lamp quartz sleeves and UV sensors or cause organisms to surface-associate with particles or aggregate (clump) thus making them more resistant to UV.

Direct effects can be the result of dissolved solutes, such as iron, sulfites, natural organic matter (color or TOC), and synthetic organic compounds or the result of particles (turbidity) and suspended solids. It is well documented that UV disinfection is not directly effected by pH and temperature. Snicer and coworkers (11) performed a study funded by the American Water Works Associated Research Foundation (AWWARF) in which 30 groundwaters, 15 conventionally treated surface waters and 18 synthetic waters were examined to determine which water quality parameters directly affected the ability of UV to inactivate human enteric viruses and the surrogate MS-2 bacteriophage virus. An example of these data is shown in Figure 2. The figure displays the unadjusted applied UV dose versus the resulting microbial inactivation. The study showed that the parameters, which significantly affected UV performance, were the dissolved iron concentration, the UV absorbance measured at 254 nm (resulting from dissolved organic matter or iron) and the nature and type of particles. The effects of dissolved solutes can be accounted for by using the UV absorbance measurements to adjust the UV dose provided to the water. However, the degree to which the UV dose can be increased to account for background absorbance is limited by practical space and cost considerations.

Effects of particles (often measured by turbidity) or suspended solids on UV performance are a function of their nature, type, and concentration as well as their interaction with the target organism. Experiments looking at the effects of three different particles on the ability of UV to inactivate MS-2 are shown in Figure 3. In these studies, samples of wastewater effluent (representing amorphous biological particles); settled conventional drinking water (representing amorphous inorganic (alum) floc); and

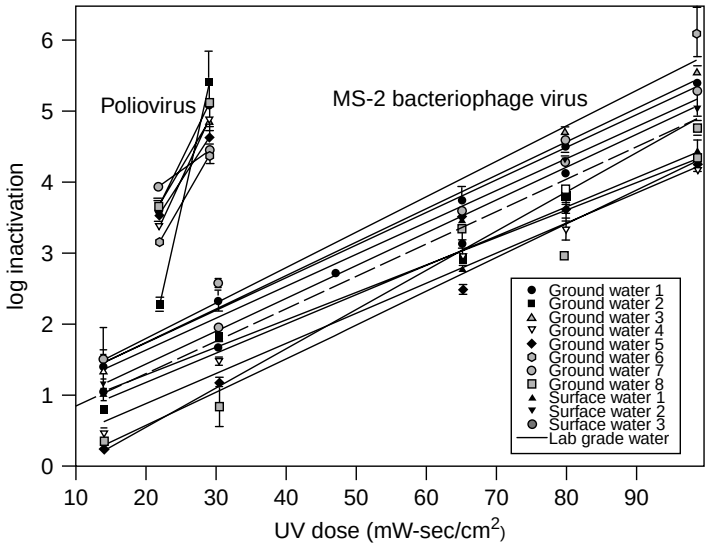

Figure 2. Effects of differing water qualities on UV performance. From Ref. 13.

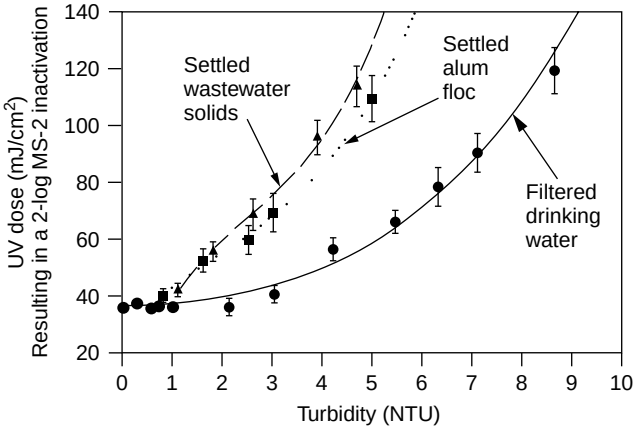

Figure 3. Effects of particle (turbidity) type and concentration on UV performance. From Ref. 13.

conventional filter effluent that had breakthrough of discrete inorganic claylike particles were collected and spiked with MS-2. After 8 hours of mixing these samples were subjected to batch bench-scale collimated beam UV tests to determine the dose required to inactivate 2-log of MS-2. These data show that amorphous solids have a much more dramatic effect on UV performance. Further, the particles passed through conventional filtration did not significantly effect performance until levels above 3 NTU were obtained. These data suggest that the type and nature of particles will be important. In addition, these data suggest that placing UV post filters rather than prior to filters is the optimal location in a conventional drinking water plant. Additional work is in progress to determine how the nature of particles, which may contain high levels of organic matter or algae, will effect UV.

These types of particles are often encountered in unfiltered water supplies and in conventional filter plant effluent that are treating highly colored waters or algal laden reservoirs.

The most significant indirect effects of water quality parameters were found to be sleeve and sensor fouling by dissolved iron, hardness, or minerals and the effects of water temperature on lamp stability. Iron and minerals were found to significantly increase the rate of UV lamp sleeve fouling especially in medium pressure UV lamp systems because of their increased operating temperatures. Water temperature was found to significantly effect low-pressure and low-pressure high-output UV lamps systems likely because these lamp systems typically operate at internal temperatures of 40 to 60 °C. Treating surface drinking water supplies in northern climates with UV is one of the first applications in which waters entering the UV system may be at temperatures as low as 0.5 °C. At these lower temperatures the UV lamps may have unstable output or take longer to reach a stable operating level. Therefore, designers must account for these effects when selecting lamp types, quartz sleeve designs, and operating procedures. Temperature effects on medium pressure UV lamp systems were not found likely owing to the fact that MP UV lamps operate at internal temperatures of 400 to 600 °C.

IMPORTANT CONSIDERATIONS IN UV SYSTEM DESIGN

As shown in Figure 4, there are several factors, which must be considered when designing UV systems. One critical factor is minimum UV dose, which is affected by UV lamp design (type, number, and orientation), UV reactor hydraulics, and water quality parameters. As previously discussed, the target organism and the degree of inactivation desired will also strongly influence the minimum design dose because organisms vary in their resistance to UV. The importance of water quality has also been demonstrated in this paper.

UV sensors are critical to the day-to-day operation and performance verification of UV systems. Concerns over UV sensor reliability remains the largest obstacle to UV acceptance by regulatory officials and water utility operators. The author has found that the precision, accuracy and stability of UV sensors vary widely. An initial survey of UV sensors in place at over 100 wastewater UV disinfection facilities found that 80% of them were unreliable and hence not used. In wastewater UV systems day-to-day performance can be verified by measuring effluent coliform organisms however, in drinking water treatment there is no acceptable surrogate that is always present in the water and UV sensors will be critical. Increased emphasis by UV manufacturers on developing reliable sensors has led to improvements. Recent AWWARF research performed by the author has shown that reliable UV sensors for low-pressure systems are now in use. However, effective sensors for medium-pressure UV systems are less common. All sensors must be properly maintained and calibrated frequently (at least quarterly) to produce meaningful results.

CONCLUSION

UV disinfection systems have been found to effectively inactivate *Giardia* cysts, *Cryptosporidium* oocysts, and human enteric viruses at cost-effective dosages. This result combined with earlier findings that UV does not increase disinfection by-products or contribute to regrowth problems in distribution systems makes it an attractive technology for meeting emerging water quality regulations in the United States. UV system design and performance is a function of lamp design and reactor hydraulics as well as key water quality parameters, such as UV absorbing constituents, particles, and solids, and constituents that can foul UV quartz sleeves and sensors. UV sensors are critical to the day to day performance monitoring of UV systems and the sensors must be carefully maintained and calibrated frequently to insure reliability.

Acknowledgments

Funding for the research presented was provided by AWWARF, USEPA, EPRI, and WERF. Albert Ilges AWWARF project officer has provided tremendous help and insights during the past eight years. V

VADOSE ZONE MICROBIOLOGY

F. J. Brockman
S. N. Bradley
Pacific Northwest National Laboratory
Richland, Washington

T. L. Kieft
New Mexico Institute of Mining and Technology
Socorro, New Medico

The vadose zone extends from land surface to the water table. In regions with high precipitation, it may be a few meters thick or less, whereas in desert regions, it may extend to depths of hundreds of meters. Generally speaking, the vadose zone is the part of the subsurface that is unsaturated with respect to water; however, it can contain intervals of perched water, that is, zones of water saturation immediately overlying relatively impervious rocks or fine-grained sediments. Apart from these perched water zones, the vadose zone can be considered to be synonymous with the unsaturated zone.

Vadose zone microbiology is important for a number of reasons. First, because aquifers are a source of drinking water, vadose zone processes are important for potential mitigation of groundwater contamination by anthropogenic chemicals and pathogenic microorganisms. Second, although deep vadose zones with very little moisture recharge represent one of the most extreme environments for microorganisms, they are of interest from the standpoint of defining ultimate limits on microbial existence and whether microorganisms may over long periods negatively impact the storage of nuclear waste buried in such vadose zones. This article will summarize the major physical, chemical, and microbiological aspects of the vadose zone, special considerations for microbiological studies in the vadose zone, and the practical and basic science themes involving vadose zone microbiology.

PHYSICAL AND CHEMICAL CONDITIONS

As an unsaturated porous medium, the vadose zone contains three phases: solid, liquid, and gas. The water of the liquid phase exists as thin, discontinuous water films coating the solids. The amount of water in the unsaturated zone is a major factor controlling the abundance and diversity of microorganisms, but it almost never poses a direct desiccation stress on microbes in the subsurface. Even in extremely arid regions of the world, the vadose zone below the surface soil layer is relatively moist. Water content in surface soils varies spatially and temporally between saturated conditions and extreme desiccation. In contrast, the moisture content below the rooting zone fluctuates more slowly and over a much narrower range. The water potential in unsaturated porous media is negative with respect to pure water and is influenced mainly by the matric potential, which is caused by adsorption and capillary effects at the solid/liquid interface. The matric water potential of the vadose zone beneath the soil layer is generally greater than (i.e., less negative than) -0.1 MPa. At 20 °C, this corresponds to a water activity (a_w) of approximately 0.999. Thus, the vadose zone presents no more of a direct water stress than a typical liquid growth medium. However, water is an important controlling factor because the thin, discontinuous water films of the vadose zone limit the flow and transport of dissolved nutrients and of microorganisms. At -0.1 MPa matric water potential in a porous medium, the average water film thickness is about 2.9 μm (1). Advection and diffusion of solutes and mobility of microorganisms are severely decreased as the water film thickness decreases. Water films may also be discontinuous, further restricting solute transport. Therefore, vadose zone moisture distribution causes extremely static conditions. Microbes experience a very limited nutrient flux, and limited motility further constrains their ability to gain access to nutrients. This nutrient limitation is especially pronounced in the thick vadose zones of arid and semiarid environments, where the organic carbon input from overlying surface soils is typically less than in more mesic regions, and where rates of groundwater recharge are considerably less than in areas with greater annual precipitation.

Rates of groundwater recharge through the vadose zone vary with climate, topography, vegetation, and subsurface hydraulic conductivity. Diffuse recharge rates (i.e., recharge of directly infiltrating precipitation in areas not influenced by runoff, land surface water) range from tens of micrometers to 80 mm yr^{-1} in arid and semiarid regions of the United States and may be as high as 500 mm yr^{-1} in high-precipitation regions of the eastern United States (2,3). Under the unsaturated conditions of the vadose zone, the bulk of groundwater recharge flows primarily through the rock or sediment matrix, that is, through small pore throats and very narrow fractures; whereas the majority of saturated flow (that can occur in the vadose zone following heavy precipitation events or beneath surface water) is via large fractures and porous material with large pore throats.

The gaseous composition of the vadose zone reflects the makeup of the overlying atmosphere and also microbial activities. Oxygen is generally present throughout the vadose zone; however, it may be in lower concentration than in the overlying atmosphere and may be depleted within microhabitats such as the centers of soil aggregates, biofilms in regions high in organic matter, and in regions that are heavily contaminated by organic carbon compounds. The vadose zone is sometimes called the "zone of aeration," indicating the general availability of oxygen. Gaseous products of microbial metabolism such as CO_2, CH_4, H_2, NH_3, H_2S, and volatile fatty acids may be present

in elevated amounts in the vadose zone, especially where organic carbon supports high microbial activities.

Organic carbon can occur in the vadose zone in the solid, liquid, or gas phases. Solid-phase organic carbon can be entrained with the rocks or sediment at the time of burial, as in the case of paleosols (buried soils). Dissolved organic carbon can be transported downwards from overlying surface soils. This tends to consist of relatively recalcitrant compounds that are not degraded by surface soil microorganisms and that are generally present in vadose zone pore waters in very low concentrations. Gaseous organic carbon compounds, for example, volatile fatty acids generated by fermentative microorganisms, may occur, especially in proximity to saturated zones containing residual organic carbon.

MICROBIOLOGICAL PROPERTIES

Primary Controlling Factors

Microbiological properties in the vadose zone are strongly controlled by nutrient availability, which is in turn controlled primarily by the climate (Fig. 1) and differential water flow. In high precipitation climates, abundant vegetation and high recharge result in relatively large inputs of nutrients. Conversely, in arid climates plant communities are very sparse and recharge is low, resulting in extremely small nutrient input. Large- and small-scale features of the geologic media such as contacts between strata and lenses, discontinuous strata, fractures, and differences in the size and connectivity of pores result in partial or total bypass of moisture and soluble nutrients to regions of the vadose zone. For these reasons, vadose zone microbiological properties can be highly variable from one location to another and with respect to the scale of measurement at a given location.

Abundance

At a given location, microbial populations are generally lower than in surface soils and underlying saturated zones. Direct microscopic counts vary from 10^4 to 10^7 cells g^{-1}. Direct counts are typically lowest in low recharge vadose zones. Very low percentages of the direct count cells can be cultured in vadose zone materials. Heterotrophic plate counts are orders of magnitude higher in shallow vadose zones ($<10^1$ to 10^3 CFU g^{-1} to 10^4 to 10^6 CFU g^{-1}) than in deep, low recharge vadose zones ($<10^1$ to 10^2 CFU g^{-1} to $<10^1$ to 10^4 CFU g^{-1}) (4–15).

The median percentage of microscopically visible cells (after staining with the dye acridine orange) that could be cultured and the median percentage of viable cells (estimated by measuring microbial phospholipid fatty acid extracted from the sediment) that could be cultured were 0.0003% and 0.01%, respectively, for deep vadose zones with low recharge. The equivalent values were approximately three orders of magnitude higher for deep vadose zones from the eastern coastal plain where

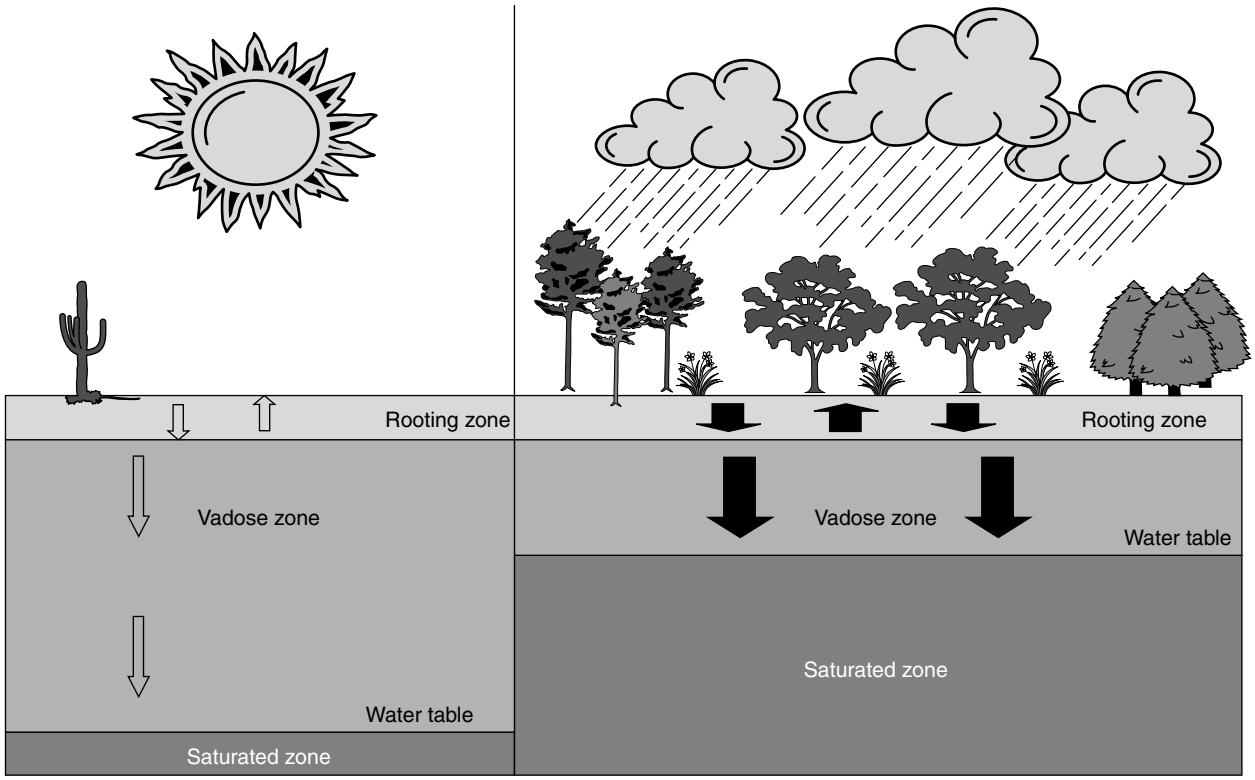

Figure 1. Contrasting moisture movement in the vadose zone in a dry arid climate with transient ponding (left panel) and wet humid climate (right panel). Arrow width represents magnitude of moisture flux with dashed arrows representing very low fluxes. Downward and upward arrows show recharge and evapotranspiration, respectively.

recharge is much higher (16). The lower percentages for the acridine orange cells that could be cultured was probably because of the presence of intact dead cells as, in a separate study, the DGA:PLFA ratio (diglyceride fatty acid [indicative of dead cells] to phospholipid fatty acid [indicative of viable cells]) increased with increasing depth from the surface to 37-m deep (11).

At contaminated vadose zone sites, microscopic counts, and heterotrophic plate counts are typically orders of magnitude higher than at uncontaminated sites (7,10). The highest densities are obtained when contaminants are present at relatively high but not toxic concentrations. Under these conditions, microscopic counts and heterotrophic plate-counts approach or exceed those found in uncontaminated aquifers and surface soils.

Activity

Actual in situ rates of metabolic activities in subsurface environments are generally extremely slow and are best estimated using geochemical modeling approaches (17–19). In aquifers with relatively high hydraulic conductivity, this usually entails modeling microbially mediated changes in groundwater chemistry along a flow path (20); however, this is not possible in vadose zone environments.

Rates of in situ microbial activities in a vadose zone sediment have been estimated based on the disappearance of organic matter since the time of sediment burial. It was estimated that 0.3×10^4 g C m^{-2} had been leached from the sediment and that 4.7×10^4 g C m^{-2} had been biologically degraded in the 7-m-thick vadose zone sediment. Assuming a spatially and temporally constant rate of biodegradation during 11,500 years since the end of the last glaciation, they estimated the in situ rate of microbially mediated carbon mineralization activity to be 0.6 g C m^{-3} yr^{-1}. This corresponds to a rate of CO2 production of 8.0×10^{-4} mmoles CO_2 m^{-3} pore water yr^{-1}. In a separate study, CO_2 concentrations were measured in the same sediments and a mass-balance approach used to estimate rates of microbial activity. They estimated relatively low rates of metabolic activity in most of the depth interval between the surface soil and the water table and a higher rate of 7.1 mg C m^{-3} yr^{-1} in a zone immediately above the water table (termed the "capillary fringe"). This is approximately 9×10^{-3} mmoles $CO_2 m^{-3}$ yr^{-1}. The higher rate in the capillary fringe is consistent with the idea that electron donors may diffuse up from the saturated zone and mix with oxygen in the unsaturated zone to stimulate microbial activities. The water table can also fluctuate up and down at the capillary fringe, thus redistributing nutrients by advection.

Although the rates of metabolic activity estimated by these studies are slow relative to most other types of environments, much slower rates of microbial activity have been estimated for thick unsaturated zones in arid and semiarid environments. Rates of CO_2 production in deep vadose were estimated to be less than 1×10^{-10} mmoles CO_2 m^{-3} yr^{-1} (18). The faster rates that were estimated in the former studies are explained by the fact that these are shallower vadose zones in a moderately high precipitation region beneath pastureland (i.e., abundant vegetation and relatively large nutrient inputs).

Transport

Microbial transport and movement in the vadose zone is key to successful bioremediation success and protection of groundwater from pathogens. Many physical, chemical, and biological factors affect transport and movement of microorganisms in the vadose zone, however physical factors unique to the vadose zone play a major role in controlling transport (Table 1). Given a particular subsurface location, microbial transport is much more limited if the system is unsaturated. This is because the presence of air in the pores results in films and/or pendular rings of water. At a relatively wet −0.1 MPa matric (−1 bar) water potential in a porous medium, the average water film thickness or *effective* pore diameter for the microorganism is about 2.9 μm^3 (1). In addition, in laboratory experiments bacteria appear to have a propensity to adsorb to air-water interfaces, adsorption increases with decreasing saturation, and adsorption may be irreversible in some cases (22–24). If microorganisms are not adsorbed to the porous media or to the air-water interface, they may move chemotactically or by water advection at such relatively wet matric potentials. However, active (via chemotaxis) and passive movement (via advection) are unlikely at matric potentials below approximately −0.05 MPa (25). As the volumetric water content (and water-filled porosity and matric potential) decreases the films and pendular rings become more discontinuous both on the surface of individual particles and at the intersections of particles, thereby increasing the tortuosity and eventually separating the system into a myriad of isolated microcompartments. Fine-textured porous materials may retain a network of continuous films at much more negative matric potentials than coarser materials, however, the water films are thinner and microbial transport is inhibited by adsorption and/or filtration.

Laboratory investigations of microbial transport under unsaturated conditions have typically been performed in homogenous sand columns or in simulated porous media with high concentrations of bacteria and/or nutrients.

Table 1. Factors Affecting Microbial Transport in the Vadose Zone. Factors Unique to the Vadose Zone Are in Bold

Physical
Pore size distribution, pore connectivity, local water flux, **water film thickness, connectivity of water, adsorption of cells to air-water interface, transient saturated flow**
Chemical
Organic and inorganic coatings sponsor adsorption and/or attachment, nutrient concentrations affect growth rate and detachment
Biological (cell characteristics)
Size, shape, hydrophobicity, motility, attachment behavior, detachment behavior

Bacterial transport in agricultural soil microcosms has been relatively well studied; however, soils are structurally and chemically different from the vadose zone. Although these laboratory and field studies do not accurately represent most vadose zones, transport processes in soil can be extrapolated to the vadose zone. In soils, microbial transport occurs primarily by preferential (saturated or near-saturated) flow within soil channels or macropores (26–30) and matrix flow during transient saturated conditions (31). Likewise, transport of microorganisms in the vadose zone probably occurs primarily within preferential flow pore networks or fracture systems during transient saturated or near-saturated flow following storm events or rapid snowmelt, or underneath transient surface water channels and streams. This conclusion is supported by a study of the distribution of indigenous microorganisms in vertical (4- to 15-m deep) unsaturated flow paths at 5 semiarid field sites with either high recharge accompanied by rare saturated flow, high recharge via solely unsaturated flow, or low unsaturated recharge (4). This study found several lines of evidence suggesting transport of microbial cells at the high-recharge sites with rare saturated flow and lack of evidence for microbial transport at the other sites. Saturated flow in preferential flow paths is common in shallow vadose zones with high precipitation climates but rare in deep vadose zones in arid and semiarid climates.

Microbial transport and colonization can be major processes in contaminated vadose zones if the contaminant(s) supports growth and is present at high but nontoxic concentrations. In addition, contaminants are typically delivered to the vadose zone by a transient saturation event and/or lengthy periods of elevated pore saturations, which enhances transport and colonization as described in the preceding text. Cells have been shown to be transported between saturated pores by gas bubbles generated by fermentation (32), and a similar process may occur in the vadose zone during bioventing and in the capillary fringe during biosparging (see Bioremediation section).

Heterogeneity

A number of processes discussed in the preceding text, several of which are reiterated in this paragraph have potential for generating a high degree of microbiological spatial heterogeneity at a given vadose zone site. Differences in nutrient flux (in pristine and contaminated systems) in regions that experience preferential flow, only matrix flow, or only diffusion are likely to generate large differences in number, type, and activity of microorganisms. Interfaces between sedimentary layers often generate localized regions of greater saturation where microorganisms may exhibit increased numbers or activity due to improved access to sediment-associated nutrients. Finally, low water contents in coarser porous media results in a highly fragmented moisture distribution where diffusion within each pore-scale water compartment is the only process supplying nutrients to trapped microorganisms (in the absence of any gas phase transport of electron donors and macronutrients). Under these conditions, chemistries in the individual subpore water compartments can be very different as a result of the heterogeneous distributions of minerals and sediment-associated nutrients at this scale. Thus, microbes may survive in rare favorable microsites and die from extreme nutrient deprivation over geologic time periods in the majority of the microsites, giving rise to heterogeneity (33). These and other heterogeneity-promoting processes are likely to impact the distribution of specific microbial functional types and specific contaminant-degraders to a greater extent than the microbial population as a whole. Although spatial heterogeneity of some soil microbiological processes has been examined in detail (34–36), little research has been devoted to systematic examination of microbial spatial heterogeneity in the vadose zone and its impact on contaminant transformation. Similarly, the presence and distribution of specific microbial functional types, such as different types of strict anaerobes (in high recharge vadose zones with high nutrient concentrations) and chemolithotrophs, has rarely been addressed.

The impact of water flux, and by extension nutrient flux, on microbial distribution was studied by comparing sites receiving 0.015 μm, 0.1 to 10, and 200 mm average annual recharge. Approximately 10^4 viable cells g^{-1} were present in multiple samples from the three sites, based on phospholipid fatty acid analysis performed on 75-g samples. The spatial distribution of microorganisms capable of metabolism were examined by performing several 50-sample transects (5 to 10 cm sample spacing) at each site, and 1-g aliquots from a 15-g homogenized sample were assayed for ^{14}C-glucose mineralization (with postincubation acid treatment to recover dissolved ^{14}C-CO_2) and ^{3}H-acetate incorporation into membranes in 2- to 3-month unsaturated incubations. Microbial activity was not detected in 60 to 70% of the samples from the low-recharge sites compared to 0 to 25% at the 20-cm recharge site (37). Samples from the low-recharge sites were 4- to 8-fold more likely to have detectable activity in silts than in the lower water content sands. Because the silt and sand had similarly low organic carbon content, this result is probably attributable to greater water connectivity at the pore scale in the

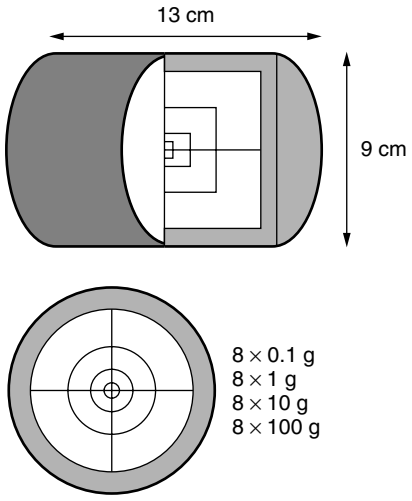

Figure 2. Longitudinal sectioning and sampling of an intact core section for multiple-scale assays of microbial activity.

silt and thus greater survival on account of improved diffusion of nutrients to isolated microorganisms. The large percentage of samples lacking detectable activity with the highly sensitive ^{3}H-acetate incorporation assay at the low-recharge sites indicates that large volumes

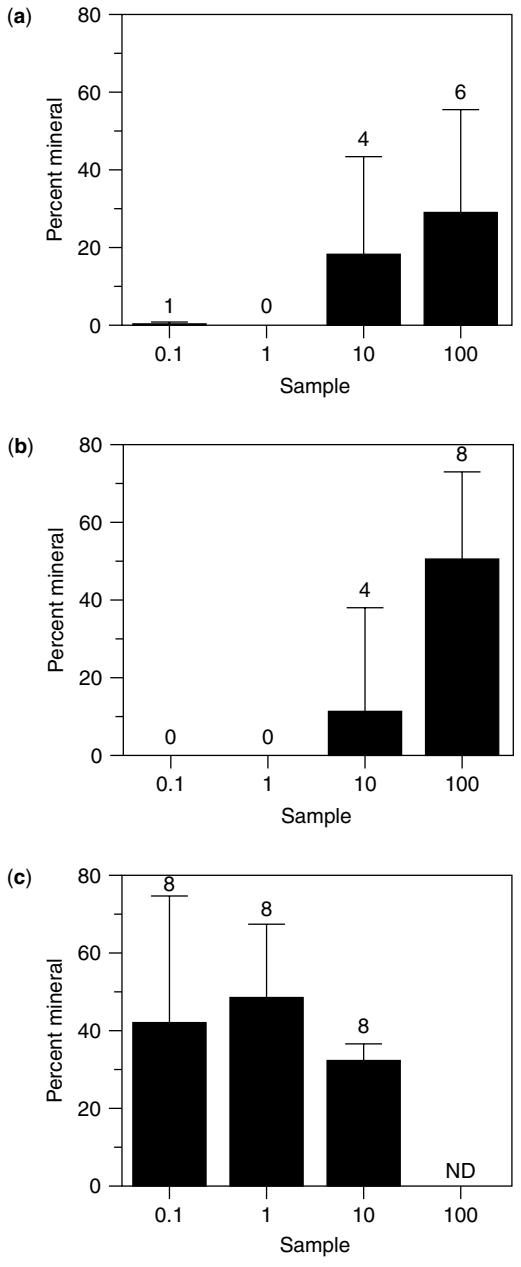

Figure 3. Microbial activity (mean and standard deviation) in eight replicate samples, obtained as shown in Figure 2, from cores at different sites. Values above bard indicate the number of replicates in which activity was detected. Panel A: average annual recharge (AAR) of 15 micrometers, 60 day aerobic incubation. Panels B and E: AAR between 100 micrometers and 1 mm, 60 day aerobic and anaerobic incubations, respectively. Panels C and F: AAR of 20 centimeters, 3 day and 26 day aerobic and anaerobic incubations, respectively. Panel D: surface soil B horizon in mesic climate, 7 day aerobic incubation (for purpose of comparison). ND = assay not done.

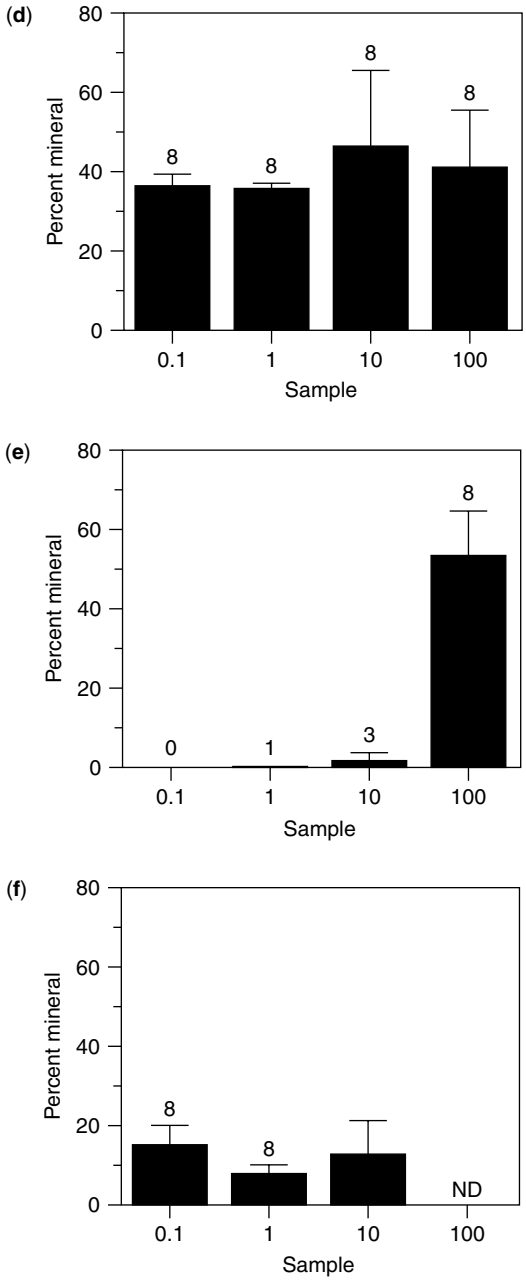

Figure 3. (*Continued*)

of sediment (several tens of cubic cm) may have very few if any microorganisms capable of metabolism. This conclusion was supported by activity assays of 0.1-, 1-, 10-, and 100-g samples ($n = 8$ at each scale) removed without sample homogenization from the same core (Fig. 2). The assay system was designed and validated to prevent scale-dependent artifacts. In the low-recharge sites, activity was rarely, if ever, detected in the small samples and the frequency of detection of activity increased with increasing sample size (38). In contrast, at the 20-cm recharge site, activity was detected and approximately equal in all eight replicates for all sample sizes (Fig. 3). Thus, microorganisms capable of metabolism were very patchy

at the low recharge sites and homogeneously distributed (at the scales of resolution examined) at the high-recharge site. The patchiness of activity in these transect and multiscale studies using easily metabolized substrates mirrors that observed for denitrification in soils (34–36) and suggests that the distribution of specific contaminant-degraders in uncontaminated low recharge vadose zones will be extremely patchy.

SPECIAL CONSIDERATIONS FOR VADOSE ZONE MICROBIAL STUDIES

Sampling Access

There is generally a greater number of options for vadose zone sampling than for saturated zone sampling. In addition to using traditional drilling and coring techniques, one can also access the vadose zone via sediment and rock outcrops, by excavation, and through caves and tunnels. Drilling and coring methods have been reviewed in detail elsewhere (39,40), including methods for sampling in mines and tunnels (41).

Drilling and coring techniques have the advantage that they can be continued into the underlying saturated zone to obtain multiple depth intervals at a single site. Cores can be obtained from shallow unsaturated, unconsolidated sediments using relatively simple drilling technology such as a hollow-stem auger and a split-spoon sampler (142). Hollow stem auger techniques can be used to depths of approximately 100 m. Cable-tool drilling is a simple and ancient technology that has been used with good results to depths of 90 m in unsaturated, unconsolidated sediments (43), and much deeper in a saturated zone study (44). Hollow-stem auger and cable tool drilling have the advantage that they do not require drilling fluids, which can be sources of chemical and microbiological contamination of core samples. Deep, hard-rock vadose zones require more aggressive approaches such as the rotary drilling and wire line coring, as exemplified by the air-rotary, diamond drill bit method (45,46).

Tracers should be used whenever possible to quantify contamination from the drilling process (16,17,20,47) When drilling fluids are used, the tracers can be added to the drilling fluid; for drilling/coring methods not requiring fluids, the tracers can be added directly to the borehole at intervals during the drilling and coring process. Tracers are subsequently quantified in the outer portions of cores and in the interior subcores that are sampled for microbiology. Ideally, tracers should include conservative solute tracers (e.g., bromide) and particulate tracers that serve as surrogate bacterial tracers, for example, fluorescently-labeled, carxboylated microspheres. Tungsten carbide has also been used as a particulate chemical tracer during vadose zone sampling (7).

Rock and sediment outcrops (and also roadcuts) of vadose zones can be directly accessed for physical, chemical, and microbiological analyses. The advantage of this sampling approach is that it allows direct observations and sampling of spatial patterns over a wide area; the major disadvantage is that exposure at the surface leads to physical, chemical, and microbiological alterations of the vadose zone materials. Physical weathering, desiccation, chemical oxidation, and colonization by allochthonous microorganisms can contribute to alteration of vadose zone rocks and sediments at outcrops and roadcuts (13,14). These near-surface alterations can be avoided if one drills or excavates laterally far enough into the formation. In a study in a dry climate, moisture content was measured during horizontal coring into a roadcut. Moisture loss extended 2 m into the formation, yet laboratory measurements of microbial activity and culturability stabilized 30 cm into the formation (F. J. Brockman, unpublished data). The extent of this near-surface alteration of the vadose zone at outcrops in undoubtedly highly variable and dependent on texture, degree of fracturing, and recharge rates.

Caves, mines, and tunnels can provide relatively easy access to vadose zone environments. For example, extensive sampling was performed at a proposed nuclear waste repository by excavating rock in tunnels (8,9,22,23). However, as with surface outcrops, the exposed rock surfaces are subject to desiccation and airborne contamination. These effects can be minimized when a freshly mined area is sampled (21). Surface rock is aseptically removed exposing fresh rock surface that is then collected for microbiology. This approach can be combined with the use of tracers such as Br^- (23) or fluorescent microbeads to preserve intensity of samples (49a). The tracers are applied to the rock surface after a layer of surface-contaminated rock has been removed; subsequently the surface is further excavated to remove fresh rock, and that fresh rock is subsequently sampled. Tracers are quantified in rock collected from the surface and at depth; tracers should not be detectable in sample collected from the rock face or should be no more than three orders of magnitude less than that collected at the surface. This approach was used to ensure integrity of volcanic tuff samples collected in the Exploratory Shaft Facility of the proposed Yucca Mountain high-level nuclear waste repository at the Nevada Test Site (21).

Airborne contaminants within the mine can be assessed by exposing agar growth media in petri dishes during the sampling process and subsequently incubating the plates. Because fungi are common airborne contaminants but are uncommon within deep vadose zone samples, they have been used as serendipitous tracers for microbial contamination of rock samples (18). An alpine miner, a mechanical device with multiple high-speed carbide steel bits capable of excavating large volumes of rock quickly, has been used to sample a 27 m^3 volume of volcanic tuff (9,23). By stopping the alpine miner at intervals.

Unsaturated Incubation Conditions

Laboratory incubations are often used to measure rates of potential microbial activity (e.g., rates of $^{14}CO_2$ production from ^{14}C-labeled substrates, enzymatic activities, etc.) in vadose zone rocks and sediments. These laboratory microcosm assays are useful for comparisons of relative microbial abundance and activities among environmental samples, and they can also be used to test for the presence of a particular metabolic activity, for example, ability to degrade a specific contaminant compound. However,

the data should be considered to estimate *potential* microbial activity, not actual in situ rates of metabolic activity. Even when exogenous substrates are not added to samples, the laboratory microcosm approach yields activities that are considerably faster than in situ rates (14,15). This is because the process of sample collection, handling, and storage can stimulate microbial activities by redistributing nutrients, moisture, and microorganisms such that nutrient availability is increased (4). This stimulation can occurs even when intact cores are used (33).

Simulating vadose zone conditions in laboratory microcosms requires special care. Saturated slurries generally do not represent vadose zone conditions. Addition of solutes to adjust the water potential to that of the vadose zone is inappropriate because the effects of solute water potential and the effects of specific ions on microbial activities are different from the effects of matric water potential. However, the total water potential in a porous medium can be set by equilibration in a sealed container with an atmosphere that has had its relative humidity set by a solution of known solute water potential. Sample handling can partially desiccate vadose zone samples (10,21). Moisture can be added back when it has been lost from a sample, but these moisture changes can alter microbial community structure and activities. Amendment with nutrient solutions will increase moisture contents and water activities, so this should be minimized by using small volumes of more concentrated solutions.

PRACTICAL IMPORTANCE OF VADOSE ZONE MICROBIOLOGY

Wastewater Treatment by Artificial Recharge

Artificial recharge of wastewater is a low-cost method for disposing of and treating wastewater, while restoring water to underlying aquifers. This process, also known as soil-aquifer treatment and infiltration-percolation treatment, is an especially attractive option for water conservation in arid and semiarid regions, where heavy reliance on groundwater can contribute to aquifer depletion. The wastewater can be from industrial and/or domestic sources or from agriculture, for example, runoff from concentrated animal feeding operations (50). The wastewater can be treated, partially treated, or untreated. Application can be by injection, spraying on the surface, or through surface infiltration basins. In some arid and semiarid regions where water conservation is an especially vital issue, treated wastewater is reused as irrigation water for agriculture and the water subsequently recharges underlying aquifers (51,52). The expectation is that wastewater contaminants (chemical and biological) will be removed during infiltration through the vadose zone before it reaches underlying groundwater. This can include mineralization of organic contaminants, immobilization of inorganic contaminants (e.g., heavy metals), transformation of inorganic contaminants (e.g., nitrate) to harmless products, and sorption and inactivation of pathogens.

Nitrogen contamination of aquifers, especially in the form of nitrate, is a major concern when wastewater is treated by artificial recharge. Nitrification results in oxidation of ammonia to nitrate in the vadose zone (53). Nitrate removal requires denitrification to nitrogen. In studies of artificial recharge of wastewater runoff from concentrated animal feeding operations through playa lakes in Texas, denitrification activity in the vadose zone was sufficient in most cases to prevent significant contamination of the underlying aquifer with nitrate (50). In soil-aquifer treatment pilot projects in Phoenix, Arizona, 30 to 70% N removal from wastewater treatment plant effluent was reported during percolation through the vadose zone (54). The efficiency of N removal was dependent on the hydraulic loading rate (recharge rate) and the organic C content of the effluent. Recharge rates <1 m/day were most effective. Intermittent recharge, that is, alternating flooding and drying periods, appeared to favor denitrification. Phosphate removal was 40 to 80%, also depending on hydraulic loading. Organic carbon was reduced to very low levels, as indicated by near-zero biological oxygen demand (BOD) after passage through the vadose zone.

The effectiveness of pathogen removal from wastewater during artificial recharge depends, in part, on the rates of infiltration and the thickness of the vadose zone. Column studies have shown greater than or equal to 90% removal of bacteriophages (used as surrogates for human enteric viruses) during unsaturated flow through 4.5 m of vadose zone sediment at a high infiltration rate of 15 m day^{-1}, and much more efficient removal at 1 m day^{-1} (55). Transport rates for pathogenic microbes are generally directly related to water content. Virus concentrations in effluent from 1-m long saturated laboratory soil columns have been reported to equal influent concentrations within two pore volumes. Comparatively, the effluent virus concentrations from similar columns under unsaturated conditions were shown to be 5 to 27% the influent concentration (56). The same study found little adsorption of viral particles to the soil material, indicating a substantial inactivation process. The inactivation rate of viruses is dependent on environmental conditions (57). Likewise, adsorption, dispersion, and advection may be important factors for virus removal (55,57,58) under certain types of vadose zone chemical and hydrological conditions.

Efficient removal of indicator bacteria (coliforms and fecal streptococci) has also been demonstrated in column experiments and field measurements (59–61). Helminth eggs have also been shown to be eliminated during wastewater treatment by artificial recharge (Guessab and coworkers 1993). However, in some cases, sorption and/or inactivation of microorganisms during artificial recharge in the field has been disappointing, a finding that is usually attributed to high pore water velocities, especially as a result of preferential flow through heterogeneous systems (62,63).

Bioremediation

The vadose zone, with its various physical, chemical, and biological processes, can be important in protecting groundwater from surface contaminants. These processes, under favorable conditions, can slow the migration of contaminants by sorption to soil particles, entrapment of gas and liquid phase contaminants in the pore space,

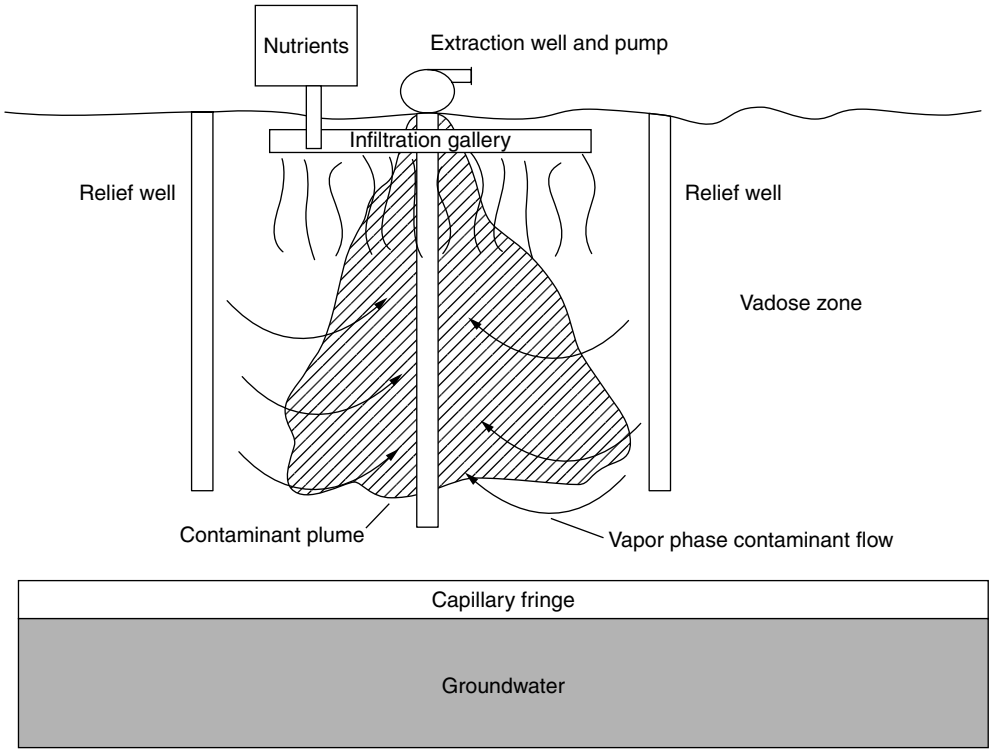

Figure 4. Schematic of bioventing showing air being extracted from the vadose zone and air (oxygen) being pulled through the unsaturated contaminant plume. Soluble nutrients such as nitrogen and phosphorus can be supplied through an infiltration galley or a slotted horizontal pipe to further increase the number of biodegrading microorganisms.

transformation, degradation, and even mineralization of the contaminant. To some extent, this process progresses without human intervention, and has been shown to reduce the mass, toxicity, mobility, or volume of contaminants in the vadose zone and groundwater (64). To enhance these natural processes, engineered remediation processes have been developed that exploit the physical, chemical, and biological process intrinsic to vadose zone environments. Reviews of current technologies and innovations have been written (65–69).

The first commercial application of bioremediation was in 1972 to treat a gasoline pipeline spill in Pennsylvania (70,71). As the use of bioremediation matured, it became apparent that a major limiting factor in the process was oxygen availability. Nutrient limitation was also problematic. Dick Raymond patented the use of water amended with oxygen and nutrients to promote biodegradation in 1974 (70). Hydrogen peroxide was also used as an effective source of oxygen, but had limitations when used in unsaturated vadose zone environments. Soil vapor extraction (although initially used to physically extract vapor phase contaminants) was found to have a significant biological component in the early 1980's (70).

The process, called bioventing when focused on stimulating biological activity takes advantage of the unsaturated nature of the vadose zone and its gas-filled pore space. The process is similar in design to soil vapor extraction in that air is moved through the contamination area either through air injection or soil gas extraction. In the case of soil vapor extraction, this air movement is used to carry the contaminant vapor to the surface for removal/recovery. In the case of bioventing, the air movement is meant to deliver oxygen and other nutrients to indigenous microbes, in turn stimulating biotransformation, biodegradation, or mineralization of the contaminant (Fig. 4; 72). Bioventing has developed into one of the most cost-effective petroleum hydrocarbon remediation processes (EPA webdoc, 1995). As of 1995, the EPA and U.S. Airforce had more than 150 successful bioventing remediation sites (web doc, 1995).

Volatile organic compounds are common vadose zone and groundwater contaminants. Although chlorinated solvents are a serious threat to groundwater at many sites, petroleum hydrocarbon contamination is the most common. These sites usually occur from underground leaking fuel storage tanks, refineries, military airfields, and petroleum spills. As these contaminants enter the vadose zone, they partition into one (or more) of four phases including nonaqueous-phase liquid (NAPL), soil solids, soil water, and interstitial air (Yu, 1995). This partitioning within the vadose zone effectively slows the migration of the contaminant toward the groundwater.

Sites contaminated with toxic metals and highly structured polychlorinated biphenyl compounds remain a challenge in terms of engineered bioremediation strategies.

Radioactive/Hazardous Waste Repositories

Deep vadose zone environments in arid and semiarid environments have been targeted as potential sites for

storage of hazardous waste materials, including radioactive waste. Examples of such sites are (*1*) Yucca Mountain, Nevada, which is a proposed site for a high-level nuclear waste repository, (*2*) the Waste-Isolation Pilot Project (WIPP) Site in southeastern New Mexico, where transuranic waste is now being deposited within a 700-m deep unsaturated Triassic salt deposit, and (*3*) various underground storage facilities within the Hanford Site in south-central Washington state, where nuclear weapon-production-related wastes are stored. These sites have been chosen in part for their low recharge rates. Low recharge rates mean that should a spill occur within the repository, the flow of contaminants to underlying aquifers will be relatively slow. In the case of the Yucca Mountain site, ongoing studies are being performed to predict the fate of the contaminants over a period of 10,000 years or more (See also NUCLEAR WASTE RESPOSITORY IN YUCCA MOUNTAIN: MICROBIOLOGICAL ASPECTS, this Encyclopedia) Predicting the fate and transport of contaminants is always challenging, but the task is especially difficult when one attempts to factor in the effects of microorganisms. The problem has been separated conceptually into two areas, the "near field" and the "far field." The near field refers to the area in the immediate proximity to the stored waste; the far field refers to the more distal, unsaturated regions of Yucca Mountain that separate the near field from the underlying aquifer (150 m below the repository) and the land surface. Microorganisms are a concern in both the near and far fields. In the near field, microbially mediated corrosion of containment vessels can lead to waste spills. Once a spill has occurred, transport through the surrounding vadose zone can be influenced by microbial activities. Hersman (73) reviewed the possibilities for microbial influence on the fate and transport of spilled radionuclides. Microbes may retard transport of radionuclides through sorption, biodegradation of organic-radionuclide complexes, oxidation/reduction reactions, and pH changes; or they may accelerate transport by production of chelates, oxidation/reduction reactions, and pH changes. Unfortunately, there are no current models that can predict with any accuracy which of these processes will predominate.

The volcanic tuff at Yucca Mountain has been shown to harbor native microbial populations (21). Culturable cells were measured at 10^1 to 10^3 cfu g^{-1}; total cells were estimated from phospholipid fatty acid (PLFA) concentrations to be 5.9×10^3 to 2.2×10^5 cells g^{-1}. Although these are relatively low numbers relative to aquifer environments, the activities of these microorganisms could be significant when integrated over time and distance (10,000 years and 150 m, respectively, at Yucca Mountain). Moreover, the numbers of microorganisms in the repository environment can be greatly increased by tunnel-boring and construction activities. Microbial biomass (estimated from PLFA data) was found to be 10^2 to 10^4-fold greater in sand deposited on the tunnel floor than in pristine tuff (74). This stimulation of microbial activities by repository construction activities could increase corrosion problems in the near field, and possibly influence microbial activities in the far field. When the waste is actually deposited at Yucca Mountain, there will be radiation flux in the near field that will probably be damaging to some microorganisms. However, Pitonzo and coworkers (75) found that many indigenous microorganisms are capable of surviving gamma irradiation at the dose rate that is expected within the repository (1.6 Gy min^{-1}) by entering a viable but nonculturable state. Microbial threats to repository performance should also be considered at other sites. Microbes have been isolated from halite at the WIPP site (76), and Hanford Site vadose zone sediments are known to harbor metabolically active microorganisms (7,10).

The Vadose Zone as an Extreme Environment

On the basis of estimates of 10^4 viable cells g^{-1} and a growth yield of approximately 3.6%, calculated average generation times for microorganisms in the vadose zone has been calculated to be in the range of 3×10^3 to 3×10^5 yrs (77). Considering the ages of vadose zone sediments, this means that many vadose zone populations have undergone fewer than 100 cell division since the time of burial. Clearly these vadose zone microbes are in long-term starvation survival mode rather than active growth. This long-term starvation survival is especially remarkable when one considers that many vadose microorganisms appear not to be spore-formers, and thus are surviving nutrient deprivation as quiescent vegetative cells. The low nutrient fluxes and concomitantly slow rates of metabolic activity indicate that deep vadose zone environments are among the most nutritionally extreme in the entire biosphere. Low concentrations of dissolved organic carbon combine with extremely slow rates of groundwater recharge make for infinitesimal nutrient fluxes. Microbes that are sequestered in these relatively static, diffusion-dominated vadose zone sediments and rocks are among the most nutritionally challenged in the biosphere.

In some vadose zone environments with very low recharge rates, the microbial communities may date from the time of geologic deposition. One can constrain the age of the microbial community by determining the age of the groundwater (youngest possible age of the community) and the age of the geologic material (oldest possible age). This approach has been applied to thick vadose zone loess sediments in semiarid eastern Washington state, where recharge rates are relatively slow (5,11, Balkwill and coworkers 1998). Pore water ages were estimated from groundwater recharge rates that were measured using the chloride mass balance method. A diversity of bacterial types were cultured in vadose sediments with pore water ages of 15,000 and 30,000 years (4). Viable microorganisms (evidenced by phospholipid fatty acids, mineralization of organic substrates, and plate counts) were found in loess sediments with pore water ages as great as 1,200 years and sediment ages approaching one million years) (11). In this case, the microbial communities may be as young as the pore waters; however, microbial transport through sediments is generally greatly retarded, and so the age of the communities may be much older than 1,200 years. Age of the communities does not mean age of individual cells. The microbes in these communities have probably undergone

occasional cell division; however, as noted above, this is probably a very infrequent event given the low nutrient fluxes. Similarly, spore-forming and non-spore-forming bacteria and were cultured PLFAs indicative of approximately 10^4 cells/g measured in sediments for which the age of the communities was estimated to be between 12,000 years (time since last significant recharge event in the form of postglacial flooding) and four million years (sediment age) (5). Although these microbes are not nearly as ancient as those reported to have been recovered from Dominican amber (78) and Permian halite (79), they do support the concept of bacteria persisting in deep vadose zones for thousands of years or more with little access to exogenous energy sources. Whether these vadose zone microbes have special adaptations for survival under vadose conditions has yet to be determined.

Comparisons of closely related surface and subsurface bacteria for their abilities to survive in unsaturated sediments for more than a year showed no significant differences between surface and subsurface strains (80); however, laboratory survival studies conducted over a one-year time frame are probably not adequate to discern differences in microbial abilities to survive for geologically relevant lengths of time. Further studies of vadose zone rocks and sediments may reveal microbial strains that exhibit adaptations for long-term survival under the low-nutrient flux conditions that are typical of deep vadose zone sediments.

VIABLE BUT NOT CULTURABLE (VBNC) MICROORGANISMS

ARTHUR L. KOCH
Indiana University
Bloomington, Indiana

Bacteria can grow rapidly, yet there are some circumstances where it appears that they should grow, where they grow slowly, or not at all. There are many interesting cases where resources are present, so seemingly the cells could grow, but they do not, presumably for some more important reason than that of just increasing the number of independent propagules. Therefore, they forego a growth opportunity. An especially interesting case has been called the "viable but not culturable" (VBNC) (1) state in which cells appear to be alive but do not immediately produce colonies and is the topic of this article. However, there are a number of other cases that will be briefly covered here or in the article on Oligotrophism because they are or may be related to VBNC and more explicitly provide aspects of the VBNC way of life. These and key references for them are

- being an obligate oligotroph (2)
- being in a state of "shutdown" metabolism (3)
- substrate activated death (SAD) caused by a substrate in nongrowth medium (4)
- lactose death caused by lactose to an organism with multiple *lac* operons (5)
- quiescent cells intermittently growing under almost starvation conditions (6)
- SOS response after DNA damage (7)
- osmotic rupture when pumps are too effective (8)
- oxidative stress causing an abundance of oxidative damage to the DNA (9,9a)
- blockade of nucleic acid and protein synthesis by inhibition of wall enlargement (10)
- streptomycin killing (11)
- destruction by a lysogenic bacteriophage of the host cells (12)

- suicide of individuals for the 'good' of the community (12)
- sporulation/germination (13)

The last is quite familiar and common in gram-positive organisms. Sporulation results when nutrient is temporarily missing in the medium, there is a special division that protects the organism and results in a nongrowing cell (i.e., the spore). Spores may later germinate and resume vegetative growth. For this case, the reason for stopping and starting growth is clear, it has to do with a special strategy to respond to specific starvation. Sporulation allows the bacterium to remain indefinitely in a state in which metabolism is essentially nil under conditions where they are much more resistant to environmental stresses than is the vegetative cell. In VBNC and in many other cases, the rationale for decreased growth is not so obvious and has consequently been the subject of many arguments and much discussion. It is usually pointed out that the VBNC strategy gives long-term selective advantage. However, I believe the aforementioned phenomena have similar advantages and disadvantages, but all may backfire, for example, when resources are available but missed and not utilized while cells are in the spore or other quiescent state.

THE CONCEPT OF THE VIABLE BUT NON CULTURABLE (VBNC) CELL

The phenomenon of VBNC was formulated by Xu and coworkers (1) and became of more general interest to microbiologists with the appearance of the seminal review by Roszak and Colwell (14) in 1987. They itemized many observations that the viable count of a culture declined before (or much faster) than the total count in the test tube. Possibly the first convincing observation of this phenomenon was that of Fliermans and Schmidt (15) who used both autoradiography and immunofluorescence to study *Nitrobacter* in natural systems. However, this work only shows that some cells of the *Nitrobacter* strain are metabolically inactive. Recent work in the VBNC area has been carried out with *Vibrio cholerae* by the Colwell group (16) and *Vibrio vulnificus* by Oliver and his collaborators (18,18a). Bogosian presented very significant studies with the latter organism and with enteric bacteria that argue very effectively against the reality of the VBNC State (19,20).

The VBNC Phenomenon

To demonstrate the VBNC state it is necessary to follow a growing culture under defined conditions that cause cells to enter this special state; usually these conditions are starvation or a lowering of the growth temperature (18). If there is subsequently a decrease in colony count, but little decrease in total count with time, and if evidence can be produced to show the cells are capable of metabolic activity, then the term VBNC is deemed by some workers to be appropriate. Other workers prefer the term VBC and others such as Kell and coworkers (19) would prefer ABNC to signify "active, but not culturable." "Dormant" is an inappropriate term because it means "sleeping" and although sleeping people have some signs of life they can be easily awakened. The activities of cells in the presumed VBNC state that have been followed experimentally are few and of limited scope.

It should be noted that a good deal of the objection to the validity, reality, and legitimacy of VBNC state has appeared in the recent literature mainly as very short articles or letters. The terminology used in the VBNC field is confusing, not clearly specified, and facts are often not well documented. Kell and coworkers (19) have dealt especially critically with the terminology and logic. In order to obtain an appreciation of this field the original review by Roszak and Colwell (14) and the reviews by Oliver (18) and Barer and Harwood (20) are particularity cogent.

Rationale for the Existence of the VBNC State

There need not be only one unique reason for the VBNC state. There many reasons for some of the related conditions in the long list given that may apply to VBNC. The reason why single-cell organisms do not grow could come from five major directions:

Firstly, when the failure to grow (or death of a cell) is actually favorable for the growth of the species or colony. The classical case (24,25) has to do with preventing a pathogen, such as a lysogenic bacteriophage from infecting a cell; the cellular response is to commit suicide presumably to protect the neighboring cells.

Secondly, the cell may have adopted a strategy that is purposefully an intentionally irreversible process. This would be equivalent to one exhibited by many plants and animals in aging and leaving reproductive propagules, but not themselves.

Thirdly, by a species having specialized to interact with another species for their mutual good. In this third case it may be impossible for one organism to grow without the other. One can think of plants and their pollinators or many other pairs of organisms coexisting commensally, mutualistically, or symbiotically. For example, many trees must be rooted in a mycorrhizal environment.

Fourthly, a cell may have adopted a strategy that has the negative aspect that puts it at risk of being sensitive to environmental factors, such as too much of a nutrient, too much of a strong oxidant, etc. It has been suggested that oligotrophic organisms may take up osmolytes when available and, then unfortunately swell and burst (26). For cases in this latter category, the microbiologist often is the cause of the problem. If the experimenter were to adequately take these possibilities into consideration and feed only smaller amounts at a time, it should be possible to culture such cells without killing them.

Fifthly, the cell may have entered a physiological state in which it has specialized for movement and not for growth, as in the phenomenon dubbed "the shutdown cell" (3) as exhibited by *Rhodomicrobium* and *Caulobacter*. Some of the other phenomena listed earlier are special and additional reasons will be given in the following text.

Sixthly, there are other aspects that might cause the appearance of not growing when growth seems possible. One has to do with the property of organisms of being able to exhibit different sets of properties in

different environments. There are many situations in which pathogenic bacteria greatly alter their metabolism when they enter a host and later return to their original behavior when no longer in an active pathogenesis mode. The strong implication is that the cells can exhibit more than one quite different appearance and behavior to the outside world, dependent on their circumstance. Conversion between these states fluctuates more rapidly from one to another compared to ordinary gene mutations, but much more slowly than adaptive responses. It has become clear in the last few years that bacteria have some genes that have been modified in the past so that they are capable of reversible mutations at rapid rates (24,25). This can occur, for example, when a tandem array of repeats whose unit length is not a multiple of three is present. Tandem repeats can be gained or lost through copying errors or by failure in repairs and thus changes the frame of protein translation and consequently alters the protein product of the gene. This situation creates a circumstance in which the process of forward and back mutation are rapid and equally possible.

Methods of Study

Roszak and Colwell (14) enumerated some 40 methods and techniques that have been employed in the literature to distinguish living from dead cells. Kell and coworkers (19) and Barer and Harwood (23) gave more methods. Methods in use to detect various metabolic activities were also reviewed by Oliver (18). His list, as do some of the others, starts with the Kogure's Direct Viable Count (DVC) method (26). For this test an agent is added to block some limited aspect of replication, usually this is nalidixic acid that blocks DNA gyrase. The important aspect is that it does not stop other processes directly. It does, however, prevent the next rounds of cell divisions from occurring although both protein synthesis and wall synthesis would continue. Then if a cell elongates during a short experimental period when cell division and cell separation cannot occur, it is concluded that the cell has a broad variety of metabolic processes that can actually function. These would be needed for cytoplasmic and wall growth. With nalidixic acid the observation of cytoplasmic growth is not confused by the occurrence of cell division. If elongation takes place the cell is not dead, but if the cell does not elongate, it is assumed to be dead. Although this is a most powerful approach, it could give false-negative responses because the control mechanisms of the presumptive VBNC cell might block elongation processes. On the other hand, if the VBNC state blocks DNA synthesis or cell division uniquely, the cells will have already elongated to their limit before the nalidixic acid is added. It should be noted that cells engaged in the SOS response to ultraviolet radiation would meet this test (see following text).

A second common method uses a tetrazolium dye. When cells have metabolic ability and sufficient available reducing power via the electron transport system to reduce the colorless oxidized form of the dye to the colored formazan, the test is positive. Reduction of the tetrazolium requires integrity of the cell, an active redox enzyme system plus an available reductant, but does not require a capability for macromolecular synthesis.

A third test, like the second test, requires that the cell's integrity has been maintained so that the cells are still intact. The basis of this test is to identify cell-shaped objects that have nucleic acids. Acridine orange (AO) and/or 4′,6-diamidino-2-phenylindole (DAPI) are used. The DAPI stain binds selectively to double-stranded DNA, whereas the former binds to the more abundant single-stranded RNA. In addition however, AO binds to double-stranded DNA, but it then fluoresces a different color. Consequently, this dye can provide additional useful information because cells that are actively growing have much more RNA than DNA and become stained orange instead of green.

A fourth method involves measuring the level of ATP as a measure of biomass; ATP content has been presumed in microbial ecology for 50 years to be a valid measure of viable cellular biomass. Existence of cellular ATP implies that the cell envelope is intact and that the energy-trapping machinery is functioning to some fraction of that during normal growth.

Many complaints have been registered that none of these tests in any sense measures viability because viability means to be alive and to be able to reproduce. Being alive requires the combination of many special properties, not just one. Obviously, after long periods of incubation, any of the methods cited would carry more weight in the assignment of VBNC. This is because it is reasonable to assume that after months or years a dead organism would decompose or be decomposed on account of autolysins or other hydrolytic enzymes or be converted into a hollow shell and not have any of the properties mentioned earlier.

Of the set of techniques listed earlier, the first, demonstrating the ability of a cell to elongate, in the presence of nutrients and of an agent that blocks cell division is believed to be the most effective in providing evidence that the cell has many of the aspects of life. A cell that passes this test was almost certainly alive before the nalidixic treatment, even if it is not able to grow indefinitely afterward. The Kogure test should probably be the first test performed. Oliver's laboratory has used it (28,29) very critically to demonstrate that resuscitation was not obscured by growth of residual living bacteria. On the other hand, Weichart and Kjelleberg (30) had earlier thought that instead of resuscitation, regrowth could be the explanation of cultures passing the test.

THE REALITY OF THE VBNC PHENOMENON

One might reasonably assume that a "viable, but not culturable" organism is actually culturable, and that the microbiologist has not yet discovered the secret. Barrer and Harwood (20) designate this state AYU for "As Yet Uncultured." Our ignorance in this regard applies to a majority of the organisms given the VBNC appellation and to most organisms that exist in this world.

Sometimes regeneration of apparently nonculturable organisms has been obtained. Now the problem is finding out how common the return from the VBNC state is.

Doubters (37–43) claim that there was a rare colony-forming organism present that had multiplied and that most of the presumptive VBNC cells are really dead and thus the measurement has not been properly carried out. Believers hold that the switch from vegetative to a cell apparently incapable of division and vegetative growth is a highly rational strategy for long-term survival of the species. This leads me to a detour into some of my own research to show that many organisms are capable of charting and following a strategy that appears to be contradictory to their immediate success.

The Problem of Seeming Irrational Self-Choice

Bacteria in exponential growth, particularly if they have been cultured in this state for many generations, should be growing as fast as possible, limited only by their genotype and the resources in their medium. This is the philosophy we inherit from Malthus and Darwin. In ecological or evolutionary terminology such typical organisms should have maximized their inclusive fitness. But there are many organisms that do not seem, to us humans, to obey this rule.

Insights into the fundamental nature of bacterial growth emerged in the 1950's from pioneers such as Sir Cyril Hinshelwood, Aaron Novick, Leo Szilard, Seymour Cohen, Herbert Kubitschek, Elio Schaechter, Jacques Monod, Ole Maaløe, and Allan Campbell. The essential concept was that of balanced growth. The way to study bacterial physiology, it was believed, was to examine steady state growth so that the organisms were increasing exponentially in number. Subsequently, while measurements were being made the cells were not changing in properties. The proportion of cellular amounts measured during balanced growth made it possible to calculate the rate of biochemical reactions (see 39). The best way that cultures in the balanced state can be obtained readily is by using a chemostat. Much understanding of microbial physiology resulted from studies of such cultures.

Not only was basic microbial physiology elucidated, but the considerably more complex ways in which organisms interact with their environment were discovered. As an example, let me describe an early experiment (35) of my own that has left me puzzled ever since, but emphasizes the versatility and commitment of bacteria and their ability to "choose" and adopt a particular strategy. A chemostat culture of *Escherichia coli* ML 308 was under study; it was limited by glucose in a minimal medium and caused to grow with a doubling time of 10 hours. This was subcultured into a sample of the reservoir medium. Because of continued bacterial action, the culture medium in the reactor (growth chamber) had a thousand times lower glucose concentration than was in the reservoir. Therefore, this subculturing constituted a shift-up in the glucose concentration of a thousandfold. It took six hours to achieve the characteristic (steady state) doubling time of 45 minutes in the glucose medium. This was the control part of the experiment. At this time I had on hand in the laboratory (27) a constant temperature growth apparatus within a double-beam spectrophotometer linked to a computer. With it the cell biomass could automatically be measured every two seconds, very precisely and accurately. The output of the spectrophotometer was sent to the computer that could estimate the growth rate on-line to a precision of 1% in a three-minute measuring period. Surprisingly, when the same chemostat culture was "shifted-up" into Luria broth, a rich medium with yeast extract and tryptone as a source of amino acids, supplemented with the same high level of glucose, and made up in the minimal salts medium that had been used for the chemostat culture, the results were much different. In less than a minute the cells had shifted to the definitive doubling time of 25 minutes. This growth rate was then quite stable during further growth.

This clearly demonstrates the ability to the organisms to select or be directed into different courses. It poses the highly important question of what "biology" allowed the organism "to decide" that conditions had become "just" satisfactory and therefore cautious acceleration was appropriate. How did the organism "decide "that conditions had become very good and that an immediate acceleration of growth rate should take place to the maximum allowed either by the enriched medium or by some internal limitation? Conversely, in the absence of the added yeast extract and tryptone why were the organisms unable to exploit the resource, and in anthropomorphic terms, why were they "suspicious" of the sudden increase in the glucose concentration? Why did they not immediately grow with the 45-minute doubling time that was then possible? They certainly could synthesize all the necessary amino acids. The biosynthetic enzymes must have been present in excess, but subject to a feedback inhibition that could be rapidly relieved. Instead, these organisms only slowly adapted to exploiting fully their new environment that now had a surfeit of glucose. On the other hand, the cells had been growing for many generations in a minimal medium, in which there would be no signals to elicit the production of the many permease systems needed to take up the amino acids, peptides, and cofactors that became available after the LB broth was added. Note that the shift-up in growth rate in the LB broth was accomplished faster than a gene could be transcribed and translated. Gene regulation could not be the answer, because to become functional, additional time would be required for insertion of new transport proteins into the membrane and allowing them to gain the right conformation. So, how is it that the increased growth rate was achieved in a few seconds in the enriched medium in LB?

An anthropomorphic (teleonomic) explanation that might come to mind is that the bacteria had existed in the chemostat in an environment in which the glucose concentration had fluctuated widely depending on the cell's position at each instant of time relative to the inflow tube. In the past I argued against this because of experiments showing that the bacteria could store 18 seconds worth of glucose (and products) and this result suggested that the cells were not being starved for a part of the time under the culture conditions used (27). Still it is possible in spite of the effective stirring used that the cells have a regulatory circuit that had been turned on by the fluctuations in the very small limiting glucose concentrations in the

environment that caused the cells to be 'suspicious' of even a massive increase. (Note: that all other components were present in excess and their amounts could fluctuate only infinitesimally. For pedagogic reasons over the years, I have descriptively called this phenomenon the "New York" effect, because if you stand in Times Square and offer people five dollar bills gratis, they will not accept the bills because they know that there must be a "catch").

With still more anthropomorphic speculation, one could believe that the cells "hoped" that good times would come and therefore invested resources in uptake systems even in a glucose-only chemostat. This is similar to the idea that I have proposed to account for the maintenance of more than enough protein synthesis machinery in slowly growing cells (35). This is a supposition and belief that I have expressed in a number of publications, but it is not a fact.

The Limitations of the Chemostat

Several workers for various reasons have questioned whether the chemostat is truly a continuous culture. I have voiced these ideas (35) as has Chesbro (personal communication) and Poindexter (36). The latter has gone so far as to rename the usual chemostat culture as only being a "perpetual" culture and not being a "continuous culture." This fluctuation of the environmental concentration is not a problem with the biology of the bacteria but more with the apparatus used and the way the experimenter uses it. The problem lies in the mixing. Mixing must be adequate so that none of the organisms of the culture perceive a fluctuation in their environment. The substrate would be more uniform during actual experiments, if there were faster stirring, if more and smaller drops were used, or if a limiting substrate was chosen that had a higher K_m for uptake. It could be best tested by supplying a nonutilizable substrate with the main fluid flow and with a second inflow add a slow input of an enzyme that converts that substrate into a nutrient utilizable by the bacteria. The mechanical mixing of the original substrate and the enzyme is very easy to achieve as they are not being depleted by the bacteria and their concentrations remain essentially constant. The feeding of the bacteria in this case is equivalent to a chemostat that had many quadrillions of inflow tubes distributed all over the culture volume. I hope that such types of systems will be tried in physiology laboratories. Only then will we know how continuous the fermenters and chemostats in use, actually are.

OTHER CASES OF ORGANISMS 'CHOOSING' NOT TO GROW MAXIMALLY

Some of the categories from the list presented at the beginning of this article are discussed in this section. Those selected have been chosen because they are not adequately discussed elsewhere.

Relationship of VBNC with Oligotrophs

From the list provided in the introduction, the one case most clearly related to the VBNC phenomenon is that of oligotrophy. Although this topic is covered under Oligotrophic Bacteria, in this Encyclopedia, there are some additional concepts presented here because of their contrast with the VBNC state.

Some organisms are usually found in environments in which nutrients are chronically in low concentration or generally scarce. To use the terminology of Poindexter (40), these would be oligotrophs as distinct from copiotrophs. Oligotrophs are characterized by their inability to grow at high levels of nutrients, not solely by an exceptional ability to use low concentrations of substrates. In fact, an ability to use a substrate has a lower limit imposed not by biology but by the physics of diffusion (32–34). For example, when cultured in the chemostat and diluted into a very low glucose minimal medium, the *E. coli* took up glucose at such a fast rate that it could be calculated that if they had no outer membrane their uptake would be the theoretical maximal rate limited by physical diffusion. Therefore, no gram-negative organism of the same size could conceivably do better than *E. coli*. This is relevant here because this organism is not considered an oligotroph, but is considered a drudge; that is, that it is a single-minded workaholic copiotroph.

The essential point for the present topic is that oligotrophs, particularly when freshly isolated do not grow rapidly in a sufficient medium. In fact, they may die. Although many cases are known in which they can be slowly adapted to rapid growth, it must be assumed that in their usual state they are destroyed or inhibited by too rich a medium, if suddenly applied. On the other hand, in contrast with the VBNC state, they do grow when fed, although initially slowly.

Those organisms that are isolated as oligotrophs behave in a more extreme way than do the glucose-grown chemostat cells described earlier, on dilution into the higher, but usual culturing levels of glucose. *Escherichia coli* cells from slow chemostats change their oligotrophic behavior gradually in a period of hours, but the usual obligate oligotrophs do not change their behavior in days or weeks (although in months they may). Also, while the *E. coli*, described earlier, may respond immediately to a rich environment and grow fast, obligate oligotrophs do not grow. The word "obligate" implies that the oligotrophic state is permanent. Morita (40) and Gottschal (41) feel that there is no such thing as a truly obligate oligotroph; that is, a bacterium that is permanently in the state of an inability to cope with high substrate concentrations. On the other hand, I wish that someone would find, grow, and document the existence of an oligotroph in a state that is truly permanent. Such an organism would be a worthy subject of study because it would mirror the behavior of organisms before the division of life-forms into the three Domains. At that time cells were almost always chronically starved because anoxygenic photosynthesis and methanogenesis were rare or nonexistent and oxygenic photosynthesis and respiration based on oxygen had not as yet been invented. Therefore, because the available mechanisms to trap energy and fix carbon should not have been very common or efficient, there was nearly continuous famine of energy and of compounds of intermediate oxidation/reduction state

because organic molecules would have only been derived extraterrestrially or made very slowly abiotically.

Pheromone and Quorum Sensing Interactions

Cold-shock proteins can be produced that block DNA replication in vivo (42). Additionally, dormancy of *Micrococcus luteus* can be related to a proteinaceous factor (43) secreted by the organisms. There is now extensive literature concerning *E. coli's* response to starvation (44). Extensive work in several laboratories has demonstrated the existence of mechanisms that aid in the long-term starvation of this organism (and there would be every reason to suspect that such mechanisms would be quite general). Consequently, there may be evolutionary reasons, not appreciated now, for a mechanism involving social interaction; still it is difficult to appreciate conceivable reasons for not growing when it is presumably possible.

Classical Oligotrophs, *Caulobacter crescentus* and *Cycloclasticus oligotrophus* RB1

Caulobacter crescentus is often cited as the prime (and first mentioned) example of an extreme oligotroph. After it was brought into laboratory and repeatedly cultured, it became adapted to extensive and rapid growth on high nutrients and consequently grew to a quite high cell density at a fairly high growth rate; now it should not be called an oligotroph. It is in this form that it is studied in the molecular biology laboratory (45). Jeanne Poindexter informed me (personal communication) that *crescentus* is not a typical *Caulobacter*. Many other caulobacters are difficult to study or to grow by most bacteriologists, not to mention molecular biologists.

Another potential case for an obligate oligotroph was *C. oligotrophus* RB1 (46). This small, marine organism was isolated as a pure strain as an obligate oligotroph by an MPN (most probable number) technique. However, further study showed that it could be grown to higher titers with aromatic compounds such as carbon substrates (47). For more discussion, see OLIGOTROPHIC BACTERIA, this Encyclopedia.

Relationship with the "Shutdown" Cell Concept and a Cell with a Compact Nucleoid

Dow, Whittenbury, and Carr (3) showed tremendous insight in their studies of *Rhodomicrobium vanneilii* and other prosthecate bacteria. These organisms, like the more well-studied *C. crescentus*, undergo a differentiation process as part of every cell cycle. This means that, on division, one daughter cell becomes flagellated and has the important function of searching for a new habitat, the other persists as a sessile vegetative cell that remains localized and proceeds to grow and divide. The authors' insight was that the swarmer is metabolically a "shutdown" cell — and synthesizes only very few proteins and in a real sense is largely metabolically inert; it appears that growth is not its activity, but motility is. So it is similar to the VBNC case in many ways. For these two prosthecate organisms the major role of the shutdown organism is to move until it finds a new environment with an adequate nutrient supply. This can be correlated with the fact that the nucleus of these cells is very compact and moves faster in a velocity gradient centrifuge (45). This compaction of the chromosomal DNA is by virtue of a higher degree of coiling [Koch, in preparation], and may also be associated with more attachments of the nucleus to the envelope.

The compaction of the nucleoid in this special phase of growth is a consistent pattern and is a pattern followed by quite diverse and widely taxonomically distributed bacteria. Generally, under such a situation messenger RNA synthesis is largely stopped, subsequently the nucleoid compacts and, in so doing, expels water. For example, this happens during sporulation of *Bacillus* and other cells. This may protect the genome from certain kinds of damage, such as free radicals generated by the "indirect" irradiation of cell water. This density shift also happens in starved *E. coli* (Baldwin and Koch, in preparation). It has been observed that either the cell or the isolated nuclei have a greater density in this kind of resting stage.

For the major purposes of this review, the important facts are that the "shutdown" cell does not need the ribosomal and the enzyme content that vegetative cells must have and that its genome acquires a smaller volume, and therefore these cells with a compacted, denser nucleoid can have a reduced size and the chromosome may be only available for limited or special transcriptions.

Substrate Activated Death (SAD)

Postgate observed in the 1960s that cells that had been grown with a certain carbon source died more rapidly if incubated in a medium not supporting growth but containing that particular substrate (4). If the cells have not been accustomed to the carbon source in question then this effect did not occur. Later work by Calcott (52), who had worked earlier with Postgate, showed that SAD was correlated with cyclic AMP (cAMP) depletion inside the cell. Another peculiarity of cAMP metabolism is that internal concentrations of cAMP are in the μM range, whereas cellular effects depend on supplementing media with cAMP in the mM range. It also should be noted that cAMP is effective in regulating the phosphotransferase system (PTS) (49,51).

It is possible that lack of cAMP regulates some transport properties and leads to starvation for resources. This leads to the possibility that this internal starvation is the actual cause of three responses in the initial list: oligotophy, the "shutdown cell," and VBNC. This possibility calls for measurement of the intracellular cAMP levels in the relevant situations.

Lactose Death

When cells are grown in a lactose-limited chemostat, the selection pressure for improved uptake activity is strong. This leads to the selection of constitutive mutants of the *i* gene of the lactose operon; these strains continuously form the permease, and in a lactose-limited chemostat they take over the chemostat. Besides these constitutive regulatory mutations, other mutations that have extra copies of the constitutive *lac* operon accumulate. The result is that the cells have very high levels of galactoside permease in their

cytoplasmic membranes. When such cells are cultured in normal batch minimal medium with the usual amount of lactose (>0.1%), they die (5).

We (Burt and Koch, unpublished) studied selected *E. coli* cultures isolated from human infections that behaved similarly. Initially they were of clinical interest because these cell would be suspected of being pathogenic *Shigella*, but on further analysis it was found that they were actually Lac-negative *E. coli*. We determined that these *lac*-negative strains actually had the *lac* operon intact except for the y-gene (or permease gene). The regulatory elements of the operon were intact, including the i, o, and p genetic elements and also the transacetylase. Our conclusion was that the galactoside permease itself was the cause of death. This was consistent with the finding of Dykhuisen and Hartl (5). In the presence of too much of a galactoside, the destruction of the cell occurred whether the supplied galactoside was metabolizable or not. How the killing process occurs has never been adequately explained.

Quiescent Cells in Low-Dilution Rate Chemostats

Koch and Coffman (6) found that when *E. coli* cells were cultured at low-dilution rates in the chemostat, some cells at any time were in a state in which they were not synthesizing protein for hours at a time. A fuller discussion of this phenomenon is given in Koch (27).

In these experiments, it was shown that all cells in batch and chemostat cultures growing with doubling times of up to 13 hours had a uniform and rapid response to an inducer in the formation of β-galactosidase. On the other hand, cells in chemostat cultures growing more slowly, were heterogeneous with respect to enzyme synthesis. The obvious interpretation is that under these conditions, a particular cell may be temporarily quiescent in protein synthesis, but be accumulating reserves for later growth. At various times each cell appeared to self-activate and synthesize proteins at the normal rate until it used its reserves. The amino acid step time was found to be that characteristic of cells from a faster growing chemostat culture or from cells growing in an a large amount of glucose in medium of otherwise the same composition (6). For a 24-hour chemostat culture under our conditions, only about one-third of the cells were inactive at any time, but all cells were active over a 3-hour period. The cause of this heterogeneity could not be because of inadequacy of mixing in the chemostat culture because such mixing effects are at most for a few seconds. The plausible explanation of the different behaviors of individual cells in the culture is that at the time of assay there are variations in the internal energy resources available to individual organisms. Consequently in a slow dilution rate chemostat, the time needed for accumulation and the time needed to utilize the stockpile of amino acids once synthesis start, will determine the proportion of cells engaged in a period of protein synthesis and its duration.

The suggestion then is that chronic starvation can block synthesis of proteins and other macromolecules. However, if the low level of resource is available then slowly the resource will be accumulated to an adequate level. It is possible that an individual cell can sense this and switch its strategy and start and stop macromolecular synthesis. It may utilize the resource until depletion stops biosynthesis and forces it to return to a quiescent period.

The SOS Response

The SOS phenomenon was discovered incidentally to ultraviolet light irradiation studies of *E. coli* K12 (7). This bacterium happened to bear a prophage and UV illumination of the bacteria induced excision of the prophage, the destruction of the cell, and the production of a large burst of virus. This lysogenic virus, now called lambda, uses a protective device of the cell (the SOS system) for its own purposes. Presumably, the prokaryotes had developed the SOS system to protect themselves from UV damage to their DNA. The observation of virus induction led to the finding and dissecting of the SOS system (7). Damage that forms single-stranded regions of DNA causes the *recA* gene product to bind to these regions and subsequently act as a "co-protease" with the LexA protein. This causes the LexA protein to cleave itself. Cleaved LexA is no longer able to repress the synthesis of more than 20 bacterial, plasmid, and viral genes. One of the consequences of the induction of this system is that the lambda C1 repressor is cleaved causing the excision of the viral genome and promoting the lytic cycle of the virus. This was the original event, mentioned earlier, leading to the finding and understanding of the SOS phenomenon. One gene induced by the cleavage of LexA protein relevant for this review is *sulA*. Ordinarily the background level of the SulA protein is small because it is rapidly degraded by the protease Lon. When there is sufficient extra SulA present, because of derepression, it inhibits FtsZ, whose action is needed for the cell division process. For the present review, it can be imagined that a similar system might prevent cell division indefinitely until a reversing signal becomes developed.

This SOS system is a possible prototype for VBNC. Except for the fact that with the SOS phenomenon the inhibition of the two aspects of growth, cell division, and chromosome replication, is only several hours long (7). In the SOS and VBNC processes, a system is triggered by an environmental signal that needs a qualitatively different signal to reverse the blockade and to signal the start vegetative growth.

Osmotic Rupture

This section deals with death due to the microbiologist's action or due to lethal shift-up events that the bacteria are not able to overcome. External compounds can frequently be concentrated many thousandfold by active transport systems (35). So cells not only need to have effective active transport systems, but they also need ways to control the overactivity of the transport systems (49,50). To prevent the internal concentration of a given compound of osmolytes from becoming dangerously high, the transport mechanism must be attenuated by feedback inhibition caused by the accumulated internal pool of substance. Alternatively, some other safe way to eliminate the danger of the incoming compound is needed. Speculative hypotheses presented previously (23,23a) presume that

protective pathways exist to dispose of a surfeit of internal pools in copiotrophs and in facultative oligotrophs. Several possible ways are: by reversal of the uptake system and secretion of the excess nutrient, excreting a metabolite derived from it into the medium, or inhibiting the uptake system by something like a two-component system. The presumption is that none of these processes is successfully executed by strictly obligate oligotrophs.

Consider the problems that a cell would encounter while revising its growth strategy from one appropriate for an environment with adequate resources to a strategy designed for a chronic low level of nutrients or for an indefinite time in the essential absence of some essential nutrient. Evidently an important part of the shift in adapting the cell to a slow growth-rate state is that functional mechanisms to extrude or passively leak small compounds from the cytoplasm must now be blocked so scarce resources can be frugally conserved. Once the cell has converted to the strategy appropriate for the oligotrophic state a new problem arises. The cell now faces the problem that a surge of internal resource may cause damage due to the osmotic pressure difference across the cell envelope. Such a surge would follow introduction of a moderate level of a resource if the cell had an efficient active uptake system for it. Possibly this might occur in seconds, much faster that synthesis of controlling or enzymatic proteins can take place. This may, therefore, be the reason that some cells from natural environments may be killed by high concentrations of a substance in the medium and subsequently may not grow at all. Of course, many kinds of organisms may adapt over time, particularly if gradually exposed to this type of challenge.

This may be analogous to the phenomenon of substrate-activated death (SAD). When osmotically sensitive cells are subcultured by investigators who give them what the investigator deems to be low levels of resources, the result of transport may result in an excess of internal materials resulting in flooding of the cell's pools with a lethally high concentration of osmolytes.

Oxidative Stress

A critical point has been made (9,9a) that oxidizing radicals can come from the environment and also be made as a by-product and side reaction to the oxidation of metabolic intermediates and resources. These may destroy cells and account for the cells that cannot be resuscitated. They could also account for the response of the cell in altering their physiology so that they were less susceptible to oxidizing radicals.

Action of a Rigid and Nonenlarging Wall in Blocking Cytoplasm Accumulation

Streptococcus mutans is a gram-positive coccus that has a very thick wall. In the presence of the penicillin types of inhibitors, cell wall growth stops (10), but the cells do not lyse or die.

Contrast this with the well-known behavior of typical gram-negative rods; under these conditions "rabbit ear" structures form. These are the results of the sacculus rupturing in the middle of the rod-shaped cell where division is scheduled to occur. Such structures are the result of the old poles and sidewall remaining intact, whereas the nascent cross wall, which ordinarily forms very rapidly, does not stay intact. Most gram-positive cells will do the same. As this does not happen with *S. mutans*, it is reasonable to assume that this failure to be killed in the presence of penicillin type antibiotics is because its wall's strength is too high and does not rupture under the heightened turgor pressure. Although DNA, RNA, and protein synthesis initially continue, they soon halt. I suggest that the osmotic pressure rises so high in this case that water and perhaps potassium salts are extruded as a response to high pressure. This is on the assumption that these are the only major molecules that can escape the cell and this change in the cytoplasmic ionic environment leads to the inhibition of macromolecular synthesis; that is, the cell becomes metabolically inactive and dormant.

Thus, some aspects of oligotrophy, the "shutdown" cell, and VBNC could possibly be explained by a cellular change that eliminates or blocks the penicillin binding proteins (PBP) that are essential for wall growth. On this hypothesis, the result is the indirect blockade of some metabolic processes but later (maybe some months later) the change is reversed to allow wall enlargement.

Complete Elimination of the Function of a Factor Needed for Protein Synthesis

There are many antibiotics that function by stopping protein synthesis. Streptomycin is a well-studied antibiotic and much has been said about its mechanism of action. It is highly positively charged and, therefore, binds to phosphate residues of nucleic acids. Additionally, it binds to a protein component of the ribosome; namely, S12. These properties should make it block growth while it is present and thus it should be a bacteriostatic agent. However, interestingly, although one would expect that the cell would recover when the antibiotic is removed, this is not so. Instead, the cells die. One suggestion for this is that the antibiotic irreversibly binds to and inactivates a factor needed for elongation (Robert Harvey, personal communication). This blockade would be absolute and irreversible when all molecules of the factor needed for protein synthesis have been inactivated. Then restarting protein synthesis after the antibiotic has been removed is not possible.

This type of process may be the prototype of the way that the VBNC state cells have stopped macromolecular synthesis. Restarting could be because of some special trigger that bypasses the factor's action in a way that only needs to be temporary and need not even be highly effective.

STILL OTHER KINDS OF LETHAL PROCESSES

There are processes other than osmotic and oxidative stress that may kill. See (24) for a list and (21,22) for a description of a chromosomal gene that can kill; also see the large literature on addiction genes that enable low copy number plasmids to cause the death of their host if not transmitted to a newborn cell. These will not be further considered here.

THE DIFFERENT KINDS OF BACTERIAL DEATH

The microbiologist's functional definition of a living or a dead bacterium is whether it can produce a colony or clone under conditions that usually support indefinite growth. A lethal injury is something that damages the cell so that a colony cannot result, but within this definition, it can happen that a few, but not continued, divisions may occur. It should be noted that the usage of the term "living" in microbiology differs from the common usage where an animal or person is not thought to be dead just because it stops reproducing. But colony formation is the operational definition in microbiology; we will have to use it, but there is much more to be said.

Although a lethal event ultimately leads to death, it may be that following this event, that another event occurs or is triggered, which is the actual proximate cause of irreversible death. Thus in the SOS case, DNA may be damaged in a potentially lethal way, but the actual lethal event is the failure to repair the DNA correctly and in a timely fashion before the defect is permanently encoded in double-stranded DNA. Throughout the history of microbiology, a good deal of attention has been focused on the destruction of organisms with heat sterilization, disinfectants, antibiotics, chemotherapy, radiations, virus infections, bacteriocins, host immunity mechanisms, etc. Some of these events are the primary, but some are secondary death processes. Although many examples could be given, I will cite only the finding of Evelyn Witkin (54) on cells treated with ultraviolet light. This causes "lethal" mutations. She found that if good growth conditions are provided, more cells will fail to give colonies than if the cells are incubated temporarily under poor or nongrowing conditions. She showed that given time, repair may undo the damage under these conditions and the repaired cells will grow when nutrient conditions are provided later. As in the other cases, it is easy to see a parallel in the microbial choices of the slower, decreased, halted processes for more precise growth.

CONCLUSION

There is good reason why there ought to be a VBNC state. There is good reason to object to some experimental studies purporting its existence. There is good reason to believe that many of the cases in nature depend on special signals from other organisms, such as the role of *Acanthamoeba castellanii* with *Legionella pneumophilia* (55). There is good reason to extend the studies being highly critical and designing more critical experiments; such as Ref. (53,55–60).

Acknowledgments

VIRAL AEROSOLS

SYED A. SATTAR
University of Ottawa
Ottawa, Ontario, Canada

Viruses cause a variety of diseases in human and animals (1,2) and air can play an important role in the spread of many viral diseases. In general, such spread of viruses is rapid and difficult to prevent and control (3).

SOURCES OF VIRAL AEROSOLS

Activities such as sneezing, coughing, flushing toilets, and changing diapers, as well as shaking, homogenization, and sonication of virus-containing materials can generate infectious aerosols. Preventing the generation of, and avoiding exposure to, such aerosols are particularly important in laboratories and other settings where infectious material is handled (4,5).

When any virus-containing liquid is ejected into air, larger droplets settle out rapidly in the immediate surroundings, whereas "droplet nuclei" (usually <5.0 μm in diameter) become airborne and can be transported over long distances. Windblown carriage of animal pathogenic viruses has been documented to result in outbreaks of disease several kilometers downwind from the source (6–9).

Inhalation of air containing viral aerosols can lead to their retention in the respiratory tract, and airborne spread has been clearly documented for a variety of viral infections of humans (10,11) and animals (11). Figure 1 shows how susceptible hosts can be exposed to airborne viruses. However, infection through the inhalation and retention of droplet nuclei is generally regarded as true airborne spread. Infectious viruses (11) or their nucleic acids (12) have been detected in field samples of air. Air may also play a role in the spread of viral infections of the gut (13) through the capture of airborne viruses in the upper respiratory tract and their subsequent ingestion (14).

STUDY OF VIRAL AEROSOLS

Study of airborne viruses requires stringent safety precautions (15) and equipment (16) that may not be readily available commercially. Suspensions with relatively high titers ($>10^7$ units/mL) of viable viral particles are also essential for such studies because virus infectivity can be reduced during generation and collection of aerosols and by dilution of the aerosolized material in air. Basically, one needs the following equipment and procedures for the study of viral aerosols. Please refer to other published studies for further details in this regard (11,17–23).

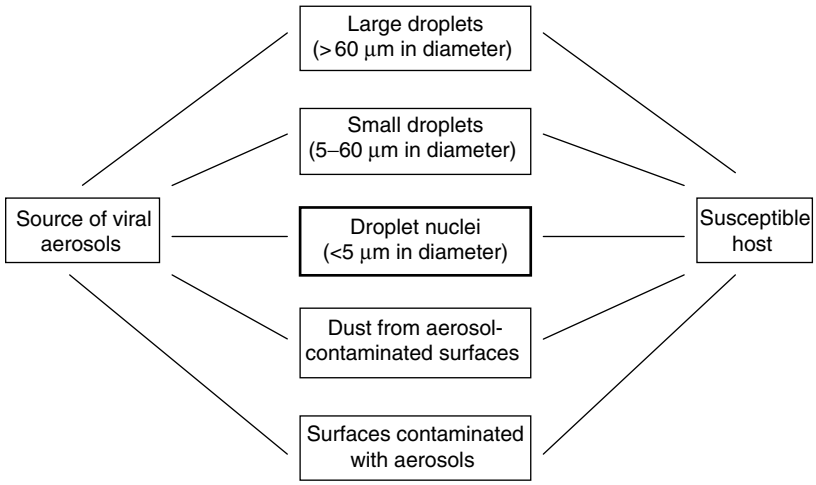

Figure 1. Direct or indirect exposure of susceptible hosts to viral aerosols (12).

Aerosol Generation

The study of viral aerosols requires the generation of particles that are small enough (<5 μm in diameter) to remain suspended in air. Several nebulizers are commercially available for this purpose (11,17,23,24). Nebulizers for the aerosol delivery of therapeutic drugs also produce particles in the respirable range (25) and can be adapted for generating viral aerosols. The size distribution of the aerosolized particles and the stability of the virus in them will depend to a large extent on the nature and composition of the medium used for suspending the virus to be aerosolized (11).

A change in the level of infectivity of the aerosolized virus is usually caused by a combination of: (*1*) virus inactivation during the process of nebulization, (*2*) dilution of the aerosolized particles in air, (*3*) settling out of a proportion of the aerosolized particles (physical decay), and (*4*) the actual loss in virus infectivity in air (biological decay). An accurate determination of the rate of biological decay makes it necessary to incorporate a "physical tracer" in the virus suspension to be sprayed. To be useful, such a tracer must be safe for the virus while being resistant to breakdown during aerosolization and the aging of aerosols. The best tracer is a radioisotope incorporated into the virus particles because such virus particles can act as their own tracers. Another but perhaps a less satisfactory way is to simply add a radioisotope to the virus suspension to be aerosolized.

Uranine, a fluorescent dye, added to the virus suspension, has been found to be as effective as a radiolabeled virus (26); the dye is harmless to viruses and cell cultures and is also much less expensive and safer to use than radioisotopes. One possible drawback of the use of such dyes may be their potential to enhance the photosensitivity of viruses (17). Bacterial spores, which can readily withstand nebulization and are relatively resistant to biological decay, can also be used as tracers (17,23).

Virus suspensions to be aerosolized often contain proteins that tend to froth during the process of nebulization, and an addition of a suitable antifoam agent to such suspensions is necessary to address this problem (26).

Retention and Aging of Aerosols

To investigate the influence of various environmental factors on the stability of aerosolized viruses, a custom-built rotating stainless steel drum (23,27,28) is generally used to store the aerosols in a dynamic state (Fig. 2). The drum, which is usually housed in a sealed chamber, is continuously rotated mechanically along its axis at a predetermined rate (e.g., 4 rpm) to keep the aerosolized material from settling out. The air inside the drum can be preconditioned to the desired relative humidity (RH) level and temperature. Thorough air flushing of the drum is required between experiments.

Ultrafine (<1 μm in diameter) natural (spiderweb) and artificial (tungsten) threads can be used as supports for small virus-containing particles. Such anchored particles are still subject to the influence of various environmental factors around them (17,23,28). Despite the limitations (23), ultrafine threads are the best means to study the influence of atmospheric chemicals (24) and light and irradiation (29,30) on airborne viruses. Ethylene vinyl

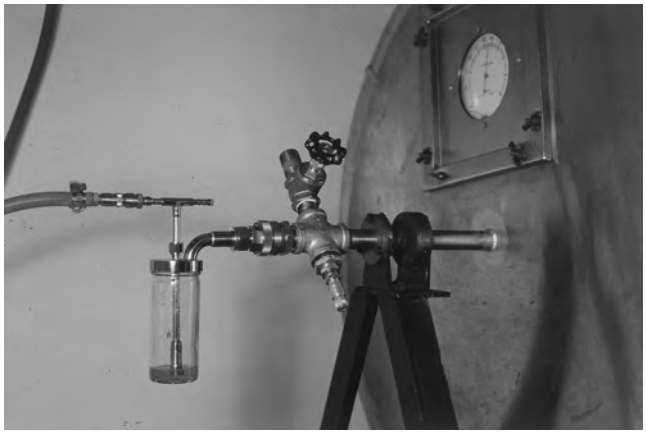

Figure 2. Stainless steel drum for the aging of aerosols. A Collison nebulizer is ready to spray a viral suspension into a 300-L stainless steel drum on the right.

acetate fibers (2–3 μm in diameter) have been found to be as suitable as spider threads to study the airborne survival of bacteria (31), but their suitability for working with viral aerosols remains to be investigated.

Collection and Sizing of Aerosols

Most commercially available aerosol collectors (15,19–21,32) have been designed primarily for working with bacteria and fungi and are not suitable for dealing with airborne viruses. All-glass impingers (AGIs) are often the devices of choice for collecting viral aerosols (11,23) in relatively small volumes (2–3 liters L/minutes) of air. The air to be sampled is drawn into the impinger, where it passes through a tube with a limiting orifice and impacts on the surface of the collecting fluid containing an antifoaming agent (26). Use of preimpingers with AGI sampling improves the collection of airborne viruses (11). The volume of air sampled must be replaced with fresh air to avoid creating a vacuum in the aerosol-holding device such as a rotating drum.

In the field, commercial large volume air samplers (LVAS), which can easily process 10 m^3 of air per minute, can be used to recover airborne viruses (11,17,23,33). The collection efficiencies of various LVAS vary considerably depending on the type of virus, the type and volume of air sampled, the nature of the collection fluid, and the rate of sampling. The use of acidic buffer-moistened cartridge filters to recover polioviruses aerosolized during the flushing of toilets has been reported (34).

The Andersen six-stage sieve sampler (35) can be used to determine the size distribution of viral aerosols by replacing the agar-based medium in the sampler's petri plates with tryptose phosphate broth containing 3% gelatin (26). After sampling, the collection medium can be liquefied by holding the plates at 37 °C for 1 hour and poured out for virus titration and measurements of the physical tracer levels.

Experimental Exposure to Viral Aerosols

To determine the susceptibility of humans or animals to airborne viruses or to assess the minimal infective dose of viruses by the respiratory route, experimental subjects are exposed to standardized clouds of viral aerosols under controlled conditions. The Henderson apparatus (36) is used for the aerosol exposure of small animals such as mice where individual animals are placed in cylindrical holders, with only their nostrils protruding, and exposed to airborne viruses.

Devices for working with larger animals such as cattle (37) or pigs (38) also have been described. In the design and performance of any such aerosol challenge studies it is extremely important to avoid the exposure of the experimental animal to the test virus by means other than inhalation. Chung and coworkers (39) have reported the development of a low-cost wind tunnel for exposing human subjects to aerosols of more than 2 μm in diameter. Particles generated by a Collison-type nebulizer and introduced into the tunnel by using an aerosol injector are uniformly distributed to expose human subjects; the device is yet to be tested with viral aerosols.

AIRBORNE SURVIVAL OF HUMAN AND ANIMAL PATHOGENIC VIRUSES

How long a given virus can remain infectious in air depends on the nature of the virus and the medium in which it was suspended before becoming airborne, ambient temperature, RH, atmospheric gases, lighting, and irradiation (11). The absence of standardization of the experimental protocols and wide variations in the system of reporting the results make direct comparisons of the findings from different studies extremely difficult. Table 1 is a summary of published information on the airborne survival of selected human and animal pathogenic viruses (11,40).

CHALLENGE WITH VIRAL AEROSOLS

Several studies have challenged human or animal hosts with artificially generated viral aerosols (11). Because of the difficulties inherent in the design and performance of such experiments, their findings should be interpreted with the following limitations in mind: (*1*) often the amount of challenge virus inhaled was either not determined or may have been too high to be relevant to levels encountered in nature, (*2*) exposure of test subjects by means other than through inhalation could not be excluded because of flaws in the experimental design, (*3*) many reports failed to specify important parameters such as RH and air temperature in such experiments, and (*4*) in the absence of standard procedures for aerosol challenge studies, it is virtually impossible to compare the findings of different investigations.

The limitations enumerated earlier point to the need for much developmental work before accurate and reliable information on the behavior of viral aerosols could be generated.

COLLECTION OF NATURALLY OCCURRING VIRAL AEROSOLS

When compared to studies with experimentally aerosolized viruses, collecting infectious viruses from naturally occurring aerosols is even more challenging. The devices currently available for the purpose are generally noisy, bulky, expensive, and somewhat inefficient. As is true for many other types of environmental sampling, it is often too late to look for the suspected virus in air in an outbreak investigation. Even if it were feasible, regular monitoring of air for viruses is not recommended because of the limited significance of the findings. However, there are certain situations where sampling of air for naturally occurring viral aerosols can be extremely valuable. This is exemplified by the studies of bat caves for airborne rabies virus (65).

Air is probably the main vehicle for the spread of viral infections such as measles and influenza. Viruses, which normally spread through other means and vehicles, have been found to spread through air in rare instances. The airborne spread of rabies is a case in point (33). But it must be noted that any virus, which can survive aerosolization, has the potential for airborne transmission.

Table 1. Summary of Published Information on the Ability of Selected Human and Animal Viruses to Survive in and Spread Through Air

Virus	Cause Of	Comments
Foot-and-mouth disease virus	Foot-and-mouth disease in animals	The virus has been studied extensively for its capacity to spread through air (11), and several airborne outbreaks of the disease documented (8). Sheep breathing air from cabinets housing virus-infected pigs contracted the disease (41).
Hantaviruses	Respiratory and kidney infection	Infections in those handling these viruses or animals carrying them now well documented (2,42–44); the most likely means of exposure was by inhalation of infectious aerosols. Artificially generated aerosols of Hantaviruses can infect rats (45).
Influenzaviruses	Influenza	The behavior of aerosolized influenzaviruses has been studied in some detail (11). Recent studies in this regard have focused on challenging vaccinated animals with viral aerosols to study the protective effect of immunization.
Lassavirus	Hemorrhagic fever	Survival of Lassa fever virus in artificially generated aerosols was favored at low (30%) RH levels, and even at 32 °C the virus survived long enough to permit its dispersal by air (46). Experimental aerosol exposure of monkeys and guinea pigs could infect and kill them.
Newcastle disease virus	Newcastle disease in poultry	Convincing evidence for the airborne spread of the virus and air filters in poultry houses highly effective in preventing outbreaks of the disease (47). A vaccine strain of virus used as a model to study the airborne behavior of enveloped viruses (29,48) and to field test protective equipment and methodologies for the rapid collection and identification of viruses in air.
Norwalk virus	Acute diarrhea	Airborne spread strongly suggested from patterns of spread in outbreaks (14,49–52). Contamination of air may occur by aerosolization of virus during vomiting (53,54). Aerobiology cannot be studied because no animal models or cell culture systems available thus far.
Papilloma viruses	Warts and cancer	Reports of warts in the respiratory tract of laser therapists (55) suggest exposure to the viruses in the smoke from vaporized warts (56). A PCR-based study (57) showed widespread contamination of the facial area of the therapists and the operating room environment with viral DNA released during laser treatment and electrocoagulation of human warts and neoplasia.
Pseudorabies virus	Infection of nervous and respiratory systems in animals	Even though this enveloped virus is relatively fragile, its capacity to spread through air parallels that of foot-and-mouth disease virus (8), a picornavirus. The virus in air survived the best when RH was 55% and the air temperature was 4 °C (58); the half-life of the virus under these optimum conditions was less than one hour.
Retroviruses	Cancer and AIDS	Little is known about their airborne spread nor is there any evidence that they can spread by air. However, infectious HIV-1 detected in aerosols from certain types of surgical power tools (59), and the blood-containing aerosols were in the respirable range (60). Potential for airborne spread of HIV-1 and other retroviruses exists where high-titered suspensions of such viruses are handled.
Rhinoviruses	Common cold	The half-life of a human rhinovirus was nearly 14 hours at 20 °C with an RH level of 80%, clearly indicating its potential to survive and spread through air (61).
Rotaviruses	Acute diarrhea	Airborne spread strongly suggested from patterns of spread (62–64). Survival in air favored by lower levels of RH (26).
Varicella-Zoster Virus	Chickenpox and shingles	Spreads by air. Its DNA found in air samples from rooms housing patients with chickenpox or shingles (12) showing that PCR technology may prove useful in studying the airborne spread of viruses.

CONCLUSION

Despite decades of studies, our knowledge of the aerobiology of viruses remains somewhat rudimentary. This is while the potential for the airborne spread of many human and animal pathogenic viruses continues to increase because of the increasing use of recycled air (66,67), presence of ever-larger numbers of immunosuppressed and transplant patients, and changing lifestyles (68). We also need safer and more economical methods for removal and/or inactivation of infectious viruses from recycled air.

Airborne dissemination of nonviable viruses or their components can lead to problems in laboratories using PCR or other such techniques, and presently available containment facilities may not be quite adequate to address this issue (69). Aerosol generation by surgical tools (11,59,67,70,71) and laboratory equipment (72) suggests that the potential of any such technology should be assessed at the design stage and corrective measures taken. Effective means are needed for protecting animals and humans in case of deliberate or accidental release of viral aerosols (23).

Rapid inactivation (30) and higher levels of dilution of vertebrate viruses in open air suggest that they may be less likely to spread outdoors. However, the airborne survival and transport of such viruses over long distances has been documented (73,74), thus showing their potential to cause outbreaks at distant locations (6–8). Perhaps long-distance transport of viruses may explain the peculiar transcontinental movement of outbreaks of rotaviral infections (75).

Airborne viruses continue to be a threat to human and animal health in spite of the sophisticated design and efficient protective functioning of the respiratory system (60). Much of the research thus far has documented outbreaks of airborne viral infections and identified to some degree the factors that influence virus survival in air. Currently greater emphasis is needed on reducing generation of infectious aerosols in indoor and outdoor settings and on enhancing the removal and/or inactivation of viruses (20) and other infectious agents in air. Many human and animal pathogenic viruses continue to be considered as potentially useful bioweapons and recent accounts (76) of their production and stockpiling testify to this. The details of past and possibly ongoing work in this regard may never become available to the general scientific community.

VIRAL DISINFECTION

JEANETTE THURSTON-ENRIQUEZ
USDA—Agricultural Research Service
Lincoln, Nebraska

Disinfectants do not necessarily kill all microorganisms, but are intended to reduce the number of disease-causing microorganisms to a safe level. Disinfectants used for the inactivation of viruses are termed viricides. To limit the transmission of pathogenic viruses at home, in childcare and health care facilities, in water and wastewater, and on living surfaces, physical or chemical viricides are applied. Human pathogenic viruses may be present in an infectious state in water supplies, body fluids, food products; or on inanimate objects (fomites) such as tables, countertops, children's toys, etc. Thus, viricide practices include the disinfection of the home, office, water and wastewater treatment plants, childcare centers, health care facilities, and industry. The action of viricides includes destruction or blocking of viral capsid proteins important for host cell attachment and/or destruction, or fatal mutation of viral nucleic acid. Chemical disinfectants include chlorine and its related compounds, alcohols, detergents, and phenolics. Physical disinfectants include heat, ultraviolet light, and radiation. Important chemical and physical disinfectants, disinfection kinetics, mechanisms of viral inactivation and factors important in disinfectant effectiveness are discussed in the following sections.

APPLICATIONS FOR THE INACTIVATION OF VIRUSES

One of the most important uses of disinfectants is for the inactivation of pathogenic viruses in drinking water. Drinking water disinfection has been practiced in the United States since the early 1900s to circumvent the outbreak of waterborne disease (1). Examples of chemical and physical disinfectants employed in water treatment

Table 1. Disinfectants Applied for Water Treatment Purposes

Chlorine
Chloramines
Ozone
Chlorine dioxide
Potassium permanganate
Ultraviolet light

are listed in Table 1. In drinking water treatment, disinfection is the final barrier between viral pathogens and drinking water consumers as viruses, because of their small size, can bypass filtration processes. In addition to drinking water, appropriate disinfection of wastewater is also critical because receiving waters may be used for drinking, recreation, shellfish harvesting, and irrigating food crops that require minimal processing before consumption.

Viricides are widely used in health-related fields for the inactivation of viruses on tables, benchtops, floors, medical instruments, and bodily fluids to prevent transmission to susceptible individuals. An excellent example of the important use of viricides is the disinfection of blood and blood products. To secure clean blood supply, pathogenic viruses such as human immunodeficiency virus (HIV), hepatitis B and C and other bloodborne viruses must be inactivated using physical or chemical disinfectants. Moist heat disinfection, specifically autoclaving, is one of the most popular methods in the health-related industry for the sterilization of biohazardous materials and medical instruments. Even in the home, disinfectants are used to reduce the number of microorganisms on the countertops and floors of kitchens and bathrooms, on laundry and dishes. Commercial products often contain chlorine, ammonia, and detergents for the reduction of microbes in domestic settings. Also, detergents are used for the removal and inactivation of viruses from the hands or other parts of the body. Classes of commonly used disinfectants, their modes of action and associated applications are listed in Table 2.

VIRUS STRUCTURE AND REPLICATION

Viruses have a much simpler makeup compared to bacterial and animal cells because they lack ribosomes, cannot multiply independently, do not respire or undergo any energy generating processes, their genome may be composed of either deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) and may be single- or double-stranded, and the nucleic acid itself may be infectious. Moreover, viruses are much smaller in size, ranging from 0.02 μm to 0.3 μm.

The structure of the viral particle consists of an outer protein shell, called a capsid. The capsid is composed of protein subunits, termed capsomeres that are arranged in two main types of symmetry: cubical (icosahedral) and helical. The capsid and the nucleic acid constitute the nucleocapsid. For lipid viruses, the capsid is surrounded by a lipid membrane, which is acquired from the host cell on release. The capsid may also surround a protein core that encloses the viral nucleic acid. The viral genome consists of either DNA or RNA, and may be double- or single-stranded. Viruses cannot replicate independently; instead they must infect a host cell and utilize the host cell's metabolic machinery for their replication. For animal viruses, the key steps for their replication include (*1*) attachment to the host cell by specific viral proteins; (*2*) penetration of the host cell by either endocytosis or fusion; (*3*) uncoating of the viral particle; (*4*) replication of viral nucleic acid; (*5*) synthesis of viral proteins important in replication of the nucleic acid and/or capsid proteins;

Table 2. Classes of Some Commonly Used Disinfectants, Their Modes of Action, and Associated Applications

Viricide	Mode of Action	Disinfectant Applications
Physical Disinfectants		
Moist heat (autoclaving, steam, and boiling)	Denaturation of proteins and nucleic acid	Health field: Sterilization of health-related supplies/equipment
Radiation Ionizing (gamma)	Nucleic acid destruction	Sterilization of pharmaceuticals and health supplies/equipment
Nonionizing (UV)	Pyrimidine dimer formation	Same as mentioned earlier and wastewater treatment
Chemical Disinfectants		
Chlorine and related compounds (chlorine, chlorine dioxide, and ozone)	Oxidation of protein and nucleic acid	Water, wastewater, industrial, and household disinfection applications
Metal ions (copper and silver)	Many mechanisms: damage to proteins and nucleic acid	Pools, spas, hot tubs, and home-faucet purification units
Photoantimicrobials (Titanium dioxide and phenothiazines: methylene blue, toluidine blue, azure B, and others)	Damage to nucleic acids	Wastewater, blood, and blood products

(*6*) assembly of the viral particle; and (*7*) release of the mature viral particle from the host cell via budding or lysis.

VIRAL INACTIVATION BY DISINFECTANTS

Because of the simple structure of viruses, the ways in which disinfectants inactivate viral particles are limited (Table 3). Disinfectant action may include the destruction, blocking, or altering of capsid host cell receptors so that host cell attachment cannot occur. Chemical viricides, which are strong oxidizers, for example, ozone, can destroy capsid proteins rendering the virus noninfectious. Also, changes in pH can produce conformational changes in viral proteins that may either aid in disinfectant action by exposing proteins involved in host cell attachment or internalize them leaving them unavailable for disinfectant interaction (2). Adsorption of molecules onto viral capsid proteins may effectively block attachment to receptors on a host cell. Immobilization of a viral particle onto a surface is another example of disinfectant action. In the case of aluminum, viruses adsorb onto it's surface and when released, are rendered noninfectious (3). Destruction or fatal mutations in the viral genome are other ways by which viricides may inactivate viral particles. To react with the viral nucleic acid, the disinfectant must be able to diffuse through the capsid, destroy the capsid ejecting the nucleic acid or prior dissociation of the nucleic acid must have occurred. For RNA viruses, destruction of their nucleic acid is critical because previous studies have demonstrated the ability of susceptible cells to uptake viral RNA and produce infectious viral particles (4).

Table 3. Possible Mechanisms of Viral Inactivation by Viricides

Viral capsid	Blocking of viral host cell receptors
	Destruction of capsid proteins
	Conformational change of viral host cell receptors
Viral nucleic acid	Fatal mutations
	Complete destruction

Table 4. Factors Affecting Viral Disinfection

Factors	Effects/Concerns
Temperature	Higher temperature = increased inactivation rate
	Lower temperature = decreased inactivation rate
pH	Affects ionic species of disinfectant
	Affects conformational form of virus (capsid proteins)
	May induce clumping or aggregation
Organics	Consumes oxidizing chemical disinfectants (chlorine and related compounds)
	Particulate organics: shields from disinfectant action
Salts	Increase capsid stability, thus increasing viral resistance (heat inactivation)
	Increase viral inactivation rate (chlorine)
Aggregation	Protects inner particles from disinfectant action
Different viral types	Varying susceptibilities among closely related viral types to same disinfectant
	Use of surrogates or indicators may not be useful to describe closely related viruses
Laboratory vs. naturally occurring viruses	Laboratory strains may not represent the resistance of naturally occurring viruses to disinfectants

FACTORS AFFECTING PHYSICAL AND CHEMICAL DISINFECTION

The effectiveness of a disinfectant to inactivate a viral particle is dependent on many physical and chemical characteristics of the virus, disinfectant and the medium in which the virus and disinfectant are in contact (Table 4). Temperature influences the rate of viral inactivation, at which higher temperatures tend to have higher inactivation rates. Temperature may also affect the stability of some viruses. The pH of the disinfecting medium may affect the ionic species of chemical disinfectants such as chlorine and chlorine dioxide. In addition, changes in pH above or below the isoelectric point (IEP) of a virus, may alter the conformation of disinfectant target sites on the capsid, reducing or diminishing interaction with the disinfectant (5). The IEP is the pH at which the viral particle has no charge. Viral particles are either negatively or positively charged, depending on whether the pH of the suspending medium is above or below the IEP of the virus. Concentrations of salt have been reported to significantly increase the viral inactivation rate by disinfectants such as chlorine (6). However, a decrease in thermal inactivation rate has been observed in the presence of salt, which may increase capsid stability (6,7).

Clumping or aggregation of viral particles protects the inner particles from the action of disinfectants. The enteric viruses are shed clumped and associated with cell debris in the feces of infected individuals (8). Several studies have demonstrated the increased resistance of enteric viruses, which are aggregated or debris-associated compared to dispersed viral particles (9–11). Viral aggregation may be caused by changes in virion hydrophobicity; where pH changes induce virion hydrophobicity or by the presence of salts (5,12).

Dissolved organic matter and particulates are other important constituents that may lower viricide effectiveness. Dissolved organic matter reacts with disinfectant, either oxidation or adsorption, reducing the concentration available to react with the microorganisms. For most disinfectants, particulate matter (organic or inorganic) may consume the disinfectant and protect or shield any embedded or adsorbed microorganisms. Particulate matter may also scatter light (ultraviolet light or sunlight), decreasing its intensity. However, UV research conducted with

inorganic particulates varies, because some studies conducted with viruses associated with inorganic particles were inactivated similarly to unassociated viruses (10).

Individual virus properties may affect the efficiency of disinfection. In general, the resistance of viral groups is in the following order from least to most resistant: lipid viruses < large nonlipid viruses < small nonlipid viruses (13). Viruses have been shown to have varying susceptibilities to disinfectants even within one population or between different viral types (5,14,15). Use of surrogates or indicators that are supposed to represent similar viruses may not be adequate, due to the differences in resistance between closely related viral types. The viral particle's state of hydration has also been shown to affect disinfection kinetics, in which hydrated viral particles are less resistant than nonhydrated particles (5). Further, laboratory viral strains have been shown to be less resistant to chlorine compared to chlorinated drinking water isolates (9,16). However, for some viral types, greater resistance of the chlorinated drinking water isolates was not observed (9). Finally, like all microorganisms, viruses are more sensitive to some disinfectants compared to others; for example, viruses are more susceptible to inactivation by ozone than chlorine.

Multiplicity Reactivation

If a disinfectant produces random damage to a viral particle, many of these particles, under the appropriate conditions, may aggregate or clump. Infectious viral particles may be produced if there is at least one functional copy of each damaged unit (protein or nucleic acid), and these viral components are able to enter a susceptible host cell. In 1942, Luria first postulated this phenomenon, termed multiplicity reactivation (5). Sharp (1982) demonstrated an increase in titer following chlorine disinfection of clumped versus dispersed echovirus. Differences in titer between these two treatments ranged by a factor of 10-3,000. Because of multiplicity reactivation, a disinfectant must effectively destroy the viral capsid proteins important in attachment to the host cell, fragment the nucleic acid, and not produce conditions conducive to clumping or aggregation of these viral components (5).

Disinfection Kinetics

Viral inactivation by chemical and physical disinfectants proceeds at specific reaction rates, are controlled by kinetics and affected by a number of factors including disinfectant concentrations, temperature, pH, and the presence of interfering substances (17). Developed on the basis of experimental data, kinetic models have been used in the formulation of disinfection design criteria for water treatment (18). Specifically, these models attempt to predict the complex interactions of different microorganisms, from bacteria to viruses, with different disinfectants, which have different cellular targets and modes of action (18). Consequently, because of these complex interactions, predicting microbial inactivation is difficult.

There are many kinetic models that have been used to predict the interaction of disinfectant with microorganisms, but probably the best known is the Chick-Watson model. This model combines Chick's rate law and the Watson function. According to Chick's rate law, the number of microorganisms destroyed per unit time is proportional to the number remaining for a given disinfectant concentration. Thus, Chick's law assumes that the reaction between a chemical disinfectant and a microorganism follow first-order kinetics. In this law, however, the effect of varying disinfectant concentrations is not taken into consideration, so Watson derived an empirical logarithmic function called the Watson function. The incorporation of Watson's function into Chick's rate law produces the Chick-Watson pseudo first-order rate law (18) (Table 5). More often however, first-order kinetics are not observed for microbial inactivation by disinfectants, instead various types of inactivation kinetics are observed as demonstrated in Figure 1. Curve 1 illustrates first-order or exponential inactivation kinetics, which usually describes microbial UV light inactivation. Curve 2 represents a shoulder curve which may be caused by one or more of the following, ineffective dispersion of the microorganisms or disinfectants, delays in disinfectant diffusion to critical sites on the microorganism, and

Table 5. Examples of Kinetic Models Used for Prediction of Microbial Inactivation by Water Disinfectants

Model Name	Kinetic Equation[1] $\mathrm{Ln}\,(N_t/N_0) =$
Chick's Law	$-k\mathrm{t}$
Watson's Function	$\mathrm{C}^n\mathrm{t}$
Chick-Watson	
Disinfectant demand-free conditions	$-k\mathrm{C}^n\mathrm{t}$
Disinfectant demand conditions	$-k/\mathrm{k}' = n(\mathrm{C}_0{}^n\text{-}\mathrm{C}_f{}^n)$
Efficiency Factor Hom	
Disinfectant demand	$-k\ \mathrm{C}_0{}^n\mathrm{t}^m[(1\text{-}\exp(\text{-}n\mathrm{k} = \mathrm{t}/m)/(n\mathrm{k} = \mathrm{t}/m)]^{\mathrm{m}}$

Source: Adapted from L. L. Gyurek and G. R. Finch, J. Environ. Eng. 124, 783–793 (1998).
[1]Refer to Table 6 for term definitions.

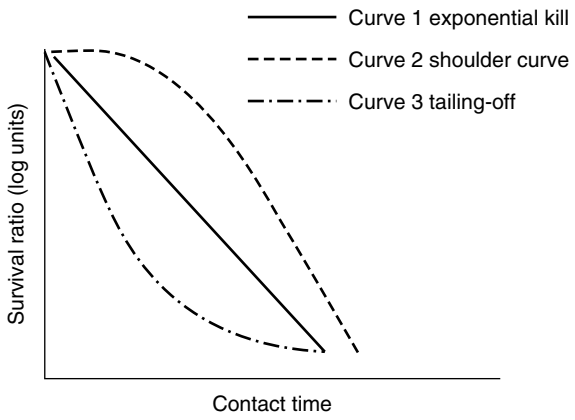

Figure 1. Typical microbial survival curves.

disinfectant interaction of multiple targets necessary for microbial inactivation (18,19). Curve 3 displays the effects of clumping or aggregation, presence of different microbial populations having varying disinfectant resistance or increased disinfectant decay (5,18,19). While the Chick-Watson can only accurately predict inactivation kinetics represented by Curve 1, other kinetic inactivation models have been mathematically proposed to describe curves that deviate from first-order kinetics. Examples include the Hom, Hom-Power, Efficiency Factor Hom, and the Selleck models. Definitions for all kinetic model constants are presented in Table 6. These models have been shown to provide a statistically improved fit to the bench-scale inactivation process over the Chick-Watson model (18).

The *Ct* concept was derived from the Watson's function, where C represents the concentration of the disinfectant and t is the time required to inactivate a predetermined percentage, usually 99%, of the population at specific pH and temperature conditions (20). The higher the *Ct* value, the more resistant the microorganism is to inactivation by the disinfectant, whereas a lower value would indicate decreased resistance. By comparing these values, evaluation of the effectiveness of pathogen inactivation by various chemical disinfectants can be determined. In addition, differences between different groups of microorganisms and variability within groups may be ascertained. The Ct method is used by the water treatment industry to help predict the amount of disinfectant needed to inactivate pathogenic microorganisms occurring in the water supply (18). For chlorine and it's related compounds, the Ct is measured in milligrams per liter multiplied by the time in minutes (mg/L * minutes). For UV light, the UV dose is measured in milliwatts multiplied by seconds per centimeter squared (mWs/cm^2).

Table 6. Kinetic Model Parameters and Definitions

Parameter	Definition	Comments
k	Disinfectant decay constant	Units usually 1/minutes first-order decay assumed rate assumed to be independent of the microorganisms present
T	Time required to achieve a given level of inactivation	Units usually in minutes
N	Coefficient of dilution	Represents the average number of molecules to have combined with the microorganism necessary to cause inactivation
k, m	Microbial inactivation constant	Specific for the microorganism and set of conditions
C, C_0, C_f	Concentration of disinfectant, at time zero and final time of inactivation experiment	Units depend on disinfectant

Physical Disinfectants

Thermal Inactivation. Inactivation of pathogens by heat is one of the most widely used disinfection or sterilization procedures in the medical (autoclave sterilization) industries. Moist and dry heat methods are described in Table 7. To describe the inactivation of viruses or other microorganisms by heat, three concepts have been devised. The thermal death point (TDP) is used to define the lowest temperature in which all microorganisms are killed/inactivated in 10 minutes. Secondly, the thermal death time (TDT) is defined as the minimum amount of time in which all microorganisms are inactivated at a specific temperature. The DRT, (D value) or decimal reduction time is the time in which 90% of the studied microorganisms are killed at a given temperature. Any of these concepts may be used to determine and compare the heat resistance of one microorganism to another.

The type of heat sterilization, moist or dry heat, and the conditions (moisture content, organic matter, and solute concentration) of the medium to be sterilized may affect the efficacy of viral heat inactivation. For example, with increasing moisture, the effectiveness of heat to inactivate microorganisms also increases. Dry viral preparations require higher temperatures and longer times than viral suspensions. Many microorganisms are quickly killed by moist heat because hydrogen bonds, important for protein structure, are quickly broken. This is especially true for moist heat methods such as autoclaving. Boiling, another moist heat method, may not be as effective as autoclaving for the inactivation of all viruses. Dry heat inactivates microorganisms through oxidation and is typically not as effective as moist heat (longer time and higher temperatures required). Enteric viruses have been shown to increase resistance to heat inactivation in the presence of cationic salts. This increased resistance may be caused by stabilization of the viral capsid. Other substances that may increase viral resistance to heat may include the presence of sugars which decrease water activity. Finally, the presence of organic matter or particulates may also increase resistance to heat inactivation (21).

Ionizing Radiation. Gamma rays and high-energy electron beams are an effective form of radiation because the ionization of water and other substances effectively cause mutagenic effects. In fact, gamma irradiation is one of

Table 7. Moist and Dry Heat Methods

Moist Heat	
Boiling	100 °C, 10 minutes
Autoclaving	121 °C, 15 pounds of pressure per square inch, 15 minutes
Dry Heat	
Incineration	Burning to ashes
Hot air sterilization	170 °C, 2 hours

the most frequently used methods for the sterilization of large batches of small volume items used in the medical field, such as needles and catheters. Free radicals, especially the hydroxyl radical, produced through the ionization of water, interact with viral proteins and nucleic acid. Because damage to the nucleic acid may cause incorrect transcription of pertinent genes, ionization can be lethal. This is especially true for disinfection with high doses of radiation in which multiple hits may occur. The absence of oxygen and water and the presence of organic matter all contribute to increased resistance to ionizing radiation. Viruses are the most resistant to ionizing radiation compared to other microorganisms possibly because of their small size (21). Determination of the effectiveness of gamma irradiation to inactivate different viruses is by comparison of their D values. The D value is the dose of radiation needed for 90% inactivation. The D values for selected viruses in different media are listed in Table 8.

More widely used than ionizing radiation, ultraviolet (UV) radiation or ultraviolet light exposes substances to a germicidal wavelength of 254 nm. This wavelength is very close to the absorption maxima of nucleotide bases where the pyrimidines, thymine (T), cytosine (C) and uracil (U), undergo photodecomposition at a much higher rate than the purines (adenine and guanine). The most important class of photoproducts formed by photodecomposition are the 5, 6-cyclobutyl dipyrimidines, more commonly referred to as pyrimidine dimers (25). Three types of dimers may be formed that include T-T, C-C and T-C. Of these, T-T dimers are produced more often because their formation has a greater quantum yield than either C-T or C-C dimers (25). It is the formation of these dimers that inactivates microorganisms by blocking replication of the nucleic acid (26). Protein damage due to UV absorption at the germicidal wavelength is much lower than nucleic acids; therefore it is not as important in microbial inactivation compared to the formation of pyrimidine dimers (25).

First-order kinetics involving UV inactivation of microorganisms, including viruses, has been reported in the majority of studies. In addition, double-stranded (ds) DNA viruses have been shown to be more resistant than single-stranded (ss) RNA viruses, and varied resistance among closely related viruses has been reported (15,21,27). Turbidity of suspending medium, aggregation, or clumping and UV intensity can affect the effectiveness of UV disinfection. Table 9 demonstrates the differences in resistance between closely related viruses.

Table 8. Gamma Irradiation of Selected Viruses Suspended in Sludge, Ice, and on Lettuce and Strawberries

Virus (medium virus was irradiated in/on)	D Value	Reference
Bovine herpesvirus-1		
(frozen with cell debris)	4.72 (kGy)	22
(frozen without cell debris)	7.31 (kGy)	
Hepatitis A virus		
(surface of strawberries)	2.72 (kGy)	23
(surface of lettuce)	2.97 (kGy)	
Poliovirus		
(sludge)	350 (krad)	24
Adenovirus		
(sludge)	150 (krad)	24

Table 9. UV Light Inactivation of Selected Enteric Viruses

Virus	Dosage mWs/cm^2	Reduction (%)	Reference
Poliovirus 1	5.0	90	28
	7.7	90	29
Coxsackievirus B1	15.6	90	30

Adenovirus 41	23.6	90	33

Chemical Disinfectants

Chlorination and Chlorine-Related Compounds. For more than 100 years, chlorine has been used as a disinfectant for the reduction of disease-causing microorganisms in water (1). In fact, chlorine and related compounds are applied for the treatment of water more frequently than any other water disinfectant (34). In water treatment, chlorine gas is added to water resulting in two reactions, hydrolysis

$$Cl_2 + H_2O \leftrightarrow HOCl + H^+ + Cl^- \quad (1)$$

$$HOCl \leftrightarrow H^+ + OCl^- \quad (2)$$

(Eq. 1) and ionization (Eq. 2), in which HOCl is hypochlorous acid and OCl^- is the hypochlorite ion. Free available chlorine refers to the amount of unbound HOCl and OCl^- present in water, whereas total available chlorine refers to both bound and unbound forms. The concentration of HOCl and OCl- present in a water sample is governed by pH, and is described in Figure 2. Furthermore, HOCl is a much stronger oxidant, and therefore better disinfectant, compared to other forms of chlorine (Table 10). Because of chlorine's strong oxidizing properties, it not only reacts with pathogenic microorganisms, but also other easily oxidizable substances present, including metals such as iron and manganese, organic matter, hydrogen sulfide and ammonia. These reactions reduce the chlorine forms to the unreactive chloride ion (1). This effect, where disinfectant is consumed by water constituents, is commonly referred to as disinfectant demand.

Table 10. Estimated Effectiveness of Residual Chlorine Forms

Chlorine Form	Estimated Potency Compared to HOCl
Hypochlorous acid (HOCl)	1
Hypochlorite ion (OCl^-)	0.010
Monochloramine (NH_2Cl)	0.007
Dichloramine ($NHCl_2$)	0.013
Trichloramine (NCl_3)	Possibly more effective than $NHCl_2$

Source: Adapted from AWWA, 1995 (39).

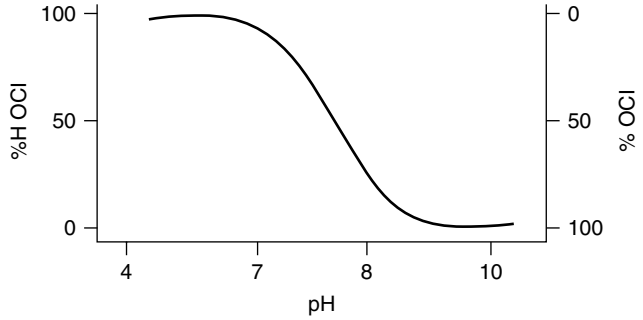

Figure 2. Distribution of HOCl and OCl in water as a function of pH. Adapted from Bitton 1994 (27).

Table 11. Inactivation of Selected Enteric Viruses by Chlorine

Virus	°C	pH	Chlorine Dose (mg/L)	Estimated Ct (% Reduction)	Reference
Poliovirus 1	5	6	0.5	1.05 (99%)	39
	5	10	0.5	10.5 (99%)	39
Hepatitis A	5	6	0.5	2.3 (99.99%)	11
Hepatitis A cell-associated	5	6	0.5	29 (99.99%)	11

However, when chlorine combines with ammonia, chloramines are formed in three sequential reactions:

$$NH_3 + HOCl \rightarrow NH_2Cl(\text{monochloramine}) + H_2O \quad (3)$$

$$NH_2Cl + HOCl \rightarrow NHCl_2(\text{dichloramine}) + H_2O \quad (4)$$

$$NHCl_2 + HOCl \rightarrow NCl_3(\text{nitrogen trichloride or trichloramine}) + H_2O \quad (5)$$

in which the di- and trichloramines are eventually oxidized to nitrogen gas. These three competing reactions are affected by pH, temperature, contact time, the ratio of chlorine to nitrogen and most importantly, the initial chlorine and ammonia nitrogen concentrations. Continual application of chlorine will eventually increase the chlorine to nitrogen ratio to 7.6 : 1 and higher, at which chloramines will be oxidized to nitrogen gas, nitrate, and other end products and a free chlorine residual appears. This point in the ammonia-chlorine interaction is termed the breakpoint (1). Ammonia-chlorine reactions are important in wastewater treatment, in which naturally occurring concentrations of ammonia convert applied free chlorine to chloramines. Because chloramines are considerably weaker disinfectants, chlorine is applied until the breakpoint reaction is reached (1).

The mechanism by which chlorine inactivates viral pathogens is controversial. Viral inactivation may be caused by interaction with the viral capsid proteins and/or the nucleic acid. In some studies, viral RNA had a greater affinity for chlorine than the capsid, whereas other researchers observed that the virus became noninfectious before damage to the capsid occurred (35,36). Furthermore, depending on the concentration of chlorine, studies have indicated that nucleic acid damage may occur at low (0.8 mg/L) concentrations, whereas high (>0.8 mg/L) chlorine concentrations may result in damage to both the nucleic acid and protein capsid (37). Varied resistance among closely related viruses has been reported. Differences in chlorine resistance and Ct values of selected viruses are shown in Table 11.

Chlorine dioxide (ClO_2) is a gas that is highly soluble in water at low temperatures. However, chlorine dioxide in water is extremely volatile and is lost to the atmosphere readily. Unlike chlorine, chlorine dioxide produces fewer trihalomethanes (THM) and does not combine with ammonia. Thus, for disinfection of substances that contain high concentrations of organic matter, chlorine dioxide may be a better alternative than chlorine. In the food industry, chlorine dioxide has been used successfully for the disinfection of the recycled water containing high concentrations of organic matter. In the health industry, chlorine dioxide gas is effective for the sterilization of packaged medical products. For drinking water treatment, chlorine dioxide destroys phenols that cause tastes and odors, and removes iron and manganese (1).

As a viricide, ClO_2 is a very effective, especially under conditions of high pH (40). At these high pH values, ClO_2 is a better viricide than HOCL for feline calciviruses and adenovirus (Thurston, unpublished data). Like chlorine, differences in the mechanisms of inactivation have been reported. It appears that both viral proteins and nucleic acid are damaged (21,26).

Bromine and Iodine. Bromine and iodine are not used for the disinfection of drinking water because of a combination of expense and possible adverse health effects. Free bromine(Br_2) forms trihalomethanes, reacts quickly with organics reducing disinfectant concentration and residual, produces a medicinal taste to water, and production of bromine is costly (1). Consequently, Br_2 applications are restricted to disinfection of water in cooling towers, small swimming pools, hot tubs, and spas. Bromine chloride (BrCl), an interhalogen compound, has been recommended as an alternative to chlorine for controlling biofouling of industrial (cooling towers) equipment. Further, BrCl has been suggested to be a better disinfectant compared to Br_2 (1). Viral inactivation by low (0.3 to 5 mg/L) concentrations of bromine have been suggested to occur by either prevention of viral attachment to the host cell, by damage to the protein coat, or by prevention of uncoating of the viral particle. However, at higher bromine concentrations, the protein capsid was degraded (40).

Iodine is also applied for small-scale water treatment. Iodine was first used by military troops for the sterilization of water in World War I. More recently though, iodine-containing quaternary resins have been placed in portable and home water disinfection systems. For treatment

purposes, iodine has been shown to be effective in herpes eye infections. Iodine at high pH values (above pH 8) has increased viricidal effectiveness because of the predominant form, hypoiodous acid, which has stronger oxidizing power over other forms of iodine (41). Although some authors report structural damage to the viral capsid, more recent evidence suggests uptake of iodine and subsequent destruction of the inner components of the viral particle, including the nucleic acid (21,42).

Metal Ions. Several metals may produce a viricidal effect including aluminum, copper, silver, mercury, and others. Because of the low toxicity of silver and copper, they are used for the disinfection of pools, spas, and home-faucet water treatment systems. Although, the rate at which metal ions inactivate viruses is slow compared to oxidizers such as chlorine, they are advantageous because the duration of their activity is much longer (22).

Metal ions can inactivate viral particles in a number of ways. Metal ions may adsorb to the virus capsid, blocking receptor sites. Once absorbed, the metal ion may be reduced, and the possible generation of hydroxide radicals may cause multihit damage on the viral capsid. Other damaging reactions to the viral capsid include decarboxylation and hydrolysis. In the case of metallic aluminum, viral binding to the surface of the metal was shown to render poliovirus noninfectious (5,14). Other work with aluminum demonstrated degradation of poliovirus RNA without damage to the viral capsid (43). Damage to the viral nucleic acid may occur if the nucleic acid is free in solution, or if the metal ion is able to diffuse through the capsid. Degradation of the phosphate backbone, intercalation, and disruption of base-pairing are ways in which viral nucleic acid may be damaged by metal ions (5,14).

CONCLUSION

The effects of viricides bear immeasurable importance for the prevention of viral transmission and thus, prevention of viral diseases. With an increasing immunocompromised population, viricide research directed at improving the safety of the blood, water, and food supply is essential. Currently, a great deal of information is lacking or controversial regarding the effectiveness or mechanisms of disinfectant viral inactivation. Disparities between viral disinfection studies make conclusions regarding the effectiveness and mechanisms of various disinfectants difficult. Future research must be conducted under similar conditions to allow comparison of results between different research groups and investigations should aim to determine the effectiveness of viral disinfectants under conditions natural to their use.

VIRUS SURVIVAL IN SOILS

MARYLYNN V. YATES
University of California
Riverside, California

The potential for pathogens in wastewater to contaminate potable water supplies is dependent on a number of factors including the physical characteristics of the site (e.g., soil texture), the hydraulic conditions (e.g., wastewater application rate, wetting/drying cycles), the environmental conditions (e.g., rainfall, temperature) at the site, and the characteristics of the specific pathogens present in the reclaimed water. The factors that influence the survival and transport of pathogens in the subsurface have been the subject of a number of reviews (1–5). The factors that affect the survival of viruses in soil will be discussed in detail in the following sections of this article.

TEMPERATURE

Temperature is probably the most important factor influencing virus inactivation in the environment, including soils (6). Lefler and Kott (7) found that it took 42 days for 99% inactivation of poliovirus in sand at 20–25 °C, whereas more than 175 days were required at 18 °C. Poliovirus was found to persist for more than 180 days in saturated sand and sandy loam soils at 4 °C, whereas no viruses could be recovered from the soils incubated at 37 °C after 12 days (8). Hurst and coworkers (9) studied the survival of poliovirus at three temperatures: 1, 23, and 37 °C in loamy sand. They also found that the inactivation rate was significantly correlated ($p < 0.01$) with incubation temperature, noting faster inactivation rates at the higher temperatures.

The exact mechanism whereby temperature inactivates viruses in soils has not been determined, but several theories have been proposed. The inactivation may be due to denaturation of the viral capsid (6); however, it has been shown that the RNA released during thermal denaturation remains infective, as it is more resistant to heat inactivation (10). Dimmock (11) suggested that different mechanisms might be at work, depending on the temperature. At low temperatures (less than 44 °C), the rate of virus inactivation corresponds with the inactivation rate of the viral RNA. However, at high temperatures (greater than 44 °C), the rate of virus inactivation exceeds that of the inactivation rate or the viral RNA, and is associated with structural changes in the viral capsid. Kapuscinski and Mitchell (12) suggested that temperature itself may not be responsible for virus inactivation, but may merely control whether other inactivation mechanisms can occur.

MICROBIAL ACTIVITY

There are conflicting reports regarding the role of microorganisms in virus inactivation; many of these have been reviewed (12,13). Sobsey and coworkers (14) found that the inactivation rates of poliovirus and reovirus in eight different soil suspensions were almost always greater under nonsterile conditions compared with sterile conditions. Hurst and coworkers (9) reported that virus inactivation rates were similar in nonsterile anaerobic soils and sterile soils at 1, 23, and 37 °C. Under aerobic conditions, poliovirus and echovirus inactivation rates were more rapid in nonsterile soil preparations than sterile at 23 and 37 °C. At very low temperatures such as 1 °C, inactivation rates were similar in both sterile and nonsterile soils.

Further studies by Hurst (15) investigated the influence of the oxygen status of the soil, and conditions of sterility on the survival of poliovirus 1 in soil. These studies showed that the virus inactivation rate was significantly affected by the presence of aerobic microorganisms. Two- to threefold increases in virus inactivation rates were found in the presence of aerobic microorganisms. This observation was made at all three incubation temperatures, 1, 23, and 37 °C. Anaerobic microorganisms did not have any significant effects on the virus survival in this study.

Several mechanisms by which microorganisms may influence virus inactivation have been suggested (16). Proteolytic enzymes released by certain bacteria were capable of destroying the capsid of coxsackievirus A9, but polioviruses were unaffected (17). Some microorganisms produce substances, which render viruses more susceptible to inactivation by photodynamic processes (18) or enzymes (19). Other compounds produced by microorganisms such as humic acids, tannins, phenols, and ascorbic acid may act as oxidizing or reducing agents, which lead to virus inactivation (16). Studies by Lipson and Stotzky (20) on the adsorption of reovirus to clay particles suggested that microorganisms may enhance virus inactivation in two ways. One is by the production of a soluble metabolic product that is virucidal; the other is by interfering with virus adsorption to soil particles.

SOIL MOISTURE CONTENT

The moisture content of the soil also influences virus persistence in soils. Although some investigators have

observed no difference in inactivation rates in dried versus saturated sand (7), the majority of the reports have indicated a difference. Bagdasaryan (21) observed that several enteroviruses, including poliovirus 1, coxsackievirus B3, and echoviruses 7 and 9, could survive for 60 to 90 days in soil with 10% moisture, as compared with only 15 to 25 days in air-dried soils. In another study, 99% inactivation of poliovirus occurred in one week, as the soil moisture content was reduced from 13 to 0.6%; however, 7 to 8 and 10 to 11 weeks were required for the same amount of inactivation in soils with 25 and 15% moisture content, respectively (22).

Hurst and coworkers (9) found that the moisture content affected the survival of poliovirus in loamy sand. The inactivation rate increased as the moisture content was increased from 5 to 15%, then decreased as more liquid was added. It was noted that the fastest inactivation rate occurred near the saturation moisture content of the soil (15 to 25%). The slowest inactivation rates were observed at the lowest moisture contents, 5 and 10%.

In another study, it was observed that virus inactivation rates were greater in more rapidly drying soils. In a field study of virus inactivation during rapid infiltration of wastewater, it was shown that allowing the soils to periodically dry and become aerated, enhances virus inactivation (23). Using radiolabeled viruses, Yeager and O'Brien (8) showed that the viruses are inactivated during the drying process, rather than becoming irreversibly bound to the soil particles.

Other studies by Yeager and O'Brien (24) suggested that the mechanisms responsible for poliovirus inactivation are different in moist and drying soils. In moist soils, under both sterile and nonsterile conditions, the viral RNA was recovered in a degraded form, suggesting that the nucleic acid was degraded prior to its release from the capsid. In dried, nonsterile soils, complete loss of viral infectivity was observed, and the RNA was recovered in degraded form. In contrast, the nucleic acid was recovered intact from sterile dry soils.

pH

The effect of pH on virus survival in soil has not been extensively studied. It has been suggested that pH indirectly influences virus survival by controlling adsorption onto soil particles which, in turn, affects virus survival (25). A few investigators have studied the direct effects of pH on virus persistence. Sobsey (26) reported the results of a study using simian adenovirus SV-11, in which it was shown that inactivation was more rapid at pH 5.0 and 6.0 than at pH 4.0 and 7.0.

The stability of five enteroviruses including hepatitis A virus, coxsackievirus A9, coxsackievirus B1, poliovirus 1, and echovirus 9, was studied under conditions of extreme acidity at room temperature (27). Of the viruses studied, hepatitis A virus was the most resistant to inactivation. In order to eliminate the possibility, that attachment to cellular material was responsible for the high resistance to inactivation, the studies were repeated with highly purified hepatitis A virus. The purified virus was found to be even more resistant to inactivation, remaining infectious for eight hours at pH 1.

Salo and Cliver (19) found that in the aqueous environment, pH affects different viruses in different ways. While poliovirus 1 was inactivated more rapidly at pH 3 and 9 than the near-neutral values of 5 and 7, coxsackievirus A9 was inactivated more rapidly at pH 5 than the extremes of 3 and 9. Murphy and coworkers (28) observed that mouse encephalomyelitis virus survival was longer in neutral soils than in soils with the pH adjusted to 3.7 or 8.5. Hurst and coworkers (9) studied the survival of poliovirus 1 and two bacteriophages, MS2 and T2, in nine soils with pH values ranging from 4.5 to 8.2. They found that virus inactivation was significantly correlated ($p < 0.05$) with soil saturation pH, with longer survival at the lower pH values.

The exact mechanism whereby pH causes virus inactivation has not been fully elucidated, but one investigator (29) found that the inactivation of adenovirus 2 was accompanied by an increase in sensitivity to DNase and the loss of structural proteins from the virus capsid. Results obtained by Salo and Cliver (19) also suggested that virus inactivation involves alterations in the virus capsid. These investigators found that the RNA of the inactivated virus particles became sensitive to ribonuclease at all pH levels tested (pH 3–9), and at pH 5 and 7 the RNA was hydrolyzed in the absence of ribonuclease.

Burge and Enkiri (30) found that the adsorption of bacteriophage ΦX174 to five soils showed a significant negative correlation with soil pH. The adsorption of poliovirus 1 and reovirus 3 to eight soils suspended in wastewater at pH values from 3.5 to 7.5 was generally greater at the lower pH values (14). The adsorption of the encephalomyelitis virus to montmorillonite clay was greatest at pH 5.5 (31). At pH 9.5, the adsorption was less, but the poorest adsorption was observed at pH 3.5. In an extensive study of poliovirus adsorption by 34 minerals and soils, no significant correlation was found between substrate pH and virus adsorption (32). The investigators reported that although adsorption by most of the neutral and acidic materials was strong, the variation in percentage of virus bound in the alkaline materials was so great that no significant correlation could be detected.

Loveland and coworkers (33) studied the effects of pH, on the reversibility of virus attachment to mineral surfaces. Their experiments on the attachment of PRD1 to quartz and ferric oxyhydroxide-coated quartz indicated that the isoelectric point of the mineral surface controls attachment. The attachment of PRD1 was observed at pH values 2.5 to 3.5 units above the isoelectric point of the mineral surface. Below this pH, the attachment of PRD1 was found to be complete and irreversible, while above this pH, the adsorption was minimal and reversible.

The mechanism(s) whereby pH affects virus adsorption to soil particles has been explained in terms of the electrochemical nature of the virus and soil surfaces (25,26,34). The outer surface of the enteric viruses is made of protein; therefore, the surface charge is influenced by the ionization of the carboxyl and amino groups in the capsid. The isoelectric point (pI) of many enteric viruses is below

7 (34), thus, at neutral pH, most viruses are negatively charged. Most soils are also negatively charged at neutral pH, and virus adsorption is not favored due to the mutual repulsion. If the pH of the environment is decreased, the surface charge of the virus will become positive (or less negative) due to increased ionization of the amino groups and decreased ionization of the carboxyl groups. While soils also become less negatively charged at lower pH values, soil pI values are generally lower than those of viruses, thus they may still have a net negative charge at acidic pH levels. This results in an electrostatic attraction between the virus particle and the soil, which leads to adsorption. In reality, the effect of pH on virus adsorption is not so clear-cut. There are many complicating factors that can interfere with the mechanism discussed earlier. One is that a given virus may have more than one isoelectric point: poliovirus 1 (Brunhilde strain) has isoelectric points at pH 4.5 and 7.0 (34). The factors responsible for passage from one form to another are unknown at this time. Other soil factors such as cations and humic and fulvic acids may also influence the net surface charge of viruses.

SALT SPECIES AND CONCENTRATION

The presence of certain chemicals may render a virus more or less susceptible to inactivation. Burnet and McKie (35) found that bacteriophage inactivation at 60 °C was partially prevented in the presence of 0.002 to 0.01 M $CaCl_2$, or $BaCl_2$. However, when the concentration was increased to 0.15 M or greater, thermal inactivation was increased. Enhanced stabilization of poliovirus at temperatures ranging from 4 °C to 50 °C in the presence of high concentrations (1 M) of $MgCl_2$ has been reported (36). Echoviruses have also been found to possess this property (37). Cords and coworkers (38) found that many type A coxsackieviruses were inactivated more rapidly in low ionic strength media than in high ionic strength media.

Thurman and Gerba (39) studied the effects of modifying soil with several metals on the survival of MS2 and poliovirus. The addition of aluminum metal, magnesium oxide, and magnesium peroxide had a significant negative effect on the inactivation rate of MS2 when compared with unmodified control soils. The addition of unrefined substances such as zeolite, bauxite, limonite, and glauconite (which contain multivalent cations and oxides of iron and aluminum) did not have a significant negative effect on the inactivation rate of MS2. Rather, they seemed to have a protective effect, as indicated by the lower inactivation rate as compared with the unamended control soil. Exposure of poliovirus to the aluminum-amended soil also resulted in significantly higher rates of inactivation, as compared with controls. Further experiments by these investigators indicated that contact between the aluminum and virus was necessary for inactivation of the viruses. They postulated that a combination of electrodynamic van der Waals interactions and electrostatic double layer interactions promoted virus adsorption to the surface of the aluminum, where inactivation of the virus could then take place.

The role of the soil cation exchange capacity (CEC) in virus adsorption has also been investigated. Burge and Enkiri (30) found that the CEC of four of five soils was correlated significantly ($p < 0.05$) with virus adsorption. In contrast, Goyal and Gerba (40) did not find a significant correlation between soil CEC and adsorption of 15 different viruses. Additionally, no correlation was found between virus adsorption and total phosphorus, or total and exchangeable iron, calcium, and magnesium.

Experiments to determine the effects of water quality on virus retention in soil columns were conducted by Sobsey and coworkers (41) using poliovirus 1, echovirus 1, and hepatitis A virus. Little difference in the amount of virus adsorption was noted, when the columns were dosed with either groundwater or primary wastewater effluent. Dosing with simulated rainwater resulted in considerable elution of all three viruses from the Corolla sand columns at 5 °C. Elution of the three viruses from columns of FM loamy sand was also observed, although the effects were more pronounced for echovirus 1 than for the other two viruses.

VIRUS ADSORPTION TO SOIL

The adsorption of viruses to soils and other surfaces may prolong or reduce survival, depending on the properties of the sorbent. The survival of poliovirus and reovirus was not always prolonged in soil suspensions, as compared with soil-free controls in a study using eight different soil materials (14). Murray and Laband (42) found that poliovirus adsorption onto some inorganic substances, such as CuO, results in decreased infectivity of the virus. These investigators suggested that van der Waal's interactions between the virus and the particle surface induced spontaneous disassembly of the virus.

More commonly, however, adsorption to soils has been found to prolong virus survival. Jorgensen and Lund (43) compared the survival of viruses in groundwater to survival in soil-groundwater mixtures. Coxsackievirus B3, adenovirus 1, and echovirus 7 were seeded into groundwater and groundwater-soil mixtures, and incubated at 4 to 7 °C. Their studies showed that the viruses survived for longer periods of time in the soil-groundwater mixtures than in the groundwater alone. Their results indicated that the majority of the viable virus particles were contained in the soil fraction of the mixture, rather than in the groundwater. A similar study on the survival of hepatitis A virus in several soils showed that, in all cases but one, virus survival was prolonged in the presence of soil as compared with freely suspended in groundwater (41). These studies suggest that the protective effects of soil are the result of adsorption to the solid surface.

The mechanisms whereby adsorption to a solid surface prolongs or reduces virus survival have not been elucidated. However, Gerba and Schaiberger (44) have suggested several possibilities, including interference with the action of virucides, increased stability of the viral protein capsid, prevention of aggregate formation, and adsorption of enzymes and other inactivating substances.

AGGREGATION OF VIRUS PARTICLES

The formation of aggregates influences virus survival in natural waters. It has been suggested that this is because virus particles within the aggregates are highly resistant to destruction by environmental factors (6). It has been shown that aggregation renders virus particles more resistant to inactivation by chemical disinfectants such as bromine (45), free chlorine, and monochloramine (46). Although there are no definitive reports on the effects of aggregation on virus survival in soil, the results of studies in aqueous media would suggest that aggregates would survive longer in soils than would monodispersed viruses (26).

SOIL PROPERTIES

The influence of soil properties on virus survival is probably related to the degree of adsorption. Hurst and coworkers (9) suggested that the correlation between pH and virus survival was probably mediated through its influence on virus adsorption. A positive correlation between virus survival and soil exchangeable aluminum, and a negative correlation with resin-extractable phosphorus were also attributed to influencing virus adsorption to the soil.

Sobsey and coworkers (41) compared the rate of inactivation of hepatitis A virus in five different soil types including clay soil, clay loam, loamy sand, sand, and organic muck. The survival was greatest in the clay soils, in which at least eight weeks were required to inactivate 99% of the infectious viruses.

VIRUS TYPE

As is obvious from the previous discussions, different viruses vary in their susceptibility to inactivation in the subsurface environment. Sobsey and coworkers (14) found that the rates of inactivation of poliovirus and reovirus in eight soils were different. Hurst and coworkers (9) also showed that the inactivation rates of seven different viruses varied even when incubated under the same conditions. In a comparative study of the survival of poliovirus, echovirus, and coliphage MS2 in several different groundwater samples, no significant difference ($p < 0.01$) was found overall (47). There were, however, differences in the inactivation rates of the viruses in individual water samples. In a recent report on the survival of hepatitis A virus (HAV), it was shown that this virus, generally, survived longer than poliovirus and echovirus at 25 °C (41).

Lefler and Kott compared the survival of poliovirus 1 and f2 coliphage in dry sand (7). Poliovirus survived for at least 77 days at room temperature. The f2 phage survived considerably longer, possibly for as long as one year under dry conditions. On the basis of the previous discussions, it is possible that the survival times of both viruses would be greatly increased if water were added to the soil.

The survival of human rotavirus strain Wa was compared to that of poliovirus 1, which is commonly used as a model for virus behavior in the environment (48). Inactivation experiments were conducted using five water samples (lake water, creek water, groundwater, nonchlorinated secondary effluent, and tap water) at 20 °C. The inactivation rates for the two viruses were significantly different from one another in all water samples except the tap water. This led to the conclusion that poliovirus is not a good model for the behavior of human rotavirus in water. The authors proposed that human rotavirus strain Wa can be used as a model for the persistence of other rotaviruses in water, as it survived for longer than has been reported for simian rotavirus SA11 in similar environmental conditions. Reported virus inactivation rates are given in Table 1.

ORGANIC MATTER

The influence of organic matter on virus survival has not been firmly defined. In some studies, it has been found that proteinaceous materials present in wastewater may have a protective effect on viruses; however, in others no effect has been observed (6). Lefler and Kott (7) found that poliovirus survived longer in sand columns saturated with oxidation pond effluent than distilled water. They suggested that the prolonged survival was probably due to the protective effect of proteinaceous materials in the effluent. Hurst and coworkers (9) did not find a significant correlation between virus survival and percent soil organic matter.

Humic and fulvic acids in soils may cause loss of virus infectivity and prevent adsorption (51). The infectivity could be partially restored by treatment with 3% beef extract, pH 9. Sobsey (26) observed a similar phenomenon: poliovirus infectivity was reduced in the presence of humic acid. At least some of the infectivity could be restored when the samples were filtered, probably by disruption of the humic acid–virus complexes.

Dissolved organic matter has generally been found to decrease virus adsorption by competing for adsorption sites on soil particles. In their study of poliovirus adsorption by 34 minerals and soils, Moore and coworkers (32) found that organic matter showed a strong negative correlation ($p < 0.001$) with virus adsorption. Bitton and coworkers (52) suggested that the organic material in secondary effluent interfered with virus adsorption to a sandy cypress dome soil. Powelson and coworkers studied the effects of natural humic material and wastewater sludge–derived organic matter on the transport of MS2 bacteriophages in unsaturated soil. (53). The transport of MS2 was found to be higher in a loamy fine sand column that had been treated with the organic material, than in a parallel column that had not been treated. In a series of experiments, Bales and coworkers (54,55) studied the effects of hydrophobic organic material on the attachment of bacteriophages MS2 and PRD1 and poliovirus 1 to silica beads. These investigators found that even very small amounts of hydrophobic organic material (>0.001%) can retard the transport of viruses in porous media.

Several investigators have found that organic material can act not only as a competitor for virus adsorption

Table 1. Reported Virus Inactivation Rates in Soils

Virus	Medium	Sand %	Silt %	Clay %	pH	Inactivation Rate log10/d^{-1}	Reference
Poliovirus 1	Dune sand					0.029	49
Poliovirus 1	Pomello sand	89	8	3	7.1	0.019	50
Poliovirus 1	Rubicon sand	92	4	4	7.1	0.007	50
Poliovirus 1	Flushing meadows sand	89	8	3	7.8	0.02–0.027	50
Poliovirus 1	Pomello sand	89	8	3	7.1	0.016	50

sites, but also as an eluting agent, that is, it can cause sorbed viruses to desorb from the soil (34). Pieper and coworkers (56) studied the effects of wastewater-derived organic matter on the transport of bacteriophage PRD1 in a sand and gravel aquifer on Cape Cod, MA. They found that the removal of the virus was greater in an uncontaminated area (83%), than in an area that had been contaminated by secondary wastewater effluent (42%). They concluded that the difference in removal was due to the higher content of organic matter in the contaminated zone (2.0–4.4 mg/l vs. 0.4–1.0 mg/l dissolved organic carbon), which blocked the adsorption of the PRD1. The attachment of the viruses to the soil surfaces was reversible, as demonstrated by the recovery of viruses upon addition of linear alkylbenzene sulfonates (LAS) to the system. In the contaminated zone, 87% of the attached PRD1 bacteriophages were remobilized. Jin and coworkers (57) also found that addition of a solution of 1.5% beef extract, which is high in organic matter, could remobilize ΦX174 bacteriophages from Ottawa sand.

Widespread use has been made of this property of organic matter, to remove viruses from filters in order to detect them in environmental samples. Mucks and other soils with high organic matter content are poor adsorbers of viruses (58), and may not be suitable for wastewater application sites (26).

In contrast to the other studies, Powelson and coworkers (59) found that the type of effluent (primary, secondary, and tertiary) had no significant effect on the transport of three viruses (poliovirus 1, MS2 and PRD1) through columns of alluvial coarse sand.

HYDRAULIC CONDITIONS

The rate at which water or effluent is applied to the soil affects the amount of virus removal or adsorption to the soil particles. Several investigators have shown that the amount of virus removal increases as the application rate decreases. Lance and Gerba (60) found that increasing the application rate from 0.6 to 1.2 m day^{-1} caused an increase in the number of virus particles in the column effluent. Increasing the application rate above 1.2 m day^{-1} up to 12 m day^{-1} did not, however, cause any further increase in virus movement through the columns. Vaughn and coworkers (61) also found that application rate had a large influence on the movement of poliovirus through a coarse sand-fine gravel soil. They speculated that the formation of a surface mat of wastewater solids might have been responsible for greater virus removal at the lower application rates.

MECHANISMS OF VIRUS SORPTION

The mechanisms of virus sorption to solid surfaces have been summarized in several review articles (34,62,63,64,65). Sorption of viruses has been studied with various types of viruses and sorbents (Table 2). It is difficult to draw general conclusions because the experimental conditions differ from study to study. Virus sorption depends on the chemical composition of the liquid phase and the nature of the solid surface. Key variables influencing sorption are pH and ionic strength of the solution, presence of compounds competing for sorption sites, functional groups, and isoelectric points of virus and sorbent. Depending on the type of virus and sorbent, sorption is dominated by electrostatic interactions, van der Waals forces, hydrophobic effects, and covalent binding to surfaces.

Table 2. Virus Adsorption to Soils

Virus	Soil Texture			pH	Surface Area (m^2/g)	CEC (meq/100g)	Organic Matter (%)	Adsorption Coefficient (ml/g)	Reference	Comments

Sorption usually increases with increasing cation concentration in solution, particularly in the presence of divalent cations (52,54,66,67). The enhanced sorption is attributed to the decrease of the thickness of the electric double layer (34). The pH determines the net charge of viruses and sorbents and is therefore a dominant factor (40,54,66). Hydrophobic effects may also play a major role. Bales and coworkers (54) showed that sorption of MS2 was dominated by hydrophobic factors. Bales and coworkers (54) also demonstrated increased sorption with increased temperature. This temperature effect might be due to the endothermic unfolding of protein structures at the interface or due to increased sorption rate at higher temperatures (54).

THE ROLE OF THE GAS–LIQUID INTERFACE

It is well known that certain proteins and viruses are sorbed and inactivated at the gas-liquid interface. Adams (68) and Zittle (69) presented excellent reviews on this topic. Shaklee and Meltzer (70) observed that shaking a pepsin solution in the presence of an air–liquid interface resulted in degradation of pepsin, whereas in the absence of the air–liquid interface, that is, when the bottles were completely filled with liquid, no degradation occurred. Shaklee and Meltzer (70) also observed that bubbling air or carbon dioxide through the solution results in denaturation of pepsin, and that the denaturation rate increased with decreasing pH of the solution. These early observations have been confirmed and extended in other studies (Table 3).

The mechanisms of denaturation or inactivation are closely related to sorption of viruses and proteins at the gas–liquid interface. Proteins spread at the gas–liquid interface and form a monomolecular surface film (71,72,73). The spreading at the interface results in denaturation of proteins, and the sorbed proteins become insoluble in water (71,72,74). Unfolding of the globulax protein structure due to interfacial forces causes the denaturation (68,73,75). The unfolding of the molecular structure is an endothermic process (69). When proteins desorb from the interface, the native state cannot be regained anymore. Due to the significant change in physicochemical properties of the molecule, protein sorption at gas–liquid interfaces has been considered as an irreversible process (73,74,76). The inactivation of viruses is presumably an analogous process to denaturation of proteins. The forces at the interface alter the virus structure in a way that affects the infectivity (68).

Under static conditions, proteins form a monomolecular film at the interface, and once the interface is saturated, dissolved protein molecules cannot reach the interface anymore. Shaking a solution destroys old and creates new interface, unfolded proteins at the interface coagulate, and new native proteins may be sorbed, resulting in increased denaturation or deactivation (68,71).

Sorption of proteins at the gas–liquid interface is in principle the same mechanism as sorption on solid surfaces. On solid surfaces, proteins seem to sorb in monolayers and do not desorb easily. However, in contrast to the gas–liquid interface, when the chemistry of the solution (pH, ionic strength, addition of macromolecules competing for sorption sites) is changed, proteins and viruses desorb from the solid surface and regain their native configuration. It has been argued that the unfolding at a solid–liquid interface does not lead to denaturation or inactivation because the interface is rigid, and therefore it

Table 3. Virus Inactivation and Protein Denaturation at the Gas-Liquid Interface (Modified from Yates and Coworkers) (77)

Compound	Observation	References
Bacteriophage	Inactivation by violent shaking	78
Proteins	Protein unfold at interface and form monomolecular film, film is insoluble, stirring creates new interface area	71
Proteins	Spreading of protein at gas-liquid interface results in denaturation of protein, the proteins become insoluble	72
Proteins	Proteins form surface film, coagulum formed when solution is shaken, rate of denaturation dependent on size of bottle, shaking intensity but not concentration	73
Influenza A virus	Inactivation by bubbling air through virus solution	79
Equine encephalitis virus	Inactivation by shaking in buffered saline solution and by bubbling gas through solution, inactivation increased as pH reduced form 7 to 5	80
Bacteriophage T1,.., T7	Inactivation by shaking and bubbling air through solution, inactivation dependent on pH, presence of gelatin prevents inactivation	68
Enzymes, proteins	Unfolding of macromolecules largely determined by interfacial energy, sorption follows Langmuir isotherm	75
Proteins	Irreversible binding of proteins to interface	76
Viruses	EMC virus not affected, Bacteriophages T3,T5 only little affected, MS2 and Semliki Forest virus inactivated by bubbling air or nitrogen gas through solution, inactivation prevented by adding peptone and apolar carboxylic acids, rate of inactivation dependent on salt concentration, more sorption at higher salt concentration	81
Proteins	Denaturation at interface due to unfolding, insoluble coagulum formed when solution is shaken	74

is more likely that the proteins can return to their original state (69).

CONCLUSION

There are a number of factors that have been shown to affect the length of time that viruses remain in an infective form in the soil environment. The magnitude of the effect varies among viruses, and interactions among the factors undoubtedly occur. To date, it has not been possible to quantitatively describe the relationships between the rate of virus inactivation and these factors. This has severely hampered the development of mathematical models that can be used to independently predict the length of time that viruses may pose a potential public health risk in contaminated soils.

Davis, California

All the pathogens to be considered in this entry have been described biologically, and the methods of final detection for each are given in other sections of this Encyclopedia. This article discusses the selection and processing of food samples to enable final laboratory detection of viruses and protozoa. As water and shellfish are covered in other entries, they are not discussed in this article. Before describing methods for extracting viruses and protozoa from foods, it is important to consider why testing needs to be done. There are at least four possible occasions for detecting viruses and protozoa in food: (*1*) investigation of outbreaks, (*2*) validation of processes as critical control points in hazard analysis-critical control point food safety systems, (*3*) routine quality control testing, and (*4*) random surveys. Applications (3) and (4) are of limited value and are not discussed in detail. Application (2), appropriately done, should allow processing of foods without testing them for the presence of these agents in the finished product; thus, methods of quantification, either of the starting level of the pathogen, the level of survivors, or both, are needed. Application (1) receives the most attention despite the fact that incubation periods of the illnesses caused by these agents are often so long that it is very doubtful that appropriate food samples will still be available for testing. On a positive note, the pathogen that is being sought is usually known in the cases of applications (1) and (2), so specialized methods are appropriate. In the following sections, the relative emphasis on one or another pathogen or on one or another food depends considerably on the available, limited epidemiological record.

FOOD VEHICLES OF VIRUSES AND PROTOZOA

Viruses and Protozoa Among Agents of Food-Borne Disease

Human enteric viruses and parasites have been increasingly recognized worldwide as important causes of

food-borne diseases. Among food-borne viral diseases, hepatitis A and acute viral gastroenteritis associated with Norwalk virus, rotaviruses, and other small, round gastroenteritis viruses are most common (1,2). Food-borne outbreaks are usually associated with consumption of raw or undercooked shellfish contaminated by fecal materials and ready-to-eat food items contaminated by food handlers (1,3).

Parasitic agents of food-borne illness belong to intestinal protozoa, tissue protozoa, and tissue helminths, with protozoa being especially prominent in the United States. Clinically significant protozoa include amoebae (*Entamoeba histolytica*), flagellates (*Giardia*), and coccidia (*Cryptosporidium*, *Cyclospora*, and *Toxoplasma*). Although few food-borne protozoal diseases were reported before the mid-1980s, these have since been more commonly reported, due to increased awareness and improved diagnosis and detection methods. *Entamoeba histolytica* has been a recognized food-borne agent for long, especially in communities with poor personal hygiene and drinking water supplies (4). *Cryptosporidium parvum* and *Giardia lamblia*, the only human-pathogenic species in the respective genera, cause the most common human enteric parasite infections in the United States (5,6). *Cyclospora* has recently been associated with the consumption of contaminated fruits (7,8). *Toxoplasma gondii* is of particular concern because it affects both pregnant women and the fetus. It causes the third most deaths among all food-borne pathogens (following *Salmonella* and *Listeria*) (9). Other intestinal protozoa that are transmissible via food, such as *Isopora*, *Microsporidia*, and *Sarcocystis*, and intestinal helminths, such as *Ascaris*, *Anisakis*, *Taenia*, and *Trichinella*, will not be discussed.

Food-associated outbreaks caused by viruses and protozoa are much less commonly reported than those caused by bacteria. As many cases of such diseases are not reported because important information or samples may be inaccurate or unavailable, and because of the lack of sensitive methods for the detection of these agents, the significance of viral and parasitic agents in food-borne transmission is believed to have been underestimated. A report cited viral gastroenteritis as the most common food-borne illness in Minnesota from 1984 to 1991 (10). The same report ranked human enteric viruses as fifth and sixth among identified causes of food-borne disease in the United States. It was indicated that 10% of the 4,617 outbreaks of food-borne disease of unconfirmed etiology reported from 1973 to 1987 met at least two of the clinical criteria for the outbreak of acute viral gastroenteritis (11,12).

In a review of food-borne diseases in the United States (selected years 1952–1982), only one incident of protozoal disease was recorded — five cases of *E. histolytica* infection in 1967. In 1973–1987, only 1.9% (140 out of 7,458) food-borne outbreaks in the United States were attributed to parasites (11). *Trichinella spiralis* accounted for 128 of those outbreaks, *G. lamblia* for 5, and other parasites for 7. In 1993–1997, only 0.7% of the food-borne outbreaks were determined to be parasite-caused, among them four were caused by *G. lamblia* (13). Intestinal protozoa have also been implicated as important causes of sporadic intestinal illness in the United States. According to a recent survey conducted over a portion of the country comprising 6% of the total population, *C. parvum* alone ranked fourth among identified agents (following *Campylobacter*, *Salmonella*, and *Shigella*) (14).

Viruses and protozoa present a range of transmission patterns that influence the likelihood that one or the other may be present in food and needs detection. Viruses known to be transmitted via foods are all human-specific and are shed only in feces (except for a few that are also shed in vomitus (1)). In contrast, the potential food-borne protozoa present several host patterns: *Cyclospora cayetanensis* and *E. histolytica* are essentially human-specific; *C. parvum* and *G. lamblia* are shed in feces and are transmissible from person to person but are more often harbored by nonhuman species (with some possible exceptions); and *T. gondii* is associated with cat feces or with undercooked meat and is probably not transmissible from person to person under any circumstance. These properties are significant to find how food may become contaminated with the pathogens of concern. In contrast to the situation in areas where night soil fertilization is practiced, contamination of foods by human-specific viruses and protozoa in most developed countries results from contact with the unwashed hands of infected persons or with water that has been inadequately treated after being used to carry human feces. The possibility of *Cryptosporidium* or *Giardia* contamination of vegetables via manure or of *T. gondii* in garden soils from buried cat feces may lead to very different associations of the pathogens with the food. No food other than bivalve mollusks is known to be able to concentrate pathogens from the environment; and none of these pathogens can multiply in soil, water, or even cells of unsusceptible animals. Therefore, a viral or protozoan contaminant of food can only retain its infectivity until the food is eaten. If the final test method to be applied is capable of distinguishing between infectious and inactivated pathogens, the sampling and sample processing methods must be selected so as not to inactivate pathogens that were infectious at the moment of sampling.

Peroral Infectious Dose. There is a general perception that a test for a food-borne pathogen is adequately sensitive if, and only if, it is capable of detecting a single infectious dose or less in a serving-sized sample of the food. Test sensitivity is governed by the size of the food sample, the efficiency with which the pathogen is extracted from the food and concentrated to a volume that can be tested, and the sensitivity of the test that is finally applied.

This approach of defining adequate sensitivity is inherently reasonable but is complicated by some further considerations: (*1*) There are no generally agreed-upon units of measure for most of these agents. Protozoan cysts and oocysts can generally be counted on a microscope, but the counting techniques do not ordinarily include a viability-infectivity criterion. It is not generally feasible to count viral particles, so those that can be quantified in cell culture are usually enumerated in plaque-forming units, which may each be equivalent to approximately 100 particles. (*2*) Distribution of the agent in the food is likely to be very heterogeneous, whereby one serving may

contain little or none, while another contains at least enough to cause an infection. (*3*) Although it is usual to speak of infectious doses, what is meant often is a dose that causes illness. The likelihood that infection and illness will result from a given infectious dose is a function of many host factors, such as age, pregnancy, and impaired immunity caused by immune suppressants (say, following an organ transplant), cancer chemotherapy, or HIV infection (10). Although the aspiration to have a test that will detect one infectious dose or less per serving of food is reasonable, the selection of methods is ultimately arbitrary and incapable of scientific validation by means that are currently at hand. A peroral infectious dose of virus may well comprise 100 to 1000 physical particles, whereas 30 or less oocysts of *C. parvum* have infected human volunteers. The polymerase chain reaction (PCR), for example, can often detect smaller copy numbers of nucleic acid than these, so the onus is on sampling and processing to collect the equivalent of an infectious dose from a relatively larger sample of food and then concentrate the pathogen from the extract to harvest its nucleic acid in a volume that the PCR will accommodate. And because positive PCR results are often obtained with nonviable organisms, one would wish that the process included some means of selecting only viable agents for PCR.

Selected Food-Associated Outbreaks. A few reported outbreaks are summarized here as a basis for the selection of foods for which sample-processing methods are described. Again, mollusks and water are not included because they are covered elsewhere.

Hepatitis A

- The staff of a hospital in St. Louis, Missouri, suffered an outbreak of 28 cases of hepatitis A in 1962 (15). A worker who was apparently infected by the virus had thawed and reconstituted frozen orange juice in a manner that evidently led to contamination. She did not become ill, but her husband, who was not at the hospital, developed hepatitis at the time of the outbreak.
- Outbreaks involving 82 cases in Arkansas and 58 cases in Texas were traced to a single worker in 1978 (16). The man prepared sandwiches and salads in vegetarian health food restaurants. He was visibly ill while working at the second location.
- Food from a single bakeshop in the United Kingdom transmitted hepatitis A to 50 people in several villages in 1989 (17).
- Lettuce, apparently handled by an infected worker, transmitted hepatitis A to 110 people in Missouri in 1990 (18).
- Caviar, illegally imported from Latvia, was the apparent vehicle of hepatitis A virus that infected four people in Denmark in 1994 (19).

Norwalk-Like Virus

- In 1982, Norwalk virus was transmitted to some 3,000 people in the area of Minneapolis and St. Paul, Minn., by butter cream frosting prepared by a baker's assistant, who was ill, and later applied on a great number and variety of pastries (20).
- A small, round virus in ice, made with contaminated water, that was used to cool drinks served at a college football game and a fundraising gathering caused gastroenteritis in approximately 5,000 people in 1987 (21).
- Residents (155 illnesses, 2 deaths) and employees (28) who ate shrimp dishes at a retirement facility in the area of San Francisco Bay, California, were sickened by the Snow Mountain agent, a small, round, structured virus (SRSV) that is antigenically distinct from the Norwalk virus (22).
- Norwalk-like viruses in school lunches from a preparation center that served nine schools affected 3,236 students and 117 teachers in Toyota City, Japan (23).
- Freshly cut fruit served in a Hawaiian cruise ship transmitted gastroenteritis virus to 238 people in 1990 (24), and in another Hawaiian cruise ship in 1992, approximately 200 people served with contaminated ice were infected (25).

Cryptosporidium

- Fresh, hand-pressed apple cider, served at a school agricultural fair in central Maine in 1993, transmitted *Cryptosporidium* to an estimated 160 people, many of whom passed on the infection to others (26). Apples were collected from the ground in an orchard where calves grazed.
- Chicken salad, prepared by a woman operating a licensed day care home (including diaper changing), was the apparent vehicle in a Minnesota outbreak of cryptosporidiosis that affected an estimated 50 people in 1995 (27).
- Drinking unpasteurized apple cider, from apples that may have been contaminated by well water during washing, led to 10 or more cases of cryptosporidiosis in Connecticut and New York in 1996 (28).
- Green onions, probably contaminated in the field, may have been the source of *Cryptosporidium* that infected 54 people who attended a banquet in Spokane, Washington, in 1997 (29).

Giardia

- Salmon and a cream cheese dip, served at a school in Minnesota, led to 29 cases of giardiasis in 1979 (30). The probable source of contamination was a woman who helped prepare the food and had changed the diaper of her 12-month-old grandson, an asymptomatic shedder of *Giardia* cysts.
- In a 1988 outbreak, cold noodle salad served at a picnic transmitted *Giardia* to 13 of the 16 people who attended (31). Spices were added by hand to the noodles by a neighbor who became ill the next day; her children, who did not attend the picnic, were shedding *Giardia* cysts.
- An outbreak following a family party, in which 9 of the 25 persons became ill, was associated with the

consumption of a fruit salad (32). The woman who prepared the fruit salad had a child in diapers and a pet rabbit, both of whom were shedding *Giardia*.

- In 1990, 21 of the 108 persons who attended a church dinner in New Mexico were infected. Lettuce, onions, and tomatoes were implicated epidemiologically; however, no obvious contamination was found (33).
- An outbreak among insurance company employees in November 1990 comprised 18 laboratory confirmed cases and 9 suspected cases of giardiasis (34). Case-control studies implicated raw vegetables, sliced by a food worker infected with *G. lamblia*, which were served in the employee cafeteria.

Cyclospora

- The first reported food-borne outbreak of *Cyclospora* in nontravelers occurred in 1995 in eastern Florida. At that time, the outbreak was erroneously associated with strawberries from California (35).
- In 1996, 1,465 cases of cyclosporasis were reported in 20 states of the United States and in Canada. Some 55 events were identified as being a part of this outbreak, whose suspected vehicle was Guatemalan raspberries (36–38).
- There were 25 outbreaks in nine states in 1997, involving 1,450 cases associated with raspberries, basil, and lettuce (39–41). In some outbreaks, implicated raspberries were imported from Central Guatemala (42,43). In two events in restaurants in Florida, no raspberries were served and infection was associated with eating mesclun (a mixture of baby leaves of various types of lettuce (40)). In the outbreak in Northern Virginia, Washington, D.C., and Baltimore (39), consumption of fresh basil (believed to have been contaminated in the field) from a specific company was identified as the probable vehicle of *Cyclospora* transmission.
- In 1998, few cases were identified in the United States; but there was an outbreak in Canada in which 192 cases of cyclosporiasis in 13 clusters were associated with eating fresh raspberries from Guatemala (44). Canada permitted the import of raspberries from Guatemala that spring, but the United States did not.

Toxoplasma. Food-borne infection in man is generally uncommon and reports of food-borne toxoplasmosis are relatively few, owing to the often asymptomatic nature of infections in immunocompetent hosts. Having cats (that may eat infected birds or rodents) as pets is a major factor in the maintenance of *T. gondii* as a food-borne pathogen. On the other hand, livestock that eat feeds or hay contaminated by the feces of *T. gondii*-infected cats develop infections that eventually result in tissue cysts in edible parts of the animals. Although cooking and freezing readily kill the tissue cysts, eating raw or undercooked meat, such as pork, beef, mutton, and horsemeat, is a possible route of infection.

- It was demonstrated in an outbreak that eating inadequately cooked venison might represent an important vehicle of human toxoplasmosis infection (45).
- A family outbreak of toxoplasmosis in Australia was thought to be associated with the consumption of a homemade meat dish with raw lamb (46).
- In another family outbreak, drinking unpasteurized goat's milk was associated with the illness and *Toxoplasma* was isolated from the milk (47).
- In September 1993, there were 17 cases of symptomatic acute toxoplasmosis acquired by the ingestion of raw mutton offered during a party (48).
- Two outbreaks of acute toxoplasmosis involving eight adult patients in Korea were linked to eating undercooked pig organs. The first outbreak was owing to the consumption of a meal consisting of raw spleen and liver of a wild pig, whereas the second outbreak was owing to eating a meal consisting of the raw liver of a domestic pig (49).

Entamoeba. Amoebiasis is caused by the parasite *E. histolytica*, which is estimated to infect about half a billion people worldwide and cause about 100,000 deaths per year; but is now rare in the United States. Transmission by food and water was described in the 1940s, especially as a result of shedding by food handlers. In recent times, food handlers are suspected of causing many scattered infections. For example, in a limited outbreak of symptomatic intestinal and extraintestinal amebiasis within an Italian family, the infection was believed to be transmitted by a Philippine housemaid, who was an asymptomatic carrier of *E. histolytica* infection acquired in her native country (50). However, there have been no large outbreaks of food-borne disease.

It is apparent that a great variety of foods may be contaminated by viral and protozoal pathogens. Foods that are contaminated and then not cooked before being eaten (e.g., fruits and some vegetables) are relatively frequent vehicles.

PROBLEMS IN TESTING FOR VIRUSES AND PROTOZOA IN FOODS

Food-associated outbreaks of viral or protozoal disease are most often recognized on the basis of diagnosis in those who are ill, followed by case-control studies that implicate a food. Detection of the pathogens in the suspect foods is rare. This is partly because the incubation periods of hepatitis A and many protozoal illnesses are so long that food samples are often unavailable by the time testing is considered. Gastroenteritis caused by the Norwalk-like viruses has a short incubation period, but laboratory diagnosis of these illnesses is seldom attempted in the United States because the laboratory results do not influence the course of treatment of those who are ill.

Viruses or parasites are likely to be present in a food sample in small numbers. Failure to confirm a viral or parasitic etiology of a food-borne outbreak is therefore partially due to the lack of adequate methods to detect the causative agent. In the past few years, improved diagnostic methods have been developed, some of which are applicable to detection of these pathogens

from suspected food samples. For human enteric viruses, earlier methods were based on infectivity assays in established cell cultures and enzyme immunoassays; however, cell culture methods are not available for detection of the hepatitis A and Norwalk-like viruses, and enzyme immunoassays are relatively insensitive. For protozoa, detection procedures have included microscopic methods, such as wet mount and trichrome staining, modified acid-fast, and auto-fluorescence of *Cyclospora* oocysts, and immunofluorescence methods employing pathogen-specific antibodies. More recently, the ability to extract viral and parasitic nucleic acid and amplify by reverse transcription-polymerase chain reaction (RT-PCR) or direct PCR from clinical samples has increased the usefulness of nucleic acid-based molecular methods. With the theoretical potential to detect a single copy of the viral or parasitic genome, PCR-based methods are the most sensitive detection methods available today and are highly specific. Not only are PCR-based approaches increasingly applied in diagnosis and pathogen identification, but sequence analysis approaches for genetic analyses of isolated pathogens have also become increasingly feasible and affordable.

Assuming that molecular methods are the best available for detection of food-borne viruses and protozoa, there is a need to increase the efficiency of food sample preparation so that the results can be better and more accurately interpreted. Unlike bacterial agents, which can be enriched in specific growth medium, both viruses and parasites are environmentally inert and cannot replicate in food, water, or environmental samples. On the other hand, food-transmitted human enteric viruses and parasites are environmentally stable, can withstand many methods used to inactivate bacterial pathogens and commonly practiced food storage and processing conditions. Therefore, virtually any kind of food could serve as a vehicle for their transmission. Detection of food-borne bacteria often relies on enrichment culture and selective medium to increase numbers of the suspected pathogen and to differentiate it from nonpathogenic microflora. The lack of an equivalent to the bacterial enrichment in detection of viral and parasitic agents makes it extremely important to have a suitable method for the concentration and preparation of viruses and parasites, so that maximal sensitivity is obtained when a food sample is assayed. At present, emphases are being placed on cost- and time-effective concentration methods to improve recovery and detection limits and to prevent inhibition of the detection methods by food-related compounds.

Food-borne viral and parasitic pathogens are more frequently transmitted via contaminated water, and a number of concentration techniques, most of which are applicable to liquid foods, have been developed for the recovery of such agents from water (see other sections describing waterborne viruses and parasites). Therefore, efficient methods to recover and detect viruses and protozoa from solid foods are the greater challenges. As food contaminants, viruses and parasites differ from bacterial pathogens in that the bacteria are often inside food, whereas viruses and protozoa are usually surface contaminants. The exceptions to this norm are virus-contaminated shellfish, in which viruses are found in the edible intestinal portion, and *T. gondii* cyst-containing meats. Therefore, getting virus and protozoa out or off food, with minimal inclusion of the foodstuff, is a major concern of sample preparation.

Much of the difficulty in implementing (RT)-PCR for the analysis of food samples lies in the problems encountered during the preparation of template DNAs or RNAs from food matrices. Frequently, concentrated samples are directly used for (RT)-PCR. However, during the sample concentration steps, undefined food components are often concentrated as well and they might be inhibitory to (RT)-PCR. Substances in concentrated food samples may also interfere with other detection methods, such as immunofluorescence assays (IFAs) and tissue culture assays. Therefore, one emphasis on improving detection efficiency is to get rid of inhibitory materials present in the food samples. Currently evaluated measures include the separation of viral and parasitic agents from such inhibitory substances by the application of magnetic beads coated with antibodies, a technique known as immunomagnetic separation (IMS) (51,52). IMS-(RT)-PCR has been used for the capture of various pathogens, including *Giardia*, *Cryptosporidium* (53–55), hepatitis A virus, and other human enteric viruses (56–60). Alternatively, the inhibitory effects may be reduced by the use of additives. For example, detection of enteric viruses in shellfish was found to be obstructed by the presence of RT-PCR inhibitors and such inhibitors can be removed by guanidinium isothiocyanate extraction (60,61).

EXTRACTION AND CONCENTRATION OF VIRUSES FROM FOOD

Because generally there are no specific techniques available to detect viral and parasitic pathogens in foods, methods are adapted from procedures that have been proven useful in detecting such agents from clinical samples. Detection of the viral and parasitic food-borne pathogens from foods is usually more difficult than their detection in clinical samples because the number of pathogens present in food is much lower; and detection efficiencies are widely variable, depending on the contamination level and concentration techniques.

The choice of extraction method depends not only on the type of pathogens to be tested, but also on the type of foods from which the pathogens are to be detected. Generally speaking, methods used for extraction of parasitic agents are not appropriate for extraction of viruses, and vice versa. This is mainly due to their difference in physical characteristics: during gravity centrifugation, protozoa are in the sediment, whereas viruses are in the supernatant; in filtration, the pore size of the filter is usually smaller than the size of a protozoa but larger than the size of a virus particle, so protozoa are retained on the membrane, whereas viruses are in the filtrate.

Sampling and Sample Size

Steps in processing a sample for virus testing generally comprise liquefaction (if the food is not already a liquid),

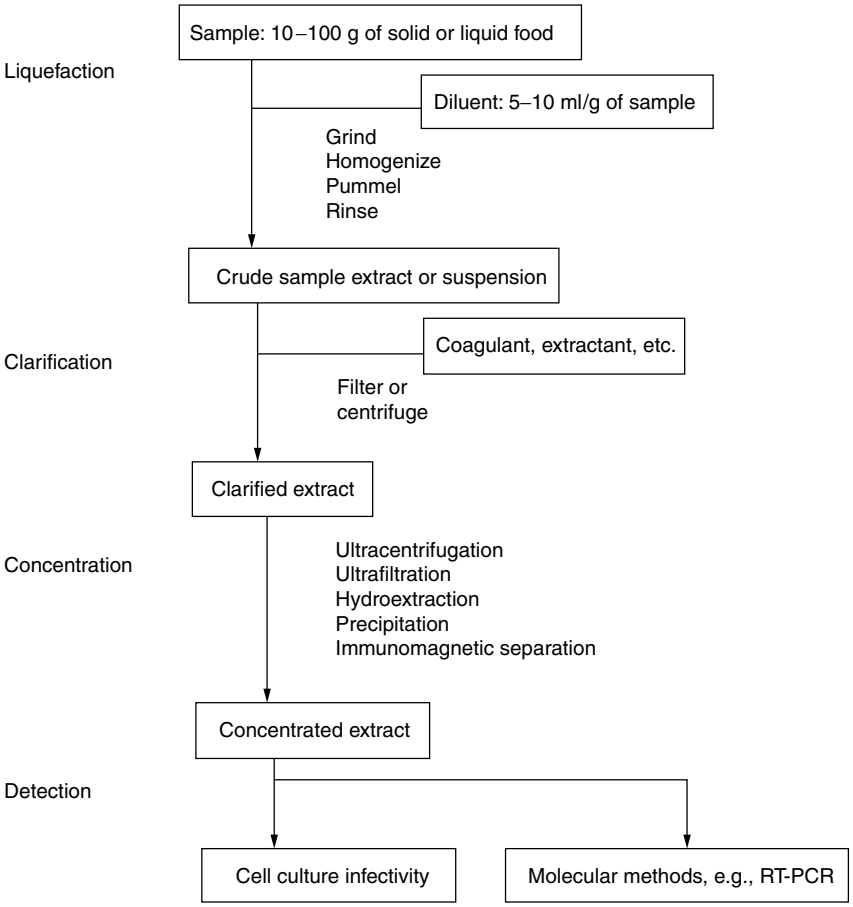

Figure 1. Extraction and concentration of viruses from food — flow diagram.

clarification, and concentration (Fig. 1). The size of a sample for virus extraction might be chosen on the basis of the probable serving size of the food and the desirability of being able to detect a human infectious dose therein. In fact, sample sizes have been more usually based on expediency, with quantities of 10 to 100 g being usual. It may be desirable to make a composite sample, assuming that enough is known of the probable distribution of the virus in the food to make such a decision.

Liquefaction

If contamination is likely to be limited to the surface of the food, larger samples may be processed, using methods that recover virus with minimal inclusion of the food in the resulting suspension. Published methods for recovering viruses from the surfaces of fruits and vegetables (62–68) are fairly old. Devices such as the Stomacher® and Pulsifier® probably deserve testing in these applications. Methods for recovering viruses from milk have also been described (68,69).

If the virus contaminant is thought likely to be within a solid food, the sample will have to be liquefied. This has most often been done with a high-speed homogenizer (70), taking precautions against overheating, although a sonic apparatus might also be used. Laboratories that process small numbers of samples might even resort to a mortar and pestle with sterile sand. The liquid in which the food is to be suspended is usually an alkaline buffer, at a ratio of 5 to 10 ml per gram of sample. Because the food solids will need to be removed from the sample suspension, it is important not to reduce them to a size that complicates this. The most common approach is to keep the pH of the suspension at or above neutrality, to discourage adsorption of the virus to the food solids.

Clarification

Clarification is intended to remove food solids from the sample suspension to enable concentration of the remaining fluid and, ideally, to remove substances that are toxic to cell cultures or that may inhibit RT-PCR test procedures. Bacteria are often removed at this stage as well. Clarification may be done by filtration or centrifugation, perhaps aided by the polycation sewage flocculent, Cat-Floc® (Calgon Corp., Pittsburg, Pa.), at a final concentration of 0.1 to 0.5% (67,71,72). Freon TF® (1,1,2-trichloro-1,2,2-trifluoroethane) (E. I. DuPont de Nemours, Wilmington, Del.) extraction has also been used for this purpose (70).

If the suspension has been sufficiently clarified, it may be possible to remove bacteria at this point by filtration at 0.22 to 0.45 μm porosity, taking care that the virus is not adsorbed to the filter (73). Alternatives to filtration include treatment with antibiotics, chloroform, or ether, in instances where the sample extract is still somewhat turbid.

Concentration

Concentration of the sample is intended to reduce the sample volume to the amount required for testing by the chosen method. Cell cultures usually accommodate a volume of about 0.02 ml per square centimeter of monolayer surface, although volumes as large as 1.4 ml cm^{-2} may be tested under some circumstances (74). Volumes to be tested by RT-PCR are not likely to exceed 1 ml — usually much less.

Early concentration methods employed hydroextraction (dialysis against polyethylene glycol) (70,75), preparative ultracentrifugation, or ultrafiltration (67,71). These are relatively expensive and labor-intensive. More recently devised methods are based on precipitation of the virus by adsorption of the virus to the precipitated protein under acidic conditions (76). The selection of the protein to be used for this purpose is critical, as some may inhibit expression of the virus in cell culture. Polyethylene glycol can also be used to precipitate viruses from food extracts, for the purpose of concentration (77–83). Other methods of final concentration and of removing substances inhibitory to RT-PCR entail addition of the cationic detergent cetyltrimethylammonium bromide (83–86) or of Pro-Cipitate, a protein-precipitating agent that has also been used successfully to remove inhibitors of RT-PCR (77,79,87).

EXTRACTION AND CONCENTRATION OF PROTOZOA FROM FOOD

Most of this section will necessarily deal with the recovery of *Cryptosporidium* and *Giardia*, inasmuch as methods for other protozoa are exceedingly limited. A number of methods have been developed for the concentration of protozoa from feces and in environmental samples. Traditional methods to concentrate parasitic agents from water samples (including surface, drinking, and irrigation water) are based on membrane filtration or cartridge filtration, and subsequent centrifugation of the retained materials (88,89). For the concentrations of smaller sample volumes, simple centrifugation or the flocculation technique can also be used (90). On the other hand, *Cryptosporidium* and *Giardia* in stool specimens are frequently concentrated via gradient centrifugation (Sheather's sucrose, sodium chloride, Percoll's solution, etc.). It is possible to process fluid foods suspected of being contaminated with (oo)cysts in a similar manner to concentration from water samples, whereas solid foods must be done in other ways.

Extraction from Liquid Foods

Contaminated apple juice (cider) and raw milk (and some milk products) are identified examples of potential vehicles of *Cryptosporidium* and *Giardia*. Although it is possible to use simple centrifugation or filtration-centrifugation to concentrate (oo)cysts in a similar manner to extraction from water samples, the presence of other food components makes it necessary to add extra processing steps for the extraction of (oo)cysts from liquid foods (Fig. 2). Deng and Cliver (91) investigated oocyst recovery from milk and milk products using a Sheather's sucrose flotation-based procedure. While low fat milk and thawed ice-cream were directly centrifuged, an ether-extraction step was added

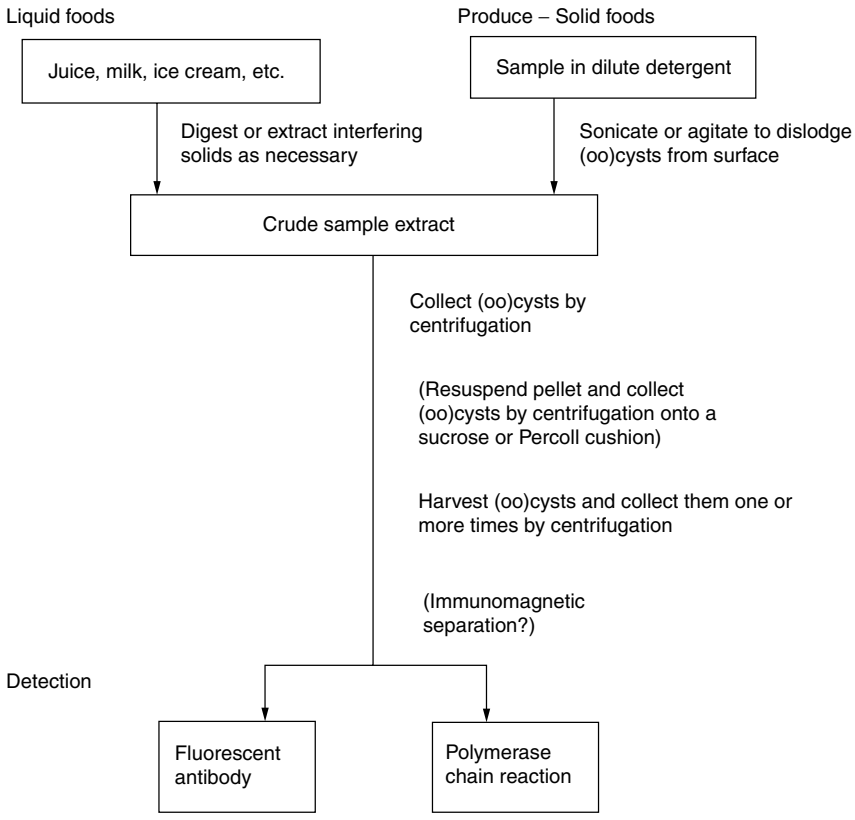

Figure 2. Extraction and concentration of protozoa from food — flow diagram.

before centrifugation for yogurt made from low fat milk. Following centrifugation, the pellet was overlaid over a sucrose solution, with specific gravity 1.20 $g\,ml^{-1}$, and centrifuged for 10 minutes at $1,000 \times g$. The interlayers containing oocysts were pooled, washed, and further centrifuged. The average respective recoveries were 82% from 100 ml of low fat milk, 61% from 100 g of yogurt made from 1% fat milk, and 62% from 100 g of ice cream.

A problem encountered with such filtration-centrifugation and gradient-centrifugation procedures is that not only the protozoa, but also other types of particles, are concentrated. In addition to decreasing extraction efficiency, the presence of such food components could be inhibitory to IFA and PCR-based procedures, so additional treatment may be necessary to improve the ultimate detection efficiency.

Laberge and coworkers (92) developed a PCR assay for the detection of *C. parvum* oocysts from raw milk. The raw milk samples were treated with trypsin and Triton X-100 at 50 °C, to remove milk proteins and other inhibitory substances before the samples were processed by simple centrifugation and examined by PCR. This treatment enabled the detection of 1 to 10 oocysts in 20 ml of experimentally contaminated raw milk.

An alternative to get rid of inhibitory food components is to use specific IMS. Deng and Cliver (93) compared efficiencies of different methods for extraction and detection of *C. parvum* oocysts from apple juice. When an IMS step was added following Sheather's sucrose flotation, higher detection efficiencies were consistently attained. In a similar study, PCR following IMS was able to detect 10 oocysts in 100 ml of apple juice or low fat milk (94). In such a procedure, the preconcentrated (by simple centrifugation or gradient centrifugation) sample reacts with *C. parvum*-specific antibody and is then incubated with paramagnetic beads coated with a secondary antibody against the *C. parvum*-specific antibody. The magnetic beads-oocyst complex is then separated from other food components by means of a magnetic field.

Extraction from Produce

Vegetables, including cabbage, tomato, lettuce, cucumber, carrot, and radish, can play an important role in the spread of *Cryptosporidium*, *Giardia*, *Cyclospora*, and *Entamoeba*. Fruits, especially raspberries and blackberries, have been associated with a number of outbreaks of cyclosporiasis. In nonindustrialized countries, the use of excreta as fertilizer is a common cause of contamination in the field. In addition, water used for irrigation, from rivers that receive industrial, domestic, and agricultural wastewater — especially during the rainy season — could be highly contaminated. Salad mix could also be contaminated when prepared by an infected food handler.

Methods for extraction of protozoa from produce are relatively simplistic. Protozoa are usually recovered by the rinse solution method (95). This involves dislodging (oo)cysts from the surfaces of the vegetables or the fruits by washing with a detergent-containing saline solution and sedimentation or centrifugation of the organisms from the cleaning water. The concentrate can then be used for conventional staining, IFA, or PCR-based assays. Such methods have been used in a few surveys on risk of protozoa-contaminated vegetables (96–99). In the U.S. Food and Drug Administration procedure (97), a 1-kg portion of fruit or vegetable is divided into 200-g subportions and sonicated for 10 min in a sonic cleaning bath with 1.5 l of detergent solution containing 1% sodium dodecylsulfate and 0.1% Tween 80. The sample is then thoroughly drained and the wash water is collected and centrifuged for 15 minutes at $1,500 \times g$. When the sediment contains a larger quantity of extraneous matter, it is further concentrated by layering over Sheather's fluid and centrifuged for 15 minutes at $1,500 \times g$.

While the extraction procedure is fairly straightforward, unsatisfactory efficiencies have been reported. This problem is mainly associated with the inability to wash (oo)cysts off produce surfaces, as they appear to stick to the surface, especially on rough fruit and leaf surfaces. Another reason for the lack of efficiency is that only a small percentage of the crop or batch can be sampled. To overcome these, methods capable of efficiently dislodging protozoa from food-contact surfaces without dislodging food solids are required. Alternatively, it may be appropriate to sample irrigation waters or to develop a large batch-rinse technique and sample the rinse water (99).

Extraction from Solid Foods

For *Cryptosporidium*, *Giardia*, *Cyclospora*, *Entamoeba*, and not for *Toxoplasma*, contaminated foods are usually ready-to-eat foods contaminated by the hands of a food worker. When the contaminating pathogen resides on the surface of food, the key point is to dislodge the organism from the food surface without disturbing the food material; one might try shaking the food and diluent in a plastic bag, or use a Pulsifier®. Under other conditions where the whole sample has to be tested, the sample is usually homogenized and can be processed similarly to oocyst extraction from fecal and soil samples. If suspended food solids and other materials may interfere with large volume collection and the detection process based on microscopic examination, IFA, and PCR, IMS could be applied. It should be pointed out that because an antibody is not yet available for *Cyclospora*, IMS does not yet have an application with this agent.

In the case of *Toxoplasma*, recent epidemiological studies have associated acute toxoplasmosis in pregnancy with ingestion of both raw meats and ready-to-eat cured meat (100). Detection of tissue cysts in these foods would probably proceed approximately as in histopathology.

Entamoeba histolytica cysts can be recovered from contaminated food by methods similar to those used for recovering *Giardia* cysts and *Cryptosporidium* oocysts from feces. Filtration is probably the most practical method for recovering cysts from liquid foods, while flotation and sedimentation could be used to recover cysts from solid foods. It is important to differentiate *E. histolytica* cysts from cysts of other, nonpathogenic amoebae (101).

VIABILITY (INFECTIVITY) CRITERIA IN TESTING

Viruses and protozoa in the environment and foods may be inactivated by a number of agents, including heat, UV

irradiation, chemical action, or other biological factors. Therefore, when detecting viruses and protozoa from a food sample, it is important to consider the viability of the virus particles and (oo)cysts and hence their infectivity to humans. This should also be taken into consideration while new methods and procedures are developed for detection of viral and parasitic pathogens from foods.

Viruses

Traditionally, viruses have been detected by their effects on cells. The cell culture propagation procedure, namely *plaque assays* and *cytopathogenicity assays*, can be used to enumerate viable polioviruses, adenovirus, and to a lesser extent, rotaviruses. However, they are ineffective for the detection of hepatitis A virus (HAV), Norwalk virus, and other SRSVs. Only few laboratory-adapted HAV strains can effectively propagate in cell lines and cause cytopathic effects (CPEs), so as to permit quantitative assay. Wild-type HAV strains usually do not grow well in cell culture or require long incubation periods (many days or even weeks). In addition, most HAV strains do not cause CPE, so a plaque assay is unavailable. There is at least a possibility that HAV, and perhaps other food-borne viruses, do replicate silently in cell cultures. If this is so, detection of viral products, such as replicative intermediate forms of RNA or viral coat protein, in the cells may serve as an infectivity-dependent criterion of detection. There has been little or no success in developing cell or tissue culture systems capable of supporting the growth of Norwalk and related SRSVs. Cell culture propagation assays are readily available for poliovirus, and it has been suggested that vaccine strains of poliovirus may serve as indicators of the presence of other pathogenic viruses for which assay procedures are unavailable.

One major limitation of molecular-based methods in virus detection is that they cannot differentiate infectious from noninfectious viral particles. During inactivation, their capsid proteins that protect the genomic structure could be damaged. While such viruses are not infectious due to the loss of functions in host recognition and cell invasion, their RNA may remain intact for an extended period and may be amplified by RT-PCR. For example, rotavirus lost its infectivity after being exposed to ethanol, but its RNA could be amplified by RT-PCR (102). Similarly, heat and detergents can effectively destroy the infectivity of poliovirus without any significant effect on its detection by RT-PCR (103). In another study, HAV maintained in sterile artificial seawater was amplified by RT-PCR for 232 days, even though it was infectious in cell culture for only 35 days (104). Heat-inactivated HAV is also readily detected by RT-PCR — heating HAV at 99 °C for 5 minutes, which inactivates the virus, is a routine means of freeing its RNA for RT-PCR (57).

To overcome this, a few methods combining RT-PCR and antigen capture (AC) of virus particles have been developed, especially via the use of magnetic beads coated with antibodies (56–60,105,106). Because such methods detect the presence of viral genomes that are packed in capsid viral proteins, and not just the presence of proteins or of nucleic acids, they are more informative and provide a better correlation with viral infectivity than detection methods based on RT-PCR or antigen capture alone. Alternatively, some noncytopathic human enteric viruses could be detected via direct in vitro amplification of their nucleic acids (77). However, it is to be noted that such methods are unable to differentiate infectious viral particles from noninfectious ones with unchanged antigenicity and intact genome.

Protozoa

In the cases of protozoa, the morphology of parasites, surface antigen, or nucleic acids could be preserved even though (oo)cysts are inactivated. Therefore, traditional light microscopy, IFA, or PCR cannot distinguish between viable and nonviable (oo)cysts. However, unlike viruses, viability of protozoa could be assessed in vitro by different means, including in vitro excystation, vital dye staining, tissue culture assay, and RT-PCR to detect messenger RNAs that are present only in viable cells.

Giardia. Usually, the viability of *Giardia* cysts is determined in vitro by excystation and by fluorescein diacetate (FDA) and propidium iodide (PI) staining. In the excystation method, viable cysts can excyst to produce trophozoites that are morphologically distinct and can be propagated in artificial medium. In the FDA/PI staining procedure, nonviable cysts will be stained fluorescent red because PI cannot penetrate the compact membrane of a viable cell. FDA, on the other hand, is a much smaller molecule that can pass through the cell membrane freely and, only in viable cells, is metabolized from nonfluorescent to another form with green fluorescence. Both methods are indicative of cyst infectivity in animals (107). As the in vitro excystation is not included in routine detection procedures due to the rather complicated excystation induction treatment, Dowd and Pillai (108) developed a viability test in conjunction with indirect fluorescent antibody staining in which a *Giardia*-specific antibody is used for organism identification while PI is included as a viability indicator.

Mahbubani and coworkers (109) proposed a RT-PCR procedure to discriminate live and dead cysts by measuring the giardin mRNA level before and after the induction of excystation. Abbaszadegan and coworkers (110) developed a method to amplify mRNA of heat-shock protein after heat shock. A similar procedure was developed for the detection of viable *Giardia* cysts from water samples (111) and it may be used for food samples as well.

Cryptosporidium. Similar to *Giardia* cysts, the viability of *Cryptosporidium* oocysts can be assessed by in vitro excystation and by vital dye staining (112). Despite the fact that both methods, when compared to animal infectivity assay, overestimate oocyst viability, they have been widely used in investigating oocyst survival under environmental conditions and inactivation by different modes (113,114). They have also been included in various detection procedures.

The method developed by Dowd and Pillai (108) is also useful for *Cryptosporidium* detection, in which a *Cryptosporidium*-specific antibody is used for organism

identification and PI serves as a viability indicator. The Environmental Protection Agency method (EPA method 1663, 1999) combines DAPI/PI staining with direct fluorescent antibody staining so that oocyst viability could be more accurately determined.

A number of PCR-based methods capable of differentiating live from dead oocysts have been developed; all of them include an excystation treatment step. Filkorn and coworkers (115) combined a DNA digestion step and an oocyst excystation protocol prior to PCR. Because digestion with DNase I eliminated free DNA released from disintegrated oocysts and sporozoites, after excystation only the DNA from intact viable oocysts was available for amplification. Wagner-Wiening and Kimmig (116) developed a similar procedure in which an excystation protocol was applied before DNA extraction so that only DNA of sporozoites released from viable oocysts was amplified. In an IC-PCR procedure developed by Deng and coworkers (54), a simple heat-treatment was used to extract DNA from sporozoites and partially excysted oocysts following excystation treatment.

In addition to excystation-PCR-based methods, an RT-PCR procedure was developed to detect the mRNA heat-shock protein (111). Recently, it was suggested that mRNA of betatubulin could be a marker of oocyst viability (117).

Progress in in vitro cultivation of *Cryptosporidium* made it possible to detect oocysts based on their ability to cause cell infection. Owing to sensitivity considerations, such methods are currently integrated with PCR (118,119). Because the ability of oocyst to cause infection in a cell line more precisely indicates oocyst infectivity to humans, such methods are more informative than methods using excystation or membrane permeability as a viability criterion.

Cyclospora, Toxoplasma, and Entamoeba. Because cyclosporiasis is often (or strictly) associated with consumption of produce, whenever oocysts are detected from such a food item it provides sufficient information on the possibility of that particular food item as a vehicle of *Cyclospora*. However, sporulation and excystation can be used for viability determination. There are now a few PCR procedures available for detection of oocysts, so methodologies similar to those being employed for *Giardia* and *Cryptosporidium* could be useful.

For *Toxoplasma*, tissue cysts in raw meat should always be viable. For oocysts from contaminated water, an aeration procedure (so that oocysts will sporulate) followed by inoculation of sporulated oocysts into 25 to 30 g mice and examination of mouse tissue sections has been described. Another approach to detect cysts from raw meat or milk entails feeding it to a cat and looking for oocyst shedding.

INTERPRETATION OF RESULTS

It seems clear that both the procedures for processing food samples described here and the detection methods for viruses and protozoa that are described in other sections are complex and demanding. Further, none of the procedures has really been standardized, in the sense of having undergone interlaboratory comparative testing and receiving a sanction by some professional organization. Government agencies and many nongovernment laboratories have devoted a great deal of effort to developing more sensitive methods for detecting food-borne viruses and protozoa. As it is still difficult to obtain samples for testing, most of the experiments have been performed with experimentally contaminated foods.

A well organized laboratory that uses a full set of positive and negative controls can give credence to any positive test result, except that the agent detected may not have been infectious when the sample was collected (unless special criteria are applied). However, negative results probably prove little — either because the sample processing and testing methods were inadequate or because the sample tested was not representative of the entire lot of food, only some of which was contaminated. Diagnostic testing of ill persons and epidemiological investigation techniques seem likely to be critical for years to come.

Meanwhile, there is an abiding effort to identify indicators or surrogates for viral (or even protozoal) pathogens, other than bacterial indicators of fecal contamination. Indicators, found in a field sample, should convey a high probability that human enteric virus is also present. Surrogates would be used to evaluate unit processes that were supposed to eliminate viral contaminants from food. Bacteriophages are undergoing testing in these roles; although none has yet proven either an optimum indicator or surrogate, they are certainly the brightest hope in sight. Unfortunately, indicators of protozoal contamination are not in prospect; surrogates, such as *Cryptosporidium* species that do not infect humans, are a possibility if there were specific antiprotozoal processes to be evaluated.

CONCLUSION

This section has addressed processing of food samples, other than shellfish, for recovery of viruses or protozoa that would be detected by methods described in other sections. The most likely application of such methods would be in investigation of outbreaks that had been identified on the basis of diagnoses of the same illness in several human patients. Given the long incubation periods of some of these illnesses, representative food samples might well not be available for testing by the time the outbreak was recognized. The methods surveyed include steps to separate the pathogen from the food into a fluid suspension, remove food solids and other substances that might interfere with detection, and reduce the volume of the sample to what the detection method can accommodate. Ideally, the overall sensitivity of the test should allow detection of one peroral, human infectious dose or less per serving of food.

Recovery methods might also be applied in validating food processes that were designed to inactivate viruses or protozoa, using the pathogens themselves or carefully

selected surrogates. Most studies by which the methods described were developed entailed testing of experimentally contaminated foods, which means that little has been learned of the location or distribution of the pathogens in accidentally contaminated foods. Given the sporadic, infrequent incidence of these pathogens in foods, this situation is unlikely to change in the near future.

Tempe, Arizona

VIRUSES

Viruses are the smallest and most basic of known life-forms. They consist only of nucleic acid and a protein shell (or capsid), with no reproductive machinery. Their simple genetic system consists of either single-stranded or double-stranded DNA or RNA. Because of their inability to autonomously reproduce, they must take over a living cell and use the cell's reproductive mechanism in order to replicate and continue their parasitic life. After replication, and the subsequent death of the host cell, viral particles are spread to neighboring cells, resulting in the infection of the individual.

VIRUSES IN THE ENVIRONMENT

Viruses that replicate in animal cells and are subsequently shed from the gastrointestinal tract are known as enteric viruses. More than 140 different enteric viruses are known to infect humans, which are principally transmitted by the fecal-oral route. Enteric viruses are excreted in the feces of infected individuals and may directly or indirectly contaminate water intended for drinking. These viruses are excreted in high numbers per gram of feces of infected individuals and are commonly isolated in domestic wastewater, even after disinfection. Once in the environment they can survive for long periods of time, even months under the right conditions. The following groups of viruses have been identified as sources of waterborne disease outbreaks or that have the potential to cause outbreaks; enteroviruses, rotaviruses, Hepatitis A & E viruses, caliciviruses, adenoviruses, astroviruses, reoviruses, and others. These viruses infect the gastrointestinal and/or respiratory tracts and are capable of causing a wide range of illness including diarrhea, fever, hepatitis, paralysis, meningitis, and heart disease. Despite causing a variety of illness in human, many of viral infections are remarkably asymptomatic (with no clinical symptoms). However, viral multiplication in an infected individual occurs, and virus particles are shed in the environment.

Groundwater of the United States may be subjected to fecal contamination from a variety of sources, including sewage treatment plant effluents, on-site septic waste treatment discharges, land runoff from urban, agricultural, and natural areas, and leachates from sanitary landfills. Under proper conditions, viruses have been observed to travel more than 100 meters through the subsurface (1). Because of their smaller size, viruses (23 to 80 nm) are transported further in groundwater than bacteria (0.5 to 3 μm) or protozoan parasites (4 to 15 μm). Thus, the occurrence of viruses in groundwater in the absence of coliforms may not be surprising. Information on the occurrence of viruses in groundwater is largely limited to studies in which land application of domestic wastewater has been practiced (2), outbreak investigations (3), or when viruses have been purposely added (1). Surveys on viruses in groundwater have been limited because of the need to concentrate large volumes and the expense of using animal cell culture. However, the development of molecular based methods for virus detection in groundwater allows for application of less expensive methods to detect a wide range of viral contamination (4,5).

Evidence for a possible route of fecal contamination of surface and groundwater is provided by the detection of enteric viruses in either surface or groundwater, and the continued occurrence of viral waterborne disease. During early 1970s, there have been several outbreaks of viral gastroenteritis. In Michigan, restaurant patrons who drank unchlorinated well water became ill within 30 hours (45). Poliovirus 2 was recovered when 2.5 gallons of water were concentrated by ultra centrifugation. In a migrant labor camp in Dade County, Florida Hepatitis A outbreak was reported during March 1975. Water samples from that camp yielded hepatitis A, echovirus, and poliovirus. Mosley (1967) summarized 50 Hepatitis A outbreaks attributed to contaminate drinking water. Craun and coworkers (1976) reported 13 outbreaks of waterborne Hepatitis A that affected 351 people during 1971 to 1974. The Environmental Protection Agency (EPA) and Centers for Disease Control (CDC) have maintained a database of disease outbreaks in the United States since 1971 (6). The database is formulated on the responses to a voluntary reporting by state and local public health officials, but a large number of waterborne outbreaks may not be recognized or reported (7). Between 1971 and 1994, 650 drinking waterborne outbreaks of disease and 569,754 cases of illness were reported in the United States, with 58% of these outbreaks associated with groundwater sources and 33% associated with surface water sources (6). Eight percentage of all reported outbreaks (6) were due to enteric viruses (hepatitis A virus, Norwalk virus, and rotaviruses). It is suspected that many waterborne disease outbreaks for which no etiological agent was identified (about 47% of all reported outbreaks) may be caused by viruses because of the limitations of current detection

methodology and the failure to collect and analyze clinical specimens for viruses. Analysis showed that viruses caused 10% of the groundwater outbreaks, whereas 4% of the surface water outbreaks were viral (8).

Examination of waterborne outbreak data for public groundwater systems (community and noncommunity) for 1971 to 1994 showed that three types of source water contamination were involved: untreated water, disinfected water, and filtered systems (Table 1). Eighty-one percent of these 356 groundwater outbreaks were related to source contamination with 45% attributed to untreated water and 35% to improperly disinfected water. Community systems using groundwater experienced 113 outbreaks (Table 2), whereas noncommunity systems using groundwater experienced 243 outbreaks (Table 3). Thirty-one and sixty-two percentage of outbreaks in community systems were traced to distribution system and source water contamination, respectively. The vast majority (89%) of outbreaks in noncommunity systems were associated with source water contamination (7% were related to the distribution system). Among recognized causes of groundwater viral outbreaks in public water systems during 1971 to 1994, hepatitis A virus was associated with 8 community, and 9 noncommunity systems; whereas Norwalk virus was identified as the etiologic agent in 4 community, and 12 noncommunity outbreaks (8).

Table 1. Cases of Waterborne Disease Outbreaks, Public Water Systems Using Water Sources, 1971 to 1994

Type of Contamination	Total Number of Outbreaks	Percentage of Total
Source contamination	287	81%
Untreated groundwater	158	45%
Disinfected groundwater	126	35%
Filtered groundwater	3	1%
Distribution system contamination	50	14%
Inadequate control of chemical feed	8	2%
Miscellaneous, unknown cause	11	3%
Total	356	100%

Source: Tables 1 to 3 compiled by Gunter Craun and Rebecca Calderon, EPA,RTP,NC.

ENTERIC VIRUSES IN WATER

The enteroviruses (poliovirus, Coxsackie A and B viruses, echovirus) can cause a variety of illnesses ranging from gastroenteritis to myocarditis and aseptic meningitis (9). Many studies have documented the presence of enteroviruses in both raw and (occasionally) treated drinking water (1,10), wastewater (11) and sludge (12). Enteroviruses in the environment pose a public health risk because these viruses can be transmitted via the fecal-oral route through contaminated water (12), and low numbers can initiate an infection in humans.

Table 2. Cases of Waterborne Disease Outbreaks in Community Water Systems Using GroundWater Sources, 1971 to 1994

Type of Contamination	Outbreaks in Community Systems	Percentage of Total
Source contamination	70	62%
Untreated groundwater	31	27%
Disinfected groundwater	36	32%
Filtered groundwater	3	3%
Distribution system contamination	35	31%
Inadequate control of chemical feed	5	4%
Miscellaneous, unknown cause	3	3%
Total	113	100%

Table 3. Cases of Waterborne Disease Outbreaks in Noncommunity Water Systems Using Groundwater Sources, 1971 to 1994

Type of Contamination	Outbreaks in Noncommunity Systems	Percentage of Total
Source contamination	217	89%
Untreated groundwater	127	52%
Disinfected groundwater	90	37%
Filtered groundwater	0	0%
Distribution system contamination	15	7%
Inadequate control of chemical feed	3	1%
Miscellaneous, unknown cause	8	3%
Total	243	100%

Note: The source water could not be identified for 21 community and 6 noncommunity systems experiencing outbreaks; therefore, these systems are not included in Tables 1 to 3.

Rotaviruses are the leading cause of acute infantile gastroenteritis and diarrhea-related infantile death (13). The virus has also been associated with diarrhea outbreaks among the elderly and among immunocompromised patients (14). Rotavirus group A has been documented as a cause of waterborne outbreaks in humans (15). The virus has been isolated from humans, monkeys, cattle, sheep, mice, cats, dogs, other mammals, and from chickens and turkeys. The organism has been detected in fresh water and sewage (16). Although the various strains of rotavirus are usually associated with a specific species, reports have documented infections through interspecies transmission of the virus; including a human infection by a bovine strain of rotavirus (17). Additionally, recent work has shown that an isolated rotavirus surface protein, alone, can produce diarrhea in mice (14). Rotavirus infections (from all sources) are responsible for an estimated 3.5 million cases of diarrhea and 20 deaths in infants and young children in the United States every year (18). There are an estimated 500,000 physician visits and 50,000 hospitalizations yearly related to rotavirus from all source of transmission including water and food. In addition, rotavirus accounts for 30 to 50% of hospitalizations in the United States for diarrhea in children younger than five years (19).

Hepatitis A virus (HAV) is an important waterborne virus because of the severity of the disease it may cause in susceptible individuals. HAV is the cause of acute infectious hepatitis and was the first enteric virus identified as associated with a waterborne disease outbreak in the United States (20). The virus was shown to survive more than four months at both 5 °C and at 25 °C in water, wastewater, and sediments (20). Hepatitis A is a major cause of acute gastroenteritis, and its symptoms may be the most serious of those caused by the enteric viruses. In one survey, hepatitis virus was identified as the causative agent in more than 20% (68 of 322 outbreaks) of waterborne disease outbreaks in the United States from 1946 through 1980, for which a causative agent was identified (21).

The calciviruses and the Small Round Structured Virus (SRSV) groups have been implicated or suspected in several outbreaks of acute diarrheal illness. These groups are composed of members such as Norwalk virus, Snow Mountain agent, Hawaii, Taunton, Parramatta, and other viruses that are as yet unnamed (22). Shared morphological and genomic characteristics of several of these viruses, including: possession of a single-stranded RNA genome, a single protein capsid, and shared genome organizational similarities, have led to calling these viruses the Norwalk Group of viruses, with the Norwalk virus as its most typical member.

ENVIRONMENTAL WATER SAMPLING PROGRAM

Sampling program and strategies are the heart of any successful environmental microbial monitoring, which include site selection criteria, environmental sampling method, sample size, frequency of sampling and the microbial detection methodologies. A properly designed monitoring program helps in understanding the source water vulnerability and variability to microbial pathogens. The source characterization also assists water suppliers and regulators to implement strategies to better protect public health from waterborne pathogen outbreaks.

Site Selection

For the virus occurrence in groundwater sources, a proper sample collection plan is of paramount importance, which aims at gathering groundwater samples from different geographic locations and with a variety of physical and chemical characteristics.

Initially, groundwater sources can be selected at random from sites volunteered by water utilities personnel agreeing to participate in the project. Sites known to be either under the influence of surface water, which has no well log records available, or considered to be poorly constructed should be excluded. In addition, sites can be selected on the basis of their geologic characteristics to match the actual national profile for groundwater sources. The objective of such selection criteria is to ensure that the samples closely represent the various geologic formations throughout the sites used for groundwater production.

Sampling Kit

To provide consistent sampling procedures, identical sample kits should be assembled. Each kit should contain all equipment needed to collect a sample, including all hoses and connectors, a filter and a filter housing, protective gloves, reusable ice packs, sample bottles, a sample data sheet, and a detailed written protocol. The kits also need to include a flowmeter and an in-line flow-restricting device to limit the filtration rate to 4 gallons per minute. A typical sample kit is illustrated in Figure 1. In addition, to ensure a consistent water-sampling procedure a short VHS video can be professionally produced illustrating all of the details of the procedure.

Figure 1. Sampling kit. Filter Housing containing a 1MDS filter; a hose with a brass quick-connect, a backflow prevention valve and a flow restrictor; two additional hoses with a quick-connect tap connection; a brass quick-connect tap connection; pH meter; thermometer; water meter; three ice packs; two one-liter presterilized bottles; surgical gloves; sample data sheet; sample collection protocol; aluminum foil sheets; return address label with shipping instructions; and training video.

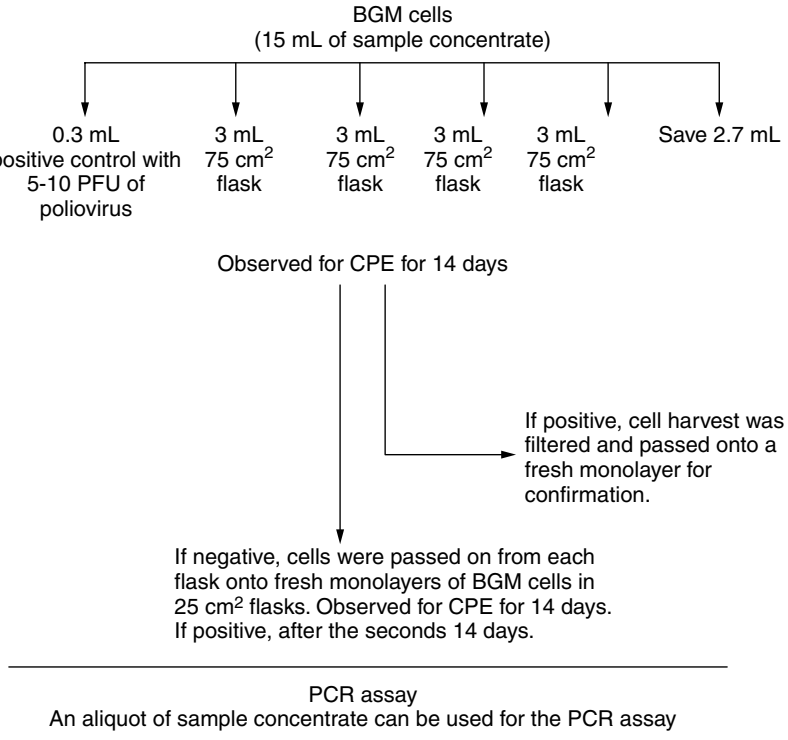

Figure 2. Cell culture assay protocol.

CONVENTIONAL CELL CULTURE ASSAY

Conventional methodology for the detection of enteric viruses from the environment relies on a few established cell lines. The Buffalo Green Monkey (BGM) kidney cell line is the most commonly used for the detection of enteroviruses in the environment (23). This cell is preferred over others, including primary cells, because it provides high sensitivity to natural isolates of enteroviruses (24). Its sensitivity can be further enhanced by pretreatment of the cells with enzymes or other substances (25). Unfortunately, the use of other cell lines is required to detect other groups of enteric viruses (26). This can greatly increase the cost and time of the sample analysis. Although the cell culture assay can detect infectious viruses in environmental samples, without additional tests, no determination can be made as to the particular strain of virus present in the sample. Additionally, the length of time needed to detect infection in the cell culture can vary greatly, from a few days to several weeks, depending on the type and number of viruses present. Figure 2 summarizes a cell culture assay protocol. Figure 3 shows an uninfected and infected BGM cell monolayers.

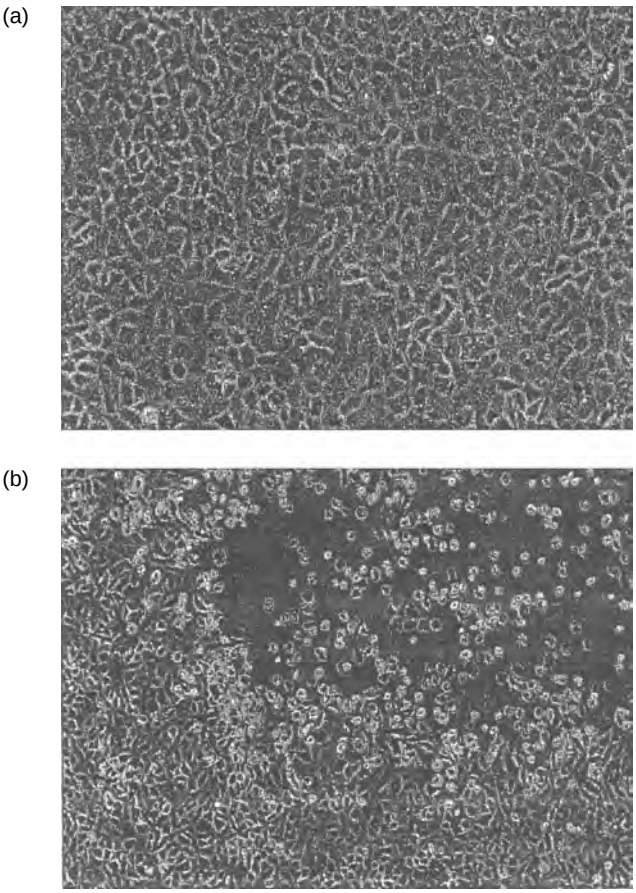

Figure 3. The figures show uninfected BGM cell culture monolayer (**a**) and an infected BGM cell monolayer exhibiting cytopathogenic effect (CPE) (**b**).

THE POLYMERASE CHAIN REACTION TECHNIQUE

Since its invention, PCR has become one of the most widely used biochemical assays. The speed, specificity, and low cost of the procedure has led to its use in fields such as criminal and pathological forensics, genetic mapping, disease diagnosis, systematics and evolutionary studies, and environmental science.

PCR can be used to amplify, to detectable levels, nucleic acids associated with low levels of pathogens in water

samples. PCR assays must be able to detect viruses after concentration from large volumes (100 to 1,500 L) of water (27). This is usually accomplished by a filter-adsorption and elution method, resulting in a concentrate containing viruses, and organic and dissolved solids. Compounds, such as humic substances, once concentrated, can interfere with the activity of the enzymes used in PCR assay.

PCR is a process in which target DNA, polymerase enzyme, and the DNA subunits are combined in a test tube and subjected to the temperature changes needed for the DNA duplication to occur. By repeating this process many times, a large amount of DNA is generated. This reaction, termed the Polymerase Chain Reaction (28,29), or PCR, can, under ideal conditions, generate millions of copies of a single DNA molecule in just 20 to 30 repetitions of the temperature cycle — each cycle requiring only a few minutes. The PCR assay, however, selectively amplifies only a portion of the target DNA for diagnostic applications. For analysis of RNA viruses in water, an enzyme called a reverse transcriptase is used to first translate the RNA to DNA. Then DNA can then be processed using the PCR technique. The combined reverse transcriptase and PCR assay is abbreviated RT-PCR.

The advantages of PCR are numerous. When compared with techniques such as cell culture for the detection of viruses, the time required for the assay can be reduced from days or weeks to just a few hours. Both the initial and recurring costs for PCR analysis are much less than cell culture techniques, and the technique is easily performed. Additionally, PCR can be used to identify a specific pathogen found in water. Standard PCR, however, cannot be used to detect the infectious state of an organism — only the presence or absence of pathogen-specific DNA or RNA.

Comparison of Virus Assays Methodologies

Both the cell culture assay and the RT-PCR assay attempt to detect viruses in the sample. However, they are not directly comparable. The cell culture assay can only detect infectious viruses, whereas the RT-PCR assay can potentially detect both infectious and noninfectious viruses. Additionally, the RT-PCR assay is designed to detect specific viruses, on the basis of their RNA sequence. Conversely, the cell culture assay can potentially detect any infectious virus capable of causing infection in the cultured cells. For instance, BGM cells used in the cell culture assay could possibly show infection from mainly enteroviruses and possibly rotaviruses or other viruses, whereas the RT-PCR assay does not result in this kind of ambiguity. Additionally, each assay differs in level of sensitivity and the effect of inhibitory or toxic substances in the sample and the equivalent sample volume examined.

The use of cell culture and PCR for virus detection differs significantly in several ways. For cell culture, the minimum detection level of viruses in a sample is, by definition, one PFU per unit volume — a quantity of virus particles that may range from just a few or many more — at least some of which must be infectious. In addition, when a sample tests positive for viral infectivity using cell culture, the infectious agent is not necessarily known. The BGM cell line, routinely used for enterovirus assays, is susceptible to infection by many viruses, including reoviruses such as rotavirus, a pathogen often present in environmental samples in numbers greater than enterovirus (30). Cell culture protocols do not detect all human viruses present in the environment. Norwalk virus, for instance, has yet to be successfully grown in cell cultures, and therefore environmental samples cannot be assayed for this pathogen. Finally, because each environmental sample is unique, little is known regarding possible sample components that may inhibit the viral infectivity in culture. Cell culture, however, does offer the advantages of isolating an infectious viral pathogen, and is widely accepted as the standard method for viral detection in water.

Conversely, RT-PCR is potentially a much more sensitive assay, in that it is possible to detect as little as a single molecule of RNA. The technique can detect less than one PFU of a virus (because some virus particles may not be infectious), and PCR can detect both infectious and noninfectious viruses. The two techniques also differ in the amount of time and cost required. Most cell culture protocols (including the procedure used in the Information Collection Rule) call for a 14-day initial passage and for a 14-day secondary passage of the sample on cells, followed by a seven-day confirmation passage of putative positive samples. To test for different viruses, multiple cell lines must be used.

Given its increased sensitivity and ability to detect an intact virus particle (5), PCR analysis would be expected to reveal more positive results than cell culture analysis. Because either cell culture analysis or PCR can only reveal a "snapshot" of the quality of the groundwater being sampled, PCR would be a desirable rapid initial screening tool, in that the presence of noninfectious or nonintact viruses would suggest that a groundwater supply may be subject to contamination and thus the potential for health risk. The most sensitive method of detection would be the most desirable, even without the ability to confirm infectivity of the sample contamination.

Although the RT-PCR and cell culture methods assayed different equivalent volumes of the original sample (5 liters versus 600 liters respectively), the difference in the assays' sensitivities must be considered while comparing the test results to understand the practical application for water analysis. The minimum detection level of viruses using a cell culture assay is one plaque forming unit (PFU) per tested sample volume. Because hundreds of virus particles may be required to produce a single PFU, assay methods such as PCR that detect virus particles directly will result in significantly greater sensitivity. The minimum detection limit of viruses using RT-PCR is one virus particle, and it has been shown that PCR can consistently detect 10^{-2} PFU of virus (4). Because the RT-PCR assay is approximately 100 times more sensitive, assaying 100 times less sample by RT-PCR approximately equates to the volume assayed by cell culture.

A Case Study

Groundwater samples collected from 448 sites throughout the United States (Fig. 4). Out of 448 sites, 25 sites were sampled more than once (average of three to four times).

Figure 4. Location of wells sampled are indicated in blue (shaded).

A total of 539 samples were collected for the study. Each sample was assayed for virus infectivity using cell culture assay, the presence of viral nucleic acid using RT-PCR, bacteriophage using three hosts, total coliforms, enterococci, *Clostridium perfringens*, total organic carbon, various metals and minerals.

Virus Cell Culture Assays

Twenty-one sites (4.8% of 442) and a total of 22 samples (4.1% of 529), tested positive for viral infectivity by exhibiting cytopathic effect (CPE) in Buffalo green monkey (BGM) kidney cells.

Virus RT-PCR Assays

Sample concentrates were assayed for viral RNA by the RT-PCR method. Four different pairs of primers, specific for enterovirus, rotavirus, hepatitis A virus, or Norwalk virus were used. Each sample was also assayed twice with each primer pair — once after having been seeded with a positive control virus, and once unseeded. The seeded reactions were performed to determine whether the sample would inhibit the RT-PCR reaction. The sample was deemed inhibitory if no PCR product was found in the seeded reaction. These samples were recorded as "unknown "with respect to the RT-PCR assay results (Table 4).

Comparative Results

Cultural methods used for various microorganisms include cell culture assays for infectious enteroviruses, double layer agar assay for bacteriophage, and membrane filtration for bacterial indicator. All these assays were performed on each sample. Besides, cultural PCR assays were used for the detection of four commonly found enteric viruses in drinking water. The target organisms for this project are indicative of fecal contamination of source

Table 4. Microbial Occurrence Results of Sites Sampled

Microorganisms Tested	N	Positive	Negative	Unknown

Table 5. Comparison Between Total Coliform, Enterococci, and Bacteriophage and RT-PCR Results

	RT-PCR Positive (positive for any* virus)	RT-PCR Negative	RT-PCR Unknown
Total [1]coliform positive	19	25	0
Total coliform negative	120	276	5
[2]Enterococci positive	9	22	0
Enterococci negative	86	236	2
[3]Bacteriophage positive	34	55	3
Bacteriophage negative	105	245	2
[4]Total cultural positive	55	99	3
Total cultural negative	86	203	2

[1]For Coliform a total of 445 sites were compared in this table. Three samples were excluded for which one assay results was undetermined.
[2]For Enterococci a total of 355 sites were compared for in this table. Samples excluded for which one assay result was undetermined.
[3]For Bacteriophage a total of 444 sites were compared in this table. Samples excluded for which one assay results were undetermined.
[4]For total cultural all 448 sites were compared with either one of cell culture, enterococci, total coliform, clostridium, and bacteriophage.
*Enterovirus, Rotavirus, Hepatitis A, and Norwalk.

water. A total of 32.6% samples were positive by all cultural assays and 31% (141/448) were positive by RT-PCR (Table 4).

Virus Assays Compared With Other Potential Indicator Assays

One objective of the study was to evaluate other biological and physical attributes of groundwater as potential indicators of virus presence. Often these assays are simpler to perform and are less expensive and more familiar to water utility personnel. To this end, the relationship between virus assay results and the results of assays for total coliforms, enterococci, and bacteriophage were examined. In addition, total cultural assays (cell culture, bacterial, and bacteriophage assays) were examined with the RT-PCR results (Table 5).

Physical Characteristics

The physical characteristics of each well were gathered through a questionnaire for the study (Fig. 5). Turbidity ranged between 0.0 and 85 NTU, temperature ranged between less than 1 to 35 °C, TOC ranged between 0.123 and 85.37 mg/L, and pH ranged between 4 and 9.6. The cell culture and RT-PCR samples that tested positive were analyzed for the distance to a source of contamination. Septic tanks, sewer lines, and wastewater plants were identified as sources of contamination. The total number of samples tested in categories <150 ft distance, 151 to

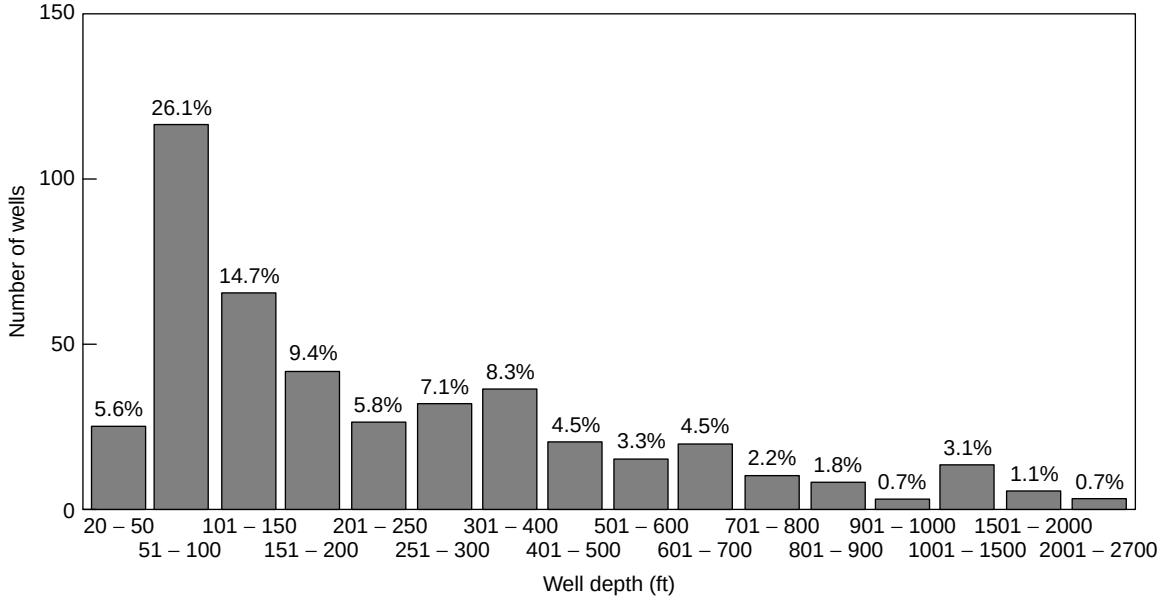

Figure 5. Number of wells sampled at different depths. Note: Over 75% of the wells ranged from 51 to 500 feet in depth.

<550 ft distance, and >550 ft to unknown distance were 147, 154, and 147, respectively. The majority of positive results from all three categories have a sewage source less than 150 feet away (all three in the 41 to 47.6% range) and 80% of sites that tested positive had a sewage source closer than 550 feet.

Analysis of Results by Geologic Formation

Geologic formations are classified into two basic groups; bedrock or unconsolidated. Table 6 categorizes the 448 wells by classification and by subgroups. The positive viral and bacterial assay results within those classifications are summarized in Table 7. The bedrock situated wells

Table 6. Comparison of Samples Collected at each Geology Deposit with the Percentage Production at National Level

Totals	448		21		68		67		92	

% = The percentages refer to the portion of the total for the assay category column. For example, in the column "Cell culture positive," 4 positive samples were from bedrock formations, which represents 19.0% of the 21 positive cell culture assays.
None of the assays — cell culture, RT-PCR, bacterial, or bacteriophage — showed any significant trends when the percentages of positive assays are compared with the percentages of the actual samples within each geologic formation category.

represented a slightly lower percentage of the positive biological assays 25.9% compared with 27.2% of the wells, whereas the unconsolidated sites showed a lower percentage of the total number of positive assays (60.9%) than their percentage of all sites (64.1%). Within the bedrock group, 63 sites were positive, 30 of those sites (47.6%) were from the sedimentary/carbonate group, whereas this subgroup represented only 37.7% (46/122) of the total bedrock geology (Table 7). Within the unconsolidated formation, in which 148 sites were positive, 92 of those sites were the alluvial subgroup representing 62.2% of the positive sites (92/148), whereas for all unconsolidated sites, this formation represented only 62.7% (180/287) (Table 6). This would seem to indicate that these two particular formations — unconsolidated/alluvial and bedrock/sedimentary-carbonate — are more likely to test positive for biological indicators and thus may represent a higher risk of fecal contamination.

Repeat Sampling

A total of 25 sites were sampled more than once with an average frequency of three to four repeats. Thirteen sites were negative for all the assays. The remaining 12 sites tested positive for one or more of the assays. When the results were analyzed considering all the 539 samples (448 sites) to determine a relationship between virus occurrence in groundwater and any of the indicators, no such relationship was observed. However, the twelve sites tested positive for repeat sampling at different occasions were positive for pathogens by cell culture and/or PCR. Only two sites tested positive for pathogens but were negative for indicators. The other ten sites that tested positive for pathogen also tested positive for bacteriophage and/ or bacteria. However, when only repeated sampling positive sites were examined, it was observed that if a site was positive for any of the microorganisms, often there was again a positive site in one of the subsequent samples by one of the assays (Table 8).

Seasonality

Seasonal trends can be seen for some of the viruses tested by PCR. Enteroviruses have seasonal peaks in summer and early fall (31). Rotavirus infections peak from late autumn to early spring and start in the Southwest regions of the country moving to the Northeast states by Spring (13,19,32). Hepatitis A virus infections do not show a seasonal pattern (33). Studies revealed a seasonal trend for the detection of virus, with a higher number of positives being observed in summer months and in the early Fall (Fig. 6). No clear trend was observed for the cultural methods (Fig. 7). Figures 8, 9, and 10 represent the sample temperature trend for PCR positive and cultural assays.

The objective of the analysis was to examine whether there was any relationship between PCR and cultural methods in certain temperature group. The number of samples in each temperature group was not the same. The number of sample in 11 to 15 °C and 16 to 20 °C temperature groups was 232 and 100 respectively, which are higher than all other temperature groups. No direct comparison was made among the temperature groups. However, within all temperature groups a similar trend was observed between the PCR positive hits and cultural methods (cell culture, bacteriophage, and bacteria). At the 11 to 15 °C temperature range, the number of positive samples by PCR was much higher than all other temperature group. This temperature range has the highest number of positive samples by the cultural methods, suggesting that indicator organisms or PCR may be used to predict the presence of human pathogens in groundwater.

As a result of the study, a comprehensive database on virus occurrence in the untreated source water of

public groundwater systems at the United States was established. In addition, various water quality parameters and the occurrence of microbial indicators in groundwater and their possible correlation with the presence of human viruses were investigated. The representativeness of the study for groundwater sites in the United States as a whole was established by the U.S. EPA after conducting a comparative study between this study and national database for nitrate data (34), which is the only comprehensive groundwater database available in the United States. Nitrate data for 216 sites from this study were compared with 216 sites in the U.S. Geological Survey database (35). Analysis of variance statistical tests conducted to compare the mean log nitrate concentrations in this study versus the U.S. GS data indicated that at a 95% confidence level, there was no significant difference (36). The U.S. EPA report concluded that the samples appropriately represented wells in the United States with low nitrate concentration.

PCR Assay Compared with Cell Culture

Analyses using the PCR assays suggest a greater viral contamination (Table 4). It is important to note that PCR assay is indicative of the presence of viral nucleic acid, and not necessarily the infectious viral particle. Therefore, the PCR results should be interpreted as indicative of the possibility of virus transport within the aquifer and a potential risk of disease rather than an absolute public health problem. It is noted that the total of the cultural indicators (coliforms, enterococci, *Clostridium*, bacteriophage) were positive in 32.6% of the samples tested, whereas 31.5% of the total samples were positive for RT-PCR, suggesting that the general overall indication of fecal contamination of groundwater sources did not substantially differ between the molecular technique (PCR) and the cultural indicators.

PCR revealed a greater level of viral contamination than did the cell culture assay, and that could be because of several reasons: (*1*) greater sensitivity of the PCR method for the detection of viruses in water samples, (*2*) not all enteric viruses cause CPE in BGM cell line, so, non-CPE forming viruses were not detected by cell culture assay, (*3*) the ability of PCR to detect a wider variety of viruses than the cell culture method, and (*4*) the possibility of detecting noninfectious viral nucleic acids by PCR.

Repeat Sampling

Male-specific bacteriophages are similar to human enteric viruses (37) in size, shape, survival and transport behavior in the environment. In addition, their removal during coagulation is similar to enteroviruses (38). Correlations between the presence of F-specific RNA bacteriophages and enteric viruses in fresh water have been reported (39). It appeared that very often when a well is positive for any

of the biological assay tested, it is very likely to be positive in future sampling for at least one of the assays. Although no direct correlation among the assays existed, it indicated the vulnerability of the wells to microbial contamination. These results suggest that microbial indicators such as coliforms, enterococci, or bacteriophage may be useful for monitoring those groundwater sources, despite the lack of a 1 : 1 correspondence to viral occurrence.

Seasonality

Seasonal trends were observed for enterovirus and rotavirus tested by PCR. An increased rate of PCR positive results were observed in the summer months and in the early Fall. No clear trend was observed for the cultural methods (Fig. 7). Enteroviruses have seasonal peaks in summer and early fall (31,40). Rotavirus infections peak from late autumn to early spring and start in the Southwest region of the country moving to the Northwest states by spring (13,19,32). A similar pattern was observed for the PCR results. PCR confirms the presence of virus genome regardless of it's status of infectivity. Figures 8 and 9 represent the sample temperature trend for PCR-positive and cultural assays. The temperature grouped data showed a similar trend between PCR and cultural methods (Fig. 10). These patterns suggest the validity of PCR assay as a tool for microbial monitoring.

Although no waterborne outbreaks were documented during the study, the high level of indicators of fecal contamination does suggest a mechanism by which illness could result in members of the community. It has been reported that annually 3 to 6% of community water systems in a six state area exceeded total coliform levels during a four-year period (41). Between 0.3 and 1.3% of the systems contained *Escherichia* or fecal coliform bacteria. However, because the Total Coliform Rule requires samples to be collected from the distribution system, these rates may not reflect the occurrence of bacterial indicators in the source water. Total coliform occurrence rates in private water systems (which are typically not disinfected) ranged between 15 and 59% (41) and are consistent with the findings of the study.

VIRUSES IN FOOD. See VIRUSES AND PROTOZOAN PARASITES IN FOOD, INCLUDING METHODOLOGY

VIRUSES IN THE MARINE ENVIRONMENT

JED FUHRMAN
University of Southern California
Los Angeles, California

Viruses are now known to be integral components of marine biological and biogeochemical systems. They are extremely abundant in both the water column and in sediments, and they play several roles in system function. They are important in the mortality of prokaryotes and eukaryotes, and in the process act as catalysts of nutrient regeneration and recycling. Because of their host specificity and density dependence, they have a tendency to selectively attack the most abundant organisms, thus "killing the winner" of competition and fostering diversity. They also are mediators in the exchange of genetic material between organisms, a critical factor in evolution and also relating to spread of human-engineered genes. Although these processes are only now becoming understood in any detail, there is little doubt that viruses are significant players in marine systems and aquatic environments in general.

Lately, the relatively increased interest in marine viruses can be viewed as part of the recent great expansion of general interest in marine microorganisms. The "microbial loop" as a major part of marine ecosystems became a topic of wide general interest starting about 25 years ago. The discovery of high bacterial abundance as learned by epifluorescence microscopy of stained cells, with counts typically 10^9 per liter in the plankton first prompted attention in this area (1–3). With such high abundance, it became important to learn how fast they were dividing, and this was determined by development and application of methods examining the frequency of dividing bacteria (4) and bacterial DNA synthesis (5,6). These methods showed that bacterial doubling times were on the order of a day, and it quickly became apparent that bacteria were consuming a significant amount of dissolved organic matter, typically at a carbon uptake rate equivalent to about half of the total primary production (7) (see also PROTOZOA IN MARINE AND ESTUARINE WATERS, this Encyclopedia). Given that bacteria are too small to sink out of the water column and that their abundance stays relatively constant over the long term, there must be mechanisms within the water to remove bacteria at rates similar to the bacterial production rate. Originally it was thought that protists were the only "sink" for bacterial production. This followed from the observations that heterotrophic protists of the types known to consume bacteria are ubiquitous in seawater, that they are capable of growth at typical natural bacterial abundance, and they are apparently capable of controlling bacterial abundance near natural levels (7). However, evidence suggested that protists are not the only agents controlling bacteria. In the late 1980s, careful review of several studies showed that the best estimates of grazing by protists often fell short of balancing the best estimates of bacterial production, suggestive of additional loss processes (8). About that same time, data began to accumulate that viruses may also be important as a mechanism of removing bacteria. By now the evidence is fairly clear that this is so, and it will be outlined below. This entry will briefly summarize much of what we know about how viruses interact with marine microorganisms, including general properties, abundance, distribution, infection of bacteria, mortality rate comparisons with protists, biogeochemical effects, effects on species compositions, and roles in genetic transfer and evolution.

WHAT ARE VIRUSES AND WHAT DO THEY DO?

Viruses are small particles, usually about 20 to 200 nm long, and consist of genetic material (DNA or RNA, single or double stranded) surrounded by a protein coat (some have lipid as well). They have no metabolism of their own and function only via the cellular machinery of a host organism. As far as is known, all cellular organisms appear to be susceptible to infection by some kind of virus. From culture studies, it has been learned that a given type of virus usually has a restricted host range, most often a single species or genus, although some viruses infect only certain subspecies and less than 0.5% may infect more than one genus (9). Viruses have no motility, and contact the host cell by passive diffusion. They attach to the cell usually via some normal exposed cellular component, such as a transport protein or flagellum. There are three basic kinds of virus reproduction (Fig. 1): (*1*) lytic infection, in which the virus attaches to a host cell, injects its nucleic acid that causes the host to produce numerous progeny viruses, and then bursts the cell to

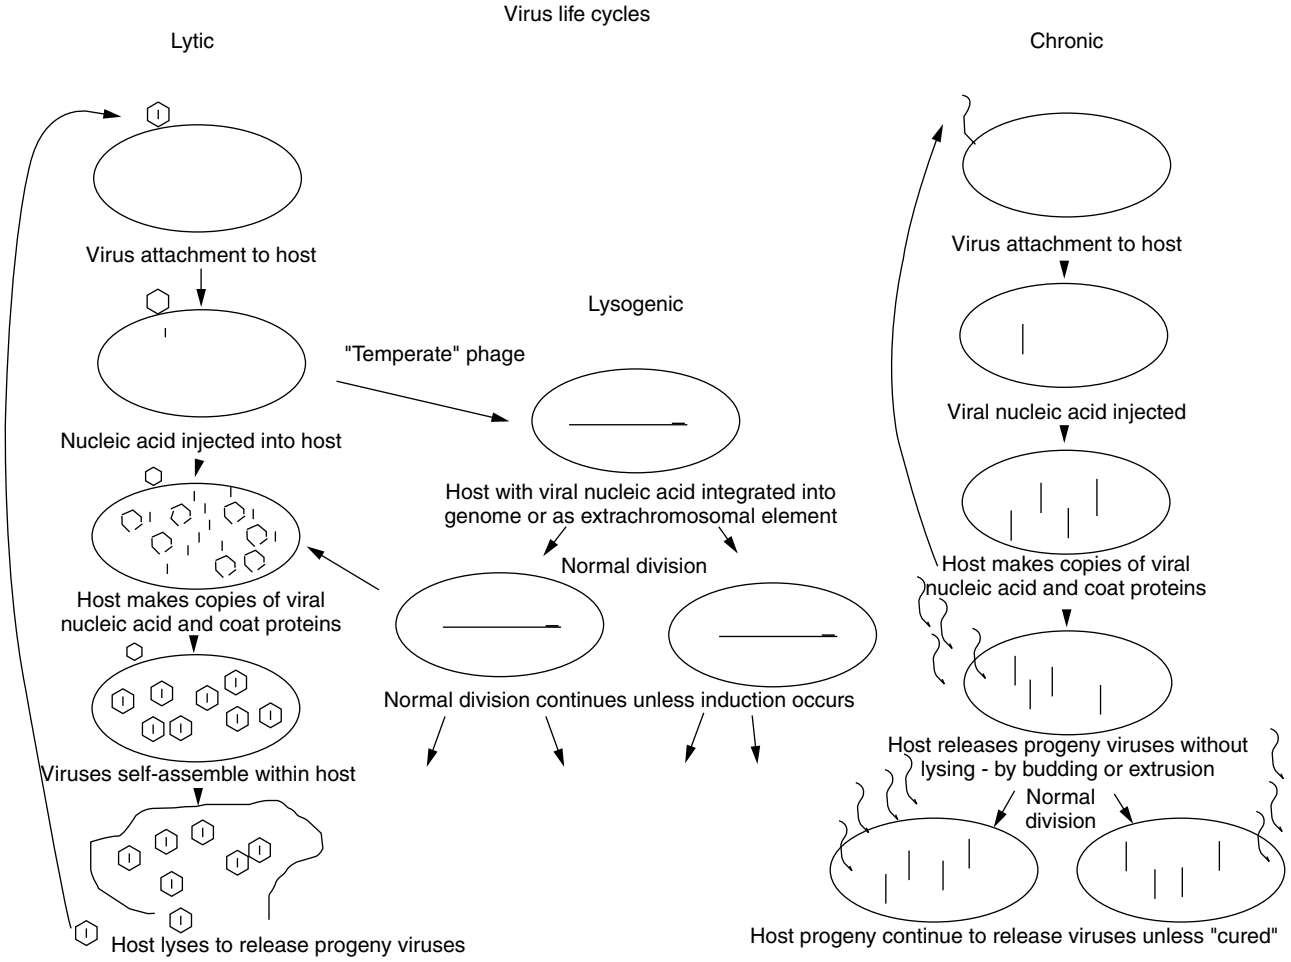

Figure 1. Virus life cycles.

release the progeny and begin the cycle again; (*2*) chronic infection, in which the progeny virus release is nonlethal and the host cell releases them by extrusion or budding over several generations; and (*3*) lysogeny, in which after injection, the viral genome becomes part of the genome of the host cell and reproduces as genetic material in the host cell line unless an "induction" event causes a switch to lytic infection. Induction is commonly caused by DNA damage, such as from UV light or agents like mitomycin C. Viruses or viruslike particles (VLP) may also be involved in killing cells by mechanisms that do not result in virus reproduction (9); also see reference (10).

DISTRIBUTION OF VIRUSES

In order to determine how viruses are distributed, it is necessary first to develop techniques to observe and enumerate them. Because of their small size, near or below the resolution limit of light microscopy (ca. 0.1 μm), the only way to observe any detail of viruses is to use electron microscopy. Sample preparation requires concentrating the viruses from the water onto an electron microscopy grid (coated with a thin transparent organic film). Because viruses are denser than seawater this can be done by ultracentrifugation, typically at forces of at least $100,000 \times g$ for a few hours (11–13); note that under ordinary gravity, forces like drag and Brownian motion prevent viruses from sinking. To be observable the viruses must be made electron-dense, and this is done by staining with heavy metals like uranium salts. The viruses are recognized by their size, shape, and staining properties (usually electron-dense hexagons or ovals, sometimes with a tail; Fig. 2), and counted. Typical counts are on the order of 10^{10} viruses per liter in surface waters, with abundance patterns similar to those of heterotrophic bacteria (see following text). Recently it has been found that viruses can also be stained with nucleic acid stains like diamidino-2- phenylindole (DAPI), YoPro, or SYBR Green I, and observed and counted by epifluorescence microscopy (14–17). Epifluorescence viewing of viruses is illustrated in Figure 3, a micrograph of SYBR Green-I stained bacteria and viruses. It graphically illustrates the high relative virus abundance. Epifluorescence microscopy of viruses is possible even though the viruses are below the resolution limit of light because the stained viruses are a source of light and appear as bright spots against a dark background (just as stars are visible at night despite their small apparent size). Such epifluorescence counts are reported to be similar or even higher than

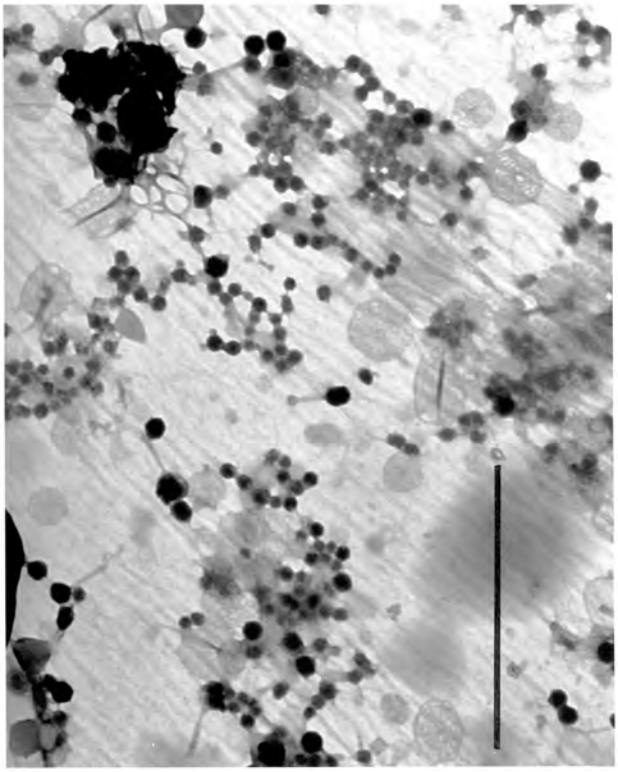

Figure 2. Electron micrograph of viruses and other microbes from Santa Monica Bay, California. The viruses are the dark small hexagonal or oval particles, some with tails. The scale bar is 1 μm.

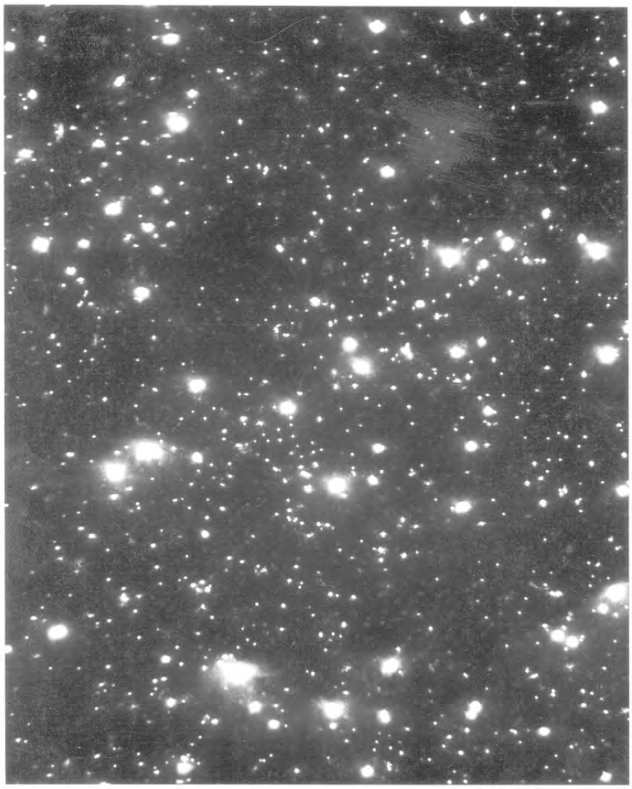

Figure 3. Epifluorescence micrograph of prokaryotes and viruses from 16 km offshore of Los Angeles, stained with SYBR Green I (17). The viruses are the very numerous tiny dots, and the prokaryotes are the larger dots. See color insert.

transmission electron microscopy (TEM) counts from seawater, especially at higher abundance levels (16,17); counts with SYBR Green tend to be about 30% higher than with TEM (17). Possible reasons for the higher epifluorescence counts may be that the TEM counts may miss unexpectedly shaped viruses or ones obscured by other dark-stained material in the TEM preparations. Particular benefits of the epifluorescence methods are rapidity, ability to work in the field (e.g., on board ship), and lower cost. However, such methods do not yield data on virus size or morphology, unlike TEM.

Electron or epifluorescence microscopy reveals the total, recognizable, virus community, and it is reasonable to ask what kinds of viruses make up this community. It is commonly assumed that most of the total virus community is made up of bacteriophages (viruses that infect bacteria). This is assumed because viruses lack metabolism and have no means of actively swimming from host to host (and depend on random diffusion), so the most common viruses would be expected to infect the most common organism, and heterotrophic bacteria are generally the most abundant organisms in the plankton, often by far (18). Data from field studies also show a strong and robust correlation between viral and bacterial abundances, whereas the correlations between viruses and chlorophyll are weaker and often not statistically significant (19,20). This suggests that the majority of viruses are bacteriophages rather than those infecting phytoplankton or other eukaryotes. On the other hand, it is known that viruses infecting culturable cyanobacteria (*Synechococcus*) are also quite common and sometimes particularly abundant in seawater, exceeding 10^5 per milliliter in some cases (21–23). Similarly, viruses infecting some common culturable eukaryotic picoplankton, such as *Micromonas pusilla*, have been found to be sometimes quite abundant as well, occasionally near 10^5 per milliliter in coastal waters (24). These studies have been done with most probable number (MPN) methods, looking for agents from seawater that lyse pure cultures when tested at various dilutions. Overall, the data suggest that most viruses from seawater infect nonphotosynthetic bacteria, but viruses infecting prokaryotic and eukaryotic phytoplankton also occur regularly and can make up a significant fraction of the total. As a final note, we are only now learning about the distribution of archaea in seawater, and that they apparently constitute a significant fraction of the total countable prokaryotes, especially in deeper waters (25,26). Whereas most of this entry discusses "bacteria," it must be considered that this practical, generic term includes the archaea plus bacteria for the purposes of general discussion. Thus, many of the viruses we observe may infect archaea, particularly in deeper ocean waters.

Viral abundance has been examined in several locations and habitats worldwide. Counts come from all sorts of planktonic environments — coastal, offshore, temperate, polar, tropical, and deep sea (Table 1, Fig. 4). Within the

[a]TEM is ultracentrifugation directly onto TEM grids for counting, without prior concentration steps. Yo-Pro and SYBR are epifluorescence of Anodisc-filtered samples with those stains.

plankton, typical virus abundance is 1 to 5×10^{10} per liter in rich nearshore surface waters, dropping to about 0.1 to 1×10^{10} per liter in the euphotic zone of offshore low-nutrient areas, and also decreasing with depth, by about an order of magnitude. A typical deep offshore profile is shown in Fig. 4. Onshore-offshore gradients are also evident, similar to those of the bacteria (19,20). As may be expected, seasonal changes are also common, with viruses following general changes in phytoplankton, bacteria, etc. (27) (e.g., see Raunefjord data in Table 1). One study indicated that virus abundance can sometimes be remarkably dynamic, changing drastically in time frames of minutes to hours (28). This has been interpreted as synchronized release from some hosts followed by rapid decay of many of the viruses. Given the relative youth of this part of the field, many parts of the world have not been investigated with regard to virus abundance, and the data are patchy. Also, there are a few measurements of total virus abundance in sediments, and the abundance there is orders of magnitude higher, on a per unit volume basis, than in the water column. Typical counts are in the range of 10^8 to 10^9 per cm^3 of sediment, with a report from Alaska waters a slightly lower (Table 2).

Counts are often also compared as virus:bacteria ratios. In plankton, this ratio is typically 5 to 25, and commonly is close to 10, even as abundance drops to low levels in the deep sea. It is unknown what factors keep this ratio in such a relatively narrow range, but it does suggest a link between these organisms, and also some reasonably tight regulatory mechanisms. Correlations to chlorophyll and other parameters have been shown in some studies, and it appears to depend on the scale examined. Given that bacteria and chlorophyll are often correlated (36), a strong possibility is that the relationship to chlorophyll is primarily a general relationship with the trophic status of the water rather than a specific relationship.

The virus:bacteria ratio has been reported to be much more variable in marine sediments, ranging from 2 to 5 in some Mediterranean sediments (35), 1 to 32 in a Canadian Lake (33), to 29 to 85 in Chesapeake Bay (34). This variation may indicate fundamental differences in processes between plankton and sediments, and between different kinds of sediments. However, because it may be more difficult to count viruses and bacteria in sediments, especially those attached to particles, there is a possibility that the variations in the ratio is in part because of a variable undercount of the viruses and/or bacteria with current techniques.

VIRAL ACTIVITIES

Viruses do not have activity on their own, so when the topic of viral activity is raised, the primary concern is usually lytic infection. Although this is an important topic and will be the main issue for discussion that follows, it should also be realized that lysogeny (where the viral genome resides in the host's genome — see Fig. 1) is common. Evidence of lysogeny is usually from culture studies or direct induction with DNA-damaging agents (37). Lysogens (bacteria harboring integrated viral genomes) can readily be found and isolated from seawater, and lysogeny, which is linked to genetic transfer in a variety of bacteria, probably has important impacts in microbial population dynamics and evolution. However, the natural induction rate seems low under ordinary conditions, and lysogenic induction appears to be responsible for only a tiny fraction of total virus production in marine systems. Evidence for this conclusion comes from two kinds of studies: (*1*) Growth of "seawater cultures" of natural marine bacteria inoculated into filtered seawater and grown under simulated in situ conditions shows rapid growth of bacteria but no appearance of viruses (as would be expected from lysogenic induction) even after several days, as long as the initial filtered seawater was cleared of viruses by filtration through a membrane with pore size of 0.02 μm.. However, when the filtered seawater is prepared by filtration through a 0.2 μm filter and thus starts with many viruses, the virus abundance increases after a few days of bacterial growth, suggesting that infection from the viruses in the inoculum is occurring (38). (*2*) When lysogen abundance is estimated from artificial induction experiments (e.g., with mitomycin C), calculation of the maximum likely number of viruses released from lysogens under optimal conditions usually represents only a few percentage of the total estimated virus production rate (37,39).

At this time, we know essentially nothing about chronic infection in the ocean, but it is often presumed to be low. Release of filamentous (or other kinds of budding) viruses

from native marine bacteria has not been noted in TEM studies, nor have significant numbers of free filamentous viruses. However, these may be hard to recognize or differentiate from other filamentous objects like cilia and bits of cells, and filamentous or nondistinct viruses may partly explain why epifluorescence methods (looking for tiny particles containing densely packed nucleic acids) usually count more viruses than TEM methods. Therefore it may turn out that chronic infection is more common than currently thought.

One of the main issues regarding viral activity in seawater is the effect on bacterial mortality via lytic infection. Several studies have been done recently on this topic, and they tend to converge on the conclusion that viruses cause approximately 10 to 50% of total microbial mortality, depending on location, season, etc. These estimates are fairly robust, having been by determined several independent ways, as described in the following text.

Percentage of Infected Bacteria

This is based on the idea that infection is visible by TEM (i.e., assembled viruses within host cells) only at the last step before lysis. Observations from ocean waters ranging from the relatively rich coastal Long Island Sound to the oligotrophic Sargasso Sea showed that about 1 to 4% of the bacteria and cyanobacteria are visibly infected (40), and subsequent measurements from other habitats have similar observations (41). Although this percentage sounds low, it represents only the final stage of infection, which apparently covers the last 10 to 20% of the infection cycle as observed with pure cultures (42). The total infection rate has been calculated from the visibly infected fraction via a relatively simple model (40,42), and the final interpretation has been that the percentage of total mortality because of viruses is approximately 5 to 10 times the percentage visibly infected, or about 5 to 40%.

Viral Decay

If virus production is stopped but viral decay continues, then one may estimate the virus production rate that would be needed to maintain observed levels. Virus production is linked to mortality of hosts via lysis, and the burst size (number of viruses released per lysed host cell) is the conversion factor. Heldal and Bratbak (43) used this concept by treating seawater with cyanide to stop production, but allow virus destruction processes to proceed. Rate measurements from Norwegian coastal waters suggested virus turnover times on the order of a few hours. This method has sometimes implied rapid bacterial mortality considerably in excess of bacterial production (44), suggesting a substantial overestimate of mortality or underestimate of production.

Viral DNA Synthesis

Steward et al. (45) adapted a method that had been used to measure bacterial production with tritiated thymidine, and applied it to estimate viral production. The idea is that the appearance of nuclease-resistant label in viral size fraction after incubation with tritiated thymidine or ^{33}phosphate is indicative of viral DNA or RNA synthesis, and can be used to calculate viral production. An empirically derived conversion factor is used to calculate the production rate. This approach has been applied in Southern California (46,47) and also the Arctic. The results from these environments show a range of results, with viruses typically causing 5 to 50% of the total ascribed mortality of bacteria. Although some of the data may suggest higher percentages in richer coastal waters, there was no consistent pattern of the variation in this percentage with trophic status. The sensitivity level of this method was found to be most suitable for rich coastal environments.

Disappearance of Bacterial DNA in the Absence of Protists

An interesting approach to investigate bacterial mortality, by means of measuring the decay of labeled DNA, was developed by Servais et al. (48,49). In this approach, cellular DNA in natural communities is pulse-labeled with ^{3}H thymidine such that all the added tracer is taken up in a matter of hours. The subsequent decline of labeled DNA is thought to track bacterial mortality, on the presumption that DNA is not destroyed in healthy living cells. When protists are removed by size fractionation, the decline in labeled DNA has been considered an estimate of virus-caused mortality. Results from this approach in Southern California coastal waters have found that protist-free mortality is about half the total, and this has been interpreted as implying a significant viral impact (47).

Fluorescent Virus Tracers

This method is based upon the same idea as so-called *isotope dilution studies*, namely that one can measure both the production and loss rate of a substance if some of the substance can be tagged and the proportion of tagged and untagged can be monitored over time. In this case, fluorescently labeled viruses are made by concentrating native viruses from seawater and staining with SYBR Green I. These are added back to seawater that is incubated under simulated in situ conditions. Over time, the amount of added labeled viruses (no extra staining) and total viruses (stained just prior to counting with SYBR Green) are counted. Production of viruses adds unstained ones to the system, reducing the proportion of stained ones. However, removal of viruses takes away both stained and unstained ones, and this should reduce the number of stained viruses but not change the relative proportions. By means of calculations analogous to those used for isotope dilution studies, one can use these results to calculate simultaneously the production and decay rates of viruses (50). This method has measured virus turnover times in Southern California nearshore and offshore waters of about 1 to 2 days, estimated to cause the majority of the total bacterial mortality (50).

COMPARISON TO MORTALITY FROM PROTISTS

Given that the earlier thinking was that protists are the primary cause of bacterial mortality in marine

planktonic systems, it is reasonable to ask how the impact of viruses on bacterial mortality compares to that of protists. A few studies have addressed this question directly, by different approaches. One study, by Weinbauer and Peduzzi (51) used multiple correlation analysis of abundances of bacteria, viruses, and flagellates to conclude that virus-induced mortality of bacteria could occasionally prevail over flagellate grazing, especially at high bacterial abundances. However, a more direct approach is to use rate measurements. A few studies have compared virus-caused mortality with other causes directly and balanced total mortality and loss rates with independent estimates of bacterial production. One study used three virus methods (frequency of infected bacteria, virus production estimated with tritiated thymidine, and size fractionated disappearance of labeled bacterial DNA) and two protist methods (removal of fluorescently labeled bacteria, size fractionated disappearance of labeled DNA) simultaneously with California coastal waters, finding that the total mortality balanced production (thymidine and leucine incorporation methods) within 30%, and that the other methods agreed remarkably well; that study concluded that viruses were responsible for about 40% of the total mortality (47). Another study examined viral processes by two methods, frequency of infected bacteria and viral incorporation of labeled phosphate, and separately estimated protist-caused mortality in the Bering and Chukchi Seas (Arctic), finding that viruses and protists were responsible for a similar amount of bacterial mortality, with protists dominating in some water samples and viruses in others (29). In the latter study, the total mortality estimates typically fell short of balancing production estimates, often by greater than 50%. Those authors also concluded that the viral effect is probably larger in eutrophic than in oligotrophic waters. A freshwater study (52) made the comparison between virus-caused and grazing mortality of bacteria in the epilimnion (aerobic), metalimnion (boundary), and hypolimnion (anaerobic) layers of Lake Plussee in Germany. They found that mortality from viruses was strongly dominant in the hypolimnion and metalimnion (where protists do poorly because of oxygen deprivation), and that viruses were responsible for up to 30 to 50% of the mortality in the epilimnion, similar to marine plankton results.

Overall, the consensus is that viruses often are responsible for a significant fraction of bacterial mortality in marine planktonic systems, typically in the range of 10 to 40%. In some waters, viruses may dominate bacterial mortality, whereas in others they may have little impact on it. Some evidence suggests that the impact is usually higher in richer coastal systems than relatively nutrient-poor ones. But there are not enough studies to back up broad generalizations or address the reasons behind any patterns. An obvious factor would be the host abundance, because when hosts are rarer, the viruses are more likely to be inactivated before diffusing to a suitable host. Host abundance is a combination of total cell abundance (lower in oligotrophic systems) and quantitative species compositions, and one must also factor in the appropriate host range for the viruses. Of these three, we only really know the total abundance at this time. One may speculate that the bacteria in oligotrophic systems are probably more diverse than eutrophic systems (analogous to zooplankton and phytoplankton (53)), and this, plus lower bacterial abundance, would tend to work against viruses in oligotrophic waters. At this time, however, quantitative evidence on natural species diversity in most marine systems is not available. Also, there is a possibility that unknown factors, such as broadened host range, may compensate for changes in host diversity.

ROLES IN FOOD WEB

Our ideas about the roles of microorganisms in marine food webs has been revised considerably following the initial discovery of high bacterial abundance and productivity, and it is now well established that a significant fraction of the total carbon and nutrient flux in marine systems passes through the heterotrophic bacteria via the dissolved organic matter (7,54). How do viruses fit into this picture? Given the accumulated data that viruses can be major agents in the mortality of bacteria, one must ask how this mechanism may alter our view of matter and energy flux in the system. Focus has been given to three pertinent features of viruses, (*1*) small size, (*2*) composition, and (*3*) mode of causing cell death, which is to release cell contents and progeny viruses to the surrounding seawater.

Viruses and the cellular debris produced when a host cell lyses consist of readily used protein and nucleic acid, plus all other cellular components, in a nonsinking form that is operationally defined as DOM. This is composed of dissolved molecules (monomers, oligomers, and polymers) plus colloids and cell fragments. Recent publications have shown that the marine DOM pool contains readily detectable remains of bacteria, such as membrane porins and peptidoglycan (55,56). Whereas such fragments could conceivably be the result of grazing by protists, it seems probable that at least the more labile components (e.g., proteins) are free in the water as a result of viral lysis of bacteria, because a protist may tend to digest them rather than release them.

What becomes of this material released by lysis? The most likely assumption about its fate is immediate or eventual availability to bacteria (27,40,54). The release and availability of the lysis products to bacteria has recently been confirmed experimentally (57,58) although a few percentage of the viruses may be grazed directly by heterotrophic flagellates (59). If the cell lysed is a bacterium, then uptake by other bacteria represents a semiclosed trophic loop, whereby bacterial biomass is consumed mostly by other bacteria. Because of respiratory losses and inorganic nutrient regeneration associated with utilization of dissolved organic substances, this loop has the net effect of oxidizing organic matter and regenerating inorganic nutrients (Fig. 5) (27,40,54). This bacterial-viral loop essentially "robs" production from protists that would otherwise consume the bacteria (8), and sequesters the biomass and activity into the dissolved and smallest particulate forms. The net effect has been illustrated by a model, showing that a food web with 50% of bacterial mortality from viruses has 27% more bacterial respiration

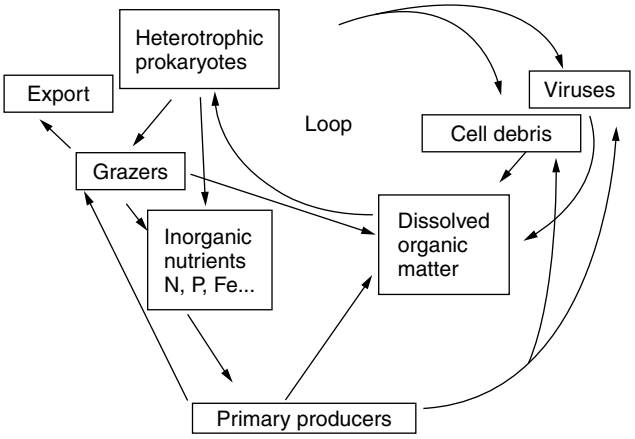

Figure 5. Bacterial-viral loop within the microbial food web. Arrows represent transfer of matter.

and production, and 37% less bacterial grazing by protists, culminating in a 7% reduction in macrozooplankton production, compared to the same system with no viruses (54). That original steady state model had only bacteria being infected and all the viral matter being consumed by bacteria (54). A modification of that model, now including a small amount of viral infection of phytoplankton (7% loss) and also flagellate grazing of 3% of the virus production, has essentially the same net effect of increasing bacterial production and respiration (by 33%) and reducing protist and animal production (60).

Sequestration of materials in viruses, bacteria, and dissolved matter leads to better retention of nutrients in the euphotic zone in virus-infected systems because more material remains in these small nonsinking forms (54). In contrast, reduced viral activity leads to more material in larger organisms that either sink themselves or as detritus, transporting carbon and inorganic nutrients to depth. This may be particularly important for potentially limiting nutrients like nitrogen, phosphorus, and iron, which are relatively concentrated in bacteria compared to eukaryotes. Thus, viral activity has the potential effect of helping to maintain higher levels of biomass and productivity in the system as a whole.

Lysis of organisms and release of their cell contents to the water have other potential geochemical effects, because of the chemical and physical nature of the released materials and the location in the water column where the lysis occurs. For example, polymers released from lysed cells contribute to small-scale viscosity of seawater that influences many biological and microscale physical-chemical processes, and may facilitate aggregation and sinking of material from the euphotic zone (61–63). On the other hand, viral lysis of microorganisms within sinking aggregates may effectively "dissolve" the particles, converting some sinking particulate matter into nonsinking dissolved material and colloids at whatever depth the lysis occurs (61). This contributes to the dissolution of sinking organic matter and its availability to free-living bacteria in the ocean's interior, as discussed by Cho and Azam (64).

The role of viruses in producing long-lived DOM is not currently known. This would probably mostly be from cell lysis products, because viruses themselves are protein and nucleic acid that are thought to be relatively labile, whereas bacterial cell walls and some other components are probably more recalcitrant to degradation. If a large fraction of the lysis products turn out to be relatively nonlabile materials, this would alter the quantitative aspects of conclusions made above, but most of the qualitative aspects would be the same. A change may be that any long-lived DOM could remain in the system a long time or be transported to deep or distant locations, to eventually fuel bacterial production.

EFFECTS ON SPECIES COMPOSITIONS

Viruses are density-dependent and generally species- or genus-specific. This combination means dominant bacteria are most susceptible to infection, and rare ones least so. Lytic viruses can only get ahead when the average time to diffuse from host to host is shorter than the average time they remain infectious. Thus, when a species or strain becomes more densely populated, it is more susceptible to infection, making viral infection work in opposition to competitive dominance (65).

This may have direct relevance to solving Hutchinson's "Paradox of Plankton," which asks how so many different kinds of phytoplankton coexist on only a few potentially limiting resources, when competition theory predicts one or a few competition winners (66). Although there have been several possible explanations for this paradox (67), viral activity may also help solve it, because as stated above, competitive dominants become particularly susceptible to infection whereas rare species are relatively protected. It may be expected that the same principle applies to bacteria in addition to phytoplankton, although we know much less about bacteria diversity.

At this time there is relatively little experimental evidence regarding viral control of species compositions. This is hardly surprising, given that we are now only starting to understand the species distributions and dynamics of marine bacteria. However, there are some data showing shifts in overall bacterioplankton community composition on scales of weeks to months (68,69). These reports indicate that the dominant members of the microbial community shift significantly over time. However, the cause of those shifts is not known. One report did correlate community composition with viruses. Waterbury and Valois (23) examined the relative abundance in temperate Atlantic waters (near Woods Hole, Massachusetts and also offshore) over several seasons of various culturable strains of *Synechococcus* cyanobacteria and viruses that infect them. They reported that although they calculated only a small percentage of *Synechococcus* were lysed daily, from less than 1 to about 3% per day, the culturable cyanobacteria tended to be resistant to the co-occurring phage. They concluded that the cyanobacteria affected the species or strain composition of the community more than the total abundance.

Thingstad and Lignell (70) have modeled the potential factors controlling aquatic microbial systems, regarding biomass and species compositions. Their models include growth limitation by organic carbon, inorganic phosphate,

or nitrogen (inorganic or organic), and cells losses include grazing by protists and viral lysis. Even when bacterial abundance is assumed to be controlled by protist grazing, the models have the robust result of showing that viruses control the steady state diversity of the bacterial community, whether bacterial growth rate limitation is by organic or inorganic nutrients. Thus, both empirical and theoretical analyses indicate a major role of viruses in regulating patterns of diversity.

RESISTANCE

The development of host resistance to viral infection is a common occurrence. Such resistance, whereby bacteria mutate to resist the viral attack, is well known from nonmarine experiments that usually involve highly simplified laboratory systems (71). It seems sensible to ask about its occurrence in nature. In the natural marine world, this phenomenon was cited to explain the results of Waterbury and Valois (23), discussed in the preceding text.

Along those same lines, Olofsson and Kjellenberg (72) have suggested that because of the development of resistance, significant mortality from marine viruses would be expected as a transient effect only as new virulent virus strains emerge. Suttle and coworkers (73) responded that in dynamic, diverse and sparse natural populations, other factors may control strain compositions more than resistance. It makes sense that natural systems with many species and various trophic levels have far more interactions than the simple laboratory systems. Obviously, a species with a large fraction of mortality for one type of virus benefits from developing resistance, and this must occur in nature. But resistance is not always a good thing. First, it often confers some competitive disadvantage via loss of some important receptor (9,71). Even complete resistance to viral attachment, without any receptor loss, if that were possible, would not necessarily be an advantage. For a bacterium in an oligotrophic environment whose growth may be limited by nitrogen, phosphorus, or organic carbon, unsuccessful infection by a virus (e.g., stopped intracellularly by a restriction enzyme, or with a genetic incompatibility) may be a significant nutritional benefit to the host organism, because the virus injection of DNA is a nutritious boost rich in carbon, nitrogen, and phosphorus (40)! Even the protein coat, remaining outside the cell, is probably digestible by cell-surface-associated proteases (74). In this situation, one may even imagine bacteria using "decoy" virus receptors to lure viral strains that cannot successfully infect them. Given favorable distributions of various types of bacteria and viruses, the odds could be in favor of the bacteria, and if an infectious virus (i.e., with a protected restriction site) occasionally gets through, the cell line as a whole may still benefit from this strategy.

Another consideration that works against resistance relates back to the system model results, showing that the heterotrophic bacteria as a group benefit substantially from viral infection, boosting their production significantly by essentially taking carbon and energy away from larger organisms. Recall also that viruses boost the entire system biomass and production by helping to maintain nutrients in the lighted surface waters. However, these arguments would require invoking some sort of group selection theory to explain how individuals would benefit from not developing resistance (i.e., why not "cheat" by developing resistance and letting all the other organisms give the group benefits of infection?). Nevertheless, for whatever reasons, resistance of native communities to viral infection may be common but cannot be close to complete because there is continued ubiquitous existence of viruses approximately 10 times as abundant as bacteria and with turnover times on the order of a day. Simple mass balance calculations, typically reported in several papers cited earlier on viral decay, show that significant numbers of hosts must be infected and releasing viruses all the time. For example, with a typical lytic burst size of 50 and viral turnover time of one day, maintenance of a 10-fold excess of viruses over bacteria requires 20% of the bacteria lyse daily. Whether lack of comprehensive resistance is due to frequent development of new virulent strains, rapid dynamics, or patchiness in species compositions, or to a stable coexistence of viruses and their hosts has yet to be learned. All these are possible and they are not mutually exclusive.

GENETIC TRANSFER

Viruses also can be agents of genetic transfer between microorganisms, through two processes. The more direct process is known as transduction, in which viruses package some of the host's own DNA into the phage head (sometimes with active phage genes and sometimes without, depending on the virus type) and then inject it into another potential host. Transduction in aquatic environments is frequent enough to measure, and has been demonstrated (75). Although transduction usually occurs within a restricted host range, a recent report by Chiura (10) indicates that some marine bacteria and phage are capable of transfer across a wide host range. A second mechanism whereby viruses mediate genetic transfer is by causing the release of DNA from lysed host cells that may be taken up and used as genetic material by another microorganism. This latter process is called transformation. Although the extent of these mechanisms in natural systems is unknown at this time, they could have important roles in population genetics, by homogenization of genes within a potential host population, and also on evolution at relatively long time scales. Horizontal gene transfer is an integral component of microbial evolution, and the genomes of modern-day microbes contain numerous genes that have obviously been transferred from other species (76). On shorter time scales, this process is of interest in the possible dissemination of genes that may code for novel properties, whether introduced to native communities naturally or via genetic engineering.

CONCLUSION

There is now substantial evidence that viruses are important players in the control of marine microbial

systems. A major effect is on mortality of bacteria and phytoplankton, with the expected result of stimulating bacterial activity at the expense of larger organisms and also stimulating the entire system via aiding retention of nutrients in the euphotic zone. Other important roles include influence on species compositions and possibly also genetic transfer. Much of this work is still in its infancy, and a great deal has yet to be done.

Acknowledgments

I thank colleagues who have worked with me and discussed various aspects of virus research, including Lita Proctor, Rachel Noble, Robin Wilcox, John Griffith, Curtis Suttle, Farooq Azam, Frede Thingstad, Gunnar Bratbak, John Paul, Åke Hagström, Doug Capone, and others. David Kirchman provided useful comments on the manuscript. This work was supported by NSF Grant OCE 9634028 and OCE 9906989.

Much of the impetus behind subsurface research is fueled by the fact that alterations of subsurface environments can be attributed to the presence or activity of bacteria (1). In addition to the role that microbes play in biogeochemical cycling, subsurface bacteria are known to be important in processes varying from the souring of oil (2) to the degradation of toxic materials (3–5). To successfully prevent or alternatively encourage microbial activity in these situations and to effectively monitor the results of remediation or other projects in the subsurface environment, an understanding of basic microbial ecology is essential. The Department of Energy (DOE) developed a Deep Subsurface Microbiology Subprogram in 1986 (a part of the Subsurface Science Program) in an effort to better understand the microbial ecology of subsurface environments. They envisioned the use of microbes for cleanup efforts at contaminated DOE facilities (6). In the first phase of the program, several boreholes were drilled at the Savannah River Site (SRS), South Carolina, with the specific intent of studying microbiota and the sediment in which they were entrained. New drilling technologies, utilizing conservative tracers for quality assurance, were subsequently developed and employed at two western Department of Energy (DOE) facilities, The Hanford Reservation (HR), Washington, and the Idaho National Engineering Laboratory (INEL) in Idaho Falls, Idaho (7,8). The Nevada Test Site (NTS), was selected as an additional site for characterization, providing an opportunity to sample without the necessity of drilling. Our research team investigated the microbiology of volcanic tuffs at the NTS. The data summarized or referenced herein describe the investigations of mined volcanic tuff materials and their endolithic microbial communities.

The NTS is located approximately 60 miles northwest of Las Vegas, in the southern tip of Nevada. At the NTS, 26 km of tunnel systems from 50 to 450 m depth were accessible, and importantly, samples of rock (volcanic tuff) could be collected from the sides of the tunnels without drilling. Drilling is technologically complex and time consuming, thus expensive, and drilling fluids are a known source of contamination. This site afforded the opportunity for sampling in three-dimensions on large (km) and comparatively small (m) scales. Because large amounts of rock could be obtained, it also allowed for microbiological, geochemical, and geological analyses as well as investigations of perturbation phenomena. Additionally, Rainier Mesa serves as a structural analog to Yucca Mt., the nation's proposed high-level nuclear waste repository, and therefore, information obtained from research on Rainier Mesa could serve to enhance microbial research efforts in the Yucca Mt. Project (See NUCLEAR WASTE RESPOSITORY IN YUCCA MOUNTAIN: MICROBIOLOGICAL ASPECTS, this Encyclopedia).

PILOT INVESTIGATION

Of primary concern in the first NTS sampling effort, was whether viable microorganisms would be recovered from the volcanic tuffs of Rainer Mesa. In a pilot study (9), culturable organisms were recovered using several media from one water sample and three rock samples, one from each of four locations within Rainier Mesa 12 n tunnel system (approximately 400 m deep). Purified isolates were

morphologically and physiologically characterized and it was demonstrated that different types of microbes were isolated from the four locations within one tunnel system. Further, it became obvious that conventional identification techniques such as API-rapid NFT strips (21 physiological tests), BIOLOG (96 physiological tests) identification plates, and MIDI (fatty acid methyl ester) analysis either failed to provide identifications that were acceptable or the systems did not agree as to the identification of the isolates. The pilot study led to three roads of investigation: (*1*) microbial characterization of the subsurface tunnel systems within Rainier Mesa, (*2*) the determination of microbial community change during sample storage, with special emphasis on changes that occur in the culturable community, and (*3*) the possibility that endolithic microorganisms have been isolated from the surface for long periods.

SAMPLE COLLECTION

The extensive tunnel systems within Rainier Mesa at the NTS provided a unique opportunity to study the microbial ecology of the deep subsurface without the need for drilling. Samples were collected by chipping into existing rock faces of tunnels with sterile tools to create a fresh sampling face. Rock was then aseptically chipped into sterile containers for rapid transport to the laboratory in coolers containing ice (10). Research described later and that of others has demonstrated the importance of immediate analysis to recover microbial communities representative of the in situ environment (11–16).

An Alpine miner (Fig. 1) was a valuable tool that aided the recovery of representative subsurface samples. The miner removed cubic meters of rock in minutes, and thus allowed sampling deeper into rock faces without the concern of contamination by drilling fluids. Others have shown that temperatures in excess of 40 °C may decrease recovery of viable microbes (17), and because the miner removed cubic meters of rock in minutes, the production of excessive heat was also avoided. While comparing coring methods with use of the Alpine miner, coring was found to be more technically challenging, although similar abundances and types of microorganisms were recovered from cores when compared to rock samples recovered with the Alpine miner (18). The recovery of large volumes of material from the tunnels permitted extensive geological/hydrogeological analysis of rock material (19). Samples could also be taken in a three-dimensional sampling scheme such as the one used in analysis of the microbiota within a 21-m^3 rock section (20). In this work, a statistically designed sampling array was selected for the analysis of 19 samples within the rock section (Fig. 2). Microbial distribution on a vertical scale had been described by others involved in drilling operations, but work describing lateral heterogeneity relied on samples taken within the same geological formation but within different boreholes that may have been quite distant from each other (7,21,22). Other investigations of lateral heterogeneity have been reported (23).

Sampling outcrops of Rainier Mesa proved to be a viable method of obtaining samples for microbiological

Figure 1. The Alpine miner was used to create passageways within the subsurface of Rainier Mesa, Nevada Test Site (**a**). The carbide bits on the rotating heads allowed rapid removal of relatively large volumes of rock without the necessity of drilling fluids or the production of excessive heat (**b**). After removal of large portions of rock, the Alpine miner was backed out of the alcove, and hand sampling was conducted with sterile implements (**c**).

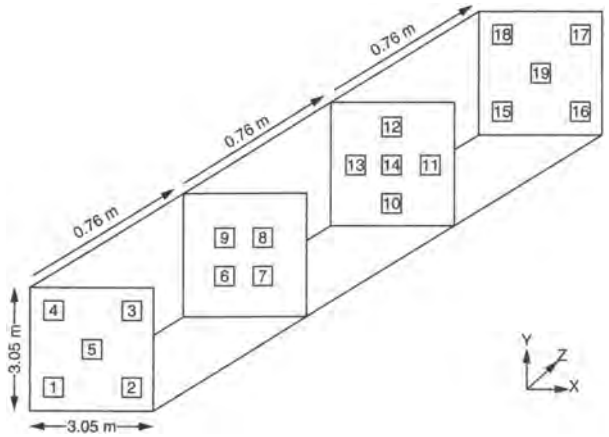

Figure 2. Sampling design showing three-dimensional array from which 19 samples were collected within a 21 m^3 section of subsurface rock.

analysis on a vertical scale at the NTS (Fig. 3). Although samples could be procured in a directly vertical axis within the tunnels, the sample range was limited by the height of the tunnel itself. When sampling between geological formations was desired over a larger vertical range, exposed outcrops on the exterior of Rainier Mesa were sampled for comparison with those collected within tunnel systems (24). Additionally, because tunnel systems were mined at various locations and elevations within Rainier Mesa, comparisons could also be made between tunnel systems. Because rock strata within Rainier Mesa are nearly horizontal (25), an elevational gradient also served as a chronosequence of depositional history. Others had reported the recovery of representative material for microbiological analysis by hand sampling into outcrops (14,26,27) or drilling horizontally into surface sandstone using sterile water as a lubricant (17).

Because sampling by mining was a relatively untried approach to sample acquisition in the subsurface, a series of controls were developed to insure that material

representative of pristine rock was obtained. Table 1 lists types of measures undertaken to ensure quality sampling.

MICROBIAL CHARACTERIZATION OF TUNNEL SYSTEMS

Strategies for Surveying Indigenous Microbial Communities

Samples of volcanic tuff were obtained from tunnels, U12 b, U12 g, U12 n, and U12 p to conduct a large-scale survey of microbial distribution (1 m–2 km) and from a variety of rock strata, including those within saturated and vadose zones (Fig. 3; 10). Physical and geological information is provided in Table 2. As a part of this tunnel survey, several different plating and enrichment media, and incubation temperatures were employed to recover maximal microbial diversity. Researchers have demonstrated that media composition affects the recovery of heterotrophic microbial communities, and specifically that minimal media may allow better recovery of microorganisms from oligotrophic environments (33–36). Fluorescent direct counting techniques and the determination of total biomass by phospholipid extraction (and subsequent determination of liberated PO_4^{3-}), were used to determine the abundance of nonculturable organisms in the tunnel characterization research (10).

A second experiment was conducted to describe the distribution of microbiota in three-dimensions on a smaller scale, specifically within a 21 m^3 section of rock (20). Analyses of bacterial isolates that were recovered from the rock section included MIDI analysis (fatty acid methyl ester/gas chromatography). An important advantage of MIDI analysis was its ability to cluster isolates into groups of related organisms such that the distribution and diversity of microbes within the rock section could be discerned, even if they could not be individually named. Microbiology and geology/geochemistry were compared as a part of this sampling effort to determine if hydrogeological/geochemical factors might be predictive of microbiological abundance or diversity (19).

Another investigation was initiated because geochemical/geological data indicated that the zeolitized rock beds of Rainier Mesa allowed negligible water flow, except in fractures, and thus probably limited microbial transport to depth in the recent past. Further, initial characterization of organisms recovered from zeolitized rock in the pilot study suggested that some isolates were capable of long-term starvation survival (37). These organisms demonstrated patterns of survival similar to those reported by others investigating long-term survival in marine and soil environments (38–40). Thus, microbiota were sampled in a vertical gradient as described earlier. Additionally, fracture water and outflow spring water were compared (24), as well as the microbiota occurring within and away from a free-flowing fracture. The hypothesis was that if surface microbiota had been rapidly transported to depth in fracture water, similar microbial communities would likely

be recovered. Tritium dating of fracture water suggested travel times of 6–30 years to reach N tunnel depth (25). Investigation included comparison of most probable number determinations (MPN) utilizing several media, total cell enumerations, and the comparison of culturable microbiota (24).

Microbial Distribution

It is now commonly accepted that a wide range of microbial types inhabit the deep subsurface and that they do not necessarily decrease in abundance or diversity with depth (7,21,41). Likewise, this holds true in the subsurface of Rainier Mesa. We recovered diverse microbial communities from depths to 450 m, containing up to 1×10^4 culturable heterotrophic organisms per gram of rock (10). Within Rainier Mesa, microbial communities appear to be distributed in a heterogeneous manner as has been described for other terrestrial subsurface environments (14,21,22,26,42–44). In our studies heterogeneous distribution was demonstrated to be as great between samples taken 1 m apart as those taken from diverse tunnel systems up to 10 km apart.

We demonstrated that different bacterial types were recovered from clay, water, and rock samples taken in very close proximity to one another, some samples less than a meter apart (10,20,24). Other researchers have also demonstrated differences between the type of microbes recovered from geological formations with various physical characteristics (21,26,43). However, while comparing recoverable microbiota to geological and/or hydrological properties of the terrestrial subsurface environments, few predictive relationships have been found. Fredrickson and coworkers (45) found lower abundances of microorganisms associated with clay layers as compared with sandy strata. In research conducted at Hanford, sediment texture and organic carbon were related to microbial abundance (26,45). Few predictive relationships were found in our investigations of Rainier Mesa, although 1,700 correlations between microbial, hydrogeological, and geochemical parameters were investigated (19). One of the few significant correlations was between levels of nitrate and bacteria positive for nitrate reduction (19). This seemed counterintuitive because bacteria capable of reducing nitrate were present in rock strata with high nitrate levels. It is probable that these microbial populations were limited by some other parameter. For example, the lack of an available carbon source would prevent use of the nitrate as an electron acceptor or as a nitrogen source.

Lack of trends or correlations between microbiology and hydrogeological/geological parameters provided evidence for the isolated nature of subsurface microbial communities in the zeolitized rock beds of Rainier Mesa [zeolitized rock has negligible water permeability (32)]. First, the lack of spatial trends in the distribution of microbiota indicated that no horizontal or vertical transport of bacteria was likely. One would expect more homogeneity in bacterial colonization if connections between rock pores would have

allowed for water, nutrient, and microbe transport. Experimental work involving determination of transport rates of bacteria through tuffaceous cores, including zeolitized tuff, supports this hypothesis (32).

Perhaps microorganisms recovered from the deep subsurface of Rainier Mesa were dormant bacterial cells; bacteria that colonized and adapted to the environmental conditions of the rock matrix in a time past, but were not actively growing/metabolizing at the time of sampling. Pore water in zeolitized tuff beds, sampled at 400 m depth in Rainier Mesa, has been age-dated to at least 250,000 years ago, whereas free-flowing fracture water is much younger (9). These bacteria may exist as dormant vegetative forms that are not currently influencing or being influenced by their geochemical environment. Other subsurface environments may also contain organisms that have been isolated from the surface for extensive periods (27,40,46).

Microbial Diversity

Heterotrophic bacteria have been recovered most commonly within Rainier Mesa, although anaerobic (47,48), microaerophilic (45), phototrophic (49), and lithotrophic (45) bacteria have been recovered from other subsurface environments. Other microorganisms, including fungi, protozoa, algae (50), and viruses (51), that have been recovered from other subsurface environments were not cultured from Rainier Mesa samples. Most probable number enrichments were used to attempt to recover phototrophic, sulfate-reducing, sulfur-oxidizing, iron-oxidizing, and nitrifying bacteria, but a number of these bacterial types were below the level of detection ($<$10/g) under the culture conditions used (10). Chemolithotrophic and sulfate-reducing bacteria have been recovered from a similar subsurface environment, the volcanic tuffs of Yucca Mountain, a proposed nuclear waste repository in southern Nevada (52,53).

The total numbers of bacteria and biomass estimates based on the extraction of phospholipids indicate that only a fraction of the microbial community was recovered with our standard culture conditions on R2A agar (DIFCO) with incubation at 24 °C for at least 14 days (10,20,24). Other media and incubation temperatures were used in initial experiments (as well as MPN enrichments) to enhance the recovery of greater bacterial diversity: malt extract agar, starch casein agar, starch, casein agar containing rifampicin, 0.1% R2A, and incubations at ambient rock temperature (16–18 °C), 24 °C, or elevated temperature treatments (60 °C for 1 hour, or 80 °C for 3 min.) followed by standard incubation to select for the recovery of spore-forming organisms. Bacterial incubation on R2A agar at 24 °C provided the best recovery (highest abundances and greatest diversity), and was subsequently used for all remaining investigations. R2A has been used by other microbiologists to investigate oligotrophic environments (34,54–57). Other researchers in the DOE Subsurface Science Program have also used a complex, but low nutrient medium (1% PTYG).

Most of the heterotrophic bacteria that have been isolated from the deep subsurface of Rainier Mesa have not been identified with a high degree of certainty by any identification system. This is not surprising as the databases used, and most in existence, were developed for the identification of bacteria of clinical importance. We have found that phylogenetic identification (partial sequencing of 16s rRNA gene and comparison of sequences to known databases) is the most definitive means of identifying bacteria to the genus level. Previous work in the subsurface of SRS relied on physiological characteristics generated from API-Rapid Nonfermenting test strips [subsequent to these investigations, much has been published about phylogenetics of subsurface microbial isolates (58–62)]. This method of comparing bacteria has limited utility in some instances because many bacteria that have the same API profile are different by genetic methods (63). However, use of the MIDI (Microbial Identification System, Co.) is a more time/cost efficient method of determining the identification of strains, and the relatedness of isolates to both known strains and to each other. This latter ability of the MIDI system has proved invaluable in describing culturable heterogeneity of microbial distribution, which would have been impossible if species identification of all or even most of the isolates had been necessary.

The bacterial genera recovered from Rainier Mesa fell into several broad groups based on fatty acid methyl ester (FAME) profiles, which clustered at Euclidean distances $\leq$45, and include *Methylobacterium*, *Micrococcus*, *Arthrobacter*, *Bacillus*/*Xanthomonas*, *Nocardiodes*, unmatched (2 groups), Acinetobacter/Gordona, and *Pseudomonas*/*Hydrogenophaga*/*Acidovorax* clusters (11–13,20). The most numerically abundant cluster was the *Arthrobacter* and mixed gram-positive bacterial groups, which contained 33% of all isolate types. The 16s rRNA gene of several isolates from the unmatched groups have been partially sequenced (62). Comparison of the sequences to then current databases indicated that these bacteria were related to known bacterial genera, including *Arthrobacter*, *Terrabacter*, *Rhodobacter*, *Mycobacterium*, *Bacillus*, and *Sphingomonas*, but it is still not clear why these bacterial types did not cluster with known organisms. Perhaps more extensive sequencing or comparison to updated databases will be required to document whether these organisms are very different, although related to common species. Perhaps a more detailed knowledge of their physiological and FAME profiles will shed light onto the classification of these organisms. Preliminary work along these lines suggests that some of the previously unidentified organisms belong to the genus *Terrabacter*, but are most likely species not described as yet.

The MIDI growth regime required incubation of cultures on trypticase soy agar (TSA) for 24 hours as a standard procedure because bacteria are known to change the composition of membrane lipids based on their growth stage/dormancy stage, temperature and nutritional conditions (64,65). While some of the bacterial types recovered on the low nutrient media could be cultured on nutrient-rich media after initial isolation, some could not, and these may truly represent oligotrophic organisms (56). Unfortunately, classification of these organisms by growth characteristics or by MIDI analysis remains a formidable task unless new libraries can be

created that are based on data developed from the use of low nutrient media.

Of the bacterial diversity that was recovered, representative colony types were selected for further characterization. It has become important to test the validity of selecting a representative colony type for analysis on the basis of colony morphology. An experiment was conducted to determine the extent of diversity within a single visual morphotype to determine if much of the potential diversity was ignored by selecting only one isolate from many, which looked identical. Although diversity is lost while using an approach such as the selection of a representative colony by morphotype (66,67), isolates from the NTS that appeared similar on initial isolation plates were all related at the genus level; most to the species level or closer (68). Thus, the selection criteria used in the initial (and subsequent) site characterization undoubtedly underestimated total recoverable diversity, but did provide a method for the selection of microbiota for study that could be feasibly analyzed with available resources and allow comparison between sampling sites. This was necessary in order to reduce the number of isolates to a manageable collection of strains, and has been used by other subsurface researchers (21,43).

STORAGE-RELATED PHENOMENA

For research of storage-related phenomena, particular advantages of sampling in Rainier Mesa at the NTS included, the proximity to the laboratory and the large volumes of rock that could be obtained. Because we realized that storing samples before analysis would affect the recovery of microbiota and distort descriptions of in situ bacterial communities, we became interested in learning more about storage-related phenomena as they pertained to protocols for the handling and transport of subsurface material. Investigations of the magnitude of community shifts during storage included (*1*) the time course of microbial change, (*2*) the effects of temperature and sample perturbation on community structure, and (*3*) the impact of the physical characteristics of sample materials (e.g., rock, clay, moisture content) on community change. Further, we were interested in ecological aspects of community change. Which microbial types were active in community change? What characteristics of microbial types appearing after different storage times allowed them to be recovered or detected in higher numbers during storage? Were changes in the abundance of culturable organisms due to the outgrowth or resuscitation of specific bacterial types? Results of investigations concerning these questions are presented in this section, while ecological aspects of storage phenomena are presented in the following section on microbial survival.

An understanding of microbial change in stored samples is of paramount importance to subsurface researchers and those interested in bioremediation. To adequately determine relationships between microbes and their environments, in situ samples need to be analyzed with minimal perturbation and delay. The microbial communities in samples stored, even for a short period can change, and this will distort an understanding of the native microbial community. The simple act of sampling irrevocably changes the community because the biotic and abiotic microenvironments associated with each organism are altered. For example, when rock is removed in small chips from the walls of the tunnels, potential changes in water, temperature, and exposure to oxygen could result (13).

One of the effects of perturbation is that microbial activity can be stimulated (11–14,69,70). This effect may be of great utility to bioremediation efforts that intend to activate in situ subsurface communities. We have observed that bacterial communities change in response to sample storage, especially increasing in culturable bacterial numbers without the addition of nutrients. Others have also demonstrated that the activity of microbial communities is stimulated by unknown aspects of sample storage or handling (14,71). Nutrients or moisture may not be limiting in some subsurface environments, but rather their bioavailability may be (69). Perturbations created during sampling may serve to redistribute moisture, nutrients, and bacteria, thus providing substrates for enhanced microbial activity. The increase in abundance observed after storage may in part be due to the outgrowth of microbes that were physically located in microenvironments, especially those in nontransmissive environments such as the zeolitized tuffs of Rainier Mesa where nutrient flux is believed to be minimal.

Evidence suggests that several mechanisms of change occur in subsurface samples, including the outgrowth of specific microbial types and the resuscitation of dormant organisms (11–13). To determine which microbial types changed in abundance throughout storage, dendrograms (see Fig. 4) were used to compare organisms recovered before and after storage. Additionally, physiological characterization and growth rates of isolates recovered at different times throughout storage were compared to determine if specific bacterial types recovered after sample storage had a competitive advantage; either the ability to use a wider array of carbon substrates or faster doubling times (12). Phospholipid fatty acid methyl ester (PLFA) analysis was employed to determine entire community shifts in phospholipid composition as compared to changes in culturable communities. PLFA analysis was then a relatively new technique that was increasingly utilized to characterize environmental samples. The types and abundances of fatty acids recovered in a chloroform/methanol extraction were used to determine microbial abundance, inclusive of viable, culturable, and dead cells, as well as the presence of specific microbial groups based on signature fatty acids (11–13).

When samples must be stored before microbiological analysis can be initiated, storage at a cool temperature is a standard procedure in ecological studies (72,73). A temperature of 4°C has commonly been employed to inhibit the outgrowth of organisms, whereas colder temperatures have been avoided to prevent membrane disruption associated with freezing. Research conducted on Rainier Mesa samples demonstrated that microbial diversity decreased in many types of samples stored at 4°C. Larger numbers of culturable organisms were recovered, but fewer types of organisms were evident

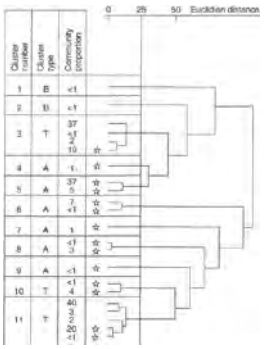

Figure 4. An example of a dendrogram that was used to compare organisms recovered before and after storage. Dendrograms were created from comparison of fatty acid methyl ester analyses of individual isolates. A Euclidean distance of ≤ 25 approximates relatedness at the genus level. The stars represent organisms recovered after one week of sample storage. Cluster type designations describe whether organisms were isolated only before (**b**), only after (**a**), or at both time points (T) of sample storage.

after storage. The time course of microbial change was as soon as 24 hours after sampling and change continued in the community throughout 45 days (12). Others have noted changes up to several months, but short-term changes were not reported (14,74,75). The temperature of sample storage affects the magnitude of microbial change. For samples stored at 24 °C, more dramatic increases in abundance and community shifts were observed during shorter periods than at 4 °C. Culturable counts remained constant in samples stored at freezing temperature (−20 °C), indicating that this temperature inhibited increases in microbial abundance. However, it should be noted that the types of bacteria recovered throughout storage at −20 °C demonstrated that the microbial community underwent structural shift although bacterial numbers remained relatively constant (12).

The magnitude of microbial change appears to be dependent on the type of material sampled. The largest increase in culturable counts has been observed in water samples, and in some cases, a direct relationship to the magnitude of change and moisture content has been demonstrated (15). Brockman and coworkers (14) demonstrated that paleosol samples with a higher moisture content exhibited a greater change, and while comparing volcanic rock samples from NTS, a similar trend was observed among samples of a similar rock type. However, a clay sample with a 35.1% moisture content exhibited less change than rock samples containing 4–10% moisture, and therefore, moisture was not the only factor that contributed to the magnitude of change.

The addition of moisture to homogenized rock led to increased abundance and decreased diversity in a shorter time than with unamended samples (11). In one experiment, rifampicin was added to inhibit the outgrowth of bacteria in stored samples, and in comparison to a control without rifampicin, microbial change was reduced. However, experiments such as these were not continued because the initial recovery of microbial diversity was diminished with rifampicin addition. Other physical properties of samples are no doubt important as well as moisture content: nutrient concentrations, permeability, levels of physical disruption, and so on. Others have shown that samples stored in 5 to 10 g intact pieces demonstrated less increase in abundance during storage as compared with crushed or ground rock samples (14,15). However, it is important to note that the shift in the types of bacteria recovered was just as great in the intact sample from Rainier Mesa as compared to the replicate sample that was ground and homogenized in our experiments.

LONG-TERM SURVIVAL OF SUBSURFACE BACTERIA

Dormant, Dead, and Viable but Nonculturable (VBNC) Microbial Biomass

The numbers of cultured bacteria obtained from Rainier Mesa samples as compared to measurements of total cell numbers or total biomass, suggest that not all microbial diversity was recovered during routine sample analyses. If the environments sampled were static and ancient as evidence suggests, it would not be surprising to find large numbers of dormant, dead and/or VBNC bacterial cells.

Dormancy is often associated with cellular survival under conditions of low nutrient availability (38–40,56,65,76). Endolithic Rainier Mesa isolates demonstrated starvation-survival patterns indicative of long-term survival (37,38,40). Measurements of diglyceride fatty acids (DGFA), indicators of dead biomass, suggested that large numbers of dead cells were present in the rock microbial community (12).

VBNC bacteria may be described as cells that are nonculturable under the current growth regime, injured or dormant (76,77). Experiments described in the following section provide evidence for the existence of VBNC bacteria in Rainier Mesa samples. Different cell types were recovered by the use of various growth media and incubation regimes. Obviously then, any one count of culturable bacteria recovered under a single set of conditions would underestimate the total number of viable bacteria in the sample and may include organisms that were VBNC under another set of conditions. This was demonstrated when heterotrophic bacteria were cultured from turbid but negative MPN tubes designed to enrich for chemolithotrophic bacteria. For example, ammonia and sulfur-oxidizing media were negative for chemical conversion but heterotrophic bacteria could be cultured from them after six weeks incubation. Heterotrophic cells were recovered on R2A agar from MPN tube inocula, and yet they were morphologically and physiologically different from cells recovered from the same samples when they were initially plated on R2A. This suggests that the new cell types were capable of growth under the conditions provided (R2A with 24 °C incubation) but only subsequent to certain unknown conditions having been met. Perhaps they were injured or dormant cell types that required resuscitation before becoming culturable. An alternative hypothesis is that perhaps outgrowth of these organisms from very small populations (during MPN tube incubation)

was required before sufficient cell numbers were available for detection by plating.

Some storage-related phenomena suggest that dormant cell types were present in deep subsurface rock as well. Not all heterotrophs were recovered with initial R2A plating. Following storage of rock samples, new bacterial types were recovered under the same culturing conditions. Some unknown process (es) may have allowed some cell types to be detected after sample storage, but not during initial isolation. One possibility is that rare bacterial types outgrew during sample storage (or in MPN tubes) and that death or lack of growth of the previously more dominant bacterial types caused an observable community shift.

Several important factors make it appear as if alternative events to outgrowth might have occurred. First, samples were stored at a restrictive growth temperature without the addition of nutrient sources. These factors should have limited microbial activity and growth. Second, some, but not all of the bacteria recovered after storage exhibited enhanced growth rates and enhanced ability to use a variety of carbon sources when compared to those recovered upon initial plating (11). Those bacteria with lower growth rates or less nutrient flexibility would have been less likely to scavenge nutrients and outcompete the initially recovered microbiota. Perhaps these bacterial types were relatively abundant in the original sample, just initially VBNC.

In summary, some cells recovered from the NTS rock samples may have been dormant bacterial populations that were resuscitated due to some aspect of sampling or sample handling. Reports of vegetative dormant bacterial populations or VBNC bacterial cells existing in natural environments have increased and include bacteria from soil and aquatic environments (74,77–82). Factors that have been demonstrated to awaken dormant cell populations or resuscitate injured cells include the use of nonselective media (79,80), and temperature (83,84) or osmotic shifts (85). Changes in all of these parameters probably occurred in NTS rock samples due to the rearrangement of water, nutrients or bacteria, during perturbation and storage of samples.

CONCLUSION

Microbiota recovered from the deep subsurface of Rainier Mesa represent a diverse set of aerobic heterotrophic microorganisms. Cells were found primarily in the vegetative form. Some were related to common surface soil genera, whereas some are not known as yet. The numbers, types, and distribution of organisms suggests that more microbial diversity could have been recovered from this deep subsurface environment. We found evidence for the existence of dormant, dead, and VBNC bacteria in subsurface tuffs of Rainier Mesa. Subsequent research at a structural analog site supported these findings in that rDNA isolated, cloned and sequenced from the subsurface at Yucca Mt. included many noncultured genera. The nature of cell physiological status is currently under investigation by many laboratories. It has implications for health, bioremediation and microbial ecology in general.

The NTS provided a unique opportunity to investigate heterogeneity at many levels. We discovered that microbial communities located within meters of each other were as different from one another as those located kilometers apart. Heterogeneity and the effects of sample storage and perturbation on subsurface endolithic bacteria are important to those interested in recovery of representative microbiota from natural environments and for those interested in bioremediation of the deep subsurface. These studies will also aid in the design of the nation's high-level nuclear repository, which is proposed to be built in the volcanic tuffs of the NTS.

Acknowledgments

We would like to take this opportunity to thank the Department of Energy for developing the Deep Subsurface Science Program, which allowed scientists the resources to learn about subsurface terrestrial environments. The necessarily interdisciplinary nature of the program brought an entire field of microbiological study to the forefront and laid the foundation for a new understanding of the enormity of microbial biomass and activity in the subsurface.

WASTEWATER AND BIOSOLIDS AS SOURCES OF AIRBORNE MICROORGANISMS

Scot E. Dowd
USDA-ARS-LIRU
Lubbock, Texas

It is well known that municipal wastewater and wastewater residuals contain a variety of pathogenic (disease-causing) microorganisms (1). When sewage from a large population is collected and treated in a centralized location or when reclaimed wastewater or wastewater residuals are recycled and applied to agricultural fields, the public health must be protected by reducing public exposure to these concentrated sources of pathogens. One potential pathway for transmission of these pathogens to the public is the aeromicrobiological pathway (2). The aeromicrobiological pathway includes aerosolization of the microbial pathogens from the wastewater source, followed by atmospheric transport (usually associated with wind currents), and eventual deposition possibly in the lungs of a susceptible human. (See: Bioaerosols: Transport and Fate, this Encyclopedia).

HISTORY OF AEROMICROBIOLOGY AND WASTEWATER

The initial link between wastewater and disease transmission dates back to John Snow (3), who showed that a cholera epidemic sweeping London was linked to the use of drinking water contaminated with sewage. He noticed that cholera occurred much more frequently in customers of the Southwark and Vauxhall Water Company. This water company drew its potable water from the lower Thames. At the time, London's sewage system emptied directly into the Thames, upstream of where Southwark and Vauxhall withdrew their water. Snow, eventually convinced London officials to remove the pump handle from a well used by a district in London, where there were an increased number of cholera cases. On removal of the pump handle, which prevented use of the well, there was a significant decrease in the number of new cholera cases. This essentially confirmed that cholera was spread via water contaminated with sewage.

Soon after Snow (3) published his epidemiological breakthrough related to waterborne transmission of cholera, another scientist, Louis Pasteur, initialized a new field of biological study. Pasteur was able to show, that invisible airborne particles termed *germs* were responsible for mysterious fermentative reactions in his laboratory experiments. These unexplained fermentations were up to that point considered by many other scientists to be a spontaneous generation of life (4). This field of biology has come to be termed *aeromicrobiology* or the study of the aerosolization, transport, and deposition of microorganisms.

Bringing the work of John Snow and Louis Pasteur together, Horrocks (5), evaluated aerosols generated in sewers, concluding that bacteria originating from sewer pipes could be launched into the air by the action of bursting bubbles. This may have been one of the first aeromicrobiology studies related to wastewater, providing initial interest in the potential for the spread of airborne disease, originating from sewage. Unfortunately, interest in this branch of science was temporarily quenched in 1917, when investigations by the Committee on Standard Methods for the Examination of Air (6) indicated that only in special cases, such as in association with concentrated animal feeding operations (CAFOs), were wastewater sources of aerosols a potential public health concern. According to Fair and Wells (7), this report may have suppressed the interest in wastewater bioaerosols for more than 20 years. In fact, only very few studies related to aerosolization of microorganisms from wastewater sources were actually performed until the 1970s, when appropriate and efficient air sampling methodologies and renewed interest truly developed.

AEROSOLS ORIGINATING FROM WASTEWATER TREATMENT PLANTS

Control of domestic wastewater began toward the middle of the 1800s, when diseases such as cholera were becoming increasingly common, and it was recognized that many such diseases were transmitted by sewage-contaminated drinking water. This knowledge prompted the initiation and development of the best management practices for the collection, treatment, and disposal of wastewater. Modern sewage treatment saw its beginnings at the turn of the twentieth century, when processes were developed to reduce the organic content found in domestic wastes, preventing fouling of clean water supplies. Now, more than 15,000 wastewater — treatment plants process, approximately, 150 billion liters of wastewater per day in the United States alone. Wastewater treatment facilities are large concentrated sources of sewage. For this reason, most of the research on wastewater bioaerosols has focused in and around them.

Following the 1907 report of Horrocks and the 1917 advisory of the Committee on Standard Methods for the Examination of Air, Fair, and Wells (7) examined the concentration of bacteria in the air around aeration basins and trickling filters at a wastewater treatment facility. It was suspected that aeration basins and trickling filters were the primary sources of microbial aerosols. They isolated coliform bacteria at 71 CFU/m^3 over the source and up to 35 CFU/m^3 downwind, concluding that a definite public health risk existed, related to aerosolization of the etiological agents of respiratory and skin diseases. Other than this, no other comments related to public health risks were made, except to indicate that dilution of aerosolized microbes during aerosolization and transport should be taken into account during risk assessment.

Randall and Ledbetter (8), in a comprehensive study, used Andersen six-stage air samplers (Andersen 2000

Inc. Atlanta, Ga.) and All Glass Impingers (AGI-30; Ace Glass Inc., Vineland, N.J.) to measure bacteria air pollution around activated sludge units. They isolated what they described as potentially pathogenic bacteria from air around the activated sludge units, noting that many of these organisms were able to travel and remain viable over considerable distances. *Klebsiella pneumonia* and *Escherichia coli* were isolated in many of their sampling runs, raising public health questions related to the role of sewage treatment plants in the spread of these pathogens. *Escherichia coli* and *K. pneumonia* were recovered up to 31-m downwind of the source. Randall and Ledbetter also concluded that the airborne bacterial populations increased dramatically, when passing over sludge treatment units (8 CFU/m^3 upwind and 1,170 CFU/m^3 downwind); respiratory tract pathogens were more prevalent in these aerosols than enteric pathogens, and respiratory pathogens were thought to be better able to survive aerosolization better than enteric pathogens. They indicated that activated sludge units represented definite health hazards, and that the best indicator of bacterial air pollution originating from sewage would be *Klebsiella* spp.

Napolitano and Rowe (9) compared the bioaerosol emission rates of activated sludge and trickling-filter sewage plants, and evaluated the effect of various meteorologic conditions on aerosolization of coliforms. They concluded that activated sludge facilities yielded higher concentrations of coliforms than trickling filter facilities. The sludge aeration tanks were identified as the source that contributed most to the airborne contamination at these facilities. They also noted that half of the airborne microbes were associated with particles greater than 5 μm in size, indicating that the primary route of exposure to these airborne microbes would be deposition in the nasal-pharynx followed by swallowing, while those particles smaller than 5 μm were potential "health hazards" that would penetrate into the lungs.

Adams and Spendlove (10) found that trickling filter sewage treatment plants were "exceptional" sources of aerosolized microorganisms. Using Andersen samplers, they detected that substantial numbers of coliforms were aerosolized from the trickling filters, and that their airborne concentrations were affected by the size of the source and the wind velocity. It was also noted that high wind velocities, high relative humidity, low solar radiation (darkness), and low temperatures allowed for the greatest recoveries of coliforms. At night, coliforms were recovered up to 1,287 m from the source.

Kenline and Scarpino (11) also evaluated the numbers and types of bacteria emitted into the air from activated sludge and extended aeration sewage treatment plants. Using a back calculation, they estimated emission rates from these sources to be 440 CFU/m^2/s and 120 CFU/m^2/s respectively. It was also noted, that the concentrations of culturable, airborne bacteria were primarily depleted by dilution and inactivation. Like Randall and Ledbetter (1966), it was also noted that there were relatively high concentrations of *Klebsiella*, *Aerobacter*, and *Escherichia* in the aerosols.

Goff and coworkers (12) considered coliforms to be an adequate indicator for the evaluation of aerosols, originating from trickling filter sewage treatment plants. Using Andersen samplers, samples were taken from 5-m to 5-km downwind of the source. At 15-m downwind, an average of 347 coliforms/m^3 were recovered, whereas at 700-m downwind the average was 90 coliforms/m^3. As in the study by Adams and Spendlove (10), Goff and coworkers stated that the conditions most conducive to high aerosol emissions were low solar radiation, high relative humidity (30 to 60%), and medium wind velocities 2.6 to 4.4 m/s. Finally, it was concluded that *E. coli* could be used as an indicator of bacterial air pollution, originating from sewage plants.

Pereira and Benjaminson (13) used Andersen samplers inside an aeration tank chamber, inside the exhaust stack for the aeration tank, and 300-m downwind of this source. *Mycobacterium*, *Klebsiella*, and *Streptococcus*, which were described as potentially pathogenic, were the major genus isolated from the air, in and around the sewage facility. *Klebsiella* was the most prevalent genera identified, and could be found in the air at all sampling locations. The effect of ozonation on the viability of airborne microorganisms was also evaluated because the plant in which they were sampling practiced ozonation of the aeration tank chamber for odor control, but they were unable to detect any reductions in the concentrations of bacteria. It was concluded, that there existed a possible health hazard (mycobacterial disease) for sewage treatment workers and highly susceptible populations, such as young children, the elderly, and the infirm, who might reside in areas where the atmosphere would be contaminated by the gaseous effluent of the sewage treatment plants.

Fannin and coworkers (14) investigated two activated sludge and two trickling filter plants, screening the air for coliphage (viruses-infecting bacteria). Using a multislit impinger, they evaluated viruses originating from wastewater treatment plants. Coliphage were recovered at distances between 2 and 15 m, and the highest concentration obtained was 6.67×10^{-1} PFU/m^3. It was noted that there was a correlation between the airborne coliphage concentration and the source strength (concentration of coliphage in the sewage). In addition, the relative humidity correlated with the recovery efficiency, with high relative humidity allowing for significantly higher coliphage recoveries. Fannin and coworkers (15), in a second study, used large-volume air samplers (LVAS) for viruses and Andersen samplers for coliform bacteria, but were unable to recover animal viruses although coliphage were recovered at average concentrations of 3.0×10^{-1} PFU/m^3. Coliform bacteria were also recovered at average concentrations of 2.1×10^2 CFU/m^3 and a correlation between increased wind velocity and increased coliform recoveries was seen. A correlation was also seen between high relative humidity and increased recovery of airborne coliphage, and it was noted that coliphage survived longer in the atmosphere than did coliforms. Finally, the potential densities of airborne animal virus was estimated by creating a ratio between coliphage in the air and coliphage in the sewage, compared to the

animal virus concentration in the sewage. These predicted concentrations of airborne animal viruses were considered a public health concern, especially if the viral aerosols could be shown to reach large susceptible populations.

Cronholm (16), using two-stage Andersen samplers, found that activated sludge tanks were a source of aerosolized bacteria, whose concentrations and makeup were related to the individual plants effluent quality. Interestingly, the relationship as stated, was that the plant with the highest quality effluent produced the most bacterial aerosols from it's activated sludge tanks, whereas the plant with the lowest quality effluent produced the least aerosolized bacteria during activated sludge treatment. It was noticed, that five species of bacteria (*Enterobacter agglomerans*, *Enterobacter cloacae*, *K. pneumonia*, *E. coli*, and *Shigella flexnerii*) predominated in the bioaerosols. He went onto evaluated deposition of enteric bacteria on foliage around the sewage treatment plant, and on the basis of his findings, reasoned that there was definitely a cause for concern, especially considering that nearby residents kept vegetable gardens well within the distance of aerosol dispersion from the activated sludge tanks. During the course of this investigation, the effects of *Klebsiella* aerosols on mice were also evaluated, and it was determined that the 50% lethal dose for mice was 1.4×10^8 organisms. Mice were then directly exposed to aerosols originating from the sewage treatment plant, but no adverse health effects were observed. Viable *Klebsiella* spp. and other bacteria were isolated from the lungs of these mice; however, showing that wastewater bioaerosols containing viable pathogens had deposited into their lungs. From these results, it was concluded that humans with compromised immunological defenses would be at risk from exposure to aerosols around sewage treatment plants.

Fannin and coworkers (17), using multistaged impaction samplers and large-volume scrubbers, evaluated aerosols around an activated sludge wastewater treatment plant, before and after these facilities began operation. In these control samples, bacteria were detected around the site, but after operation, the levels of indicators and total counts dramatically increased. Coliphage were the indicator organisms detected in the highest concentrations downwind of the sources, enteric viruses were recovered only at night, and fecal streptococci were overall the most effective indicator of fecal air contamination. They did admit, however, that background levels of fecal streptococci were high enough to raise questions regarding their origins. Finally, it was also noted that the sensitive detection of indicators would not indicate densities of pathogens, rather it would only measure the potential for airborne fecal contamination, possibly serving as a measure of exposure for epidemiological studies.

Laitinen and coworkers (18) evaluated the relationship between bacterial counts and endotoxin concentrations in air surrounding wastewater treatment plants. Using Andersen samplers (R2A) for airborne bacteria, and sterile glass fiber filters for airborne endotoxin, they collected samples within 1 m of various potential aerosol sources in the treatment plant. The results of this investigation showed no correlation between endotoxin levels and viable or total direct counts of bacteria. Airborne endotoxin levels ranged from 0.6 to 310 ng/m^3, and most samples exceeded the occupational exposure limit proposed by regulatory agencies (30 ng/m^3 in eight hours). It was calculated, that this concentration of endotoxin in the air would equal an airborne bacterial concentration of 7,200 CFU/m^3.

Sawyer and coworkers (19) evaluated the bacterial aerosol emission rates from municipal wastewater aeration tanks. Bacteria were detected over aeration tanks at concentrations of 2,068 total CFU/m^3, 410 total coliforms/m^3, 112 fecal coliforms/m^3, and 24 fecal streptococci/m^3. Emission rates were calculated from these data using two methods: (*1*) Conventional ($E = C \cdot V$ where, E is the emission rate, C is the concentration of the organisms, and V is the velocity of the air rising off the surface) and (*2*) Empirical ($E = C/(X/T)$ where X is the cross-sectional area of the tower and T is the sampling duration). Using the conventional calculation, the average emission rates (CFU/m^2/s) for total bacteria, total coliforms, fecal coliforms, and fecal streptococcus were 1.61, 0.20, 0.06, and 0.02 respectively. The empirical formula provided rates of 2.18, 0.27, 0.07, and 0.03 respectively. The benefits of the emission rate calculation they suggested were to be found when conducting mathematical modeling, related to bacterial aerosols originating from such a source.

Carducci and coworkers (20), using the Surface Air System, took samples at 2-, 20-, and 30-m downwind of the plants aeration tanks over a period of 12-months. It was noticed that there was a seasonal variation in the levels of coliphage, with the highest monthly means occurring in the summer months (12–13 PFU/m^3) at 2 m from the aeration tanks (4 PFU/m^3 at 20 m). These concentrations declined in winter and spring. Enteric virus samples were positive only in the months of August through November. They suggested that the occurrence of enterovirus was out of phase with the occurrence of phage; however, careful evaluation of their data might suggest that some environmental factor (relative humidity, solar radiation, temperature etc.) played a role in the lack of enteroviruses recovered during summer months. They concluded however, that coliphage were not useful indicators of enteroviruses in aerosols. Carducci and coworkers (21), in a second study, evaluated fecal streptococci, coliphage, and total bacterial levels, and found that both total bacteria and fecal streptococci in aerosols showed a positive relationship with the presence of animal viruses in aerosols, but coliphage did not. It was also noted that if viruses were detected in the sewage, they were also found in the air samples. Viruses were recovered only in summer and fall. It was noticed that viral contamination showed a greater capacity for spread than bacteria or bacteriophages, and appeared to remain viable in the air longer. They concluded that reoviruses were highly stable in air, and would probably serve as an indicator of viral presence in aerosols.

One of the overriding similarities in the studies related to aerosolization of microorganisms around wastewater treatment facilities was the focus was on airborne bacteria, particularly coliforms. Heterotrophic bacteria or *Klebsiella* spp. may have been better indicators than coliforms

when evaluating microbial air contamination, but even as recently as 1993, coliforms were still considered as the indicator bacteria of choice. In most studies, significant proportions of the airborne bacteria were associated with particles less than 5 μm, and were thus able to penetrate the lungs. This ability to penetrate the lungs was considered by most to be the most significant health risk. However, many of these studies also considered particles greater than 5 μm to be health hazards, as they would potentially deposit in the nasal-pharynx, where they would subsequently be swallowed. After being swallowed, these airborne particles could potentially enter the intestinal tract where subsequent infection could result. In several of these early studies, potentially pathogenic organisms were detected, and their isolation, linked to a public health risk.

BIOAEROSOLS ASSOCIATED WITH SPRINKLER IRRIGATION USING WASTEWATER

Because of the need for conservation and recycling of limited natural resources, especially in arid regions, it is becoming increasingly common for communities to reuse wastewater and wastewater residuals. For instance, since 1970, Aurora, Colorado, has used reclaimed domestic wastewater to irrigate the local golf courses and city parks. In 1980, the average cost of this water reuse system was $0.43/1,000 gallons compared with $0.78/1,000 gallons that the city of Aurora would have spent for traditionally supplied water. The use of treated municipal wastewater effluent for such purposes, offers a cost-effective opportunity to recycle and dispose wastewater while conserving available freshwater supplies. Water reclamation can also provide an alternative to disposal; in areas where surface water disposal is now banned, or where surface waters are unable to assimilate the nitrogen, carbon, and phosphorus contaminants that remain in most treated wastewater effluent discharges. Today, the majority of reclaimed water goes toward practices such as the landscape irrigation of golf courses, parks and lawns, industrial processing, air-conditioning, fire fighting, water table management, toilet flushing, and construction usage.

Merz (22) investigated aerosolization from sprinkler irrigation of wastewater, applied to a golf course, and found coliforms 41-m downwind of the sprinkler. This was the only published U.S. field study at the time that addressed the hazards from wastewater irrigation aerosols. Hickey and Reist (23) reported that Merz recovered coliforms, 41-m downwind of the sprinkler. In addition, all of them found coliforms or *E. coli* downwind of sewage spray irrigation sites. The majority of these reports estimated that coliforms could be carried 400 to 650-m downwind under moderate wind velocities (5–7 m/s). Coliforms are generally found downwind of sewage spray irrigation sites (22,24–28).

Sorber and coworkers (29) used Andersen samplers for bacteria, and an electrostatic precipitator (LEAP sampler (Environmental Research Corp., St. Paul, Minn) to sample for viruses downwind of a spray irrigation site. They were able to detect up to 330 coliform-like bacteria/m^3 at 47 m. Of these bacteria, up to 47% were assigned to the genus *Klebsiella*. They modeled the transport of the aerosolized bacteria, and estimated that it would take anywhere from 518 to 1,800 m to reduce the increased concentration of the total aerobic bacterial aerosol population to 5 organisms/m^3 above the background bacterial airborne concentrations. A 3-log decrease in airborne bacterial concentrations was found in these experiments when chlorination of the source water was implemented. It was concluded, that terminal disinfection (chlorination) of the wastewater source when properly performed, was more practical and economical than the use of buffer zones between the sprinkler aerosol source and the public. The typical buffer zone used in most cases was only about 100 m and it was felt that this distance, would result in only a very limited reduction of the concentration and viability of airborne microorganisms.

Katzenelson and Teltsch (30) recovered coliforms at a distance of 70 m using an AGI-30 and up to 350 m using an Andersen sampler. It was noted that with low wind velocity around spray irrigation site, a homogenous concentration of coliforms was formed, whereas at higher wind velocities, the concentration of aerosolized coliforms was higher but recoveries were erratic because of increased turbulence. They also pointed out that the health risk to agricultural workers and neighboring settlements from the use of wastewater spray irrigation was virtually neglected. They indicated that adequate source disinfection would probably be the most effective way of reducing this risk. Finally, it was calculated that an individual working at a distance of 100 m from a wastewater irrigation sprinkler line would inhale approximately 36 coliform bacteria in 10 minutes.

Parker and coworkers (31) sampled downwind of spray fields, where food-processing wastes were being used for irrigation, and used an area source model to perform predictions related to the downwind dispersal of the microbial aerosols. Coliforms were recovered (32 coliform-bearing particles/m^3) up to 1,493 m from the source. It was estimated, that it would take between 5 and 30 Km before the bacterial concentrations within aerosol clouds were reduced to background levels.

Teltsch and Katzenelson (32) used Andersen stacked sieve air samplers and large volume aerojet-general liquid scrubbers to evaluate the airborne concentrations of enteric bacteria and viruses associated with wastewater spray irrigation. It was discovered that if the concentration of coliforms in the wastewater was greater than 10^3 CFU/ml, then they were also recovered in air samples. Echovirus 7, was detected at a distance of 40 m from the sprinklers, and a correlation was noted between the aerosol densities with respect to relative humidity. They noted that 50% of the bacteria sampled were associated with particles smaller than 7 μm, which constituted a health hazard as they were in the respirable size range. They also went onto suggest that the larger particles were also of health significance because they could be caught in the upper respiratory tract and swallowed.

Teltsch and coworkers (33) developed a model equation, using inactivation kinetics to estimate downwind concentration of live microorganisms as well as the inactivation coefficient of an *E. coli*. Using radiolabeled *E. coli* as

tracers, they provided realistic information on the ability of *E. coli* to survive the aerosolization process. Results showed that there was a much greater inactivation during the afternoon, than in the morning. The bacterial decay rate was between 8.8×10^{-3}/sec in the morning, and 6.6×10^{-2}/sec in the afternoon, and higher relative humidity promoted survival of aerosolized bacteria.

Teltsch and coworkers (34) evaluated aerosolized pathogenic microorganism concentrations downwind of wastewater spray irrigation fields to evaluate the suitability of coliforms as indicators of airborne microbial contaminants. Coliforms were consistently recovered up to 60 m from the source, and were detected even at 120 and 200 m in concentrations of 501 and 26 coliforms/m^3, respectively. *Salmonella* spp. were also detected in 5 out of 26 samplings, at concentrations up to 5.4×10^{-2} CFU/m^3, but only at 40 m. Serotyping of the *Salmonella* identified them as *S. anatum*, *S. hadar*, *S. ohio*, and *S. infantis*. Enteroviruses (poliovirus type 2, echoviruses type 1, 25, and 17, coxsackievirus B1, and two uncharacterized viruses) were seen in 7 out of 17 samples at distances ranging between 40 and 100 m, in concentrations up to 1.4×10^{-1} PFU/m^3. It was concluded that the survival of coliforms in the air was lower than the survival of either enteroviruses or *Salmonella*, thus coliforms did not fulfill the first requirement of a good indicator organism. They also noted that the ratios of *Salmonella* and coliforms in the wastewater source and the air did not correlate, and that coliforms died out long before enteroviruses. Thus, they concluded that the use of coliforms as indicators was not an accurate assessment of the true presence, or persistence of bacterial or viral pathogens.

Bausum and coworkers (35), using Andersen, AGI-30, and LEAP samplers evaluated the use of f2 bacteriophage as a possible tracer, to aid in the mathematical modeling of the aerosol dissemination of enteroviruses, concluding that coliphage f2 was a very suitable indicator organism as it possessed a very high stability in aerosols, and could be recovered at distances up to 563-m downwind of the source.

Overall, the findings related to the aeromicrobiology or spray irrigation were similar to those seen in association with wastewater treatment. Multiple studies evaluated potential airborne fecal contamination indicators, and coliforms were once again considered as the indicator of choice. However, one study did finally prove, conclusively that coliforms were not adequate airborne pathogen indicators because they did not fulfill at least three of the major requirements for an efficient pathogen indicator. It can also be seen that, like aeromicrobiology studies around wastewater treatment plants, the focus of the more recent studies on spray irrigation also shifted from bacteria to viruses.

BIOAEROSOLS ASSOCIATED WITH LAND PLACEMENT OF BIOSOLIDS

Sludge (more properly termed "biosolids"), which is a by-product of the municipal wastewater treatment processes, contains large concentrations of organic matter as well as phosphorus, nitrogen, and other nutrients that can, following adequate treatment such as composting, be applied to farmland. The practice of land application onto agricultural land not only improves the physical properties and agricultural productivity of soils, but also serves as a logical alternative to unproductive and expensive disposal options, such as incineration or landfilling. Land application of municipal wastewater, treated wastewater, and biosolids, has been practiced since the beginning of modern wastewater treatment, in the mid-nineteenth century. Now, with restrictions placed on certain sludge disposal practices such as ocean dumping and landfill disposal, public wastewater treatment utilities have begun to view the agricultural use of sludge as a cost-effective alternative. In the United States, about 37% of sludge is surface applied to soil for several beneficial purposes, including agricultural fertilization, turf grass production, and reclamation of surface mining areas; 37% is placed in landfills; 16% is incinerated; and the remainder is surface disposed by other means (Committee on the Use of Treated Municipal Wastewater Effluents and Sludge in the Production of Crops for Human Consumption and coworkers, 1996).

Edmonds and Littke (36), using AGI-30 samplers, evaluated the aerosolization of coliforms generated by the placement of sludge (dewatered sewage) into a forest clear-cut. It was noted, that the highest bacterial aerosolization occurred after dry-weather periods when air temperature, solar radiation, and wind velocity were high. This was believed to be due to surface drying of the biosolid material, which promoted aerosolization enhanced by the action of wind currents. They concluded that the highest concentrations of indicator could not only be detected in the first few weeks following placement of biosolids but could also be detected months afterward.

Pillai and coworkers (37), using AGI-30 samplers, evaluated the occurrence of pathogen indicators during land placement onto agricultural land. A number of sampling locations were evaluated, including the hopper loading site, which represented a site with significant mechanical agitation of the biosolid material, the current application sites in the fields undergoing application, the population interfaces, which were on the edge of nearby towns, and old application sites, which were fields where biosolids had been applied several months before sampling. A number of indicator organisms such as thermotolerant *Clostridium* spp., bacteriophage, coliforms, fecal streptococci, and H_2S producers were evaluated. It was found that none of the samples tested contained *Salmonella* spp., and that H_2S producers and *Clostridium* indicators were detected only at the hopper loading site. Molecular methods were then used to link the aerosolized *Clostridium* spp. to those found in the biosolid material. They used ribosomal fingerprinting of the clostridial 16S-23S intergenic region, but were unable to develop any clear genetic link between airborne and biosolid derived isolates. They concluded that under the environmental and placement conditions described during the sampling runs, there was little health risk to populations located downwind of the biosolid application sites. Dowd and coworkers (38), using similar methods, also evaluated hopper loading sites and field sites undergoing placement. At the hopper loading sites, the most prevalent indicators recovered in air samples were H_2S producers, which were detected in 93% of the samples,

followed by *Clostridium* spp., which were detected in 73% of the air samples. At the biosolid application sites, the most prevalent indicators recovered were bacteriophage, followed again by *Clostridium* spp. The mean concentrations of thermotolerant clostridia were 6.8×10^2 CFU/m^3, and the coliphage were recovered at mean concentrations of 1.1×10^3 PFU/m^3. They also concluded that H_2S producers, and fecal streptococci, in addition to the coliphage and clostridia, were much better indicators of fecal air contamination than either total or fecal coliforms.

Dowd and Pillai (39) evaluated clostridium molecular fingerprinting as a method for evaluating the origins of fecal contamination during land placement of biosolids. Using the polymerase chain reaction (PCR), they evaluated a total of 60 clostridial isolates; 30 isolates recovered from air samples taken during land placement of biosolids, and 30 isolates taken directly from biosolid material. A total of 15 different banding patterns were found among the 60 *Clostridium* spp. isolates. A total of 10 aerosolized clostridial isolates from one sampling run showed similar banding patterns, even after restriction in digestion to four of the biosolid derived *Clostridium* spp. isolated on the same day. During the second day of sampling, a number of clostridial isolates were again shown to have genetic similarity with biosolid-derived isolates.

Dowd and coworkers (40) evaluated airborne microbial concentrations, including total heterotrophic bacteria, enteroviruses, coliforms, and *Salmonella* spp., during biosolid-enhanced remediation of mine tailings. In this study, the biosolid material was classified as "excellent quality" or highly treated biosolids. Biosolids were placed onto the surface of the mine tailings by large bottom dumpers. In air samples taken before biosolid placement, airborne heterotrophic concentrations were below detection limits in most of the air samples taken around the mine-tailing sites. During biosolid placement and up to six months after placement, these concentrations were at least 3 logs higher than the initial control samples. No pathogen or pathogen indicators were present in aerosols, but extensive genetic characterization of the airborne heterotrophic bacteria was performed. They used PCR amplification and sequencing of the small subunit ribosome of the bacterial isolates, followed by computer database homology comparison to identify the organisms to the genus level. The most prevalent bacteria associated with mine tailings were *Streptomyces* spp., whereas for the biosolid material the most prevalent isolates were *Bacillus* spp. Air samples taken after placement of the biosolids contained a wide variety of organisms but the most prevalent isolates were *Bacillus* spp. Several of the airborne *Bacillus* spp. were shown to be genetically similar to those found in the biosolid material.

Wastewater treatment facilities generate the highest concentrations of coliform bacteria. The first use of molecular tools in studies on wastewater aerosols were performed on aerosols originating from wastewater residuals being applied to soil. The benefits of molecular methods can be seen in their ability to trace aerosols to their actual source, and their ability to identify the genus and species of airborne bacteria. In these studies, the pathogen indicator issue is once again prevalent, and a new airborne fecal contamination indicator (thermotolerant clostridia) is suggested. Only one study attempted to isolate animal viruses without success, but bacteriophage were once again detected arising from biosolid sources.

MISCELLANEOUS SOURCES OF WASTEWATER AEROSOLS

Darlow and Bale (41), Bound and Atkinson (42), and Newsom (43) evaluated the microbial aerosols generated by toilets. In each case, bacterial or viral aerosols were generated. Darlow and Bale (41) indicated that these aerosols remained airborne in significant concentrations for at least 12 minutes after the flush. Bound and Atkinson (42) demonstrated the generation of aerosols, originated by flushing of toilets that contain coliforms. Gerba and coworkers (44) showed that even after the original toilet flush, indicators remained in the bowl water in significant concentrations and were aerosolized once again with subsequent flushing, and that if toilet bowls were seeded with organic matter and the concentrations of *E. coli* typically found in feces, number of *E. coli* launched into the air by flushing was up to 6.6×10^4 CFU/m^3. Similarly, when seeded with coliphage, they found that up to 2.8×10^3 PFU were ejected. It was also found by Gerba and coworkers, that *E. coli* would remain viable after settling on various surfaces in the bathroom area (e.g., faucets, floor, door handle, etc.) Thus, they could be transmitted to hands resulting in potential self-inoculation. It was noted that at the concentration of the indicator organisms seen in feces, even after the initial flush of the toilet, subsequent flushing could launch potential infective doses.

Milner and coworkers (45) evaluated the dispersal of *Aspergillus fumigatus* from sewage sludge composting piles, and found that the aerosolization of microorganisms was very dependent on the amount of mechanical agitation created by manipulation or mechanical handling of the compost. A maximum actinomycetes recovery of 1.5×10^5 actinomycetes particles/m^3 was found. They suggested the use of noncellulosic bulking agents, extended periods of storage before disturbances, and partial enclosure of composting piles to reduce the production of such aerosols and decrease health risks.

Adams and coworkers (46) evaluated the production of bacterial aerosols that were generated, by cooling towers that used wastewater effluent as makeup water. Sampling air coming from one of the cooling tower exhaust pipes, they found up to 1.2×10^3 bacteria/m^3 of air. Characterization of these organisms identified *Pseudomonas* spp., enterobacteria, and *Bordetella* spp. to be the most prevalent bacteria. It was concluded that chlorination or coagulation of the effluent would be beneficial to reduce potential health effects caused by these bacteria.

Wheeler and coworkers (47) investigated the production of aerosols generated by sludge suction tankers used to remove sewage from portable latrines and septic tanks. They found that suction tankers generated relatively low levels of aerosolized bacteriophage, although actual results indicated that up to 1.0×10^6 PFU were expelled during

operation over a three minute time period. This appears to be a relatively high concentration, especially if the organisms were actual pathogens such as the Norwalk agent. They concluded that because of the low degree of carry over, there would be no significant hazards to human health from aerosols generated by the vacuum handling of normal sewage suction devices.

Health Significance of Wastewater Aerosols

Spendlove (48) detailed problems related to aerosols that arose in industry, agriculture, and municipal processes. This report briefly mentions aerosols arising from wastewater, citing studies that described application of wastewater to land, studies that revealed microorganisms in aerosols as a result of spray irrigation, and aerosols associated with wastewater treatment facilities. Apart from reviewing the cited papers, his comments were that "the possible public health danger of aerosolized sewage organisms to people surrounding areas can be visualized when one considers the great number and variety of pathogens, which may be present in raw sewage." In addition, he felt at the time that spray irrigation had not adequately been evaluated and that there was a significant health hazard associated with aerosolization of pathogens in the vicinity of wastewater treatment plants.

Sorber and Guter (49) investigated the health and hygiene aspects of spray irrigation. After investigating aerosol contamination studies, they also stated that bacterial aerosols were more prevalent and remained viable longer, and thus traveled further, when wind velocity and relative humidity was high, and temperature and solar radiation was low. They mentioned that evaporation rates showed that a 50-mm water droplet evaporates in 0.31 seconds when aerosolized at 50% humidity and 22 °C. The resultant nuclei containing microorganisms was more likely to remain both airborne and better protected from environmental insults. It was also recognized that most of the aerosol studies related to wastewater had been centered on coliforms, and that the most frequently isolated coliform, when characterizations were performed, was of the genus *Klebsiella*. Because *Klebsiella* are known respiratory pathogens they thought that specific testing for this genus should be performed in lieu of indicators. They then discussed the infectivity mechanism of aerosols, as related to particle size. In summary: (*1*) particles 2 to 5 μm are captured in the upper respiratory tract, moved upward by cilia action and swallowed, entering the intestinal tract where infection can occur; (*2*) particles 1 to 2 μm can be deposited directly into the alveoli of the lung where infection can occur; (*3*) particles less than 1 μm slowly decrease in the probability of alveolar deposition until 0.25 μm (the size of the smallest enteric viruses not associated with airborne particles), when deposition in the alveoli again becomes more likely; and (*4*) particles greater than 5 μm are deposited in the upper nasal-pharynx where they are likely to be swallowed entering the intestinal tract. Thus, mechanisms exist for respiratory and intestinal pathogens to be transmitted by means of aerosolization. It was indicated that the minimal infective doses (TCD_{50}) for viruses were relatively low and ranged from 1.0 to <790 viruses for influenza, coxsackieviruses (A21 and B4), adenovirus, rhinovirus, measles, and respiratory syncytial virus. They stated that at an activated sludge aeration basin, it was estimated that 40 to 60% of biological aerosols would penetrate the lungs and 6 to 13% would penetrate the alveoli. Finally, on the basis of these figures they also calculated that a man working within five feet of the aeration tank would inhale a viable *Klebsiella* particle every two breaths. Overall, Sorber and Guter concluded, that the risk from aerosolization of pathogens associated with wastewater irrigation could be significant.

Katzenelsen and coworkers (50) published results of an epidemiological study in which they studied the incidence of enteric diseases in more than 200 agricultural settlements. Of these Kibbutzim (communal settlements), 77 were practicing spray irrigation with wastewater that had been partially treated by pond oxidation, whereas remaining communities did not use wastewater for irrigation. It was found that there was an increased prevalence of shigellosis, salmonellosis, typhoid fever, and infectious hepatitis (two to four times higher) in those communities practicing wastewater spray irrigation. They suggested that aerosols were probable pathways for transmission of these diseases, in addition to alternate mechanisms such as vector (clothing and bodies) transmission. They concluded that their results helped strengthen the hypothesis that a relationship existed between wastewater irrigation and enteric diseases.

Shuval and Fattal (51) performed an epidemiological study related to spray irrigation at Kibbutzim in Israel that used two types of settlements. The first settlement used effluent for irrigation during two consecutive years, followed by two years in which only noneffluent water sources were used. The second group of settlements consisted of a total of 23, 12 of which used effluent sources and 11, which used only noneffluent water sources for irrigation. Results suggested that increased disease incidence did not occur at those settlements practicing wastewater irrigation when compared with those settlements that did not. Some indications of excess enteric disease incidence in the age group zero to four years were noticed, however, in those kibbutzim that used effluent water sources for irrigation. It was felt, that such groups of previously unexposed people were the most susceptible to change in health status. They suggested that further analysis of the data was required, and thus they were unable to draw any realistic conclusions.

Johnson and coworkers (52) investigated aerosolization of bacteria and viruses associated with wastewater, and sought to identify health effects attributed to living near wastewater treatment plants. Monitoring of the environment and the health of persons near a new activated sludge treatment plant before and after its initial operation was performed; and a survey was conducted on the incidence of respiratory, gastrointestinal, eye, ear, and skin diseases, and symptoms of persons living within 5 km of the plant just before and after it's initial operation. They also monitored the environment using LEAP samplers, and collected blood, feces, urine, throat swabs, sputum, and hair samples from the test populations over time. Microbiological analysis of aerosols

was consistent with previous studies, showing an increase in airborne pathogens and indicators after the plant began operation. In clinical studies of infection, they found significant increases in throat swab isolates of *Streptococcus*-beta and *Staphylococcus aureus* after initial operation of the plant. Interestingly, they noted a slight increase in the incidence of parasites, such as *E. coli*, *Giardia lamblia*, and *Trichomonas*, isolated from feces after operation of the plant commenced. Picornavirus isolation significantly increased in the operational periods of the plant. Serology showed a significant, or borderline significant, increase in antibody titers to Echovirus 29, Echovirus 13, Echovirus 33, and Poliovirus 1, but they were unable to link any of the viral antibody reactions to exposure to aerosols. The health survey revealed significant increases in the reported incidence of skin disease, gastrointestinal syndromes (diarrhea, nausea, vomiting, and general weakness), and of pain in the chest that occurred when breathing deeply. These increases occurred primarily in the downwind areas up to 2 km from the plant. Finally, they also noticed a significant increase in sore throat and fever above 103 °F, especially in young children. No absolute conclusions were made related to any definitive health problem or lack thereof.

Camann and coworkers (53) performed a health-related investigation, concurrent with aerosol monitoring at an elementary school located 370 to 470 m from the aeration basin of an advanced wastewater treatment plant. Using local school attendance records and information derived from field monitoring, they sought to evaluate health aspects of the wastewater treatment plant's proximity to the elementary school. They hypothesized that adverse health effect related to the plants operations, would result in a higher absenteeism at the elementary school in the years following start-up of the wastewater treatment facility. Microbiological screening of the aerosols was very comprehensive, and showed elevated levels of total coliforms (12.2 CFU/m^3), fecal streptococci (4.2 CFU/m^3), Mycobacteria (19.1 CFU/m^3), and coliphage (1.5 PFU/m^3). Camann and coworkers on review and analysis of school absentee records noted that even before operation of the treatment facility, the school, when compared to other "control" schools, had a higher rate of absenteeism. After initial operation, the experimental school did show a slight decrease in absentee rates compared with the absentee rates seen before the plant began operation, and also in comparison with absentee rates at control schools that were not located in the vicinity of a wastewater plant. Following continued operation of the wastewater treatment facility, however, the experimental school actually showed a statistical increase in attendance, when compared with rates at the school before plant operation and rates in control schools. Conversely, it was noted that first and second grade students at the school showed higher absenteeism during numerous periods after the treatment plant began operation, as compared with both previous records and the control schools. They concluded that an appreciable increase in the concentration of airborne fecal streptococci and mycobacterium was observed at the school when the wind was blowing from the direction of the treatment plant, but little effect on the health of the students at the school was observed.

Scarlett-Kranz and coworkers (54) performed a health survey among municipal sewage and water treatment workers. They submitted a questionnaire to wastewater treatment workers as the experimental group and drinking water treatment workers as a control group. They found that sewage workers reported a significantly higher frequency of headache, dizziness, sore throat, skin irritations, and eye irritations when compared with the drinking water treatment workers. They postulated on the routes of transmission, and indicated that many of the reported health problems could best be explained by aerosol exposure.

Clark and coworkers (55) evaluated exposure of newly hired employees at a wastewater facility, and compared their level of antibodies to Rotavirus, Norwalk agent, and *Prototheca wickerhamii*. They noted a slightly increased incidence of gastrointestinal disease among the recently hired wastewater workers. A serological survey found a fourfold or greater antibody titer level increase in response to rotaviruses in 21 out of 30 of the inexperienced workers and two out of five of the experienced workers. There was also an increase in the antibody titers to Norwalk agents in a small number of the inexperienced workers that was not seen in any of the control groups analyzed. On further analysis of the results from the study, a positive correlation was seen that related these increases to exposure to specific aerosol sources at the plant, indicating that the aerosols may have increased exposure to these agents. On adjusting for covariables such as race and economic status, the only significant increase in titer related to aerosols was the Norwalk agent. They concluded by stressing the importance of minimizing contact with wastewater and associated aerosols as well as continued promotion of basic hygiene practices among wastewater workers.

Fattal and coworkers (56) investigated the occurrence of viral antibodies in an agricultural settlement during a viral disease outbreak. They screened sera from 777 individuals living in agricultural settlements. These individuals were grouped according to the type of exposure. Some were exposed to aerosols from wastewater irrigation at nearby towns, some exposed to other sources of wastewater aerosols, including wastewater originating from the settlement itself, and some were not exposed to wastewater. The investigation was conducted immediately following a national outbreak of echovirus type 4. Antibodies against echovirus type 4 were consistently and significantly present in high titers from children exposed to wastewater aerosols from nearby towns. It was also noted that this increase in antibody titer against echovirus type 4 was not seen among wastewater irrigation workers. They noted that there was the possibility of unusually high levels of contact infection in populations exposed to wastewater from distant urban populations, possibly related to the ongoing epidemic. They suggested that more effective wastewater treatment would result in a greater reduction in the concentration of pathogens in the effluent, which would be prudent from a public health standpoint.

Melbostad and coworkers (57) evaluated various health related symptoms, and their correlations to sewage worker

exposure to bacterial aerosols. Airborne levels of total bacteria (direct microscopic counts, which were divided into spherical and rod-shaped bacteria), endotoxins, and hydrogen sulfide were evaluated, and compared to the results of questionnaires that assessed health related symptoms, which manifested during and after the airborne measurements were taken. They found no correlation between endotoxin levels and any of the parameters screened. The aerosol exposure levels of workers reporting a symptom (headache and tiredness) were correlated to exposure to rod-shaped bacteria and total bacteria levels. It was concluded that higher exposure to rod-shaped and total bacteria were found among sewage workers with respiratory symptoms, headache, tiredness, and nausea when compared with workers not reporting such symptoms.

Laitinen and coworkers (58), using a health questionnaire, an Andersen sampler, and glass fiber filters, performed a health related survey that monitored symptoms, airborne culturable bacteria, and endotoxin levels. They performed these extensive air contaminant sampling runs at various phases of the wastewater treatment process, including influent pumping stations, influent screens, sedimentation basins, biofilter towers, aeration basins, and sludge treatment beds. Endotoxin levels ranged from less than 0.01 to 350 ng/m^3. The highest mean concentrations of endotoxin occurred in the sludge treatment area, followed by the aeration basin, and the highest airborne bacterial counts were found in the sludge treatment area. The questionnaire on work-related symptoms revealed that 6 out of 16 workers reported positive for symptoms, including fever and chills, or eye and nasal irritation (four workers), and cough or cough with phlegm (three workers). Two workers suffered from all of the symptoms evaluated. Other symptoms were headache, fatigue, and gastrointestinal symptoms. They concluded that there was an association of the symptoms, particularly eye and nasal irritation that was correlated to bacterial and endotoxin exposure. It was also admitted that for solid conclusions to be drawn, a larger study would be needed. Gregersen and coworkers (59) described an outbreak of Pontiac fever (nonpneumonic legionellosis) in wastewater workers. These workers, who had been involved in repairing a sludge decanter over a 10-day period, became ill with fever and flulike symptoms characteristic of Pontiac fever. While repairing the inoperable decanter, a second decanter was centrifuging sludge and suspected of releasing aerosols containing *Legionella pneumophilia*. The workers wore only B2 filter masks (charcoal) not meant for aerosol protection. Clinical tests showed that the workers tested positive for *Legionella* sero-conversion. In addition to a positive antibody response, *L. pneumophilia* was found in the sludge. It was concluded that the workers on exposure to aerosols from a sewage sludge decanter contracted Pontiac fever.

Dowd and coworkers (60) combined actual field sampling, mathematical transport modeling, and dose-response modeling to evaluate potential health risks associated with land application of biosolids. Actual airborne levels of *Salmonella* spp. and indicator virus were used to back-calculate the release rates of bioaerosols from the sources, which included an area source and a point source. They evaluated the concentrations of bacterial and viral pathogens predicted to be viable at various distances downwind of the source, entered these predicted concentrations into two dose-response models, and calculated the predicted percentage of exposed individuals that would inhale an infective dose. They found a 3% chance of infection from Coxsackie B3 at 100 m after only one hour of exposure, during low wind conditions. The risk at this distance from the source climbed to 47% after 24 hours of continual exposure. They also indicated that only half of the persons infected with *Salmonella* would possibly become ill, with an even a lower percentage of clinical illness attributed to Coxsackie B3 exposure. When considering bacteria, the potential risk was increased slightly more than tenfold, resulting in a 60% chance of infection after one hour of exposure 100-m downwind of the source. No significant probability or risk of infection was associated with aerosolization and transport of viruses or bacteria, to a nearby population center that was located some 3 km away from the source. It was mentioned that health risks to workers at the biosolid application site was evident although considering the lack of compromised immune status, probably evident in individuals within this limited population, the risk would be considerably less than predicted.

CONCLUSION

The concern over the aerosolization of pathogens from wastewater treatment plants, and the related public health issues date back to almost 100 years. It has been shown that a significant increase in the airborne concentration of microorganisms occurs in association with wastewater sources, and in many studies the presence of aerosolized pathogens has been shown. Another similarity in the studies reviewed has been the search for an effective airborne indicator organism. It appears that coliforms, *Klebsiella* spp., fecal streptococci, thermotolerant clostridia, and coliphage have been the preferred indicators. Unfortunately, no one indicator has been proved to be adequate in all cases for all pathogens that might actually be present. Almost 100 years after the initial studies of wastewater treatment facilities, we now see that viruses may be the concern of interest rather than bacteria.

In at least one case, wastewater aerosols have been proved to be the source of a potentially fatal disease (Pontiac fever), and in numerous cases these wastewater aerosol sources can be linked epidemiologically to various disease symptoms or syndromes. Workers at sewage treatment plants who are exposed to high concentrations of aerosolized microorganisms tend to exhibit transient symptoms such as eye, skin, and respiratory irritation, headaches, or just fatigue, which may be related to the high concentrations of aerosolized microorganisms or endotoxins they are exposed to during normal activities. Yet, it is unlikely that such workers would develop clinical symptoms, except in the most extreme cases. The other possibility for seeing increased disease manifestation in a population exposed to its own wastewater aerosols is in relation to enteric or respiratory pathogens,

which have acute symptoms, and against which little long-term immunity develops (e.g., protozoa such as *Cryptosporidium parvum*, a few viruses such as Norwalk virus, and certain bacteria such as *L. pneumophila*).

To prevent aerosolization of pathogens during the reuse of wastewater or during actual wastewater treatment, best management practices or preventive procedures can include disinfection of wastewater before application to land, aiming sprinklers at lower angles toward the ground to minimize production of aerosols, the maintenance of adequate buffer zones between aerosol sources and the public, physical barriers such as vegetation between sources and the public, and advanced treatment of wastewater and biosolids. When considering wastewater treatment plants, the best management would be to cover aeration basins, inlet streams, and trickling filters. In addition, workers at all wastewater related sites should be encouraged to wear approved protective respirators, especially in enclosed areas where sewage or sludge is aerated. In addition to adequate breathing protection, workers should also wear protective clothing that is removed before leaving work and laundered on-site (not at the workers home), they should practice liberal hand-washing before and after leaving high-risk work areas, especially before eating, and they should even be required to shower before leaving work. These procedures would help prevent contact spread of pathogens to the worker's families, and subsequently to the public.

Hickey and Reist (28) concluded that there are four basic alternatives for future action related to the issue of pathogen aerosolization in association with wastewater: (*1*) conclude that no health hazard exists from viable wastewater aerosols on the basis of present evidence; (*2*) continue to seek further evidence on the aeromicrobiological pathway spread of pathogens from wastewater to humans; (*3*) continue to perform epidemiological studies to link aerosols originating from wastewater sources to disease occurrence; or (*4*) concede that a health risk exists and initiate best management practices for aerosol control. These alternatives are still representative of conclusions forthcoming from this review 30 years later. It can also still be concluded that: (*1*) microbial aerosolization from aerated wastewater process to areas where plant workers and nearby residents are located has been adequately demonstrated; (*2*) aerosols originating from these sources contained a variety of pathogenic bacterial genera and animal viruses; (*3*) health risks have not been adequately confirmed; (*4*) future studies should be both epidemiological and aeromicrobiological in nature; (*5*) health risks arising from bacterial, protozoan, and viral respiratory and intestinal pathogens, as well as, allergic responses should be investigated; (*6*) best management practices should be implemented to prepare for outbreak situations; and (*7*) further research is needed related to aerosol monitoring and development of improved methodologies, especially for animal virus recovery.

WASTEWATER STABILIZATION PONDS

DUNCAN MARA
University of Leeds
Leeds, United Kingdom

Waste stabilization ponds (WSPs) are an extremely effective, natural form of wastewater treatment. They combine simplicity, robustness, low cost, and a very high degree of disinfection. WSPs are usually designed as one or more series of anaerobic, facultative, and maturation ponds, with the former two being mostly responsible for the removal of organic matter (biological oxygen demand, BOD), helminth eggs, and *Vibrio cholerae*, and the latter for the removal of fecal bacteria and viruses. Sometimes anaerobic ponds may not be used (Fig. 1), and sometimes (depending on the required microbiological quality of the final effluent) maturation ponds may not be needed (Fig. 2).

WSPs are a very common form of treatment, with over 7,000 systems in the United States of America, over 2,500 in France, and 1,100 in Germany, for example. They are also common in tropical and subtropical regions where the warm climate leads to increased efficiency and, consequently, lower land area requirements.

The process and physical design of WSPs is described in detail in several engineering design manuals and reviews (1–10).

BACTERIAL POPULATIONS

Little work has been done on the nonfecal bacterial communities in WSPs. In anaerobic ponds, the same

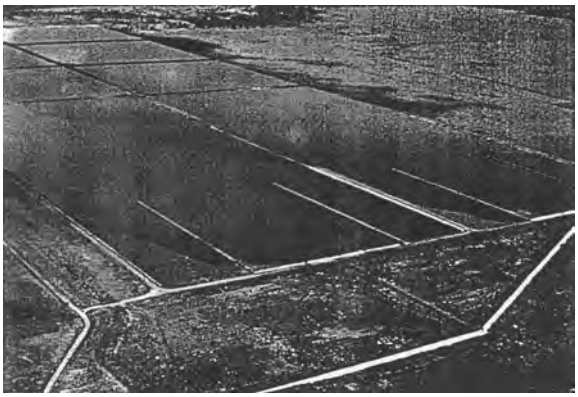

Figure 1. Phase I of the Dandora WSP, Nairobi, Kenya, comprising two series of a facultative and three maturation ponds. Phase II comprises six additional series to the right of Phase I, and Phase III will comprise anaerobic ponds at the head of the eight series.

Figure 2. Two series of anaerobic and facultative ponds at Braslândia in the Federal District, Brazil.

bacterial community is present as in other anaerobic reactors (see BIOSOLIDS: ANAEROBIC DIGESTION OF), that is, the obligately anaerobic acidogenic, hydrogenic bacteria and methanogens, together with sulfate-reducing bacteria. It is the odor-generating potential of the latter group that is of most practical concern with WSPs; however, if the volumetric BOD loading is below 400 $g/m^3\,d$ (11) and if the sulfate concentration in the raw wastewater is below 500 mg SO_4^{2-}/L (12) odor release is very unlikely to reach nuisance levels.

In facultative and maturation ponds, the normal heterotrophic bacteria of aerobic wastewater treatment are present. As these bacteria are facultatively anaerobic, they are well suited to the fluctuating dissolved oxygen conditions in facultative ponds. Anaerobic photosynthetic bacteria are also present in facultative ponds and, to a lesser extent, in maturation ponds (see Photosynthetic bacteria).

The oxygen required by the heterotrophic bacteria for the bio-oxidation of organic matter in facultative and maturation ponds comes mainly from algal photosynthesis, although some comes into the pond via surface reaeration. The carbon dioxide needed in algal photosynthesis comes mainly from the bacteria, although again some enters the pond via its surface from the air. There thus exists a mutualistic relationship between the algae and heterotrophic bacteria in facultative and maturation ponds (Fig. 3).

Cyanobacteria (blue-green algae) are often present in facultative and maturation ponds, but in only small numbers, and they are not a significant component of the pond flora, except in extremely lightly loaded ponds, such as the last maturation ponds in a series comprising a large number (6–8) of these (13).

ALGAL POPULATIONS

Facultative and maturation ponds contain high concentrations of algal biomass, and they are consequently colored dark green. The algae are extremely important in the operation of WSPs: they provide most of the oxygen needed for bio-oxidation and they create most of the conditions required for fecal bacterial die-off (high pH, high dissolved oxygen — see Removal of Excreted Pathogens). Their one commonly perceived disadvantage, that they contribute to a high effluent concentration of suspended solids, is less of a disadvantage in practice as many regulatory agencies permit WSP effluent samples to be filtered prior to BOD analysis, and so exclude the algal BOD contribution because "algal BOD" is very different in nature from "wastewater BOD." In Europe, for example, WSP effluents are required to have less than or equal to 25 mg filtered BOD per liter and less than or equal to 150 mg suspended solids per liter (14).

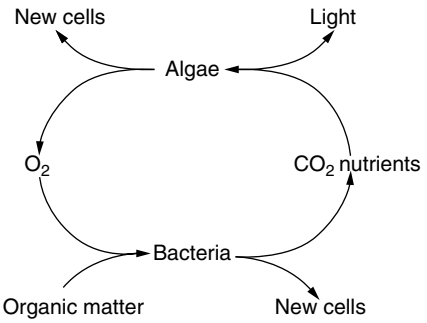

Figure 3. Algal–bacterial mutualism in facultative and maturation ponds.

The algae that tend to predominate in the turbid waters of facultative ponds (see Table 1) are the motile genera (such as *Chlamydomonas, Pyrobotrys*, and *Euglena*), as these can optimize their vertical position in the pond water column in relation to incident light intensity and temperature more easily than nonmotile forms (such as *Chlorella*, although this is also fairly common in facultative ponds) (Fig. 4). The concentration of algae in a facultative pond is usually in the range of 500 to 2,000 μg chlorophyll *a* per liter, but depends on temperature and organic loading (Fig. 5).

As a result of the photosynthetic activities of the pond algae, there is a diurnal variation in the concentration of dissolved oxygen. After sunrise, the dissolved oxygen level gradually rises, in response to photosynthetic activity, to a maximum in the mid-afternoon, after which it falls to a minimum during the night when photosynthesis ceases and respiratory activity consumes oxygen. The position of the oxypause (the depth at which the dissolved oxygen concentration reaches zero) similarly changes, as does the pH because at peak algal activity carbonate and bicarbonate ions react to provide more carbon dioxide

Table 1. Examples of Algal Genera Present in Waste Stabilization Ponds

Algae	Facultative Ponds	Maturation Ponds
Euglenophyta		
Euglena	+	+
Phacus	+	+
Chlorophyta		
Chlamydomonas	+	+
Chlorogonium	+	+
Eudorina	+	+
Pandorina	+	+

for the algae, so leaving an excess of hydroxyl ions with the result that the pH can rise to above 9, which kills fecal bacteria (see Photosynthetic bacteria).

The wind has an important effect on the behavior of facultative ponds, as it induces vertical mixing of the pond liquid. Good mixing within the upper aerobic layer ensures a more uniform distribution of BOD, dissolved oxygen, bacteria, and algae and hence a better degree of waste stabilization. In the absence of wind-induced mixing, the algal population tends to stratify in a narrow band, some 20-cm thick, during daylight hours. This concentrated band of algae moves up and down through the top 50 cm of the pond in response to changes in incident light intensity, and causes large fluctuations in effluent quality (especially BOD and suspended solids) if the effluent take-off point is within this zone (see Photosynthetic bacteria).

Maturation ponds usually show less vertical biological and physicochemical stratification and are well oxygenated throughout the day. Their algal population is more

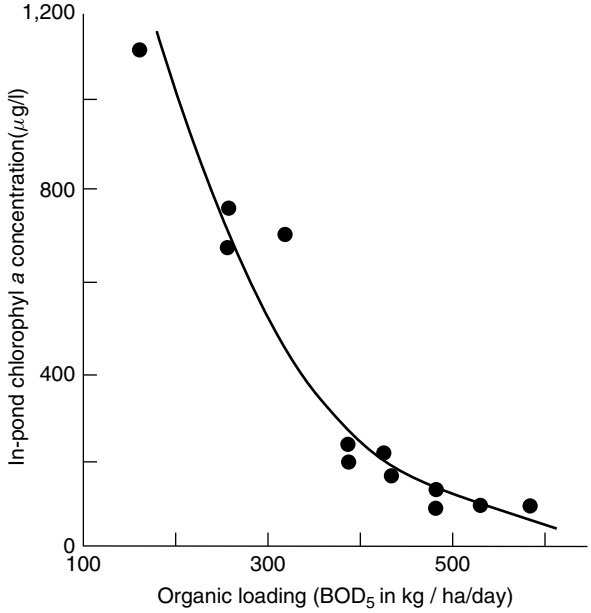

Figure 5. Variation in algal biomass (as chlorophyll *a* concentration) with organic loading in facultative ponds in northeast Brazil at 25 °C.

diverse than that of facultative ponds (Table 1), with nonmotile genera tending to be more common; algal species diversity increases progressively along the pond series.

Ammonia and Sulfide Toxicity

Free ammonia (NH_3) and hydrogen sulfide (H_2S) are both toxic to pond algae. Both dissolved gases inhibit photosystem II, the site of oxygen production. With ammonia the toxicity increases with increasing pH, and with hydrogen sulfide it increases with decreasing pH, as the proportion of these dissolved gases increases with these shifts in pH.

Abeliovich and Azov (15) found that with algae from high rate algal ponds ammonia concentration of 2 mM (28 mg/L) seriously inhibited photosynthesis at pH greater than 8, but Pearson and coworkers (16) found that facultative pond algae were much more tolerant of ammonia, up to 5 mM (70 mg/L) at pH 8 to 9 (Fig. 6).

Sulfide is toxic at lower concentrations than ammonia, with 0.25 μM (8 mg/L) seriously inhibiting photosynthesis at pH 7 to 9 (Fig. 7). *Chlamydomonas* is most resistant to sulfide, and this explains why it may be found as a thin surface film in anaerobic ponds.

PHOTOSYNTHETIC BACTERIA

The obligately anaerobic purple and green sulfur photosynthetic bacteria, mainly members of the Chlorobiaceae, the Chromatiaceae, and the Ectothiorhodospiraceae, are commonly found in facultative ponds and, to a lesser extent, in maturation ponds. Bacteriochlorophyll absorbs light of a longer wavelength than algal chlorophyll, and so the photosynthetic bacteria are often found below the algae in facultative ponds, especially primary facultative ponds,

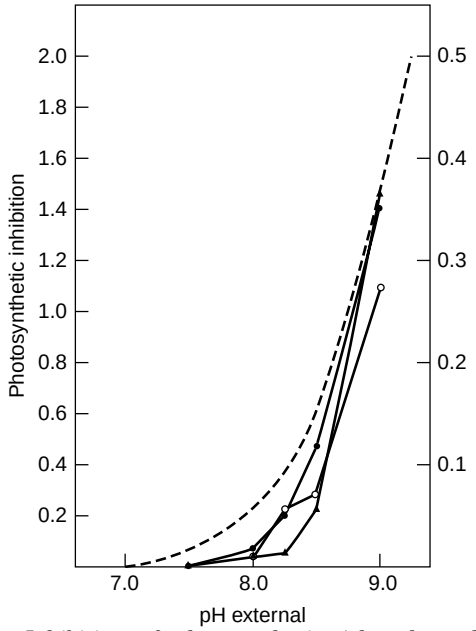

Figure 6. Inhibition of photosynthesis (plotted as $\log_{10}$ of reciprocal percentage activity) by ammonia at different external pH values for *Euglena* (▲), *Chlorella* (◯), and *Scenedesmus* (●), with pNH_3 shown as —.

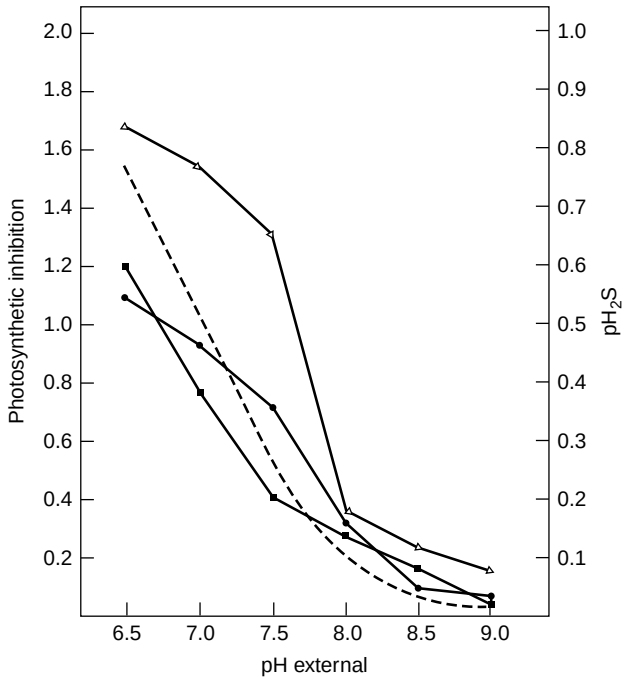

Figure 7. Inhibition of photosynthesis (plotted as $\log_{10}$ of reciprocal percentage activity) by sulfide at different external pH values for *Euglena* (△), *Chlorella* (■), and *Scenedesmus* (●), with pH_2S shown as —.

in which they fix carbon dioxide and oxidize hydrogen sulfide:

$$21H_2S + 10CO_2 + 2NH_3 \xrightarrow{\text{light}}$$

$$2(C_5H_8O_2N) + 21S + 16H_2O$$

The sulfur so formed is deposited within the cell by members of the Chromataciae (Fig. 8), and outside the cell by the Chlorobiaceae. It can also be oxidized to, for example, sulfate:

$$21S + 30CO_2 + 6NH_3 + 36H_2O \xrightarrow{\text{light}}$$

$$6(C_5H_8O_2N) + 21H_2SO_4$$

Both the Chromatiaceae and the Chlorobiacae can utilize simple organic compounds (e.g., acetate) for photoheterotropic sulfide oxidation:

$$H_2S + 5CH_3COOH + 2NH_3 \xrightarrow{\text{light}}$$

$$2(C_5H_8 - O_2N) + S + 6H_2O$$

$$S + 15CH_3COOH + 2NH_3 \xrightarrow{\text{light}}$$

$$6(C_5H_8O_2N) + 21H_2SO_4 + 14H_2O$$

Thus, the photosynthetic sulfur bacteria act as a "sulfide filter" protecting the pond algae from the toxic effects of sulfide (see Algal Populations). However, when facultative ponds are overloaded, the toxic effects of sulfide become too much for the algae, resulting in overgrowth of photosynthetic bacteria, so turning the pond from green to pink or purple. This condition may be permanent or, if the pond is only slightly overloaded, intermittent.

Also present in facultative ponds are the purple nonsulfur bacteria, the Rhodospirillaceae. Apart from adding color to the ponds, these contribute little to pond activities.

REMOVAL OF EXCRETED PATHOGENS

Helminth Eggs

The human intestinal nematode eggs (i.e., the eggs of *Ascaris lumbricoides*, the human roundworm, *Trichuris trichiura*, the human whipworm, *Ancylostoma duodenale* and *Necator americanus*, the human hookworms) are removed by settling owing to their relatively high sedimentation velocities and the quiescent conditions in WSPs. This occurs mainly in the first two ponds in the series (i.e., in the anaerobic and secondary facultative ponds, or primary facultative and first maturation ponds). The percentage egg removal (R) can be estimated from the following equation (1):

$$R = 100[1 - 0.14\exp(-0.38\theta)] \quad (1)$$

where θ is the mean hydraulic retention time (= volume/flow) in the pond, days.

This equation is equally valid for egg removal in anaerobic, facultative, and maturation ponds. For design purposes, the following Equation (2), which corresponds to the lower 95% confidence limit of Equation (1), can be used:

$$R = 100[1 - 0.41\exp(-0.49\theta + 0.0085\theta^2)] \quad (2)$$

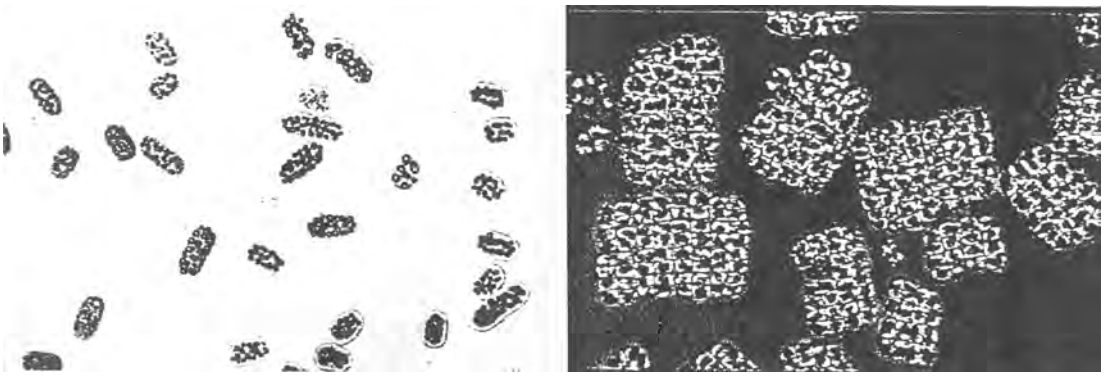

Figure 8. *Chromatium* sp. (left) and *Thiopedia* sp. (right) with intracellular sulfur granules.

Table 2. Geometric Mean Bacterial and Viral Numbers[a] and Percentage Removals in Raw Wastewater (RW) and the Effluents of Five Waste Stabilization Ponds in Series (P1–P5)[b] in Northeast Brazil at a Mean Mid-Depth Pond Temperature of 25 °C

Organism	RW	P1	P2	P3	P4	P5	Percentage Removal
Fecal coliforms	2×10^7	4×10^6	8×10^5	2×10^5	3×10^4	7×10^3	99.97
Campylobacter	70	20	0.2	0	0	0	100.00
Salmonellae	20	8	0.1	0.02	0.01	0	100.00
Enteroviruses	1×10^4	6×10^3	1×10^3	400	50	9	99.91
Rotaviruses	800	200	70	30	10	3	99.63

[a] Bacterial numbers per 100 mL, viral numbers per 10 L.
[b] P1 was an anaerobic pond with a mean hydraulic retention time of 1 day; P2 and P3–P5 were secondary facultative and maturation ponds, respectively, each with a retention time of 5 days.

It is thus possible to design a WSP series specifically for egg removal to comply with the recommendation of the World Health Organization (18) that treated wastewater used for crop irrigation should contain no more than one egg per liter, and also with the recommendation of Blumenthal and coworkers (19) that this level should be reduced to 0.1 egg per liter when children under 5 years of age are exposed or when conditions favor egg survival.

Protozoan (Oo)cysts

The cysts of *Giardia lamblia* and *Entamoeba coli* and the oocysts of *Cryptosporidium parvum* are smaller than helminth eggs, and hence their removals are lower. For example, Grimason and coworkers (20) found a minimum retention period in Kenyan pond systems of 37 days was required to ensure complete removal of *Giardia* cysts and *Cryptosporidium* oocysts; a similar time was found necessary in French ponds (21).

Viruses

Little work has been done on viral removal in WSPs. It is thought that they are removed because of adsorption onto solids, including algae, followed by sedimentation of the solids and dead algae. Oragui and coworkers (22) reported removals of 99.9 and 99.6% for enteroviruses and rotaviruses, respectively, in a series of ponds with an overall retention time of 21 days at a temperature of 25 °C (Table 2).

Bacteriophages have been used as surrogates for viral removal. Vorkas and Lloyd (23) found that phages of *Erwinia* spp., *Pseudomonas* spp., and *Serratia* spp. could be used as indicators of viral transport and removal in WSPs. They also found the phage die-off was accelerated by in-pond pH values greater than 8.5 and by sunlight-mediated effects as found by Curtis and coworkers (24) for fecal bacterial die-off in WSPs, although these factors are yet to be evaluated for human viral pathogen die-off in WSPs.

Bacteria

There is considerable information on the removal of fecal indicator (principally fecal coliform) bacteria in WSPs, but much less on the removal of bacterial pathogens. Oragui and coworkers (22) found that Campylobacter and salmonellae were removed to undetectable levels when the fecal coliform numbers had been reduced to 7,000 per 100 mL in a series of WSPs with an overall retention time of 21 days at 25 °C (Table 2). Oragui and coworkers (25) reported the complete removal of *Vibrio cholerae* in a series of WSPs after 11 days retention when the fecal coliform count was 6×10^4 per 100 mL (Table 3).

Bacterial Removal Mechanisms. The factors responsible for fecal bacterial removal in WSPs are time and temperature (26), high pH (27,28), the combination of high light intensity and high levels of dissolved oxygen (24)

Table 3. Geometric Mean Numbers of *Vibrio cholerae* and Fecal Coliform Bacteria in Raw Wastewater (RW) and a Series of 10 Waste Stabilization Ponds (P1–P10)[a] in Northeast Brazil at a Mean Mid-Depth Pond Temperature of 25 °C

Sample	*V. cholerae* (per liter)	Fecal coliforms (per 100 mL)
RW	485	2×10^7
P1	28	8×10^6
P2	8	3×10^6
P3	3	1×10^6
P4	8	5×10^5
P5	3	2×10^5
P6	0	6×10^4
P7	0	4×10^4
P8	0	8×10^3
P9	0	3×10^3
P10	0	

[a]P1 was an anaerobic pond with a mean hydraulic retention time of 1 day; P2 and P3–P10 were facultative and maturation ponds, respectively, each with a retention time of 2 days.

and, for the removal of *V. cholerae*, sulfide levels above 3 mg/L (25).

Time and Temperature. Marais' (26) Equation (3) for the removal of fecal coliform bacteria in WSPs assumes that it can be reasonably well represented by first-order kinetics in a completely mixed reactor; his equation for a single pond is:

$$N_e = \frac{N_i}{(1 + k_B\theta)} \tag{3}$$

where N_e and N_i are the numbers of fecal coliforms per 100 mL of pond effluent and influent, respectively, and k_B is the first-order rate constant for fecal coliform removal in a completely mixed reactor, day^{-1}.

The value of k_B is strongly dependent on temperature. Marais' Equation (4) for this is:

$$k_B = 2.6(1.19)^{T-20} \tag{4}$$

where T is the pond temperature, °C (for design purposes T is taken as the mean air temperature of the coldest month in the case of river discharge, wastewater-fed aquaculture, or discharge into shellfish growing areas, or of the coolest month in either the irrigation season or, in the case of coastal discharge, the bathing season). Marais derived Equation (4) from an analysis of the fecal coliform data from maturation ponds in the United States of America at temperatures of 2 to 21 °C (29).

The value of k_B depends not only on time and temperature, but also on organic loading: the higher the loading, the lower the algal biomass (Fig. 5) and therefore the lower the pH and dissolved oxygen concentration, and thus the lower the value of k_B (see next section).

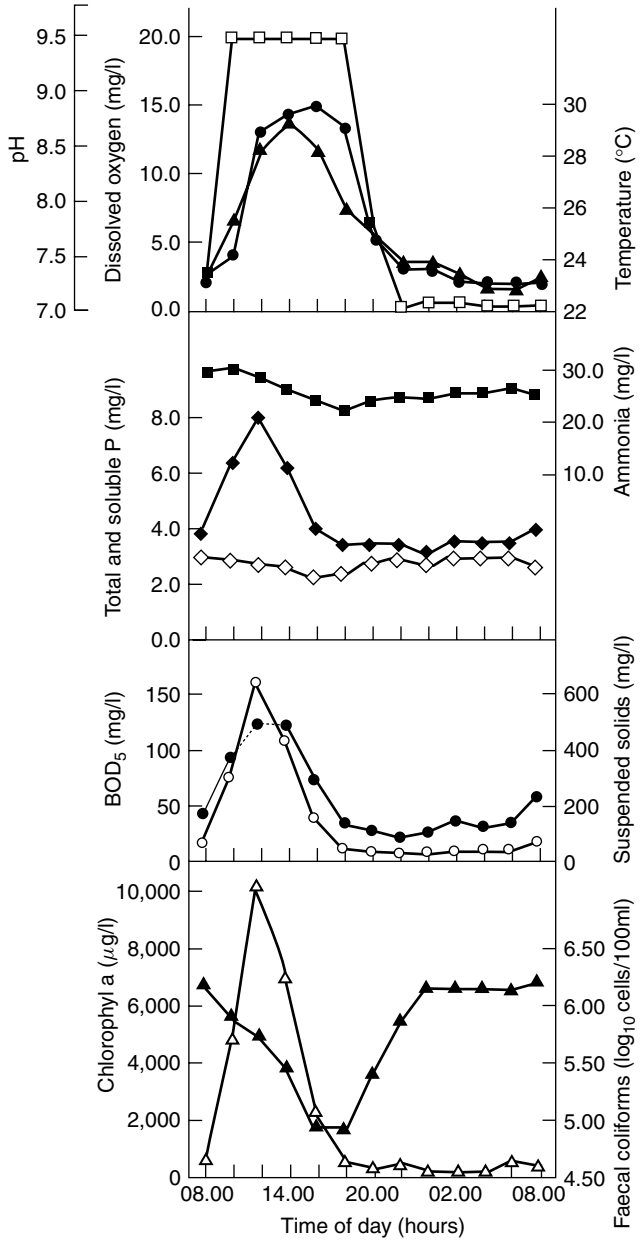

Figure 9. Facultative pond effluent variations in (a) dissolved oxygen (□), pH (▲), water temperature (●); (b) ammonia (■), total (♦) and soluble phosphorus (◇); (c) suspended solids (○), biological oxygen demand (BOD_5) (●); (d) chlorophyll *a* (△), fecal coliforms (▲). Dissolved oxygen was measured in the pond 5 cm below the surface near the effluent. Dotted lines indicate underestimated data owing either to instrument sensitivity or (with BOD) an insufficient dilution range.

For a series of anaerobic, facultative, and maturation ponds, Equation (3) becomes:

$$N_e = \frac{N_i}{(1 + k_B\theta_{an})(1 + k_B\theta_{fac})(1 + k_B\theta_{mat})^n} \tag{5}$$

where N_e and N_i are now the numbers of fecal coliforms per 100 mL of the final effluent and raw wastewater, respectively, and n is the number of maturation ponds.

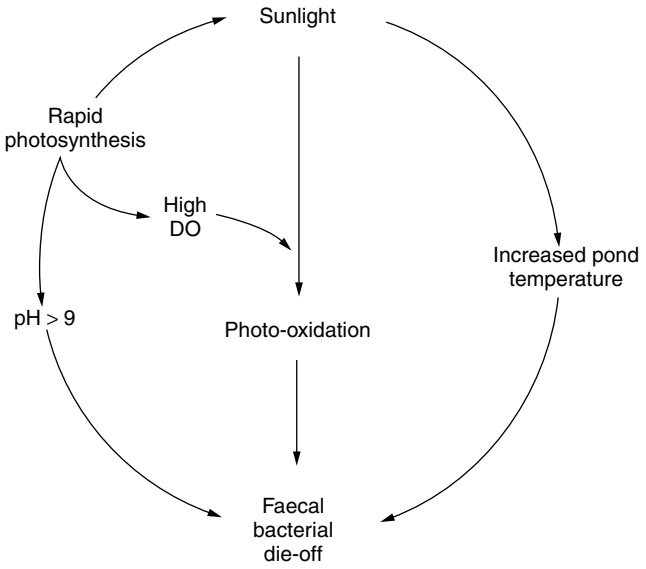

Figure 10. Conceptual mechanisms for fecal coliform die-off in WSPs.

Although Equation (5) assumes the same value of k_B is valid for each type of pond (which is, of course, unlikely), it is nevertheless a reasonable representation for design purposes, when used in conjunction with Equation (4), of fecal coliform removal in the pond series as a whole (30).

High PH and High Light Intensity with High Dissolved Oxygen. Figure 9 shows the diurnal variation of fecal coliform bacteria, algal biomass (as chlorophyll *a*), organic matter (as BOD), suspended solids, ammonia, total and soluble phosphorus, pH, dissolved oxygen, and temperature in the effluent of a facultative pond in northeast Brazil (31). There are peaks of BOD, suspended solids, total phosphorus, pH and dissolved oxygen, which are coincident with the algal biomass peak, and a fecal coliform trough nearly coincident with the algal peak. This shows that algal effects such as increased pH and increased dissolved oxygen determine fecal coliform die-off. Laboratory work shows that high pH is indeed an important factor in fecal bacterial die-off: at pH values greater than 9 fecal coliforms die-off very quickly (28). Curtis and coworkers (24) showed that high dissolved oxygen alone was ineffective in promoting fecal bacterial die-off, but its conjunction with high visible light intensities (light of wavelengths greater than 425 nm) was extremely effective, especially at high pH. The ability of light of wavelengths in the range 425 to 700 nm to damage fecal coliforms depended strongly on high dissolved oxygen levels and the presence of dissolved humic substances (24). A conceptual model for fecal bacterial die-off in WSPs is shown in Figure 10.

WASTEWATER TREATMENT MICROBIOLOGY

PETER POLLARD
Griffith University
Maroochydore, Australia

> . . . when we compromise the air, the water, the soil and the variety of life, we steal from the endless future to serve the fleeting present

Most microbiological research revolves around human health. Yet only 1% of the world's bacteria (Three major lines of primary descent, archae, bacteria, and eukaryotes have now been distinguished using molecular methods (1). In this article, the domains of archae and bacteria are referred to as bacteria) are pathogens. The rest are decomposers and nutrient recyclers that are essential to our very existence. They control the biological wastewater treatment processes that help prevent us from compromising the natural environment.

Advanced wastewater management relies extensively on the bacterial growth kinetics in biological nutrient removal (BNR) processes (2) Reliable design, control and operation of these systems depends on quantitatively predicting the growth kinetics of the bacteria in the process. What is the potential (maximum) bacterial growth rate? How will bacteria spend the energy generated during substrate oxidation? Will they grow and divide (i.e., generate more sludge) or will they expend more energy on cell maintenance (i.e., generate more metabolic products such as carbon dioxide and less sludge) rather than on growth? Measuring and predicting bacterial responses to changes in the wastewater treatment environment is essential for our fundamental understanding and the ultimate improvement of treatment processes.

Only recently have methods been developed with the ability to directly measure the dynamics (growth–kinetics) of bacterial communities or populations in open treatment processes. Existing methods cannot separate bacterial growth from metabolic activity. The chemical transformations that the bacteria cause are seen reflected in changes to substrate and product concentrations (e.g., RBCOD, COD, BOD_5, O_2, CO_2, ATP, $NADH_2$, NH_4, NO_3, CH_4). However, the ability to observe and measure bacterial dynamics is left in the void between substrate use and product formation (Fig. 1).

Historically, engineers considered biological wastewater treatment processes from a hydraulic perspective. They progressed to modeling the kinetics of microbial decomposition of substrates (3) in which influent (substrate input) is converted to a product (output) in reactions that are catalyzed by microorganisms (4). However, (micro)biologists have revealed sufficient intracellular detail to show that the blackbox in Fig. 1 consists of a complex series of reactions mediated by a dynamic and interactive microbial consortia (5–10).

As a microbial ecologist interested in water quality and wastewater research, I am concerned about the relationships of bacteria with each other, with other organisms, and with their environment. Their importance is not so much in their identity but rather the chemical and physiological changes that their growth kinetics cause to the wastewater environment. However, without the proper tools to study bacterial dynamics in situ we cannot begin to understand the ecology of the bacterial communities in the wastewater environment. Hence, this article aims to describe techniques that have the ability to directly measure in situ bacterial community and population growth kinetics (dynamics). The long-term view is to use such methods to fill the void of knowledge ("Black box," Fig. 1) between substrate use and product formation and the relationship between metabolism and growth.

In the measurement of bacterial growth kinetics Meadow and Pirt (12) aptly observed, "There is probably no other technique whose principles are so often ignored with the result that experiments are seriously limited if not meaningless." Along with biodiversity and physiology, quantifying the growth kinetics of bacterial communities in situ will bring about major advances in our understanding of the ecology of microorganisms.

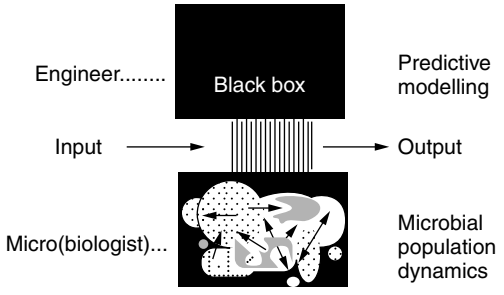

Figure 1. Linking engineering and (micro)biological approaches to quantify the dynamics of microorganisms in wastewater treatment processes. (After V. K. Bhupathiraju, M. Hernandez, P. Krauter, and C. L. Alvarez, *J. Hazard. Mater.* **June 67**, 299–312 (1999b).

A quantitative approach to the dynamics of bacterial communities is essential, rather than the traditional descriptive and qualitative approaches (13). Quantitative measures of microbial growth kinetics are necessary to predict the fate of compounds in both natural (14) and engineered environments (15,16).

DISTINGUISHING METABOLISM FROM GROWTH

Bacterial metabolism is geared primarily toward growth of cells rather than just increasing the size of existing cells. Fundamental to understanding the dynamics of bacterial communities in wastewater treatment processes is recognizing that bacterial growth and metabolism describe bacterial physiology at two different levels of complexity. The approach that will be developed here differentiates growth from overall metabolic activity. Growth, generally, is an increase in the number of cells in a population.

Metabolism, metabolic activity, or just activity are all encompassing terms that are used to describe all the chemical reactions in the cell; they are divided into catabolic and anabolic reactions (17,18). These reactions include biochemical processes that involve the generation of energy, so they are often measured in terms of the rates of respiration or the energy intermediates, such as ATP. This includes reactions that are responsible for cell maintenance, growth, transport, biosynthesis, synthesis of exopolymers and motion. On the other hand, bacterial growth is the result of anabolic reactions that involve the ability of cells to divide (12). Cell metabolism and the relationship between bacterial use of substrates in wastewater, respiration, and the generation of new cell biomass can be seen in Figure 2.

Bacterial growth is the increase in the number of individuals in a population (18,20). In the literature, bacterial growth is often used synonymous with activity. However, the techniques for measuring growth refer to bacterial division; bacteria oxidize and reduce matter to produce new bacterial biomass (Fig. 2). Activity implies metabolic activity.

In the past, the measurement of growth rate of bacterial populations was confined to the ability to culture the organism in the laboratory. Plate counts (colony forming units — CFU) is a method that has been used to determine the number of living cells in wastewater samples. However, the method has long been recognized as not representing the number of bacteria in situ for natural and engineered environments — "the great plate-count anomaly" (21).

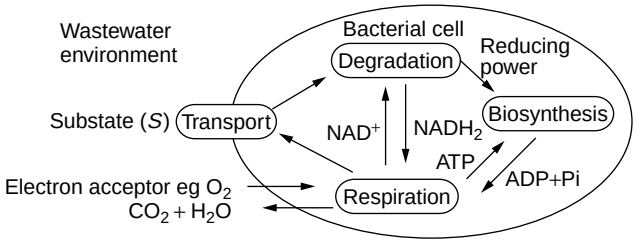

Figure 2. Metabolism and cell synthesis — the material and energy flow of a bacterial cell in a wastewater environment (After T. D. Brock, *Symp. Soc. Gen. Microbiol.* **41**, 1–17 (1987).

These methods are erroneous estimates of in situ growth because the artificial growth conditions of the culture system substantially influences bacterial growth kinetics, morphology, and physiology (20,22). At best 1% of bacteria in a natural environment can be cultivated on an artificial media (23–25) and around 15% in activated sludge (Amann, and coworkers, 1995).

Redox dyes are also used to measure cellular activity. Dehydrogenase activity is used to indicate living bacterial biomass on the basis that the electron transport chain is functioning. The oxidized form of redox dyes, such as INT (2-(4-iodophenyl)-3- (4-nitrophenyl)-5-phenyl tetrazolium chloride) and CTC (5-cyano-2,3-ditolyl tetrazolium chloride) are almost colorless and nonfluorescent. When they are incubated with environmental samples, they are taken up and reduced to formazan by dehydrogenase activity in the cellular electron transport chain. The redox dye subsequently becomes insoluble and the cells with respiratory activity fluoresce (26–28). Similar methods have been used for counting actively respiring bacteria in municipal wastewater treatment plants, and in groundwater and seawater samples (29,30). These methods do not, however, measure bacterial growth kinetics.

Metabolic activity mistakenly has also been assumed to be directly related to bacterial growth on the basis that cellular activity could be used to estimate biomass (31). These methods have relied on measuring concentrations of ATP or $NADH_2$, dissolved oxygen or the activity of dehydrogenase enzymes (31–33). Droste and Sanchez (32) critically evaluated these techniques and prefaced their work with the statement that the direct measurement of the active mass was impossible. They concluded that ATP concentrations offered the best-available estimate of activity. However, the concentration of ATP and $NADH_2$ are also involved in catabolic and anabolic processes of the bacterial cell (34), not just those of cell multiplication. These methods cannot be used as a growth rate measurement because they depend on the metabolic state of the bacterial cell.

ATP and $NADH_2$ methods have almost been abandoned by water treatment specialists as a measure of bacterial growth because the results are so difficult to interpret. The dehydrogenase activity methods are hindered by the complex wastewater environment, whereas DNA methods are tedious and unreliable (35). Currently, respirometric methods are used to estimate bacterial growth rates in wastewater treatment systems (36–38). However, the existing respirometric methods often lead to false interpretation of results (40). There is no clear consensus on how the growth kinetics should be measured or what the results from respirometric assays really mean (16,41).

Identifying the structure and dynamics of bacterial populations in biological nutrient removal (BNR) processes has involved the use of molecular techniques, such as nucleic acid homology, RNA sequencing, and RNA probes (21,42,43). These methods are not without their conceptual difficulties, for example, clearly distinguishing species and relating the ecological roles of the bacterial species that have been identified (44). However, these

techniques have considerable potential for quantifying the biomass of individual species or groups of bacteria.

Amann and coworkers (21) believe that once the problems associated with the use of in situ fluorescent-dye probes have been overcome, the method could be used to measure the growth rate of bacterial species. However, in situ probing methods still rely on quickly visualizing changes in bacterial numbers in open ecosystems, an almost impossible task amidst rapid losses of bacterial biomass through processes such as dilution, grazing, and viral lysis (45–47).

Current methods in wastewater treatment research rarely directly measure in situ bacterial growth rates; the methods that are used are very different from those used in other fields. Most notable are those used in studies of the microbial ecology of natural aquatic environments (48–51). Brock (14,52), along with these other microbial ecologists, has emphasized the need to develop tools to quantify the growth kinetics of bacterial populations in situ.

Major advances have been made in methods used to directly measure bacterial biomass and growth kinetic in fields outside wastewater research that are only now being recognized by the industry (53). Bacterial growth rates have been measured in situ in natural environments using the thymidine assay. In marine, freshwater, soil, and clinical research, the thymidine assay is the most widely accepted in situ method used to measure cellular growth kinetics (54–63).

Engineered wastewater environments are comparatively simple and better suited to use with the thymidine assay because they are engineered trophic ecosystems built on bacterial growth (division)—"Bacteria constitute the major part of the biomass and they are the basic trophic level in all stages of biological sewage treatment. . ." quote from Pike (64). This next section is concerned with the historical development and principles of an *in situ* measure of bacterial growth kinetics.

DIRECTLY MEASURE BACTERIAL GROWTH KINETICS

Historical Development

For a long time now, the thymidine assay has been validated in natural complex ecosystems as the preferred method for measuring bacterial growth kinetics for in situ studies of aquatic microbial ecology. This assay originated in clinical research long before it became a quantitative tool for use in aquatic environments.

Bacterial growth is the creation of new bacterial biomass (in the form of proteins, carbohydrates, lipids, RNA and DNA) that culminates in cell division, once DNA synthesis is completed. Growth is marked by the synthesis of new bacterial DNA and by cell division. Hence, bacterial growth rates can be measured by the rate at which new DNA is synthesized. In the thymidine assay, radiolabeled thymidine is introduced into the cell's environment. Each time the cell divides the new DNA molecules are labeled. The rate of cell growth is determined from the rate at which thymidine is incorporated into the bacterial DNA.

As early as 1965, Roodyn and Mandel (65), measured the rate at which *Bacillus cereus* divided with the thymidine technique. Thymidine metabolism and the theoretical basis of the thymidine assay was originally based on studies of the growth of mammalian cells (54).

Then the key issues identified for applying the method were

- the need for an isotope-dilution method to determine endogenous dilution of dTTP;
- correlating concentrations of exogenous thymidine with endogenous dTTP;
- estimating rates of DNA synthesis with rates of thymidine incorporation.

It was not until the early 1980s, that these same issues were addressed by microbial ecologists in their application of the method.

Brock was the first to use radioactively labeled thymidine with autoradiographic techniques to indicate bacterial metabolic activity in natural environments (66,67). Later, his review comments underpinned the direction of the thymidine growth assay in environmental research (14). He emphasized the need for studies that incorporated methods for measuring microbial growth rates in nature, that is in situ, as opposed to laboratory experiments. He also pointed out that only viable bacteria take up and incorporate thymidine into dividing bacterial DNA. On this basis, others used the thymidine assay for detecting bacterial metabolic activity in soil and lake sediments (68,69). The thymidine assay was first applied to the marine environment as a measure of the rates at which unattached bacteria were turned over by bacteriovores (70).

The breakthrough in quantitatively measuring bacterial growth rates came when the rates of incorporation of thymidine into DNA were used to estimate rates of bacterial cell division using a conversion factor for bacterioplankton (71,72) and for marine sediments (73,74). Theoretical factors were used to convert the rate of thymidine incorporation into the rate of synthesis of new bacterial cells. The conversion factor was based on the average size of a bacterial DNA molecule and its number of thymine residues (i.e., mol %[G+C]). The theoretical factor was validated with empirical estimates that were made by measuring increases in bacterial numbers (72,75). By the end of 1982, the thymidine method had been identified, as having the ability to measure the production of new cells in situ. In time, the paper of Fuhrman and Azam (72) became the most cited—a classic citation (76).

Subsequently, the specific activity of the added exogenous thymidine was shown to be significantly diluted by intracellular and extracellular sources of DNA precursors. This caused significant underestimates of bacterial growth rates. This dilution problem was overcome in the marine environment by applying an isotope dilution method (77). The same methods were latter applied to bacterioplankton of eutrophic lakes (78).

Subsequently, the method has been validated as an absolute measure of growth rate by comparing it with other methods such as ^{3}H-leucine and P^{32} incorporation and the frequency of cellular division (49,77,79–82). From 1982, microbial ecologists used the thymidine

assay in trophic studies of aquatic ecosystems. Estimates of bacterial production are determined from bacterial growth rates measured with the rate of thymidine incorporation (55,83–92).

Since 1975, aquatic microbial ecologists have thought long and hard about the best quantitative in situ measures of bacterial growth and production. They have come to accept and use the thymidine assay because it appears to measure growth

- of only bacteria
- of bacteria in balanced or unbalanced growth states
- in situ
- at a molecular level of sensitivity
- independently of bacterial biomass and mortality.

In contrast to this plethora of research, the wastewater treatment industry has struggled, and continues to struggle to confidently measure key bacterial growth kinetic parameters (16,40,41,93). The wealth of experience and knowledge associated with the development of methods to measure bacterial biomass, production, and growth kinetics in clinical and aquatic research has not yet been transferred into wastewater research.

To design, apply, and interpret the incorporation of thymidine into any new environment requires a knowledge of factors that influence thymidine incorporation. This is especially true for biological wastewater treatment processes in which the bacterial populations are complex and two to three orders of magnitude larger than those in natural systems (55,64). The wastewater industry can now capitalize on the experiences that have led to the development and application of the thymidine assay in natural aquatic environments, avoiding the "pit-falls."

Principles and Biochemical Pathways

In wastewater treatment, the measurement of a bacterial species growth kinetics is just as important as its identity. The basis of bacterial physiology is metabolic activity that is geared to maximize rates of growth (94). Quantifying growth is important because the survival of a bacterial species in any environment depends on how fast it grows.

When radioactively labeled thymidine ([methyl-^{3}H] thymidine) is added to wastewater, it is actively transported into the cell. The DNA of newly synthesized bacterial cells are radioactively tagged, whereas the DNA of nongrowing cells are not labeled (56). The bacterial growth process and radioactive labeling of the newly synthesized DNA is illustrated in Figure 3. The significance of the thymidine assay is that it is able to quantitatively measure the bacterial growth process in situ, that is without changing the wastewater environment (95).

For a long time the incorporation of thymidine has been used as a measure of DNA synthesis. Even today, Cleaver's (54) paper is still the most comprehensive review of thymidine metabolism. In principle, exogenous radioactively labeled thymidine is rapidly and efficiently incorporated into bacterial DNA as the bacteria replicate. The advantage of using thymidine as a DNA precursor

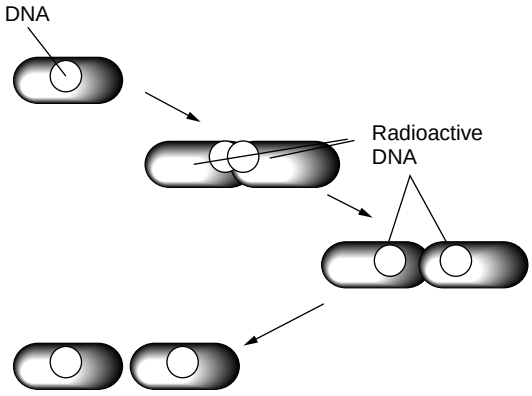

Figure 3. The bacterial growth process in the presence of [methyl-^{3}H] thymidine.

is that it is only used by bacteria for DNA synthesis; nongrowing cells do not synthesize DNA. Thymidine is not involved in other metabolic pathways, as is ATP (96). Thus, the rate at which thymidine is incorporated into bacterial DNA can be directly correlated to the rate of cell division. The method is a sensitive measure of bacterial growth rate at a molecular level. However, the quantitative use of the method requires an understanding of the biochemistry of thymidine metabolism (54).

After thymidine is actively transported across the bacterial cell membrane, it is phosphorylated to deoxythymidine monophosphate (dTMP) in a reaction catalyzed by thymidine kinase or it is catabolized by a phosphorylase to thymine (Fig. 4). The catabolism of thymine is important because it ultimately results in the formation of a radioactively labeled free methyl radical (Fig. 4) that enters the general metabolic pathways of the cell. Eventually, nonspecific label will be incorporated into macromolecules other than DNA. Some loss of thymidine along this catabolic pathway is not critical, as long as thymidine is added in excess. However, this catabolism makes it necessary to separate the radioactively labeled DNA from other macromolecules and keep incubation times short. Another advantage of using thymidine as the DNA precursor is that uracil, which is not radioactive is an intermediate in the catabolic process (Fig. 4). Hence there is no direct route for the rapid radioactive labeling of RNA.

The salvage pathway is the route through which exogenous [methyl-^{3}H] thymidine is incorporated into bacterial DNA. Once thymidine is phosphorylated to dTMP (Fig. 4), it is further phosphorylated in a series of thymidylate kinase catalyzed reactions to deoxythymidine diphosphate (dTDP) and then triphosphate (dTTP); eventually it is incorporated into DNA via DNA polymerase as shown in Fig. 5 (97). These kinases are labile in the absence of thymidine (98). When bacteria are dividing in the presence of thymidine the newly synthesized DNA becomes radioactively labeled (Fig. 3).

In the de novo pathway, dTMP is synthesized from a series of anabolic reactions within the bacterial cell. Deoxy uridine monophosphate (dUMP) is methylated to dTMP via the enzyme thymidylate synthetase. Both the de novo and salvage pathways share the one dTMP pool. The ensuing kinase reactions, leading to the synthesis of

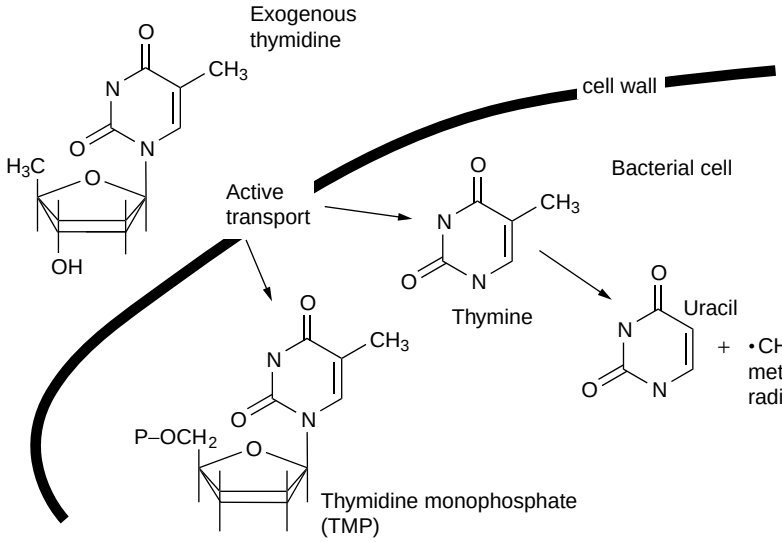

Figure 4. Thymidine uptake, phosphorylase, and kinase activity. The incorporation of exogenous thymidine into bacterial DNA is via deoxythymidine monophosphate (dTMP). Phosphorylase may also catabolize thymidine to form thymine and ultimately a nonradioactive uracil molecule with a radioactive free radical.

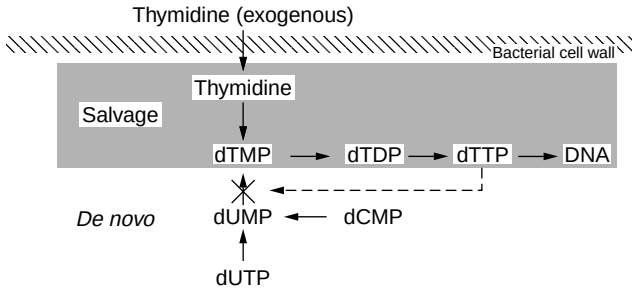

Figure 5. Salvage and de novo pathways of thymidine incorporation into DNA. At high thymidine concentrations, deoxythymidine triphosphate (dTTP) will allosterically feedback inhibit the de novo biosynthetic pathway, preventing endogenous dilution of thymidine. The abbreviated phosphorylated nucleotides are given in the text.

DNA are the same as for the salvage pathway. Because both pathways contribute to the same dTMP pool, the de novo pathway internally dilutes the exogenous supplies of [methyl-^{3}H] thymidine that are incorporated in DNA. This is referred to as isotope dilution (77).

Bacterial growth rates can underestimate growth if isotope dilution is not eliminated or measured. De novo sources of dTMP can be eliminated by taking advantage of the end-product, dTTP, inhibition. dTTP is a specific and potent allosteric inhibitor of the thymidylate synthetase in the de novo pathway (99). At appropriately high concentrations of exogenous thymidine (i.e., low thymidine specific activities) endogenous isotope dilution can be inhibited. Appreciating the intricacies of these biosynthetic pathways was, and still is, an important part of the historical development and application of the thymidine assay to natural and engineered aquatic environments.

Key Factors to Consider — "Traps for New Players"

Thymidine and thymine generally have no fate other than their incorporation into DNA. They are also rapidly incorporated into DNA. Thymidine has an advantage over thymine such that it is accumulated in the bacterial cell and is more rapidly and efficiently converted into the dTTP pool (96,97,56). Following are the key factors that must be considered when applying the thymidine assay as a quantitative measure of bacterial growth in wastewater treatment processes.

Isotope Dilution — Eliminate or Account. Bacteria can also synthesize thymidine internally via the de novo biosynthetic pathway and contribute to large intracellular pools of dTMP. When exogenous thymidine is incorporated into the dTMP pool, via the salvage pathway, it can be diluted substantially by the de novo source (Fig. 5). Both these pathways contribute to a common pool of thymine — DNA precursors. However, the de novo pathway contribution will dilute the radioactively labeled thymine that is incorporated into DNA (97), artificially lowering the estimate of bacterial growth. This isotope dilution must be dealt with before the assay can be applied to the wastewater environment.

Isotope dilution experiments are designed to take this dilution into account (77,78). These experiments are important to any new environment in which the thymidine assay is applied. The thymidine assay can be manipulated to take advantage of the fact that, at sufficiently high concentrations of thymidine, a corresponding increase in dTTP causes feedback inhibition of the de novo pathway (Fig. 5). The use of high concentrations of thymidine (i.e., low specific activity [Ci.mmol^{-1}]) of [methyl-^{3}H] thymidine have been shown to remove the effect of isotope dilution. The amount, however, must be determined for each new environment (89,100). The concentration of thymidine can be adjusted to either eliminate or minimize isotope dilution.

Thymidine Transport and Kinase Activity. There are two key underlying assumptions of the thymidine assay, that is, the bacteria being studied have the capacity to:

1. actively transport thymidine across the bacterial cell membrane; and

2. have an active thymidine kinase to catalyze the phosphorylation of thymidine to dTMP (Fig. 4).

Initially it was thought that nearly all bacteria were able to meet both these criteria (54). Subsequently, however, several workers have found that although most heterotrophic bacteria will transport and incorporate [methyl-^{3}H] thymidine, some cultured isolates do not (77,101). For the genus *Acinetobacter*, one important difference from many other bacteria is its inability to incorporate thymine or thymidine into DNA. This genus is physiologically identified by its unique lack of both thymidine kinase and phosphorylase (102).

Also, some sulfate-reducing bacteria have been observed not to incorporate thymidine (103). Some cultures of methanogens have also been shown not to incorporate thymidine (104,105), although some of this evidence is contradictory (56). Johnstone and Jones (106), for example, demonstrated a methanogen that did not incorporate thymidine into DNA, whereas others have shown that the same species did have such ability (107). Others have concluded that thymidine does not measure bacterial growth in some aquatic environments (108). However, these authors did not allow for the influence of isotope dilution, their conclusions are left in doubt.

Not taking into account the factors that influence thymidine incorporation was the most likely cause of these inconsistencies. The true test of thymidine's ability to measure bacterial growth rates will come from in situ experiments that take into account isotope dilution.

Overall, there is compelling evidence that most bacteria do incorporate exogenous thymidine. Thymidine measurements of growth rate are consistent with other measures of growth such as the frequency of dividing cells and the incorporation of tritiated leucine (49,82,109,110). In applying the thymidine assay to any new environment, the investigator needs to be aware that not all the actively dividing bacteria may have the ability to incorporate [methyl-^{3}H] thymidine into bacterial DNA.

Nonspecific Labeling of Macromolecules. Thymidine assays are deliberately short to minimize the radioactive labeling of macromolecules other than DNA (see Thymidine catabolism; Fig. 4). Preliminary kinetic studies are important to determine the optimum time that thymidine can be incubated with environmental or wastewater samples. As we have seen earlier, thymidine catabolism leads to the formation of a radioactively labeled methyl radical or forms tritiated water that enters general metabolic pathways (56). These catabolic products label macromolecules other than DNA, such as proteins (101). It is important to determine an incubation time that is sufficient to radioactively label DNA while minimizing the labeling of these other macromolecules.

Isolating bacterial DNA from the wastewater treatment environment can also be used to eliminate nonspecific labeling. There is an extensive repertoire of molecular methods for extracting and isolating DNA for qualitative studies of bacterial DNA (111). For wastewater research needs, however, it is necessary to consider methods that quantitatively recover the DNA.

Probably one of the most controversial and most lively debated subjects was the factor used to convert the rate of thymidine incorporation into the rate of bacterial growth. The calculation of bacterial growth rates requires an estimate of the number of cells produced per mole thymidine incorporated into DNA (80). The factor is controversial because it assumes an average mol %[G+C] and an amount of DNA per cell (i.e., average genome size) for complex bacterial communities (72).

Two approaches have been used to validate these conversion factors:

- empirically, from alternative growth measurement, and
- theoretically, using an average mol %[G+C] and DNA content of a bacterial cell.

Generally, there is good agreement between both these factors (72,80,112). Across the literature, factors have ranged from 1 to 60×10^{18} cells per mole of thymidine. However, reviewers of conversion factors tend to agree on a value of 2×10^{18} cells per mole of thymidine (51,57,80,92,96). This is the value used in this thesis research (K_{tdr}). The accepted mean literature conversion values used here for calculating bacterial growth rates should be checked by determining the K_{tdr} conversion factor for each new wastewater treatment system. Because the microbial physiology depends on both the type of bacteria and the environmental conditions, more accurate measures of growth rate conversion factors require in situ measurements of the conversion factor (114).

Moriarty (96) emphasized the need to consider isotope dilution and ensure that only radioactively labeled DNA is isolated when determining K_{tdr} conversion factors. This has been more recently corroborated by others who pointed out that empirical and theoretical conversion factors do not converge unless exogenous thymidine concentrations are greater than 10 nM (115,56). At lower concentrations, isotope dilution occurs.

MEASURING BACTERIAL GROWTH IN ACTIVATED SLUDGE

As early as 1942, Monod (Monod's 1942 Ph.D. thesis, in French, has never been translated into English. However, Panikov, 1995 has empathically interpreted some of his work in the context of Jacques Lucien Monod's life (1910–1976) and times; it is worthy reading.) viewed the quantitative measurement of bacterial growth as a tool for studying bacterial physiology and biochemistry. The original chemostat research was carried out by Monod (116–118), and Novick and Szilard (119). However, others (120) are credited with succinctly and mathematically predicting the steady state concentrations of bacteria and substrates on the basis of Monod's and Novik's work.

Herbert and coworkers (120), started their description of the kinetics of bacterial growth from the "familiar exponential growth curve":

$$\mu = \frac{dx}{dy} \cdot \frac{1}{x} \tag{1}$$

where x is the concentration of bacteria at time t. They described bacterial growth rate as the rate of increase in the number of bacteria (dx/dt); whereas μ was called the specific growth rate as it was the growth rate divided by the number of bacteria. Thus, μ takes into account the standing biomass.

They point out that Monod (116) first showed the simple relationship between μ and the concentration of the limiting substrate (Fig. 6; Eq. 2).

$$\mu = \mu_{\max}\left(\frac{S}{K_s + S}\right) \tag{2}$$

where S is the concentration of the substrate-limiting growth, $\mu_{\max}$ is the maximum specific growth rate of the bacteria when the substrate is not limiting growth, and K_s is a saturation constant (the concentration of substrate at half $\mu_{\max}$). This relationship is the basis of most mathematical models that are used to simulate the average growth and removal kinetics of wastewater treatment systems (3,40,121–124).

A knowledge of bacterial specific growth rates in the wastewater treatment environment is essential for designing, operating, and evaluating the state of the process; as Monod said, growth kinetic measurements give a measure of bacterial physiology and biochemistry. Reliable design of wastewater treatment processes depends on simulating the growth of the bacterial population that converts wastes to products and biomass (3,122). Yet, in the monitoring and control of treatment processes, there have been no direct measurements of bacterial growth kinetics (125). The methods the industry uses to control treatment processes are respiratory-based (38,126), however, these can lead to false and confusing results (16,39,93).

Directly measuring bacterial growth rates alongside metabolic activity allows advances in the knowledge of the key microbial processes in wastewater treatment systems. Being able to distinguish bacterial growth from metabolic activity will enable researchers to observe how the bacterial cell allocates its resources between cell maintenance and growth. For example, under the wastewater treatment process operating conditions, are bacterial cells likely to divide and create more biomass (sludge) or to allocate more energy to cell maintenance (decrease the mass of sludge)? Achieving the latter is a major objective of wastewater treatment processes (127–129).

Reliable design and operation of biological wastewater treatment systems demand robust models of the biological-degradation processes. However, methods to directly measure key stoichiometric and kinetic parameters have not been readily available. Pollard and Greenfield (100) show how to directly measure bacterial numbers, biomass, and growth rate parameters in activated sludge systems. The method is simple, as shown in Fig. 7 but does require an understanding of the factors that impact on the biochemical pathways of thymidine incorporation into bacterial DNA. They measured volumetric bacterial growth rates via the thymidine growth assay, whereas the number of bacteria and biomass were determined with epifluorescent microscopic techniques. Bacterial-specific growth rates (μ) were subsequently determined by dividing the volumetric growth rates by the concentration of bacteria. They compared the community growth kinetics in the different compartments of an activated sludge treatment process (Fig. 8). Bacterial cell counts were converted to biomass in terms of COD with a factor derived here; $20 \pm 4 \times 10^{-11}$ mgCOD.cell^{-1} as described by Von Münch and Pollard (130).

In the aerobic compartment, measurements of bacterial-specific growth rate, concentration of bacteria and biomass were 0.5 d^{-1}, 1.1×10^{10} cells mL^{-1}, 2×10^3 mg COD L^{-1}, respectively. Bacterial growth, numbers, and biomass were quantified simply and specifically in the different compartments of a biological nutrient removal

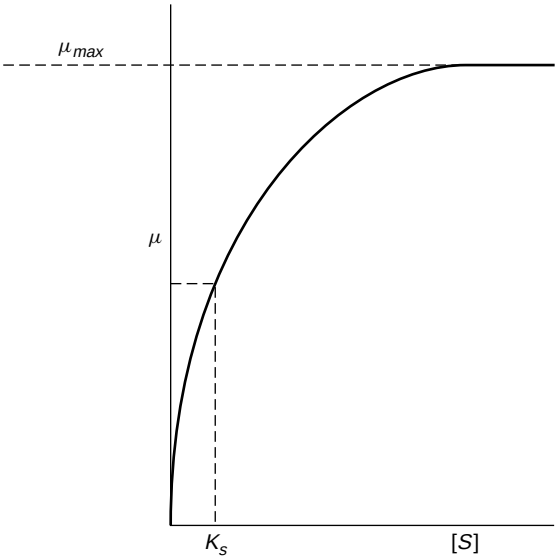

Figure 6. Relationship between bacterial specific growth rate & substrate.

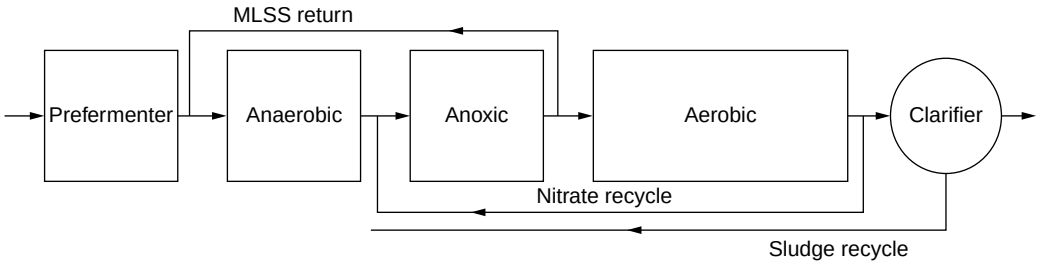

Figure 8. Schematic of UCT configured high-rate biological nutrient removal (BNR) treatment of domestic wastewater at Brendale, Pine Rivers Shire Council, QLD Australia.

process. This represents the first time these very powerful tools have been applied to directly observe the growth kinetics of bacteria in wastewater treatment processes.

Calculating Volumetric Bacterial Growth Rates

To calculate bacterial growth rates in the different stages of a biological nutrient removal (BNR) treatment process (Fig. 8), they converted the radioactivity incorporated into bacterial DNA in each compartment into the increase in the number of new bacterial cells. The radioactivity incorporated into DNA ($Radio_{act}$; dpm.mL^{-1}) was converted to μCi ($C_{dpm}/\mu Ci = 2.2 \times 10^6$ dpm.μCi^{-1}). Knowing the specific activity (SA; μCi nmol^{-1}), the rate thymidine was incorporated into new DNA ($r_{v,tdr}$), during the incubation time (t), was:

$$r_{v,tdr}[\text{nmol tdr} \cdot \text{mL}^{-1} \cdot \text{h}^{-1}] = \frac{Radio_{acr} \cdot f_{dil}}{C_{dpm/\mu Ci} \cdot SA \cdot t} \qquad (3)$$

A conversion factor (K_{tdr}) was used to determine the rate of formation of new cells from the rate of incorporation of labeled thymidine ($r_{v,tdr}$). Similar values for this factor have been derived both empirically and theoretically (80). Reviews of the literature suggest an average value for K_{tdr} of 2×10^9 cells nmol tdr^{-1}.

Volumetric bacterial growth rates ($r_{v,x}$; cells mL^{-1}.h^{-1}) were then simply calculated from the radioactivity (dpm.mL^{-1}) incorporated into DNA with the following equation:

$$r_{v,x} = r_{v,tdr} K_{tdr} \qquad (4)$$

Determining Specific Growth Rates

Henze and Harremoes (131), referred to volumetric biological growth rate ($r_{v,x}$) with dimensions−mass per unit volume per unit time, for example, Kg COD (biomass).m^{-3}.d^{-1}. The rate of incorporation of thymidine is also a measure of volumetric bacterial growth rate but it is dimensioned by the number of cells mL^{-1} h^{-1}.

Bacterial-specific growth rate is described as the volumetric increase in cell numbers divided by the concentration of bacteria (Eqn. 5). Thus, bacterial-specific growth rates (μ) were determined by dividing the volumetric bacterial growth rates by the concentration of bacteria and was multiplied by 24 to convert h to d:

$$\mu[d^{-1}] = r_{v,x} \cdot \frac{1}{C_{cells}} \cdot 24 \qquad (5)$$

A major advance of the thymidine growth assay is that it is a direct measurement of growth kinetics. Volumetric bacterial growth rate, ($r_{v,x}$), is measured directly and independently of the initial concentration of bacterial cells C_{cells}. The method allows a level of sensitivity to changes in bacterial growth rate that is immediate and that has not been previously possible for open wastewater treatment systems (132).

In biological wastewater treatment processes, the bacterial cell concentration (C_{cells}) is not measured directly, although direct DNA-staining methods and epifluorescent microscopy methods are available (130,133,134). The conventional approach is to measure biomass in terms of the particulate chemical oxygen demand (COD) or volatile suspended solids; VSS (36,135). With these measures, however, bacteria are not distinguished from the particulate material (130) that is enmeshed in the flocs of wastewater (136). Other methods have relied on measuring bacterial metabolic activity, for example, ATP and respiration rates (35,137). These methods are not reliable because they depend on the physiological (metabolic) state of the bacteria (34,138,139).

Fluorescent DNA−staining methods are well-accepted quantitative techniques that have been used for determining the number of bacteria in aquatic environments (140). The value of using these microscopic methods is that the bacterial biomass measurement is direct and specific. The methods are independent of extracellular material, abiological material, and eukaryotic microorganisms, such as protozoans.

When interpreting specific growth rate measurements, remember that within the wastewater bacterial community C_{cells} includes dormant (not dividing) and/or slowly growing bacteria. Thus, μ (Eqn. 5) is a weighted average of the specific growth rate of the bacterial populations. Only recently has the direct measurement of bacterial biomass been distinguished from cellular activity (Vollersten, 2001).

Pollard and Greenfield (100) measured the volumetric bacterial growth for the prefermenter overflow, secondary clarifier, aerobic, anaerobic, and anoxic compartments of a BNR municipal treatment process. The kinetic parameters and state variables bacterial growth and numbers, are compared in Figure 9. It is important to recognize the difference between growth and specific growth rate measurements (Eq. 4 *cf* Eq. 5).

Literature values for maximum specific growth rates measured in activated sludge range from 2 to

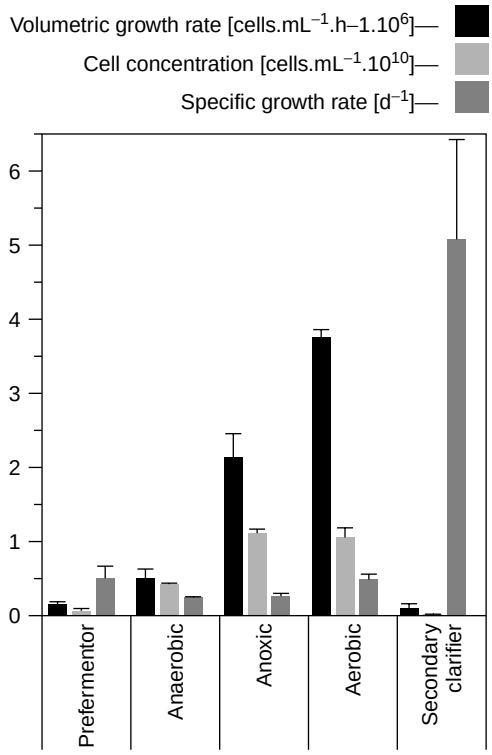

Figure 9. Growth kinetics in the different compartments of the BNR processes (After Pollard and Greenfield, 1997).

6 d^{-1} (3,40,141). These kinetic values are often used in modeling the activated sludge process. These are maximum rates determined with batch culture assays. For the activated sludge used in the study of Pollard and Greenfield (100), the direct measure of specific growth rate was 0.5 d^{-1} (Fig. 9; aerobic compartment). This in situ specific growth rate measurement was under conditions that were not at saturating substrate concentrations (117). This rate also agrees with those measured under operating conditions of municipal activated sludge treatment processes in which bacterial-specific growth rates have been determined as 0.6 d^{-1} or greater using respirometric-based methods (141,142).

RESPIRATION VERSUS GROWTH KINETICS

In biological wastewater treatment, predicting the ability of the bacterial community to degrade and assimilate influent nutrients is the basis of the mathematical models that are used to design and operate the process. For effective models, the kinetic parameters must accurately mirror the degradative ability of the bacterial community in situ.

Respirometry-based methods, such as the batch assay, derive bacterial growth rates from rates of substrate oxidation that rely on respiration measurements. They assume a constant coupling between catabolic and biosynthetic (anabolic) processes. However, physiological stress from the sudden increases in substrate or the presence of toxic compounds in industrial wastewater, for example, may stimulate respiratory activity at the expense of bacterial growth (143–145). Consequently, only using respiration as a measure of bacterial growth may be misleading when growth becomes uncoupled from catabolism (146). Ignoring the effects of toxins, such as aromatic hydrocarbons, on the viability of bacterial populations can lead to significant underestimates of the growth rate of the bacterial community in the original treatment environment (147).

In BNR systems, the rate of nutrient removal is a function of bacterial metabolism, of which bacterial growth rate is a part. Bacterial growth and metabolism are terms that describe bacterial physiology differently. Metabolic activity describes bacterial catabolic and anabolic reactions, and includes reactions that are responsible for cell maintenance and growth. Bacterial growth is the ability of the cell to divide, that is, to create new biomass, all other processes are generally referred to as cell maintenance (148).

Batch reactor assays are used to estimate maximum rates of substrate oxidation and growth for both heterotrophic and autotrophic bacteria (36). The importance of this assay to the measurement of bacterial growth is well recognized (16,40,93,149–151). Volumetric substrate consumption rate ($r_{v,s}$) and volumetric bacterial growth rate ($r_{v,x}$) are related by the yield constant (Y) (135):

$$r_{v,s} = -\frac{1}{Y} r_{v,x} \tag{7}$$

The standard approach is to assume that the relationship between substrate consumption and specific growth rate (μ) and concentration of bacteria (X) follows simple Monod (117) kinetics and so is described as follows:

$$r_{v,x} = \mu \cdot X \tag{8}$$

$$\mu = \mu_{max} \cdot \frac{S}{K_s + S} \tag{9}$$

Using this system model, it can be expected that the bacterial populations will grow at their maximum ($\mu = \mu_{max}$) when supplied with excess substrate ($S \gg K_s$), where K_s is the half-saturation constant; this is the basis of the batch assay.

In a domestic activated sludge batch assay, the saturating substrate condition is achieved by adding excess raw sewage to a smaller amount of mixed liquor from the full–scale aerated reactor. The bacterial growth rate is then inferred from the initial oxygen uptake rate (OUR) measurement (36,40). However, the method has recently been thoroughly reviewed and shown to have several shortcomings (16). At high substrate to biomass ratios ($S_o/X_o > 20$), the batch assay will measure the maximum rate of substrate oxidation, but it does not represent the growth rate and physiological state of bacteria in the original treatment environment in situ.

The greater the batch reactor S_o/X_o ratio, the greater the change in the bacterial community away from that of the original wastewater environment, the more likely it is that the measured kinetics will reflect the characteristics of the fastest growing bacteria, or changes in the physiological state of the bacterial community. Hence,

lower S_o/X_o ratios (<2) are preferred in batch assays. Under these conditions, bacterial growth rate is assumed not to be altered from that of the original treatment environment (39,93). The thymidine growth assay is an alternative approach that allows studies of the dynamics of the diverse interactive microbial consortium in the batch reactor environment.

Batch assays are used to estimate maximum specific growth rates. This measure is fundamental to the modeling of biological nutrient removal processes. However, ignoring its potential and shortcomings can lead to meaningless data and wasted research. Pollard and coworkers (152) used the thymidine assay to directly measure the specific growth rate of the bacterial community alongside a respirometric method (oxygen uptake rate; OUR), soluble substrate losses (SCOD) and bacterial biomass increases. They describe how and when bacteria allocate energy between new cell synthesis and cell maintenance, their results are shown in Figure 10.

The changing bacterial-specific growth rate measurements (μ_{tdr}) (Fig. 10) conflicted with this conventional model of the batch assay that assumes that the initial constant OUR represented a constant specific bacterial growth rate.

Ekama and others (36,124) adopt a standard Monod kinetic model of bacterial growth for the batch reactor, which dictates that during the initial period of excess substrate, the bacteria grow at their maximum rate. The thymidine measurement of the dynamic behavior of the bacteria in the batch reactors challenge the fundamental theory of the batch assay in which, in reality,

- μ is not constant, nor at its maximum
- the biomass yield varies

Simultaneously measuring respiration and in situ bacterial growth rates, using the thymidine assay and a direct measure of bacterial numbers, gave more information about how the cell allocated its energy resource from the initial oxidation of substrate (Fig. 11).

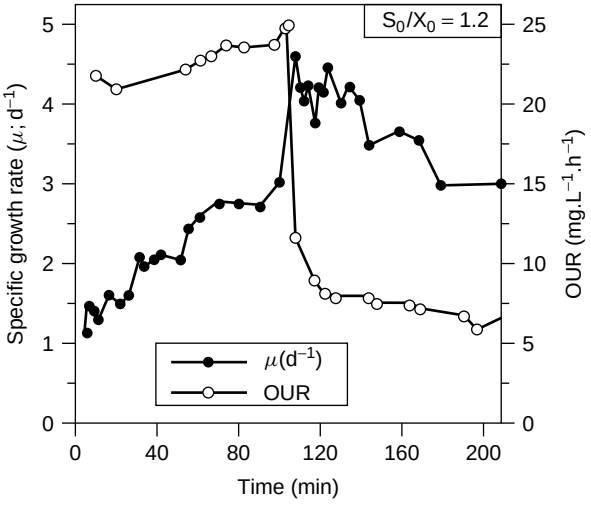

Figure 10. Municipal batch reactor μ compared with OUR at $S_o/X_o = 1.2$. The specific growth rates were derived from volumetric bacterial growth rate and the concentration of bacteria (After R. D. Robarts and R. J. Wicks, *Limnol. Oceanogr.* **34**, 213–222 (1989).

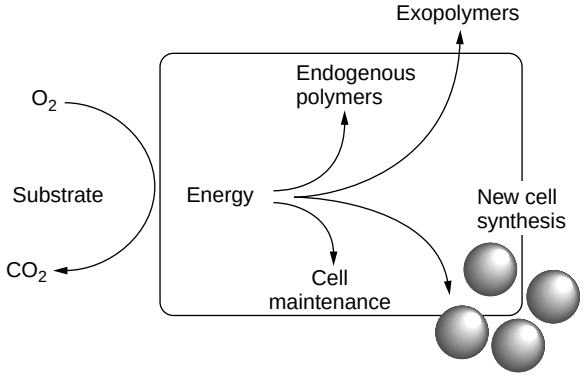

Figure 11. Energy flow, growth, and cell maintenance. The initial oxygen uptake rates (OUR) of batch reactors are related to the energy generated in the first substrate oxidation step. On its own, the OUR measurement does not indicate how the cell used this energy. (After R. D. Robarts and R. J. Wicks, *Limnol. Oceanogr.* **34**, 213–222 (1989).

For the bacterial community in municipal activated sludge, bacterial-specific growth rate increased, whereas the rate of substrate oxidation remained relatively constant. The characteristics of the bacterial community within the batch reactors does not represent those of the original treatment environment. Inferring growth kinetic parameters for continuously operated flow-through processes, using the closed environment of a batch reactor, does not reflect the degradative potential of the original wastewater treatment system.

Researchers have expressed concern over the ability of batch assay to reflect the conditions of the original treatment environment. However, it has been widely accepted because of the lack of alternative methods. Although the thymidine assay is more complex, combined with respirometric measures, it can provide far more information about bacterial behavior and energy flow in the original treatment environments. Methods to determine kinetic parameters for the biological models no longer need be restricted to respirometry.

BIOFILMS

Biofilms are found on almost any wet surface, transforming and removing soluble compounds from solution (153–155). The importance of biofilm bacterial communities is well recognized and topical (156). New Scientists described them as "Chic, urbane, sophisticated, and sometimes deadly — such are the inhabitants of the world's weirdest metropolis" (157).

Historically microbiologists' concepts of bacterial behavior have been built on laboratory isolates, far removed from their natural habitat. However, in naturally complex environments, bacteria rarely grow as single species. Rather, they grow in communities "cheek-by-jowl in slime cities," helping each other to exploit substrates through synergistic relationships (157,158).

Biofilm bacteria are held in an attached matrix that absorbs and metabolizes dissolved compounds. Most microbial metabolic activity occurs in these structured bacterial communities at the solid–liquid interface (156,159). The wastewater industry has exploited the efficiency of attached bacterial growth to remove pollutants from wastewater in fixed-film processes (135,160–162).

In the treatment of wastewater, constructed wetlands can be considered as large-scale, essentially fixed-film bioreactors (163). However, the literature that describes these processes has largely ignored the in situ growth-kinetics of the attached bacterial communities (164, Mitsch and Gosselink, 1993; Duncan and Groffman, 1993). To understand the kinetics of the bacterial communities in the biofilm's microenvironment requires a quantitative measurement of the growth kinetics of the biofilm bacteria. However, only recently have tools been available to directly measure the growth kinetics of biofilm bacteria in fixed-film treatment processes using radioactively labeled thymidine incorporation. The significance of applying the thymidine assay here is that biofilm bacterial growth kinetics can be measured without disturbing the biofilm.

For example, the surface biofilm on plant stems in constructed wetlands can be assayed by immersing the tissue in solutions of the thymidine without disturbing the biofilm as shown in Figure 12.

The measurements of in situ biofilm bacterial growth kinetics both displayed, and accommodated, the inherent heterogeneity of the complex wetland ecosystems. Biofilm bacterial metabolic activities, using the redox dye CTC (Bhupathiraju and coworkers, 1999a&b; Sherr and coworkers, 1999; Flood and coworkers, 1999) and growth rates could be measured simultaneously. The thymidine assay showed that the redox dye, CTC, does not inhibit bacterial growth rate. With CTC as a measure of biofilm bacterial respiratory activity, biofilm metabolic activities and growth kinetics can be measured simultaneously.

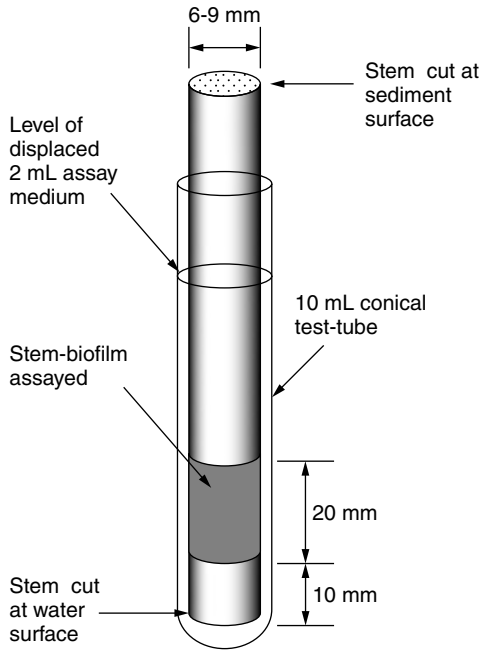

Figure 12. Biofilm on wetland plant-stem-section incubating in medium with radioactively labelled thymidine and/or the redox dye, CTC (for details see Pollard and coworkers, 1995; Flood and coworkers, 1999).

IN SITU GROWTH KINETICS OF SINGLE SPECIES

Measuring the growth kinetics of bacterial species (i.e., a population) within a microbial community is fundamental, yet it seems an almost impossible objective given the complexity of bacterial communities in situ. However, if we are to understand how microbial communities function and mediate the changes in water quality parameters, quantifying the individual species growth kinetics is essential. We need to know the fraction and populations of the community that are metabolically active and growing (Pinhassi, and coworkers, 1999; Gasol and coworkers, 1999 and Sherr and coworkers, 1999; Ducklow, 2000; Vollersten and coworkers, 2001).

We have seen how to estimate bacterial community growth kinetics with the thymidine method. However, this method does not indicate the fraction of the populations in the microbial community that are not dividing. For specific growth estimates, the thymidine growth measurement is averaged over all the populations in the community when bacterial numbers are estimated with fluorescent dyes. Fluorescent DNA stains can be used to measure the number of bacteria (Nobel and Fuhrman, 1998) and respiratory dyes used for estimates of whether cells are living or dead (Gasol and coworkers., 1999; Sherr and coworkers, 1999; Vollersten, 2001).

The assumption used here is that if the bacterial cell is intact and stains positive for DNA material, it may not be dividing but it mostly likely maintains the potential to divide. However, there are inconsistencies in the literature that report the percentage of bacterial cells that contain DNA and that are also metabolically active (Zweifel and Hagstraom, 1995; Choi and Sherr, 1996).

We have in situ methods for identifying bacteria using DNA or RNA based fluorescently labeled probes that target important bacterial species or groups of bacteria in wastewater. Individual bacterial species can then be identified in situ. Molecular studies of bacterial communities focus on identifying bacteria and/or changes in the community structure between different environments (Lee and Fuhrman, 1991 (Telang, and coworkers, 1994; Lambert, and coworkers, 1993; Raskin, and coworkers, 1995; Sevior and Blackall, 1998; bond and Banfield, 2001). However, there is little attention given to quantitative methods to measure their in situ growth rate.

For at least 25 years, fluorescent DNA probe methods have been available for counting bacteria in natural aquatic environments (Hobbie, and coworkers, 1977). The accuracy and precision of the methods are well documented (Lebaron, and coworkers, 1994; Gasol, and coworkers, 1999), and they can be applied quantitatively to engineered wastewater environments (von Münch and Pollard, 1997; Vollersten and coworkers, 2001). There is a reason these methods have not been used to measure bacterial growth rates in situ.

Molecular techniques have considerable potential for identifying and counting individual species or groups of bacteria in wastewater. Currently, these methods are thought to have the potential for measuring in situ species growth rates. This assumes that increases in the number of a bacterial species can be used as a measure of growth rates in situ, for example, the use of fluorescently labeled oligonucleotide hybridization probes combined with flow cytometry (Amann, and coworkers, 1995; Veal, and coworkers, 2000) and to a some degree, real-time PCR (Becker, 2000). However, these approaches are limited to measurements of bacterial numbers/biomass at a point in time, and the methods rely on observing in situ increases of bacterial numbers amidst an array of processes that are continually removing the bacterial biomass.

Monitoring increases in bacterial numbers with fluorescent probes could not distinguish such losses from gains. The net change in biomass may be zero, as in a chemostat, for example, where $dx/dt = 0$. The sensitivity of this approach to biomass change is limited to the time required to detect an increase in a population. This may be on the order of hours. What might be measured as a slow-growing bacterial population may well be growing rapidly in the presence of a ravenous protozoan community (Caron, and coworkers, 1993; Van Loosdrecht and Henze, 1999) or being removed from the system by dilution or death through viral lysis (Wommack and Colwell, 2000).

The thymidine assay is well accepted as an in situ measure of bacterial growth rate that is independent of bacterial biomass concentration. However, this measurement of the growth rate is an average value of the community not for a single species. The scope of the assay could be significantly expanded with the ability to measure species growth rates in situ. The thymidine growth assay may be coupled to current advanced molecular methods that identify bacteria. The combined technique then is able to quantify species growth rate in situ.

The principle has been demonstrated in laboratory cultures and in a municipal activated sludge treatment process (Pollard, 1998). The DNA of all dividing bacteria are radioactively labeled with [methyl-^{3}H] thymidine, thereby creating a mixture of radioactive DNA molecules (^{3}H-Tdr-DNA). The target DNA from an isolate of interest was subsequently immobilized on a membrane. When the ^{3}H-Tdr-DNA mixture is incubated with the immobilized-membrane DNA, the complementary (homologous) radioactively labeled DNA molecules reassociated. Only those bacteria that were dividing in the initial [methyl-^{3}H] thymidine incubation were detected on the membrane strip (Pollard, 1998).

This approach is sometimes referred to as a reverse gene probe method because the membrane-bound DNA is of the known bacterial species (Voordouw, and coworkers, 1991; Ehrmann, and coworkers, 1994), whereas it is the unknown community in the Southern blot method. In a conventional hybridization preparation, such as that of the Southern blot method (Southern, 1975), a radioactively labeled or fluorescently tagged DNA probe of a known bacterial species is synthesized. DNA extracted from an environmental sample is immobilized on a membrane. The membrane is then probed for the presence of its complementary single-strand of DNA.

Others have used a similar reverse gene probe approach to identify changes in bacterial community structure in natural environments (Lee and Fuhrman, 1990; 1991; Voordouw, and coworkers, 1991). They used "nick" translated gene probes of environmental samples, qualitatively observing changes in bacterial populations.

Further advances may be made on measurements of single species growth rates using the thymidine assay. The in situ measurement of the specific growth rate (μ_{sp}) of a single species is possible. A molecular probe could be designed and applied to identify and count the number of a bacteria species, whereas its growth rate is measured with the thymidine assay. For example, Rosselló–Mora and coworkers (1995) designed a 16S rRNA–oligonucleotide probe for *Z. ramigera* and counted the number of bacteria in activated sludge. Pollard (1998) quantified the growth rate of the same species in activated sludge. If both methods were performed simultaneously the specific growth rate of *Z. ramigera* could be determined by dividing the species growth rate by the number of these bacteria. Simultaneously applying these two powerful molecular-based methods has enormous potential. Synergistic,

Table 1. The Thymidine Assay Combined with Different Molecular Methods to Determine Key Kinetic Parameters in situ. The Measurement of these Parameters can be Used to Simulate Treatment Processes. The Specificity of the Dynamic Measurement Increases (Top to Bottom) from a Community Level to the Specific Growth Rate of a Bacterial Population

Thymidine Assay Combined With		In Situ Growth Kinetic Parameter
No other assay	⟶	Community average–volumetric growth rate (average of populations)
General fluorescent DNA probe; AO and DAPI	⟶	Community specific growth rate
DNA-DNA hybridisation	⟶	Population volumetric growth rate
DNA-DNA hybridisation & species–specific DNA probes	⟶	Population specific growth rate

Increasing specificity

symbiotic, competitive, and diauxic growth, and inhibition, may now be studied in the wastewater environment in a truly ecological fashion.

CONCLUSION

Today's advanced wastewater management extensively uses biological treatment. These processes rely on bacterial growth to remove/transform pollutants. However, few of the wastewater bacterial populations can be cultured outside the treatment environment, hence little is known about their behavior in situ. Methods used to monitor microbial activity in wastewater do not measure bacterial growth rates in situ. Measuring bacterial biomass alone cannot account for the continued removal of bacteria through dilution, death, viral lysis, and protozoan grazing.

The thymidine assay has been shown to directly measure the average volumetric growth rate. The significance in applying this approach to wastewater research is that it is a measure of the in situ volumetric bacterial growth rates at a molecular level of sensitivity independent of the bacterial biomass. It is a mean measure of the slow to the most rapidly growing bacteria. On its own, the thymidine assay is limited because high volumetric growth rate measurements may have resulted from either a few bacteria growing rapidly or many bacteria growing slowly. However, combining this measurement with other in situ measures of bacterial biomass expanded the versatility of the method significantly (Table 1).

The versatility of the thymidine assay when combined with other molecular methods is summarized in Table 1. The key growth kinetic parameters that can be derived are shown in order of increasing bacterial specificity.

Combining measurements of volumetric bacterial growth rate and respiratory activity give more information about how the bacterial populations allocates the energy generated from substrate oxidation in the wastewater environment.

Table 2 shows a summary of stoichiometric and growth kinetic parameters for a range of treatment processes. Specific growth rate measurements are compared to alternative indirect measurements. These other methods determined specific growth rates on the basis of respirometry (OUR), increases in cell numbers (AODC), and hydraulic residence time. Generally, the thymidine measurements of specific growth rates agreed with the values from these alternative techniques (Table 2).

Respirometric methods were not always the same as those determined with the thymidine assay. Estimates of μ in the OUR batch assay using phenolic wastewater (Batch reactor — Industrial; Table 2) were substantially higher than those determined by the thymidine assay. This was most probably because the respirometric method measured rates of oxygen uptake that was due to the toxic affects of phenol while inhibiting bacterial growth.

WATER FUNGI AS DECOMPOSERS IN FRESHWATER ECOSYSTEMS

Mark O. Gessner
Limnological Research Center
Kastanienbaum, Switzerland
Gunther Van Ryckegem
Ghent University
Gent, Belgium

This article provides an overview of fungi in freshwater habitats. We have organized it according to the major ecological functions that fungi assume in these systems,

rather than using taxonomic delineations as the guiding thread. On the basis of studies on nutritional strategies and systematics, fungal diversity, distribution and dispersal patterns we thus focus on the roles of fungi as decomposers, symbionts, and parasites. For each of these functions we will present one or more examples from freshwater systems. A final section is devoted to anthropogenic effects of fungi in freshwater habitats. This structure implicates that several systematic groups will be discussed repeatedly in different contexts.

The objective of the article is not to provide a complete review of the topic; the diversity of systems and organisms, and the rudimentary knowledge on some of these, prevents coverage of all potentially important aspects. Rather, our overview is meant to serve as a directory that draws attention and provides access to areas of freshwaters ecology where fungi are likely to play crucial roles, many of which still are poorly recognized at present.

ORGANOOSMOTROPHY AS A KEY FEATURE

Two modes of nutrition are realized among heterotrophic organisms. Animals and Protozoa take up particles by means of phagocytosis, a nutritional mode known as phagotrophy, whereas other heterotrophic eukaryotes and prokaryotes rely on dissolved low-molecular weight compounds. Organic particles and dissolved organic carbon of higher molecular weight are first broken down and cleaved extracellularly into small units before they are assimilated by these organisms. This mode of nutrition is referred to as organoosmotrophy.

A GLIMPSE ON FUNGAL SYSTEMATICS

The eukaryotic organoosmotrophs occurring in freshwaters are phylogenetically diverse, McLaughlin and coworkers (1). Although traditionally considered fungi, major groups bear no relationship even at the highest taxonomic level and have consequently been assigned to different Kingdoms (2,3). This classification is well supported by both ultrastructural and molecular evidence and is now generally accepted. Representatives of the Fungi *sensu stricto* include the Chytridiomycota, Zygomycota, Ascomycota, and Basidiomycota, which collectively are referred to as Eumycota (1). The Microsporidia have recently been added to this group (2,3). Deuteromycota — also known as Fungi Imperfecti, anamorphic, mitosporic, or conidial fungi — are asexual forms that are mostly related to the Ascomycota or, less frequently, to the Basidiomycota and thus belong to the Eumycota as well. They comprise the Hyphomycetes and Coelomycetes (4,5).

Chytridiomycota, Deuteromycota, Ascomycota, and probably also Microsporidia are the predominant groups of Fungi in freshwaters, although members of the other groups may also be present. Basidiomycota are notably rare. In addition, a major group of phylogenetically distinct organoosmotrophs is prominent in freshwater environments. These organisms, previously known as Oomycota, bear a much closer relationship to heterokont algae than to the true Fungi (1). Together with the Hyphochytrea, or Hyphochytriomycota, another unique group of fungal-like organisms with about 25 species known at present, the oomycetes are thus placed in the Kingdom Chromista (3).

This and other taxonomic delineations and terms used in this article are adopted from the authoritative treatise edited by McLaughlin and coworkers (1) with some modifications following Cavallier-Smith (3). A host of other names and systems pervades the mycological literature, reflecting differences in opinion but also the fundamental progress in the systematics of these organisms in recent years. The term fungi, in particular, has given rise to much debate. For the purpose of this article, we will thus use Fungi with a capital letter to refer to Fungi sensu stricto, that is, to the Eumycota. For convenience, we will also refer to fungi, spelled in lower case, to designate the entire range of organisms traditionally studied by mycologists. It must be emphasized, however, that this usage is simply one of convenience, implying no phylogenetic relationship whatsoever.

DIVERSITY, DISTRIBUTION, AND DISPERSAL

Current world estimates of the number of Fungal species range from a few hundred thousand (6) to 1.5 million (7), 72,000 of which are known to science (8). These numbers illustrate that Fungi have been greatly underexplored, particularly compared with plants and animals, although in terms of species numbers, effects on other organisms, and significance in ecosystem functioning they may well be one of the most important groups of eukaryotes that have evolved on Earth. However, only about 1% of the species known at present have been recorded from freshwater habitats. Wong and coworkers (9,10) estimated their number as some 600, although a more extensive literature survey and inclusion of the Microsporidia would certainly yield a much higher number. Nevertheless, and even if the proportion of known to extant species is lower than the 5% estimated for fungi in general, the total number of species occurring in freshwater habitats would be distinctly lower than 20,000.

As with other microorganisms, many species of fungi occurring in freshwaters have a widespread, often cosmopolitan distribution (11–15) although in the Ascomycota notable differences exist between genera of temperate and tropical regions (Ho & Hyde 1997). The number of recorded species is also lower in the tropics than in temperate climates. However, this discrepancy may simply reflect the less intense investigations carried out in tropical areas rather than a real underrepresentation of freshwater fungi at low latitudes.

Freshwater fungi are adapted to life in aquatic environments most obviously by the development of effective mechanisms for colonization and dispersal in a viscous medium such as water. Dispersal may occur via either motile or nonmotile spores. The former are typical of the Oomycetes, Hyphochytrea, and the Chytridiomycota. Nonmotile spores characterize the aquatic Ascomycota and Deuteromycota. Many of these nonmotile spores have elaborate shapes, appendages, or wall ornamentations, or are surrounded by various sheaths, all of which

have been interpreted as adaptations to dispersal and/or attachment (16). Wong and coworkers (9,10–22) give a more complete account of these putative adaptations.

DECOMPOSERS

Mycelial Growth and the Availability of Resources

Mycelial growth is a characteristic feature of filamentous fungi, which ultimately has major repercussions on the functions of these organisms in freshwater ecosystems. Growth in ramifying filaments allows to assimilate nutrients over a large surface area relative to body volume, and facilitates internal translocation of substances (e.g., organic carbon compounds, inorganic nutrients, oxygen) over appreciable distances. The older hyphae are rigid and permit a high turgor pressure to be exerted at the plastic and extensible hyphal tips (Money 1994), favoring penetration of hard surfaces and subsequent spreading within the substrate underneath. As a result, filamentous fungi do not typically grow on top of surfaces in biofilms as is often erroneously assumed. They are rather fully embedded in their substrate. Hyphae could in fact be viewed as self-extending digestive tracts that have been turned inside out. Clearly, therefore, mycelial growth is an effective adaptation to exploiting solid coarse-particulate organic substrates such as plant and animal tissues, and it is not surprising that the mycelial growth form has evolved independently in different lineages of both prokaryotic (Actinomycetes) and eukaryotic (Oomycota and Eumycota) organoosmotrophs.

The organic substrates most suitable for exploitation by filamentous fungi occur in greatest abundance where aquatic systems are intimately linked with their terrestrial surroundings. Streams, for example, that are fully shaded by a riparian canopy typically receive some 400 to 800 g of coarse-particulate organic matter m^{-2} yr^{-1}, the bulk of it in the form of leaf litter, twigs, and small branch wood derived from the streamside vegetation (Weigelhofer and coworkers, 1994; 23,24,25). This sort of allochthonous matter is of utmost importance for stream food webs and total system functioning (Wallace and coworkers 1997). Inputs of large branch wood and whole trees are more episodic and therefore more difficult to quantify but likewise are a key feature of pristine forest streams (26,27) and other water bodies, permanent or temporary, with tall woody vegetation in their perimeter (e.g., swamps and many river floodplains).

In marshes and littoral zones of lakes, coarse-particulate organic matter is produced mainly by emergent macrophytes. These macrophytes may form extensive, often monospecific stands in freshwater marshes, littoral zones of lakes, floodplains, and river deltas. Common plants occurring in these areas are members of the sedges (*Carex* spp.) and other Cyperaceae (e.g., *Cladium*, *Cyperus*, *Eleocharis*, *Scirpus*), rushes or Juncaceae (*Juncus*), grasses or Poaceae (e.g., *Phragmites*, *Glyceria*) and cattails or Typhaceae (*Typha* spp.). Emergent macrophytes are often highly productive (28,29), rivaling crop production in intensive farming. Hocking (30,31), as extreme examples, estimated the annual aboveground plant production of *Phragmites australis* and *Juncus effusus* at almost 10 kg/m^2. Because little of this production is normally removed by herbivorous animals during the growing season (28), large amounts of plant matter senesces and hence becomes available as a habitat, carbon, and energy source for fungal decomposers. Thus, large amounts of plant litter characterize aquatic habitats at the interfaces with terrestrial ecosystems. These are the environments in which, owing to their lifestyle, one would expect filamentous fungi to be competitive decomposers of organic matter.

Although most of the coarse-particulate organic matter in freshwaters is plant litter, animal carcasses may sometimes be an important component as well. An impressive example comes from streams along the Pacific coast of North America, where some salmon species suffer mass mortality following upstream migration and spawning in the headwaters. Historically, the massive mortality of these fishes may have resulted in the deposition of 1.1 kg of dry fish body mass per m of stream length (32). The role of fungi in the decomposition of salmon carcasses is, however, unknown and will not be further considered here. Instead, we will first give a brief account of the fungi colonizing decomposing leaves and wood in streams, and subsequently address the fungi associated with emergent macrophyte tissues decomposing in lentic water bodies under both submerged and standing-dead conditions. Fungi no doubt act as decomposers of a variety of other litter types in many other freshwater systems, but for the most part much specific information is not currently available (33).

Leaf Litter Decomposers in Streams

The fungi associated with leaves decomposing in streams have received considerably more attention than any other fungal decomposers in aquatic ecosystems (33–42). Both Oomycota and Chytridiomycota are prevalent in streams and are regularly found in association with decomposing leaf material (34,35,43). Hallet & Dick (11,44) and others (Park & McKee, 1978; 45,46) have postulated a role in leaf decomposition for the Oomycota, but significant involvement in the process has not been convincingly demonstrated to date. Likewise, the sexual stages (teleomorphs) of ascomycetes are rarely observed on leaf litter in stream habitats (18). Terrestrial hyphomycetes are common inhabitants of the phylloplane before leaves fall into streams (34,35,37). Although the importance of these Fungi in decomposition is not certain, but most evidence suggests that their activity is limited at the low temperatures prevailing during and after autumn leaf fall in temperate streams (Suberkropp and coworkers 1976; 34–36,43,47–50).

The fungi most active in the leaf decomposition process in streams are the so-called aquatic hyphomycetes or Ingoldian fungi (20,34–51). They are found nearly invariably associated with leaves decomposing in stream habitats. Aquatic hyphomycetes possess elaborate enzyme complements for degrading plant polymers (33,38–40,52) with the possible exception of lignin, and produce these enzymes when growing on

submerged leaves in culture (33,53–55). The ability to produce pectinases (pectin-degrading enzymes) is especially noteworthy and probably instrumental in the degradation of leaves (39–42,52–54,56). Aquatic hyphomycetes cause mass loss of leaves when grown in pure culture (41–43,49,53,55,57–60) and sporulate (i.e., reproduce) abundantly under submerged conditions both on pieces of agar and submerged leaf litter collected from the field. The dynamics of spore concentrations in stream water tend to correlate with the seasonality of leaf inputs, suggesting that the life cycle of aquatic hyphomycetes is tied closely to the seasonal availability of leaves as their main carbon and energy source. Increases in spore concentrations in stream water of several orders of magnitude may occur during (and shortly after) periods of bulk leaf fall (34,35,40–42,61).

Aquatic hyphomycetes are considered to be well adapted to the stream environment (9,10,34,35,38,40). Colonization of leaf litter by aquatic hyphomycetes is initiated by the landing of spores on submerged leaf surfaces. It is favored by the distinct shapes of their spores, often tetraradiate or sigmoid, interpreted as a morphological adaptation for attachment in flowing waters (20,21). Efficient trapping of tetraradiate and sigmoid spores on submerged surfaces has indeed been demonstrated experimentally (62). Additional explanations have been proposed (Bandoni, 1974; 38,63). Apart from efficient impaction of surfaces, aided by spore morphology, aquatic hyphomycetes are adapted to colonization in flowing water environments by the fast attachment after settling (*Lemonniera aquatica* within 30 min), aided by mucilage secretion and apressorium formation, and germinate within two to six hours in most species (19). In addition, the germination potential of the spores is high (64). Aquatic hyphomycete spores survive gut passage in stream invertebrates (65,66) and transitory residence in moist terrestrial environments remarkably well (67,68).

Once a spore has germinated, the growing hyphae extend inside the leaf matrix, thereby degrading the leaf tissue and producing significant amounts of biomass within a few weeks of leaf colonization. Many species show a rapid growth at the low water temperatures prevailing in the season following leaf fall in temperate climates (49,69,70). Instantaneous growth rates are highest at the initial stages of colonization and subsequently decline (58,71). Maximum growth rates of $0.2\ d^{-1}$ have been measured under field conditions (58,71,72) although typical rates are an order of magnitude lower (51). The high growth rates result in the rapid accumulation of considerable biomass ((71,73) overview in Gessner (51)), which greatly outweighs the biomass of bacteria associated with leaves (41,42,72,74–76). More than 15% of the total detrital mass (leaf + fungal mass) may be accounted for by fungi (71,73), even when apart from signs of tissue degradation the presence of fungi is not obvious to the naked eye.

On the basis of an average fungal growth efficiency of 35% (60) and estimated fungal production on standardized leaf packs submerged in streams, it has been calculated that fungi may account for 8 to 66% of overall leaf mass loss (74,75). Leaf decomposition rates are correlated with both fungal biomass accumulation and sporulation activity, as well as with concentrations of the recalcitrant leaf constituent lignin (73,77) and dissolved nutrients in stream water (78) (Sridhar). Taken together, these results suggest that fungi are key mediators in controlling leaf decomposition rates as a function of litter quality and environmental conditions (33,41,42).

The only available estimate of secondary fungal production in streams has been published by Suberkropp (79). His figure of 34 g dry mass $m^{-2}\ yr^{-1}$ is well in the range of production estimates for stream macroinvertebrates (24), demonstrating the quantitative importance of fungi for total system metabolism. Model calculations based on litter inputs to streams and decomposition rates and fungal biomass dynamics confirm that the magnitude of Suberkropp's (79) estimate is realistic (51). Significantly, the production of $34\ g\ m^{-2}\ yr^{-1}$ was achieved in a stream characterized by low concentrations of dissolved nutrients (flow-weighted annual average of 2.3 μg soluble reactive $P\ l^{-1}$ and <38.9 μg dissolved inorganic $N\ l^{-1}$) and a riparian vegetation that delivers primarily recalcitrant leaves (*Fagus grandifolia and Quercus* spp.). Both factors are unfavorable to fungal productivity (33,73,77,80).

Fungal biomass production (growth) within the leaf matrix is closely followed by the production of conidiophores (spore generating structures) and release of spores. Aquatic hyphomycetes may thus complete their full asexual (anamorphic) life cycle within the stream and, by doing so, virtually swamp their habitat with propagules during periods when resources tend to be most available. As leaf decomposition proceeds, sporulation rates first increase rapidly and subsequently decline equally abruptly, giving rise to pronounced temporal pattern of reproductive output. Sporulation early in the life cycle is typical in aquatic hyphomycetes (39,40,76,81–83). In aquatic hyphomycetes, this trait has been interpreted as an adaptation to the highly ephemeral nature of leaf accumulations in streams; leaves not only decompose rapidly in this environment (Bärlocher (81,82) has created the picture of a sinking archipelago) but also run the risk of being swept downstream when discharge increases (39–42). Maximum sporulation rates can reach 7×10^6 conidia per g of litter dry mass per day (34,35,55,73,84), resulting in spore concentrations in stream water that may exceed 20,000 per liter (20). How many of these are able to establish new colonies is unknown, as is the proportion used as food by invertebrates. Nevertheless, a simple model calculation testifies to the potential importance of this organic matter pool: If a concentration of 20,000 spores l^{-1} and a conservative individual spore weight of 0.3 ng is assumed (83), a stream with a discharge of $100\ l\ s^{-1}$ (say about 4 m in width) would transport some 50 g of organic matter per day in the form of aquatic hyphomycete spores. For comparison: This number exceeds the total annual production of bacterioplankton (pelagic bacteria) in many marine and freshwater environments.

As leaves decompose, community composition of the associated — sporulating — aquatic hyphomycetes changes. Distinct patterns of community shifts are not always apparent (34,35), partly because they may be masked by differences in successional speed of

individual leaves (samples) coupled with the pronounced sporulation dynamics during decomposition (cf. Chamier and coworkers (85)). As a result, large numbers of replicate samples would be required to discern a clear picture. Recurrent successional patterns have nevertheless been observed in several instances (34,35,86,87). Community shifts result, however, from changes in relative abundance of species rather than veritable true species replacements (86,70). Some species, such as *Flagellospora curvula*, have been identified as early colonizers, whereas others start to sporulate consistently at later decomposition stages (34,35,86). *Heliscella stellata* is a good example of the latter group (87). Some species tend to persist throughout, however, and others cannot be clearly assigned to a particular stage because their temporal occurrence has varied among studies (34,35). *Tetrachaetum elegans*, for example, normally recognized as an early colonizer (34,35,86), was dominant in all but the first sample in the study by Chamier & Dixon (54). Reasons for these discrepancies are potentially complex and largely obscure at present. They might be elucidated in the future as progress is made in understanding the ecological requirements of individual species, their metabolic capacities, life-history patterns including potential sexual stages, genetic and phenotypic variability, and their competitive and trophic interactions within decomposer communities.

Superimposed on successional changes during decomposition are seasonal shifts in species composition. According to Suberkropp's (70) temperature threshold hypothesis, species such as *Lunulospora curvula* and *Triscelophorus monosporus* become dominant on leaves as stream water temperature exceeds the threshold of 16 to 18 °C for any longer period of time. Conversely, *L. curvula* and associate species are replaced by cold-water assemblages when temperature drops below 5 °C. Either one assemblage persists in the intermediate temperature range between 5 and 15 °C. This temperature threshold hypothesis is supported indirectly by observations in both permanently warm (88) and cooler streams (70,86) where no seasonal species replacement occurs. In addition, prolonged colonization required by one sort of leaves compared with another coincided with a decrease in water temperature and a concomitant disappearance of *L. curvula* (34,35). Species such as *L. curvula* and *T. monosporus*, which in temperate streams may dominate at the higher summer temperatures (70,89), are often important components of aquatic hyphomycete assemblages year-round at lower latitudes (Sridhar & Kaveriappa 1989; 38,88) Some dominant cool-water species characterizing winter assemblages (e.g., *Alatospora acuminata*), in contrast, are less common in tropical and subtropical streams (34,35). These patterns of seasonal occurrence are partly, but not fully, congruent with both the growth and sporulation responses to temperature of pure cultures grown on either agar plates or leaves (34,35,69,70,83,90).

What is the spatial configuration of aquatic hyphomycete communities in leaves and what are the driving forces determining it? The spatial arrangement of species on leaves has been mapped in two meticulous studies (85,91). Their results indicate that substantial spatial overlap of individuals occurs in a given leaf (39,40), provided the areal resolution considered in these studies (36 mm^2 and 4 mm^2, respectively) is in the range of hyphal extension in leaves (colonies in culture can be much larger). This overlapping spatial association, together with the similar enzymatic complements of different species (39,40,52) and the persistence of some communities after transplantation to environments with a different species pool (15,70,78), suggests that there is potential for interspecific competition to influence community structure. In line with this idea, some aquatic hyphomycetes may inhibit the growth of other fungi associated with submerged leaves and wood in streams when grown on culture media (92,93). However, these standard tests for fungal interaction have mostly failed to indicate strong competitive abilities of those species typically associated with deciduous leaves rather than wood (92). Hyphal interactions among aquatic hyphomycete species likewise are weak or absent in culture conditions (94); however, whether the outcomes of these culture experiments are pertinent to the markedly different growth conditions in submerged leaves is currently unknown. When Bärlocher & Kendrick (43) inoculated leaves with mixed-species assemblages, rates of leaf decomposition were significantly higher compared with the best performing component species. This results indicates that positive interactions within the communities — that is, facilitation rather than competition — might have prevailed overall. The synergistic effect known as overyielding (95), if true, implies that aquatic hyphomycete species diversity may enhance the rate of an important ecosystem process. In view of the current trend of accelerated species losses worldwide, this is an issue of tremendous theoretical and practical interest at present (96). Aquatic hyphomycetes on decomposing leaves may constitute an excellent general model system for examining relationships between biodiversity and ecosystem functioning.

Interactions of aquatic hyphomycetes with detritivorous/mycophagous stream invertebrates are much better understood than interactions within the fungal assemblages in leaves (40). When given the choice, most stream detritivores (shredders) select partly degraded leaves colonized by fungi (15,40,97) and also prefer pure fungal mycelium to (uncolonized) leaves. Craneflies (*Tipula* spp.) are an exception (98–100). These preference patterns tend to be correlated with the nutritional quality of leaves as judged from the effects of food type on survivorship, growth rate, and fecundity of shredders (15,39,40,97,101,102). It appears, thus, that the choice of colonized leaves for food is instrumental in determining shredder fitness.

The enhancement of leaf palatability and nutritional quality as a result of microbial colonization has been termed conditioning (40,103–105). Highly selective feeding on pure mycelium and fungal patches on otherwise uncolonized leaves (and leaves coated by mycelium) indicates that the conditioning effect is caused by the presence of fungal biomass (34,35,39,40,102,106). Feeding experiments with artificially modified leaves (e.g., treatment with NaOH, HCl, organic solvents, fungal enzyme extracts) that lack fungal growth, have established that chemical-structural changes of the leaf matrix contribute further to the conditioning effect (107), although the

biomass effect appears to be greater (40,102). As fungal establishment proceeds, leaves become increasingly palatable and nutritionally enhanced, up to a point at which leaves are said to be fully conditioned. Subsequently, leaf quality and palatability declines (40,108,109). The timing of full conditioning appears to correspond approximately to the point at which fungal biomass concentrations are at a maximum and about 50% of the initial leaf mass has been lost.

The exact outcome of the trophic interactions between leaves, fungi, and detritivores are complex. The preferences exhibited by shredders depend not only on the degree of conditioning, but also on environmental conditions, the leaf species and fungal species involved, with different shredder taxa showing distinct responses (40). Fungal identity may affect leaf palatability to the extent that preferences of detritivores for different leaf species are reversed. However, although unsaturated fatty acids have been invoked as feeding stimulants in last, but not earlier, instar larvae of the detritivorous caddisfly, *Clistoronia magnifica* (110), it is still entirely unclear which physical and/or chemical cues exactly trigger the selection behavior of stream detritivores shredders that feed on decomposing leaves (39,40,111).

What, in turn, are the effects of detritivore feeding on fungal community structure on leaves? Bärlocher (81,112) analyzed aquatic hyphomycete communities on leaves confined in fine-mesh bags and thus protected from detritivore feeding with communities on accessible leaves in coarse-mesh bags, and found that fungal species richness was reduced when shredders had access. However, Howe & Suberkropp (113), in a similar experiment, found no evidence suggesting an impact of detritivores on aquatic hyphomycete communities in their study stream.

In conclusion, then, aquatic hyphomycetes act both as effective decomposers of leaves in streams, and as mediators of organic matter flow in stream food webs (40). The temporal and spatial patterns of community structure are complex, and the major driving forces shaping the communities at scales ranging from the individual leaf piece to continents are for the most part poorly understood. Apart from environmental factors such as temperature (70) and water chemistry (41,42,114–116), trophic and competitive interactions, and perhaps also synergistic effects, may play critical roles.

Wood Decomposers in Streams

A significant portion of allochthonous material entering freshwaters consists of twigs, branches, and logs (23,24,117). The amounts stored in streams in a given physiographic and forest setting is highest in the headwaters and decreases with increasing stream size (26,27). More than 100 g of pieces greater than 10 cm in diameter may be stored per m^2 of stream bed (26). Wood plays multiple roles in stream ecosystem structure and functioning (26,27). It influences channel morphology, retains organic matter and dissolved nutrients, provides habitat, and serves as an indirect or direct carbon and energy sources for microbial decomposers, invertebrates, and fish (18,26,27,117–119). Probably, it also plays important roles in other freshwater systems, such as forest ponds or littoral zones of lakes, but wood in those systems has been barely studied (120). Because of its persistence even when large fluctuations in discharge occur, wood has been suggested to have a reservoir function for aquatic hyphomycetes, ensuring initial inoculation following fresh leaf inputs in autumn (121). In addition, wood might play a role in the long-distance dispersal of aquatic hyphomycetes (121), although to date conclusive data to support this idea are lacking.

The decay of wood is slow and therefore often thought to have a less distinct impact on stream energy budgets than the decomposition of leaves. Webster and coworkers (25), for example, found no evidence for significant mass loss of large experimental logs submerged in a stream over a period of eight years, and dendrochronological evidence indicates that the complete decay of large pieces may take decades or even centuries (26,27,122). In part this long duration appears to be due to the fact that wood decay in freshwaters is largely a surface phenomenon (123), which is in contrast to both terrestrial and marine ecosystems. Nevertheless, when the amount of wood stored in a stream or other freshwater habitat is large, even a slow decay and transformation would have an appreciable effect on overall ecosystem metabolism.

Wood clearly is an important habitat for Fungi in freshwaters. Shearer (website) reports 275 species of Ascomycota and, in 1992, an additional 46 species of aquatic hyphomycetes (review). More than 100 species of hyphomycetes have been added since (119,124–130). This brings the total number of lignicolous Fungi in freshwaters to more than 400, even if one takes into account that some of the ascomycetes may have anamorphs on wood (Shearer, website; (131)). The hyphomycetes associated with twigs and logs are commonly found also on submerged leaves (121), which has fostered the idea that lignicolous Fungi in freshwaters show little substrate preference (132,133,134). However, in contrast to the hyphomycetes, only a small number of ascomycetes from submerged wood have been observed on leaves, implying a close if not specific relation of these ascomycetes to the woody substrate (18).

The communities of Fungi on wood submerged in streams undergo successional changes that involves species replacements (Yuen and coworkers 2000; 132,134,135). This is in contrast to the simple changes in the relative abundance of species that are observed on leaves. The differences between substrates appears to be due to the longer persistence of wood compared with leaves, and the abrasion of wood surfaces and scraping by invertebrates, constantly creating opportunities for new fungal colonization (121). *Nectria* species such as *N. lugdunensis* (Ascomycota) and its anamorph, the aquatic hyphomycete *Heliscus lugdunensis* Sacc., as well as *Pythium* and some other oomycetes have been identified as early successional species (132,133,135). They are thought to take advantage of the relatively labile components of wood (soluble sugars, starch, and proteins) but not to attack cellulose or lignin, which make up the bulk of their substrate (132,136). As a result, these species cause relatively little mass loss. The early successional species are later replaced by other fungi. It is

not clear, however, whether the species shifts are caused by changes in substrate quality or by seasonal changes in environmental conditions (18), although a number of observations point to the first hypothesis (see in the following text)

At least two patterns of wood exploitation can be distinguished among wood-colonizing fungi in freshwater habitats (121). The so-called soft-rot fungi are characterized by their ability to form distinctive cavities in lignified cell walls and to cause extensive weight-loss of wood. These constitute the second group of colonizers, which are better adapted to the wood habitat than the early successional species. Polysaccharide components of the cell walls are degraded preferentially, but there may be some ability to attack lignin as well (137). Soft rot is the most common type of fungal wood decay in both permanent and alternating water-logged conditions. Most species known to cause soft rot are Ascomycota or Deuteromycota (136,138–142)). Species of the other group cause only minor weight-loss and form no soft-rot cavities (121,136,138,142). This group is thought to take advantage of the relatively labile wood components (soluble sugars, starch, and proteins) and not to attack cellulose or lignin, which make up the bulk of their substrate (132,136). These Fungi are typically early successional species, such as *Nectria* spp. The typical brown-rot and white-rot fungi pervading logs and stumps in terrestrial environments are notably absent from water-logged wood.

The species appearing later during succession often show antagonistic behavior in culture experiments (92,143). In general, they are also more inhibitory to potential invaders and resistant to invasion than their counterparts on leaves (92). Growth inhibition over a distance has been demonstrated in several ascomycetes, including *Chaetosphaeria*, *Massarina*, *Ophioceras*, and *Pseudohalonectria* (143,144) (Yuen and coworkers 2000). This is consistent with the discovery of antibiotics in some of these fungi (93). Furthermore, wood panels inoculated with some single fungal strains, or combinations of two, before placing them in a stream for three months (145) were colonized by significantly lower number of species than uninoculated control panels. Thus, at least in some established cases, species or species combinations can clearly prevent invasion of new arrivals. Competition may even occur intraspecifically, as is suggested by the slower wood mass loss observed when a single fungal isolate was inoculated on two opposite sides of a wood block compared with a control where only one side of the block was inoculated (139). Taken together, the results of these experiments and observations suggest, thus, that apart from a possible deficiency of labile wood constituents for those fungi unable to degrade recalcitrant constituents (such as cellulose), competitive interactions might be involved in determining successional patterns of fungi on submerged wood (18). On the other hand, the enhanced wood decay by species mixtures compared with single-species inoculations (139), and the increased resistance to invasion when certain species combinations are present (145), suggests that positive interactions (synergisms, facilitation) may also be effective in these communities.

Many freshwater fungi, including wood colonizers, possess a wide range of enzymes for degrading plant polymers, and differences in enzymatic capabilities among species appear to be small (121,136,138). Lignin, however, can only be degraded by a relatively small number of species, and even in those cases the available evidence of ligninolytic activity is not conclusive. It may be indicated, for example, when lignocellulose is mineralized in the absence of organisms other than fungi. However, in culture experiments with aero-aquatic hyphomycetes, Bergbauer & Newell (146) found that the destructive capabilities of lignocelluloses varied with experimental conditions, calling for caution in the extrapolation of such results to field situations. Similarly, it is known that the extracted lignins often used in agar plate assays are modified forms of the native lignin (121), and additional difficulties have been encountered when assessing lignolytic activity using agar plate techniques (147).

The dynamics of enzyme activities on wood panels submerged in streams have been followed in several studies (148–151). Enzyme activity is detected already during the first days of colonization, reflecting rapid microbial colonization, growth, and degradative activity. Activity of β-glucosidase, a key enzyme in cellulose degradation, increase rapidly following wood submergence and subsequently remains high (148,149,152). Phenoloxidase, which is involved in lignin degradation, show different patterns. Peaks in activity may first increase and subsequently decline (151) or increase continuously (148,152). Although these enzyme activities may be due to organisms other than fungi, scanning electron micrographs of wood biofilms and bacterial direct counts by epifluorescence microscopy have shown that microbial colonization on wood is primarily fungal (Tank & Winterbourn, 1995) (153).

The limited information available on the biomass of fungi associated with submerged wood also suggests that fungi are an important component of the microbial decomposer assemblage (148,151,153,154). In surface scrapings or small pieces of wood, concentrations of ergosterol, a measure of fungal biomass, increase following submergence of wood in streams (148,151,152,153). On areal basis, concentrations can even be much higher than on leaves (148), indicating that fungal growth on wood can indeed be extensive.

Tank & Webster (153) observed an interaction between leaf litter availability and wood biofilm processes in small forest streams. Experimental exclusion of leaf litter input enhanced microbial respiration, extracellular enzyme activity and fungal biomass on wood logs, with biomass being as much as seven times higher than in a reference stream, implying competition between leaf- and wood-associated microorganisms for nutrients in these streams (153). This is in accordance with the observation that nutrient addition to wood enhances microbial mineralization activity (123). Whether these effects are actually caused by fungi or other microorganisms is currently unknown.

Decomposers in Freshwater Marshes

Fungal communities associated with emergent macrophyte plant litter in freshwater marshes, littoral zones

of lakes, floodplains, and river deltas represent a diverse assemblage of decomposer microorganisms, comprising a number of both taxonomically and ecologically distinct groups (18,155–165). The well studied ingoldian fungi (aquatic hyphomycetes), which are the dominant assemblages on submerged leaf and wood litter in streams, are notably scarce in macrophyte-dominated wetlands.

A unique feature of many emergent wetland plants, which is often overlooked, is the absence of leaf or shoot abscission following senescence and death. Frequently, leaves, leaf sheaths, and culms of emergent macrophyte remain attached to the parent plant in a aerial standing position for long periods of time, and are heavily colonized by terrestrial decomposer fungi well before their eventual collapse into water surface sediments. Growing evidence has established that fungal assemblages inhabiting this litter are adapted to the harsh environmental conditions experienced in the aerial standing-dead phase (Kuehn and Suberkropp 1998, Kuehn and coworkers 1998) (166), suggesting that these microorganisms can contribute significantly to plant litter decay before its entry into the aquatic environment. As a consequence, decomposer fungi associated with plant matter in wetlands are exceedingly more ecologically diverse, ranging from terrestrial taxa, which inhabit standing litter, to aquatic forms, which inhabit plant litter after its entry into the aquatic milieu.

In 1889, Saccarodo reported 168 fungal taxa that were known to be associated with the common reed, *Phragmites australis*, an emergent macrophyte with a worldwide distribution. Our recent compilation of data from the literature now suggests that nearly 600 species have been recorded from this single plant, despite the fact that relatively few comprehensive surveys have been conducted (156–158,167,168). Ascomycetes (42%) and hyphomycetes (30%) were among the most common taxa associated with decaying plant litter, with coelomycetes (22%) and basidiomycetes (6%) occurring less frequently. However, recent increases in reports and new species descriptions (10,169–172) suggest that many more species have yet to be discovered on *P. australis* and probably other wetland plants as well.

Distinct fungal communities have been observed on both aerial standing-dead shoots and fallen litter of emergent macrophytes (157,158). Often different plant parts, such as leaf blades, leaf sheaths, culms (nodes and internodes), rhizomes, and roots, harbor different fungal taxa (155–158), possibly resulting from the varying amounts of recalcitrant compounds found in emergent macrophyte tissues and the environmental conditions of decay. Prior studies have documented a spatial distribution of fungal taxa associated with standing-dead shoots of emergent macrophytes (155,173). Apinis and coworkers (157), reported that ascoma of *Massarina arundinacea* were frequently observed to occupy standing-dead culms of *P. australis* in a region just above the water surface. It was believed that this fungal species was responsible for the weakening of reed culms near the water surface, thus making culms more susceptible to toppling by wave-action.

Besides spatial differences, distinct temporal differences in fungal taxa associated with particular plant components may also occur (174). Often, one sees a succession of differing fungal species as plant litter decomposition proceeds (155–158,175). Pugh and Mulder (155) found that leaves still attached at the parent plant often have an inhabitant fungal community that is different from that on submerged leaves. Their studies revealed a distinct succession in fungal taxa during decomposition of *Typha latifolia* leaf litter. Leaves of *Typha* proceeded through early stages of decay, which were similar to terrestrial plants, with primary colonization by typically leaf surface fungal taxa such as *Aureobasidium pullulans*, *Cladosporium herbarum*, *Phoma typharum*, and *Epicoccum nigrum*. This was followed by a secondary phase in which ascomycetous fungi (i.e., *Leptosphaeria* spp.) were the dominant decomposers. Final stages of leaf decay following toppling of plant matter into the water were dominated by predacious fungal taxa (i.e., *Arthrobotrys* and *Dactylaria* spp.).

Recent studies by Kuehn and coworkers (176) support the idea of a potential shift in fungal taxa between an aerial (terrestrial) and submerged litter decay phase. Kuehn and coworkers (176) observed a rapid decline in fungal biomass and production associated with decaying leaf litter of the emergent macrophyte *Juncus effusus* following its movement from a standing-dead to a submerged litter decay environment. This decrease was followed by an increase in fungal biomass and production after a period of submerged litter decay. These results suggest that fungal taxa associated with standing-dead leaf litter cannot adapt and survive in an aquatic decay environment following shoot collapse (176,177).

In *P. australis* and related plants, leaf blades begin to die from the bottom to the top. As this process proceeds, ergosterol contents of leaves, a measure of associated fungal biomass, increase from nondetectable to several hundred μg per g of leaf dry mass (178). Based of an average ergosterol conversion factor of about 5 μg/g fungal biomass (179) and a growth efficiency of 35% (60), these ergosterol concentrations suggest that some 5% of the standing-dead mass can be fungal, rather than foliar, and that half of the leaf mass lost during the standing-dead phase is accounted for by fungal assimilation (178).

Active mineralization of lignocellulose from freshwater macrophytes is demonstrated in a few studies (180,181). Lignocellulose of *Carex* leaves is degraded by aquatic hyphomycetes and aero-aquatic hyphomycetes (180). Fungal decay of thatched *Phragmites* stems causes soft-rot cavities and a rot causing a thinning of secondary wall from the lumen side toward the external cell walls of the lignified cells (181), these observations are comparable to the depolymerization of macromolecules by *Spartina* fungi by two different types of soft rot (182).

CONCLUSION

The taxonomic affiliation and ecological functions of fungi in freshwater environments are diverse. Functions range from the decomposition of a variety of organic matter in various freshwater systems to regulatory functions of population dynamics of both freshwater animals and algae. The latter aspects have not been covered

here. However, parasitism (Powell 1993, Canter-Lund & Lund 1995, Holfeld 1998, 2000, Van Donk & Bruning 1992, Srivastava 1987, Diéguez-Uribeondo and coworkers 1995), commensalism (Lichtwardt 1986, Misra 1998) and symbiotic mutualism (Wigand & Stevenson 1994, Wigand and coworkers 1998, Miller & Sharitz 2000) occur. Fungal parasitism on both animals and plants is common. In some cases, the impact of fungal parasites is so strong that species once abundant have been nearly complete wiped out/eradicated by an invasive fungus (Canter-Lund & Lund 1995, Holfeld 2000). The dramatic spread and effects of the crayfish disease of the European crayfish, *Astacus astacus*, by the oomycete, *Aphanizomenon*, is a case in point.

Institut für Allgemein Botani
Hamburg, Germany

Most natural materials are susceptible to some kind of microbial attack often called microbial weathering or bioweathering. In general, all microorganisms may contribute to microbial weathering. Thus, in actual cases, the contribution of bacteria, algae, fungi, and lichens has to be taken into account. The higher plants may contribute due to root growth and indirectly by the excretion of substances that serve as substrates for microorganisms. However, the latter is not the subject of this article. The materials either serve microorganisms as substrate, meaning as energy and carbon source like organic compounds, for example, cellulose, or as substrata-like inorganic compounds, for example, mineral materials or metals, mainly as a growth support (for attachment) and/or for a removal of metabolic endproducts. The microbiological degradation of organic substances, called *biodegradation*, has to be distinguished from the term *biodeterioration*, which describes the attack of mineral materials such as natural stone, mortar, and concrete. For example, the reaction of biogenic sulfuric or nitric acid with the binding material calcium silicate and/or calcium carbonate/hydroxide to become neutralized is regarded as biodeterioration. In the

case of metal corrosion by biogenic hydrogen sulfide, this compound reacts with metal ions to form insoluble metal sulfides and, thus, the inhibitory sulfide (inhibitory for the growth of sulfate reducing bacteria) becomes removed from the solution. In both examples, the microorganisms excreting the deleterious compounds find improved living conditions in their environment allowing for further and/or more rapid growth. The energy, however, has to come from an external source.

It should be mentioned that a few artificial compounds, termed xenobiotics do not fit into this scheme. These compounds are not biodegradable nor susceptible to any strictly microbiological attack. Thus, they need additional chemical and/or physical steps to allow for degradation.

The mechanisms that interact jointly in microbial weathering are highly complex. Forces resulting from physical, chemical, biological, as well as fields such as materials sciences, mineralogy, geology, electrochemistry, and others have to be taken into account if a causal explanation is to be given. These explanations, although difficult to derive, are essential for an appropriate selection of materials and/or for protective measures. An important strategy to understand the processes involved includes simulation experiments. However, it always must be considered that microbial weathering is an ongoing, natural process. Throughout the history of the Earth, it is the process that causes soil formation by weathering/deterioration of rocks (together with physical and chemical forces). Without the involvement of microorganisms, this planet would still lack higher forms of life.

MICROORGANISMS INVOLVED IN BIODETERIORATION

Algae and Phototrophic Bacteria

Growth of photolithoautotrophic algae and cyanobacteria occurs independently of any supply of organic substrates. Therefore, they belong to the primary colonizers of building materials such as natural stone and mortar (1). Although algae are primarily found in relatively moist areas, cyanobacteria are also present in dry parts of buildings (2,3). Because phototrophic microorganisms accumulate organic substances on stone material, they may support proliferation of chemoorganotrophic microorganisms. Above this, biofilms of algae and cyanobacteria may exert mechanical stress on the material (2), may change the water characteristics of the material (3), and may contribute to discoloration (4).

Chemoorganotrophic Bacteria

Building materials exposed to the atmosphere are soon colonized with chemoorganotrophic bacteria, because many chemoorganotrophic bacteria can live under oligotrophic conditions (4,5). On strongly alkaline materials such as mortar and concrete, the colonization is suppressed as long as the pH at the surface remains above nine. It is difficult to estimate the weathering potential of chemoorganotrophic bacteria, because diverse genera with different metabolic activities inhabit building materials. Acidogenic and nonacidogenic representatives of chemoorganotrophic bacteria were isolated (6). Because high numbers of airborne chemoorganotrophic bacteria are deposited on aboveground buildings (7), it is impossible to distinguish between actively growing and adsorbed bacteria (8). Nevertheless, chemoorganotrophic bacteria are likely to cause adverse effects on building materials by carbon dioxide production, biofilm formation, and discoloration (4).

Fungi

Depending on the presence of chemoorganotrophic bacteria, fungi seem to be secondary colonizers of building materials (9). Again, the colonization of mortar and concrete is largely prevented as long as the pH at the surface remains above nine. Acidogenic and nonacidogenic fungi were isolated (6,10). Acidogenic fungi are able to attack mineral materials (11–13) and evidence for a mechanical attack by fungi was reported recently (14). Formation of melanins by some genera of fungi contributes to discoloration (15). Fungi isolated from building stones produced a similar spectrum of organic acids, as found in samples from buildings (6,8). Thus, in situ cation chelation by microbially produced organic acids may be the main effect of fungal weathering. Furthermore, in natural stone, filamentous fungi are involved in biogenic iron and manganese oxidation (16).

Chemolithotrophic Bacteria

Chemolithoautotrophic bacteria gain their energy from the oxidation of inorganic compounds. Carbon dioxide is their main carbon source.

Endolithic nitrifying bacteria are the main representatives of the chemolithoautotrophic microflora in building stones and have been identified in deteriorated mortar and concrete (8,17). The microbial conversion of ammonium to nitrate, called nitrification, is a two-step process catalyzed by nitrifying bacteria. Ammonia oxidizers produce nitrous acid that is used by nitrite oxidizers as a substrate, and then finally oxidized to nitrate:

$$NH_4^+ + 1\frac{1}{2}O_2 \rightarrow NO_2^- + H_2O + 2H^+ \text{ ammonia oxidizers}$$

$$NO_2^- + \frac{1}{2}O_2 \rightarrow NO_3^- \text{ nitrite oxidizers}$$

$$NH_4^+ + 2O_2 \rightarrow NO_3^- + H_2O + 2H^+ \text{ nitrification}$$

Nitrifying bacteria are involved in biodeterioration of natural stone mortar and concrete causing a biogenic nitric acid attack and an accumulation of nitrates (8,9,17). The weathering potential of nitrifiers has been demonstrated extensively in laboratory simulation experiments (see the following text).

Chemolithoautotrophic sulfur-oxidizing bacteria such as thiobacilli grow on reduced sulfur compounds including hydrogen sulfide, elemental sulfur, thiosulfate, and polythionates. During oxidation of reduced sulfur compounds to sulfate, protons are released. Thus, as nitrifying bacteria (18), thiobacilli have a strong weathering potential as a result of the production of sulfuric acid (sulfuric acid attack). Thiobacilli are regularly detected in sewage systems, in which they cause serious damage to concrete, mortar, and brickwork (19), whereas they

are seldom found in historical buildings (9). Neutrophilic and moderately acidophilic thiobacilli such as *Thiobacillus intermedius*, *Thiobacillus neapolitanus*, and *Thiobacillus novellus* seem to be the primary colonizers of concrete, contributing, together with nitrifiers, to the consumption of the alkaline reserve of neutral or alkaline mineral materials (19,20). After a slightly acidic pH has been reached, settling and proliferation of strongly acidophilic thiobacilli like *Acidithiobacillus thiooxidans* occurs, with all the disastrous consequences of final pH-values as low as zero (21–23).

MICROBIAL MECHANISMS CONTRIBUTING TO BIOWEATHERING

Although almost all microorganisms contribute in one way or other to the biodeterioration of mineral materials, the number of mechanisms appears to be quite limited. Known mechanisms can be summarized under seven different categories. In this context, it must be mentioned that microorganisms are generally not interested in deterioration of mineral materials per se, but favor environmental conditions permitting them to grow. This is an important difference compared with biodegradation processes occurring with organic materials because these, after breakdown, also serve as nutrients. However, in the case of mineral materials, the microbial process of deterioration/weathering "simply" serves as an improvement of the environmental conditions for growth purposes. Microorganisms can grow on and in mineral materials. These modes are called epi- or endolithic respectively. Especially the latter mode confers some kind of protection to microorganisms in harsh climates. The surrounding mineral material reduces the danger of desiccation, freezing, or solar radiation. Thus, endolithic life-forms occur, for example, in the arctic regions or in deserts. To be able to endolithically grow in mineral materials, cavities need to be generated for the "uptake" of microbial cells if suitable pores are not available. For this purpose, either chemically/physically preformed cavities may be used or the microorganisms may form them by their own action, that is, by the excretion of organic or inorganic acids able to dissolve the material, or by mechanical forces.

Inorganic Acids

As an end-product of their metabolism, several specialized groups of bacteria produce strong acids, namely, nitric acid (8,9,18) and sulfuric acid (18,19). These acids are produced and excreted in the course of microbial metabolism, if nitrogenous or sulfurous compounds such as amino acids, ammonia, and urea, or sulfides, and sulfur are available in the environment. The acids may react with acid-susceptible materials such as carbonates, hydroxides, and silicates in effect dissolving them. Often, the latter not only acts as the binding material in natural stone but they also perform a similar role in concrete and artificial stone. The dissolution of the binding material results in the weakening of the structure and a loss of filler material such as grains of quartz and so on. In the case of nitrous and nitric acid, the dissolution of the binding material results in the production of soluble compounds (nitrites or nitrates), which are easily washed away. The reaction products of sulfuric acid mostly have a low solubility and generally remain at the site of formation. For this reason, gypsum crusts are often detected and seem to indicate that only sulfuric acid was involved in the weathering process.

$$2HNO_3 + CaCO_3 \rightarrow H_2O + CO_2 + Ca^{2+} + 2NO_3^-$$

$$H_2SO_4 + CaCO_3 \rightarrow H_2O + CO_2 + CaSO_4$$

The two equations give a simplified example of this kind of attack.

The third inorganic acid, which is often forgotten or ignored, is carbonic acid, H_2CO_3. This acid, although considered chemically to be weak, can also react with binding substances of mineral materials and transform them, for example, from hydroxides or silicates to carbonates. Although the latter still remain in place and function as binding agents, the pH is considerably lowered from 12 to 14 to pH8, which is the optimal value for growth. As a consequence in the case of reinforced concrete, the steel used for reinforcement is no longer protected against corrosion. It starts to corrode with water and oxygen access, losing its reinforcing function, and because of the increased volume of the ferric oxides, exerts a swelling attack on the surrounding concrete.

Organic Acids

Almost all microorganisms may excrete organic acids in the course of their metabolism because of metabolic imbalances (12,24). The excreted organic acids are chemically quite diverse. Acidic compounds may occur from all stages of microbial metabolism, namely, glycolysis or similar catabolic pathways, anaplerotic sequences, amino acids, uronic acids, nucleic acids, and so forth. In addition to imbalanced growth, some acidic compounds are excreted deliberately. This concerns, for example, the acidic compounds in the extracellular polymeric substances (EPS), surrounding a cell as a slime layer. Here, amino acids, uronic acids, nucleic acids, and fatty acids have been detected (25).

Although these acids may be taken up again in a later stage of metabolism, the acids can react chemically with the environment and form salts by reaction with susceptible materials. In general, their action is comparable to that described earlier for inorganic acids, besides the fact that many acids may form complexes with (heavy) metals. In this way, for example, citric or oxalic acids additionally contribute to the dissolution of inorganic materials. This complexation may have a distinct advantage for the excreting microorganism by the consequently increased availability of trace metals for growth. In this context, it may be discussed whether the excretion deliberately occurred to ensure or at least increase the trace metal supply of these microorganisms. Fungi are especially known to excrete organic acids in the course of their metabolism. Recent research regarding the EPS of bacteria indicated that the structural organic acids play a pivotal role in metabolism by affecting substrate degradation and allowing surface adhesion due to complexed metals (see BIOLEACHING).

Salt Attack

Most mineral materials have a porous structure. These pores have sizes ranging from submicron up to the millimeter. The pores are filled with water and gases. Although the large pores loose their water content and dry out during periods of desiccation, the micron- and submicron-type of pores resist desiccation more effectively. This becomes even more pronounced if the pores are colonized with microorganisms. The latter excrete in the course of their metabolism various types of metabolic compounds, for example, (*in*)organic acids that after reaction with the (susceptible) mineral material may form a salt. Salts are in general hydrophilic compounds that therefore bind water molecules (hydratation). Because of this effect, molecules are formed, which are too large for the available pore space. Consequently, a swelling attack in such a pore is observed. Because of the significant physical forces of hydratation, the pore system cracks. It must be kept in mind that the formation of the salt and the hydratation are purely physical effects, whereas the formation of the original compound, such as nitrates, sulfates, and organic acids is a result of microbial metabolism. This example shows how difficult it is to distinguish between chemical, physical, and biological deterioration mechanisms.

Salt attack may cause the destruction of large surface areas of affected materials. This is called scaling. It can cause a loss of surface layers, or in the case of wall paintings, the removal of pigments from the underlying stone or concrete. As a consequence of biogenic sulfuric acid corrosion, the gypsum thus formed may undergo a series of hydratation reactions, causing the formation of ettringite. The latter compound is also known as "concrete-bacillus." Because of the hydratation, it contains a large volume ($3CaO \cdot Al_2O_3 \cdot 3CaSO_4 \cdot 32H_2O$), and seriously endangers concrete structures. Another effect of biogenic salts must also be mentioned. Besides the formation of large crystals (hydratation), salts are generally hydrophilic compounds and bind water molecules. Thus, the presence of salts result in the presence of water in the pore system of a mineral material. This water will not evaporate as easily as pure water. Thus, porous systems containing salts have an increased water content. This does not cause problems per se. However, in the case of freeze-thaw attacks, which are usual in moderate climates during autumn, winter, and spring, this water may form ice crystals, which according to their increased volume tend to exert a swelling attack that is similar to the effect of salts on porous materials.

The Role of Biofilms in Bioweathering

Most microorganisms (>90%) grow attached to surfaces. In this respect, porous mineral materials offer optimum substrata (26,27). In the course of this attached growth, microorganisms metabolize available nutrient sources, excreting intermediates and end-products of (in)organic nature, and protect themselves against dryness, predation, toxic substances and so on by the excretion of EPS. EPS, as explained earlier, consist of many different compounds, namely, sugars, lipids, amino acids, and nucleic acids as well as some complexed heavy metals. Because of this composition, the EPS function as nutrient scavengers and, as a result of their hydrophilic nature, effectively bind water in place. The system consisting of EPS, living or dead microbial cells, and (in)organic detritus is called biofilm. This biofilm is found in the case of mineral materials on the surface and in the pore system. Especially pores with a diameter between 0.5 and 10 μm are optimally suited for microbial growth. This is because these pores are large enough to allow the invasion of microbial cells and their internal growth, resulting in a totally filled pore. The latter becomes impossible for pores with an excessively large diameter. As a consequence of this biofilm formation, the same effects arise as have been described earlier for the salt attack: an increased water content in a porous system, an increased salt content, and susceptibility to a freeze-thaw attack. Finally, a biofilm tends to clog the pore system of a porous, mineral material. This means that, on the one hand, the pore water will not evaporate and therefore remains within the system and on the other hand, the blocked pores do not allow the application of stone "consolidants" because they cannot penetrate into the pores. However, for an application of these compounds to be effective, a minimum invasion of several centimeters up to the structurally sound stone is required. If this cannot be achieved, the application often causes more harm when applied than when not applied. Cases in which because of a biofilm, whole facades were lost as a result of imperfect penetration, scale formation, and a subsequent freeze-thaw attack are known.

Additional effects of biofilms may be aesthetic effects like discoloration, increased heat absorption, and reduced porosity.

Discoloration

Aesthetic effects are a major concern for porous mineral materials. Materials exposed to light and the open atmosphere tend to be colonized by phototrophic microorganisms such as cyanobacteria, algae, and lichens, all of which are colored. Thus, these surfaces become discolored, at first appearing green and very often becoming almost black, with the appearance of being dirty. Additionally, dust particles from the atmosphere like soil and/or soot are included in the EPS, contributing to the impression of dirt. In the case of bright stones, a considerable change of the optical impression may result. Because of this effect, many buildings, especially in an industrially polluted atmosphere (including traffic as a source) have turned black. Other effects are a surface growth of fungi on historical glass, which causes it to become turbid or change in color because of metal extraction. The black surface also causes an increased absorption of solar light, thereby increasing the temperature of the affected areas. Furthermore, the increasing differences between day and night temperatures and the gradient between inside and outside becomes steeper than with uncolored surfaces. As a consequence, the physical stress on the materials is increased.

Noxious Compounds

Ammonia (NH_3) is increasingly introduced into the biosphere as a result of the increase of manure production

from livestock breeding, processes for NO_x-removal in combustion processes (power plants, traffic), and the use of mineral fertilizers for farming. The biological degradation of ammonia and precursors like urea or amino acids during the process of nitrification results in the generation of nitrous and nitric acids, the effects of which have been described earlier under inorganic acids. Nitrogen oxides, summarized as NO_x, comprise NO, NO_2, and N_2O. The first two compounds arise in the course of combustion processes and can be seen as anhydrides of nitrous and nitric acid, respectively. There is some evidence that NO and NO_2 may contribute to biodeterioration of building stone by serving as substrates for nitrifying bacteria. The latter compound, N_2O, is produced in the course of denitrification and an effect of this compound on mineral material degradation is not evident.

Methane (CH_4) is a natural component of the atmosphere. Besides, it is produced by microorganisms that reduce (CO_2) under anaerobic conditions, for example, in rice fields, and it is the main component of natural gas, which is increasingly pumped off the ground for industrial and private use. Methane-degrading bacteria, besides emitting carbon dioxide, tend to produce EPS, thereby exerting negative effects on mineral materials. However, the degradation of methane itself seems to be nonproblematic (9).

Hydrogen sulfide (H_2S) is the most dangerous compound for mineral materials (19,22). It may be of chemical or biological origin (sulfate reducing bacteria). Under aerobic conditions, sulfur-oxidizing bacteria transform H_2S into sulfuric acid, the effects of which have been described earlier. Furthermore, H_2S may react with reinforcement steel and cause its deterioration as a result of metal sulfide formation.

Organic Solvents

Many microorganisms excrete organic solvents in the course of metabolism. These include compounds such as formic acid, acetic acid, butyric acid, lactic acid, ethanol, butanol, and many others. Not all of these compounds directly contribute to the weathering of mineral materials; however, they may have a negative impact in the case of a combination of minerals with organic materials.

Exoenzymes

It has been known for a long time that microorganisms excrete extracellular enzymes into the environment. Actually, the first biotechnologically based processes such as degradation of starch for beer and bread production are based on exoenzymes; however, this applies to the degradation (cleavage) of organic macromolecules into small, dissolved units, which, sensu strictu, does not play a role in the weathering of mineral materials. Exceptions are combinations of mineral materials with organic compounds and the problem of steel reinforcement corrosion. The latter may be an effect of exoenzymes causing ennoblement of stainless steel and, consequently, biocorrosion.

MATERIALS, PROPERTIES, AND EXAMPLES OF COMPLEX WEATHERING PROCESSES

Microbial processes contribute to the natural weathering of rocks and to soil formation in all its stages. Mineral materials are not only all naturally occurring rocks of magmatic origin (like granite, basalt), sedimentary rocks (like limestone, sandstone, even clay), metamorphic rocks [like marble, slate, etc. of inorganic origin (pure minerals included) used by humans], but also a large number of artificial, that is, processed or synthesized materials such as concrete, ceramics (mainly of clay origin but also oxide ceramics and special materials), and glasses. Detailed descriptions of these materials are given in appropriate textbooks. The term "microbial weathering" is generally used with reference to materials such as natural stone, for example, found at historical buildings. However, other construction materials such as concrete and mortar, brick, ceramic materials, as well as special artificial materials such as glass are also susceptible to a microbial attack. If buildings or other constructions are affected, the process becomes "unwanted."

The usual meaning of weathering is the partial or even total physical destruction of materials, but in some cases a physically minor alteration of an item may cause a total disfunction of a valuable instrument (e.g., optical glass) or may endanger the reliable function of a technical system. Thus, deterioration and degradation are closely related to weathering, because all these categories are based on similar microbiologically influenced processes.

Bacterial oxidation processes occurring on sulfidic ores and other technically useful treatments of materials based on microbially provoked dissolution processes are discussed in more detail under the topic "Bioleaching," but they should be mentioned here as well, because the biogenic sulfuric acid causes a very intensive weathering of susceptible rocks, with subsequent, in many cases, deleterious effects.

The mechanisms involved and effective in microbial weathering are best understood when case studies are discussed considering the materials' characteristics.

Natural Stone

With respect to the topic "microbial weathering" not only different kinds of construction materials (building materials) are relevant, but even naturally or even artificially formed massive items consisting of rocks, stones, or other naturally occurring raw materials should also be considered. On a large-scale, construction materials are especially used for buildings, however, mineral products are also applied for road and rail road construction.

Almost all attack and damaging mechanisms involved in microbially influenced deterioration of materials may act on mineral materials (see in the preceding text). The mechanism that plays the major role in a specific case, cannot be decided ex cathedrae, because an enormous multitude of possibilities exists.

Numerous examples from human history show that the major role in the choice of construction materials was at first their availability on-site (or nearby) and the

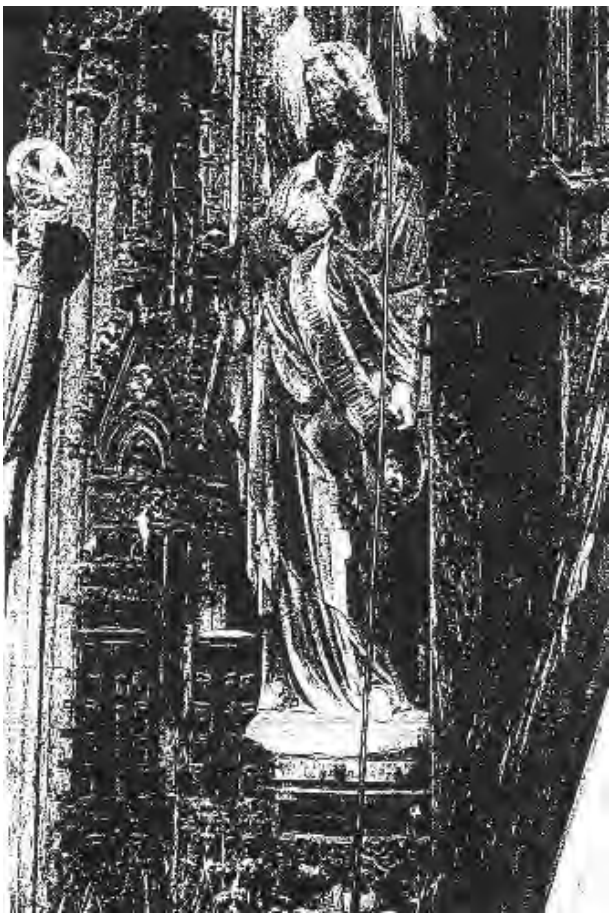

Figure 1. A sandstone sculpture from the dome of cologne, Germany, after exposure to the natural weathering process for nearly 100 years (by Dr. Wolff Köln).

ease of exploitation and processing. Different kinds of sandstone (Fig. 1), calcar, volcanic tuff, sand, and clay, all of them relatively susceptible to weathering, were the most frequently used materials. Accordingly, extremely hard materials, such as basalt and granite, were only rarely used.

Regarding microbial weathering of mineral materials, the physical, and chemical characteristics are of great importance. The combination of properties may be decisive in the susceptibility of a given material. Additionally, the properties of potential reaction products or compounds accumulating on or in the material may play a key role.

The properties of mineral materials to be considered are physical (porosity, capillarity, specific surface, physisorption, capillary condensation, thermic dilatation, thermic conductivity, susceptibility to freeze-thaw attack, color, and color-related radiation absorption), chemical (hydrophilicity, hydrophobicity, nutrient content, chemosorption of potential nutrients from air, reactivity toward potential chemical attack by acids, for example, nitric, sulfuric, carbonic acid, hydrogen sulfide, presence of complex forming ions and compounds, hydratation processes), and mineralogical (composition, structure, crystallography, homogeneity), with respect to the manifold weathering processes.

Thus, the weathering of a material depends strongly on the combination of its properties (chemical and mineralogical composition, microscopic and macroscopic structure, porosity) and on the specific environmental conditions (climatic — temperature and temperature changes, humidity, air movement; specific chemical composition of the whole surrounding environment — air, water, solids) than only on the properties or on the climatic/environmental conditions alone.

As a first example, two chemically similar but structurally different materials such as muschelkalk and marble shall be compared. The first one is a porous, structurally inhomogenous material showing a relatively high specific surface area. This enables processes like capillary condensation, capillary suction, and diffusion. In such conditions microorganisms find ecological microniches, where proper survival conditions can be maintained irrespective of extreme external atmospheric/climatic conditions. Humidity is usually available due to capillary condensation and capillary suction. High concentrations of metabolic or reaction products that are harmful to the microorganisms may be easily lowered/reduced by good diffusion (porosity and available humidity even in a dry climate). The chemical properties derived from the main component, calcium carbonate, are less important in this case, because they are similar to marble. However, marble is a crystalline, dense rock, showing nearly no porosity except for some cracks at the interface of crystallites. Thus, on marble a microbial population can settle only at the (external) surface of the material and must face considerably adverse growth conditions. Consequently, the muschelkalk will be populated to a significantly greater depth than marble. Also, only a few, very specialized organisms occur on marble, whereas muschelkalk will show a large variety and an increasing number of organisms.

A second example refers to structurally similar, but chemically different materials. Sandstones are always (more or less) porous materials that favor capillary and diffusion processes. However, significant differences arise with respect to the microbial population as a result of distinct chemical composition. In the case of acidic sandstone, possessing none or only little alkalinity in the form of calcium carbonate, acid-producing but acid-sensitive organisms such as nitrifiers are unable to proliferate. On the contrary, in sandstones with a high acid-neutralizing potential, nitrifiers will find optimum growth conditions, in which microbial weathering by the production of nitric acid is likely to occur (9).

These examples illustrate how properties and conditions influence the proliferation of certain microorganisms. This however, does not mean that other organisms, which are insensitive to the factors mentioned earlier, may not be present and that they act according to their specific metabolism in a different way. Especially chemoorganotrophic bacteria are almost always present, because they include a large number of different organisms, which are less demanding with respect to growth requirements, and contribute in a more or less evident way to the weathering process (excretion of organic acids). For instance, excretion and accumulation of organic metabolic products,

as present in biofilms (dead or alive), may alter some physical properties and the status of the materials such as diffusion-rates, gradients of temperature, humidity, concentrations of oxygen, salts etc.

Synthetic Stones (Concrete, Mortar)

Reduced nitrogen compounds such as ammonia/ammonium ions serve as energy sources for neutrophilic ammonia-oxidizing bacteria forming nitrite, which is further oxidized to nitrate also by neutrophilic nitrite-oxidizing bacteria. Hydrogen sulfide, elemental sulfur, or thiosulfate are oxidized by neutrophilic and acidophilic thiobacilli forming sulfuric acid. During these biooxidation processes hydrogen ions are released, which cause a strong acid attack on acid-sensitive compounds. These aerobic microorganisms inhabit the surface or pore system of materials and cause a direct dissolution of binding agents (calcium carbonate, calcium hydroxide, calcium silicate) in concrete and mortar. Carbonic acid may also dissolve carbonate. Calcium ions and the anions may diffuse in the pore system according to specific conditions.

Indirect microbial weathering is caused by secondary phenomena such as crystallization of salts (because of concentration by evaporation or precipitation reactions). Calcium ions formed at a certain site migrate to another site and, by a subsequent reaction with sulfate, compounds such as gypsum may form. Gypsum may be formed as well from biogenic sulfuric acid via its (neutralization) reaction with calcium carbonate or hydroxide (e.g., in concrete or mortar). Immense mechanical stress is caused by crystal growth within a pore resulting in additional deterioration (Fig. 2). The material subjected to this kind of mechanical deterioration is not necessarily involved in the primary microbial process. A combination of material properties and specific site conditions are necessary to cause these processes.

Synthetic cement-based stones (concrete) contain several calcium compounds such as (free) calcium hydroxide, calcium silicates, and/or aluminosilicates. During aging, besides internal structural changes (hardening, especially in the early stage within 28 days), carbonatization (formation of calcium carbonate) may occur. This process depends on factors such as cement content and quality, density and porosity, as well as environmental conditions. Besides the mechanical strength, chemical properties change. Cement- and/or lime-based and even non-cement mortars show changing chemical and physical properties, beginning at the surface. The changes continue with time and progress into the bulk of the material. Gradients appear, for instance, for pH. Such construction materials are subjected to a succession of continuously and progressively changing bacterial populations located in the beginning at the surface and progressively penetrating deeper and deeper into the material. The microorganisms cause primary changes by excreting metabolic products. Although on fresh concrete, survival and proliferation of organisms is impossible because of the very high pH (up to 12), as fast as the conditions change (carbonatization), the microorganisms settle in microniches. Finally, they invade large areas within the material (formation of extended biofilms). Concomitantly, depending on the actual pH, the consortium of neutrophilic organisms turns toward moderately acidophilic and finally strongly acidophilic bacteria. Values of pH as low as 0.8 occur on concrete. The consequence is a total destruction.

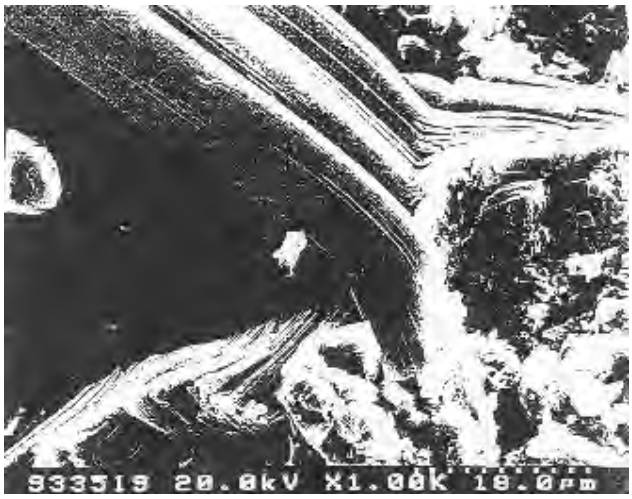

Figure 2. Gypsum crystals (ettringite) in a brick. Scanning electron microscope image showing the salt attack.

This scenario is valid for concrete and mortar. Attempts to avoid proliferation of strongly acidophilic thiobacilli by addition of (less expensive but weak) neutralizing agents (such as calcar, dolomite, marble) failed, because these neutral aggregates offer pH-neutral sites for other neutrophilic acid producers. These may prepare a proper microenvironment for a subsequent settlement and proliferation of strongly acidophilic species. Additionally, different species settle on different sites, forming distinct microniches according to their specific needs. Thus, nitrifiers and neutrophilic thiobacilli have been detected on visually sound sites with pH-values between six and eight. As soon as the neutralizing source (sacrificial aggregate) had been consumed, the pH decreased below five and the binding material was also attacked.

These processes may occur at relatively high rates. Mortar up to a depth of several centimeters was destroyed within two to three years in main sewage pipelines. Up to 5 cm of a plastic coated concrete was destroyed within two years in a sewage treatment plant, with a pH beneath the coating as low as 0.8.

A technically useful application of such processes has been developed (28) for a decontamination of radioactive concrete constructions in the nuclear industry. Spray application of a biofilm-like gel containing an inoculum of thiobacilli and elemental sulfur and the necessary trace elements allowed the extraction of a surface layer of concrete including acid-soluble radionuclides. After sufficient dissolution due to biogenic sulfuric acid production, a simple removal of the products is possible. Thus, high cost and hazardous work-intensive procedures may be replaced by biotechnological means.

Materials resistant to microbial weathering should be chemically resistant to the active agents involved. For example, different types of concrete show different resistance toward biogenic sulfuric acid produced by

thiobacilli. High calcium aluminate cements may give an acceptable, acid-resistant concrete for application in dangerous environments, for example, in sewage systems (29).

Prevention of weathering by coating of the materials may be an option for protection. Barriers against penetration of bacteria and against the active destructive agents may improve the lifetime of materials. Penetration of bacteria may be prevented only by microporous materials with a pore size maximum of 0.5 μm. However, at the surface of the coatings acid-producing bacteria may settle and proliferate. Thus, the structure of the coating must be resistant at the molecular or ionic level, because diffusion paths of molecular size are appropriate to allow for an acid attack on the underlying bulk material and a failure of the "protective" coating is the consequence.

A material used as coating, as filling material, as reinforcement, or as an addition for any other purpose (e.g., plasticizer) should not serve as a nutrient for microorganisms nor should it be susceptible to degradation by bacterial influence. Otherwise, only a limited service life will result.

An addition of inert filling materials such as glass fibers is of no use, when the bulk material is susceptible to microbial attack by any of the ways described earlier. Even an addition of specific biocides has only a limited effect because microorganisms living in microcolonies and microniches may survive the treatment. Biofilms are known to have a protective effect by creating a diffusion barrier toward the biologically "noxious" compounds. Even the effect of toxic heavy metals may be attenuated by the excretion of biogenic complexing agents such as oxalic or citric acid.

Clay Minerals

Clay is a mixture of mineralogically stable, finely grained aluminosilicate minerals resulting from primary rocks as the end-products of natural weathering. The grain size of clay particles is typically between 0.1 and 10 μm. Clays have a layered structure that allows the inclusion and exchange of cations. Depending on the stoichiometric ratio between the main cations (Si^{4+}, Al^{3+}, Mg^{2+}), the basic crystal lattice may be electrostatically balanced (neutral) as it is, for example, in the case of pyrophyllite $Al_2Si_4O_{10}(OH)_2$ and talcum $Mg_3Si_4O_{10}(OH)_2$. In the case of an isomorphic replacement of one cation with another one of usually lower valence (Mg^{2+}, Al^{3+}, Fe^{3+}, Ti^{4+}), the consequence is a net negative charge. Thus, additional cations must be included to compensate the electrostatic imbalance. This may happen with mono and divalent cations (H_3O^+, NH_4^+, Na^+, K^+, Mg^{2+}, Ca^{2+}). Depending on the exact structure of the basic lattice and on the nature of the additional cations, embedment of water by hydratation may occur. Thus, swelling and nonswelling clay minerals may be formed (30).

Clay minerals rarely occur as pure minerals. Usually, they occur with impurities or as mixtures with unaltered minerals such as quartz or feldspar, turmaline, rutile, zircon, or other weathering products of rocks such as iron oxides.

Clay minerals were used mainly for simple constructions, but valuable monuments have also been built using clay minerals during history in suitable climatic conditions. Historical buildings made of (mainly) clay with straw addition may withstand harsh climatic conditions for centuries. Organic carbon sources were often present due to animal feces added to the clay-mixture to improve adherence and coherence of the mixture. Studies regarding the microbial population in framework buildings revealed that deterioration of clay by microbial weathering is not the main cause of decay, although nitrifying bacteria occurred together with chemoorganotrophic bacteria and fungi in large cell numbers. Fixed ammonium caused by Lewis and Broensted acid sites on aluminosilicates (allowing for a strong chemosorption of ammonia) was detectable in clay samples, which proved to be accessible to nitrifiers in laboratory experiments.

A useful technical application of microbial weathering is known from ancient times. The Chinese discovered the improvement of clay quality and the transformation into high-quality kaolinite by a treatment with liquid manure for several years. A removal of reddish-brownish coloring iron compounds as a result of bacterial dissolution allowed them to obtain a raw material yielding a white "china" porcelain. Additionally, the kaolin became better processible because of its improved plasticity, exhibited an improved bending strength, and finally the fired product had an improved tensile strength. Thus, a very thin porcelain could be produced (30).

Ceramics

Brickwork (consisting of bricks and mortar) in a main sewer showed serious damage after 80 years of service. Chemical and microbiological analysis revealed that pH-gradients within the mortar joints and within the bricks themselves were correlated with species and cell counts of acid-producing microorganisms. Depending on the extent of the damage and on the specific conditions at those sites, specific consortia of coexisting microorganisms could be detected (20,31). Finally, the visual damages of the bricks could be attributed mainly to mechanical stress caused by a crystallization of gypsum needles within the pores of the bricks. The formation of calcium sulfate occurred in the carbonatized mortar as a result of the metabolism of thiobacilli (sulfuric acid excretion). As a consequence, the mortar was weakened because of a loss of its binding material, calcium carbonate. Calcium sulfate crystallized partly in the mortar, but it also partly diffused into the bricks and crystallized in the pores. In addition, thiobacilli were detected in the bricks, too; thus, sulfuric acid was formed in the brick as well. Dissolved calcium bicarbonate and/or calcium hydroxide (the deep layers of the mortar showed strongly alkaline pH) diffusing additionally from the mortar formed gypsum (crystals) with the biogenic sulfuric acid. Also, nitrifying bacteria were involved in the deterioration process. They obviously contributed to the dissolution of calcium carbonate by forming the water-soluble compound calcium nitrate, enhancing the amount/concentration of calcium ions diffusing toward the bricks.

In another case, glazed bricks (approximately 100 years old) exposed to the atmosphere showed severe weathering because of a high microbial biomass (fungi and bacteria) supported by the presence of photosynthetic microorganisms (filamentous algae and unicellular algae) (32).

Little information is available on microbial weathering of ceramic materials such as stoneware, which is supposed to be highly resistant toward inorganic and organic acids. Additionally, it is usually designed for heavy duty purposes (sewage, chemical industry, etc.) and fulfills demands regarding both corrosion and mechanical resistance. However, stoneware obtained by low-temperature firing may have remaining acid-susceptible components.

Glass (Historical and Recent Glassware)

Glass is a noncrystalline, amorphous material consisting of several oxides. Silicon dioxide, calcium oxide, and at least one alkali-oxide (sodium or potassium) are the most common components. Often, minor contents of phosphate, magnesium, aluminum, iron, and manganese are present, but heavy metals such as lead and sometimes copper are also present, which may represent major parts of crystal glass (lead glass) or ornamental glass. Special-purpose (modern) glass may contain as main or secondary components boron trioxide, barium, beryllium, lithium, or silver, but minor components or traces of many other elements are also deliberately used.

Distinct weathering processes occur, depending on the composition of the material: whether it was designed for a certain environment and used accordingly or whether it was exposed to other, inappropriate environmental conditions. Thus, weathering of glass in normal use (modern, recent, or even historical windows) (33–36) should be distinguished and differentiated from weathering under special conditions, for example, as in archaeological glassware (37).

Because numerous possibilities of different glass compositions exist, only general statements can be given. Organic compounds deposited from dust, fumes, vapors, or fingerprints may serve as nutrient source for chemoorganotrophic growth of microorganisms. Fungi seem to be the main organisms involved in a biological attack on glass materials. Excreted organic acids such as acetic, oxalic, citric, fumaric, and gluconic acid have been detected. Ion exchange of protons against metal ions in the glass matrix is the primary phenomenon, whereas alteration of the glass structure (gelification, stratification, fractures, and also pitting) may be the consequence. Differences between the tensile strength of the altered surface layers and of the sound, bulk glass mass may cause crack formation and propagation. Additionally, crystal growth and penetration of fungal hyphae can contribute to an enlargement of cracks and an exposure of new surfaces for further reaction. Dissolution of glass components may serve as the sole source for biologically essential elements for microorganisms such as iron, manganese, or phosphorus compounds. Precipitation of new solid phases, not always as crystalline minerals (biominerals), may produce color changes, reduce transparency, and alter optical performance. Biominerals such as (insoluble) calcium oxalate, lead phosphate, calcite, aragonite, and kalicinite have been identified so far. More complex, rather unknown compounds form under less controllable conditions, as found in archaeological glass samples. In these cases glass components, microbial or/and fungal metabolites, and soil components contribute to the formation of a phenomenon called “glaspest” (37).

Because nearly infinite glass compositions are possible, only very few model glass compositions have been studied so far with regard to biogenic weathering/deterioration under controlled conditions. Accordingly, simulation studies must be performed for any individual glass considering the specific environmental conditions for which it was designed. Extreme situations need to be considered in the case of glassware intended to be used in high-tech applications.

SIMULATION OF MICROBIAL WEATHERING

The colonization of a weathered material by microorganisms does not allow one to determine if microbial weathering is involved in the deterioration observed. Under natural conditions physical, chemical, and microbiological factors interact during weathering of a material. Because of this complexity a clear correlation between the presence of certain microorganisms and deterioration of the material is rarely possible. Because the weathering process under natural conditions is relatively slow, it may take years or even decades to observe measurable changes. Simulation experiments try to overcome the limitations of in-field investigations. Although approaches differ widely in their complexity ranging from simple inoculation-tests to complex environmental simulation, the general procedure of a simulation experiment can be divided into three steps (basically following Kochs postulates):

1. Quantification, isolation, and identification of microorganisms growing on the affected material.
2. Inoculation of pristine material samples with the microorganisms isolated and subsequent incubation under optimized and controlled conditions.
3. Characterization and quantification of the effects caused by the presence and/or the activity of microorganisms on the characteristics of the materials.

Simulation experiments are performed for different purposes. First of all they are used to demonstrate and quantify the weathering potential of a defined group or consortium of microorganisms and to study the mechanisms involved. In case of economically important materials such as concrete and metals, simulation of microbial weathering is often used as a standardized material-testing procedure. These tests aim at a differentiation between the susceptibility of different materials to microbial weathering and/or the colonization with microorganisms. They may include testing of countermeasures such as coatings, biocides, water repellents, and consolidants.

Although steps two and three of the procedure described earlier may appear to be the main parts of a simulation experiment, step one should not be neglected as long as the mechanisms are not fully understood. It is essential to

Figure 3. Various sandstone. Test specimen exposed to natural weathering.

correlate laboratory data with field data. Therefore, field surveys and field testing should be done in parallel with simulation experiments (Fig. 3).

Simulation aims at controlled and optimized experimental conditions. Usually, an acceleration of the microbial weathering process is achieved by the inoculation of test specimen with selected microorganisms and an incubation at conditions optimum for their growth. Optimum growth conditions are usually achieved by a high availability of substrate, a suitable temperature, and a high moisture content in the material and/or the atmosphere. The experimental time is a major influence on the results of a simulation experiment, because significant changes in the material, even under accelerated conditions, may occur only after months. Therefore, long-term experiments performed for months, a year, or even longer, are often necessary.

Significant changes of material's characteristics detectable after accelerated microbial weathering stand for the weathering potential exerted by the inoculated microorganisms. Parameters that may indicate microbial weathering are discoloration, hydrophobicity, porosity, mineral composition, water vapor diffusion, weight-loss, pH, material-loss, salt content, and loss of strength. To obtain proper results it must be ensured that the inoculated microorganisms actively grow or settle on the material and do not just survive without any significant activity. Furthermore, it is essential that changes in material's characteristics by microbial weathering are significant, when compared to noninoculated controls incubated under comparable conditions but kept free from microbial growth.

The accelerated conditions in simulation experiments can be termed "worst-case," a fact that makes them a powerful tool for the testing of materials. If a material resists microbial weathering and/or colonization under "optimum," but artificial conditions, it can be predicted as resistant to microbial attack/colonization under "suboptimum," but natural conditions. If sufficient data from case studies and/or exposure experiments are available, an acceleration factor can be calculated for a standardized test system allowing the estimation of a lifetime of the material (23,38,39).

A variety of simulation experiments have been performed to find out which microorganisms are the most relevant in microbial weathering of concrete, natural stone, and mortar.

The potential of filamentous fungi to weather mineral materials by the excretion of organic acids has been demonstrated several times by relatively simple, laboratory experiments (11,13,40). Mineral materials were immersed in nutrient-rich media, inoculated with fungi, and incubated. In a laboratory chamber experiment, the pitting of marble by slow growing dematiaceous fungi was demonstrated recently (14). After 10 months of incubation under alternating conditions of dryness and high humidity, inoculated cubes showed a weathering similar to that found on marble in Mediterranean regions. These experiments for the first time demonstrated that fungal weathering may also involve mechanical forces.

The weathering of natural stone and concrete by acid-producing thiobacilli and nitrifying bacteria has extensively been demonstrated in simulation experiments (41,42).

Microbially induced sulfuric acid attack of concrete by the activity of sulfur oxidizing thiobacilli causes severe problems in sewage pipes, which was well characterized and evaluated by simulation experiments (23,39,43,44). The microbiological weathering of concrete was accelerated 8 to 24 times (23,39). After three months, a visible deterioration of the mineral material appeared. With this test system, concretes of different composition and quality were differentiated according to their susceptibility to the biogenic sulfuric acid attack. In addition, the efficiency of coatings, paintings, and biocide treatments was tested. The microbiological attack was strongly influenced by interactions between the mineral surface and the organisms. Thus, the biological test cannot be replaced by a simplified chemical test (23,39).

In a test chamber, designed as a salt-spray-cabinet, the biogenic nitric acid attack on sandstone and concrete by nitrifying bacteria was demonstrated for the first time (45). After one year, the materials were differentiated according to their resistance to the microbial attack. The loss of calcium correlated with the weakening of the mineral structures. The conditions in the salt-spray-cabinet

resembled the ones found on wet concrete surfaces inside cooling towers, where high numbers of nitrifying bacteria were found.

In the case of historical buildings made from natural stone, weathering is a combination of physical, chemical, and microbial attack. Therefore, in a complex simulation experiment, biogenic nitric acid attack was reproduced in the presence of an artificial smog atmosphere (9,41). The air contained sulfur dioxide, nitric oxide, and nitrous oxide in concentrations 10- to 20-fold higher than the mean annual concentrations of these gases in urban environments in Germany. To differentiate between chemical and microbiological weathering, a special double-chamber-cabinet was used (41). By this approach interactions between chemical and microbiological weathering were demonstrated for the first time. Under optimum conditions a nitrifying biofilm developed on the calcareous Ihrlersteiner green sandstone. Cell numbers and activity of nitrifying bacteria increased during the experiment (lasting 40 weeks), indicating a positive effect of the smog atmosphere on these bacteria. The mean metabolic activities of ammonia oxidizers were 8 to 11 times higher and those of nitrite oxidizers 30 times higher than that of the mean values of samples from historical buildings. Compared with samples kept free of nitrifying bacteria, the formation of gypsum from sulfur dioxide was enhanced in the presence of actively nitrifying bacteria. At the same time the biogenic nitric acid attack was strongly reduced by chemodenitrification of nitric acid. Quantification of the weathering showed that the microbiologically induced nitric acid attack alone was eight times stronger than the chemical attack caused by the simulated smog atmosphere.

The latter results demonstrate the complexity of the situation, when different factors of weathering and their interactions are included in environmental simulation experiments. Therefore, most simulation experiments tend to be less complex and focus on microbial weathering alone (and may, thus, be misleading).

For algae, cyanobacteria, and chemoorganotrophic bacteria, clear evidence for microbial weathering from simulation experiments is still missing. Nevertheless, the colonization of a material with microorganisms does not necessarily imply physical and chemical degradation, but may initially be limited to less dramatic changes like discoloration and alteration of physical properties caused by the formation of biofilms. The aptitude of a material to be colonized by one or several groups of organisms without necessarily undergoing any biodeterioration is described by the concept of "Bioreceptivity" (46). In this sense, simulation/inoculation experiments can also be used to predict the susceptibility of materials that are to be colonized with certain microorganisms. From these data, guidelines for the selection of materials can be derived. In fact, the preferences of nitrifying bacteria to colonize certain types of natural stone as found in simulation experiments was confirmed in an extensive field survey concerning historical buildings in Germany. Another example of a good agreement between data from simulation experiments and observations on a building was observed during complex, long-term simulation experiments, which showed a strong colonization of hydrophobically treated natural stone. A similar observation was made at a historical building in Germany, where hydrophobically treated natural stone was significantly more colonized with fungi than nontreated material.

To conclude, it may be said that simulation experiments are essential to demonstrate and quantify the effects of microbial weathering and help choose the right material for certain applications. No other technique allows the inclusion of interactions between microorganisms and materials. Aside from the individualities of each experiment, its realization should follow the essential guidelines outlined here.

WEATHERING: MINERAL WEATHERING AND MICROBIAL METABOLISM

WILLIAM J. ULLMAN
University of Delaware
Lewes, Delaware
CSIRO Land and Water
Glen Osmond, Australia

SUSAN A. WELCH
University of Wisconsin
Madison, Wisconsin

Weathering is the process by which primary minerals from igneous, metamorphic, and sedimentary rocks, formed under one set of geologic and geochemical conditions, are altered in form and composition to new sedimentary particles and rocks more consistent with the physical and chemical conditions of the weathering environment. Weathering plays a role in soil and ore formation, the maintenance of soil, freshwater, and ocean composition and productivity, and in moderation of atmospheric chemistry and global climate. Although weathering has traditionally been considered to be primarily a chemical and physical process, there is increasing realization that living organisms play a significant role in these supposedly abiotic processes. A number of field observations and laboratory experiments clearly demonstrate that microorganisms can and do play important roles in the physical and chemical alteration of rocks and minerals and are therefore responsible for many of the geologically and environmentally important consequences of the weathering process.

Historically, weathering processes have been divided into two categories:

- Physical weathering processes leading to the reduction in particle size with little or no impact on chemical or mineralogical composition; and
- Chemical weathering processes leading to both a reduction of particle size and to chemical and mineralogical alteration.

This division, however, is quite arbitrary because these processes co-occur in many environments and are interdependent. Physical processes contribute to chemical weathering by reducing particle size leading to the exposure of new chemically reactive surfaces. Chemical processes contribute to the enhancement of physical weathering by weakening the intergranular boundaries between minerals in rocks subject to abrasion. Plants and plant roots are known to play a significant role in both the physical and chemical weathering of rocks and minerals. In addition, there is increasing recognition that microorganisms and microbial metabolism play an equally important role in these processes, together with or in the absence of higher plants.

Although the term "weathering" initially was only used to describe those processes and reactions that occur on the exposed land surface, it is now recognized that significant chemical alteration of rocks occurs in geologic settings remote from the Earth's surface. As a result the use of this

term has been expanded to include all alteration of rocks, minerals, and synthetic solids that occur in the presence of the hydrosphere, atmosphere, and/or biosphere and at temperatures characteristic of the earth's surface (1).

Many of the important geologic and environmental consequences of weathering are the result of the chemical transformations involved in the weathering process (2). Chemical weathering is an important process in the creation of soils and the maintenance of soil productivity. Weathering reactions produce secondary mineral phases such as clays and oxyhydroxides and release trace nutrients such as phosphorus, potassium, and iron to soil solutions. Weathering reactions contribute to the evolution of ground- and surface-water compositions by consuming reactants and releasing ions to solution. Most environmentally relevant silicate minerals consume protons on dissolution and therefore contribute to the moderation of environmental acidity. The flux of weathering products from continents, both particles and solutes, contribute to the maintenance of seawater composition and productivity. There are a number of types of ore bodies, such as bauxite deposits, that result from mineral and rock weathering. Secondary porosity generated by mineral dissolution contributes to the success of petroleum migration and recovery, and it may also affect the transport of solutions and solutes through aquifers. The weathering of candidate matrices for the isolation of radioactive and other wastes may ultimately impact the long-term success of waste isolation strategies. Weathering has also been implicated in the alteration and deterioration of artwork, historical buildings, and monuments (3). Weathering reactions involving the rock-forming and silicate and aluminosilicate minerals are particularly important because of their abundance in nature and because they represent an important source of noncarbonate calcium that controls the long-term concentrations of atmospheric carbon dioxide and, therefore, regulates the global heat balance (4,5).

In this review, we consider the biogeochemistry of weathering reactions, focusing on the dissolution of feldspars, the most abundant class of primary aluminosilicate minerals. Microbially mediated mineral precipitation reactions, which are an important component of the overall weathering process, are discussed elsewhere in this Encyclopedia (6). We first consider the abiotic dissolution of feldspars and the mechanisms by which microorganisms and their metabolic products may affect the rates of feldspar dissolution reactions in the weathering environment. We then review the abundant experimental and field evidence for microbial weathering and consider the conditions under which microbes, microbial metabolism, and microbial metabolic products contribute to the weathering process. Finally, we briefly discuss some aspects of the global geochemical and environmental importance of the microbially mediated weathering process.

THE GEOCHEMISTRY OF WEATHERING

All rocks and minerals are subject to physical and chemical weathering under the right environmental circumstances. The earth's surface and the global environment represent a record of the physical and chemical alteration of primary igneous and metamorphic rocks and minerals. Although the details of the weathering process for different classes of rocks and minerals may be significantly different and depend on the chemistry, mineralogy, and petrology of each class, the fundamental trends in the geochemistry of weathering can be illustrated by reference to any one class of materials. In this review we illustrate these trends using feldspars; Ehrlich (7) reviewed microbial impacts on a wider range of mineral processes than is possible here.

Feldspars are framework silicates with the general composition of $(K,Na)_xCa_{(1-x)}Al_{(2-x)}Si_{(2+x)}O_8$, in which the charge of a three-dimensional framework of oxygen-sharing AlO_4^{-5} (aluminate) and SiO_4^{-4} (silicate) tetrahedra is balanced by the alkali and alkaline earth cations, K^+, Na^+, and Ca^{2+} (8). Within this mineral group, calcium and aluminum concentrations increase at the expense of (K,Na) and silicon concentrations to maintain charge balance. Feldspar composition can therefore be expressed by reference to the alkali and alkaline earth composition alone. This stoichiometric covariance allows for the examination of systematic trends in weathering behavior with changing mineral composition. Thus, this mineral series has often been used as an experimental model in many types of geochemical studies. Feldspars crystallize on cooling at igneous and metamorphic temperatures [750 –1,250 °C, depending on composition and pressure, (8)] and are metastable under many earth-surface conditions (8). A number of classes of trace elements occur in the feldspar matrix or as accessory minerals in the feldspar matrix (9). Some of these may have nutrient or trace-nutrient character and therefore may be important in maintaining ecosystem productivity (10). These elements may be released to solution as a consequence of the dissolution process.

When exposed to dilute aqueous solution in equilibrium with the atmosphere or CO_2-enriched soil, sediment, or aquifer waters, feldspars may dissolve congruently according to the reaction:

$$\begin{aligned}(K,Na)_xCa_{(1-x)}Al_{(2-x)}Si_{(2+x)}O_8(s) + 4x\ H_2O \\ + 4(2-x)H_2CO_3 \rightarrow (2+x)Si(OH)_4^\circ \\ + (2-x)Al^{3+} + x(K^+, Na^+) \\ + (1-x)Ca^{2+} + 4(2-x)HCO_3^-\end{aligned} \quad (1)$$

In many geochemical settings, however, secondary mineral minerals, often clays, may be the secondary products of incongruent dissolution:

$$\begin{aligned}2(K,Na)_xCa_{(1-x)}Al_{(2-x)}Si_{(2+x)}O_8(s) + (2+7x)H_2O \\ + (4-2x)H_2CO_3 \rightarrow (2-x)Al_2Si_2O_5(OH)_4(s) \\ + (2x)Si(OH)_4^\circ + x(K^+, Na^+) + (1-x)Ca^{2+} \\ + (4x)HCO_3^-\end{aligned} \quad (2)$$

These two representative reactions clearly indicate the fundamental geochemical consequences of the weathering process. The primary mineral (feldspar) is dissolved (or altered), acidity (in the form of H_2CO_3) is consumed,

secondary solids (such as kaolinite, $Al_2Si_2O_5(OH)_4(S)$, in this example) are produced, and major (such as K^+, Na^+, Ca^{2+}, and HCO_3^-) trace and nutrient elements (not shown in the simplified stoichiometry) are released into solution. The above stoichiometries represent an idealization of the weathering process in which a range of primary minerals, acids, and secondary products may be involved.

Reactions 1 and 2 are examples of acid hydrolysis (referred to as proton-mediated, proton-promoted, or acidolytic dissolution in the weathering literature), only one of the mechanisms by which weathering may occur. Alternative weathering mechanisms involving alkaline hydrolysis (sometimes referred to as hydroxyl-mediated, hydroxyl-promoted, or alkalinolytic reactions), ligands (ligand-mediated, ligand-promoted, or complexolytic reactions), or redox processes may also play a role in the weathering process (11,12). Acidic or alkaline attack of the mineral surface involves the adsorption of protons or hydroxyl groups to the mineral surface resulting in the disruption of the near-surface mineral structure (in the case of feldspar the Al−O−Al, Al−O−Si, or Si−O−Si bonds of the tetrahedral framework), and the release of mineral components to solution. Redox reactions, although important for some classes of iron-, manganese-, sulfur-, and uranium-bearing minerals, are not important in the weathering of feldspars and other similar rock-forming minerals, because these do not contain elemental components that are easily oxidized or reduced under earth-surface conditions.

As with all geochemical reactions, the rates of dissolution of primary minerals, the first step in the overall weathering process, are related to the:

- Chemical equilibria describing the composition and stability of the primary minerals and secondary products;
- Temperature of reaction;
- Accessibility of reactive mineral surfaces and the exchange of solutes and water from the mineral surface to the bulk reactive (and presumably mobile) solution; and
- Other characteristics of the geologic and geochemical setting in which the primary weathering reactions occur.

As a result, there is a great deal of variation in weathering rates observed in nature and in the laboratory, and it is difficult to a priori predict, in detail, the weathering rates in any specific context (13). For this reason, we focus this review on the trends observed in the geochemistry and biogeochemistry of weathering and not on specific rates of the weathering process that may be found in laboratory or field settings. Because the dissolution of primary minerals is a required first step for all subsequent geochemical transformations and elemental releases, we focus our discussion on this reaction step and the mechanisms by which microorganisms and microbial metabolism can affect the rates of this initial reaction.

Traditionally, geochemists believed that proton-mediated reactions were the dominant weathering mechanism because there is a strong dependence of dissolution rate on pH (14,15). The influence of organisms on the geochemistry of this "abiotic" weathering process was largely ignored. However, the increasing recognition that chemical weathering takes place largely in the soil zone where microbial respiration can lead to elevated levels of pCO_2, and therefore, high concentrations of carbonic acid, has increased the awareness of the potential role of biological processes on weathering. Recent studies, however, indicate that microbes and microbial metabolism may have additional effects on mineral weathering related to the production and excretion of organic metabolites and to the nutrient and energy requirements of the microorganisms (11,12). Organic metabolites participate in ligand-mediated weathering reactions. In addition, bacterial cell walls and their associated functional groups may serve as chelators and play a role in a process analogous to that of ligand-mediated dissolution (16).

THE BIOGEOCHEMISTRY OF WEATHERING

Recent research in the field of microbially mediated mineral dissolution does not question whether bacteria enhance mineral weathering rates. The largely microbial origin of soil carbon dioxide and the role of carbonic acid in the weathering process have clearly demonstrated this principle. The research, however, continues as a number of additional mechanistic questions remain. These include

- Is the proton-mediated mechanism the only important mechanism by which bacteria influence mineral weathering rates?
- If there are additional weathering mechanisms mediated by microorganisms, what are they and under what conditions are they important?
- Is there a relationship between types or amounts of bacteria or microbial metabolism and mineral weathering rates?
- Is direct contact between bacteria and reactive mineral surfaces a necessary component of microbially mediated weathering?
- What is the nature of the reactive interface between a microorganism and the mineral surface?
- Do bacteria derive a physiological or ecological benefit from the weathering process?
- Do bacteria play a role in the global weathering cycle that controls atmospheric chemistry and therefore global climate?

It is these research questions that will be addressed in this review.

Bacteria are ubiquitous in soils, sediments, sedimentary rocks and aquifers, the environments in which weathering reactions occur, at concentrations ranging from 10^5 to 10^9 cells/cm^3 (17). Natural consortia are diverse, viable, metabolically active, and able to grow on a wide range of substrates. Bacteria are found in free-living ("planktonic") forms and attached to mineral surfaces. As such, bacteria exist at the interface of the lithosphere and hydrosphere where weathering reactions occur. It is therefore not surprising that bacteria and microbial metabolism can both

affect (regulate?) and potentially benefit from weathering reactions in these environments.

Microbes in soils, sediments, and aquifers produce a variety of compounds that can potentially affect weathering rates. Bacteria can decrease pH as a result of respiration (organic carbon oxidation) or by the oxidation of other reduced species such as iron, sulfur, and nitrogen, thereby catalyzing mineral dissolution. Microorganisms can also increase hydroxyl-mediated mineral dissolution rates by increasing pH as a result of the production of alkaline compounds, such as NH_3, or by consuming acidic compounds such as CO_2.

In addition to inorganic acid production and consumption, microbes can also enhance or inhibit mineral weathering rates by the production of complexing organic ligands. Ligands can indirectly enhance mineral dissolution rates by complexing with the reaction products released to solution and altering the equilibria driving the dissolution process. This process serves to increase the carrying capacity of the reactive solution for reaction products. Alternatively, ligands may directly enhance ligand-mediated dissolution rates by adsorption to and reaction with the mineral surface in a process similar to that of proton- or hydroxyl-mediated dissolution. Ligands can also inhibit dissolution by complexing with or precipitating on the mineral surface, thus reducing the number of sites or the "activity" of sites available for the dissolution reaction. The ligands that participate in these ligand-mediated processes may be simple small molecules with a small number of reactive functional groups per molecule or polymers containing many functional groups per molecule. These ligands may be intentionally excreted or released on cell death. The functional groups on bacterial cell walls may act as complexing ligands and play a role in regulating primary-mineral dissolution (16). The relative importance of bacteria and microbial metabolites in dissolution enhancement and/or inhibition depends on mineral composition, solution pH, temperature, and the size, chemistry, and concentration of the complexing ligands in solution, in addition to other environmental factors that may control weathering reactions. Ligand production by microorganisms, however, often co-occurs with proton production (as in organic acid production by the partial oxidation of glucose) and therefore it is often difficult to distinguish between the microbial mediation of the "abiotic" hydrolytic reaction and the alternative or additional ligand-mediated mechanism of bacterial action either in the laboratory or in the field. Although the observational and experimental evidence that bacteria and microbial metabolic processes contribute significantly to the weathering process is extremely clear, the mechanism by which the bacteria affect this process is not always so obvious. The evidence of alternative mechanisms of microbial weathering results from experimental manipulations in the laboratory and the field.

Microbial production and excretion of complexing organic ligands can occur by several different mechanisms. In anoxic environments, fermentation of organic substrates can release soluble ligands such as formate, acetate, propionate, butyrate, and lactate (18). High concentrations of these compounds have been measured in anoxic and suboxic sediments (19,20). In oxic environments, both prokaryotes and eukaryotes can produce substantial concentrations of organic ligands, especially in organic-rich environments, such as soils. Although the concentrations of soluble organic ligands are often below detection in the bulk solutions of oligotrophic environments, they may nevertheless be produced and reach substantially higher concentrations in anoxic or suboxic microenvironments such as the interface between a cell and a mineral surface. In both oxic and anoxic environments, bacteria synthesize extracellular polymers that have complexing ability. Bacteria may also degrade particulate or dissolved organic substrates to produce ligands that affect the dissolution process. This latter process may be particularly important in petroleum-contaminated environments (21). Laboratory experiments have also demonstrated that significant production of organic ligands in oxic environments can occur when substrate utilization is limited by the lack of available accessory nutrients (22). This partial oxidation process may be important in both anoxic and suboxic environments when nutrient availability is limited.

EVIDENCE FOR MICROBIALLY MEDIATED MINERAL WEATHERING

There are three lines of evidence for the importance of microbially mediated mineral weathering in nature. The first involves the abiotic experimental evidence of mineral dissolution in solutions that mimic those found in microbial cultures and in nature. These experiments are normally compared to controls lacking one or more of the solutes in the experimental medium or by systematically varying one or more of the solute concentrations. The second line of evidence involves laboratory experiments in which metabolically active microbes are cultured in the presence of mineral or mineral-analog surfaces and these experiments are compared with various control experiments lacking organisms, minerals, nutrients, and/or organic substrates. The last line of evidence involves direct observation, primarily by scanning or transmission electron microscopy and other microanalytical techniques, of microorganisms and microbially produced textures on mineral and glass surfaces produced by experiment and/or collected in the field. Controls for these experiments include the original surface before experiment, unreacted samples of the experimental materials, or adjacent, but uncolonized surfaces of the reacted material. Each of these types of experiments has limitations, but each line of evidence supports the hypotheses that the rates of weathering reactions can be and are mediated by microorganisms and that there are components of microbially mediated weathering reactions that are distinct from the reactions that might occur in the absence of bacteria and bacterial metabolism. The three lines of evidence, taken together, clearly indicate that microbially mediated weathering reactions are important in a wide range of common earth-surface environments in which weathering occurs.

Abiotic Experiments

Abiotic experiments involve the reaction of mineral material in a solution mimicking that found in nature or in separate microbial culture experiments. Experimental variables include pH, ligand composition and concentration, temperature, and mineral composition. Typically, one of these parameters is varied, whereas others are held constant in a flow-through, batch, or column reactor. One problem with these types of experiments is that the concentrations of solutes used are very much higher than those found in nature. Therefore, it is difficult to extrapolate directly from experimental results to field conditions in which both reactive solute concentrations and mineral dissolution rates may be orders of magnitude lower than those used and found in the laboratory. This type of experiment, therefore, can indicate that microbial metabolites affect weathering rates and the conditions under which the microbiological effect may be significant, but it cannot determine whether this process is important in nature. Such experiments are very useful, however, because they allow for better control of reaction conditions and for more systematic and verifiable control studies. Studies of the concentrations of ligands and protons in microenvironments in which microbial metabolism and weathering occur and where local ligand concentrations may be higher than those found in the bulk solution are needed to support these experimental results. Recent measurements of pH in microenvironments have demonstrated that the pH in close proximity to microbial cells can be 1 to 4 pH units lower than that of the bulk solution (23,24).

The following discussion focuses primarily on feldspars, but similar results have been reported for other classes of rock-forming minerals. A recent review of the ligand-mediated dissolution of feldspar minerals in abiotic experiments (25) is summarized below.

pH Dependence

As in the case of "abiotic" proton-mediated dissolution experiments (14), the rates of (ligand + proton)-mediated dissolution have a strong pH dependence due largely to the effect of the protons. This result is not surprising because the initial steps in both proton- and ligand-mediated dissolution involve the interaction (adsorption) of protons or ligands in solution with the sites on the mineral surface. As proton concentration increases, the competition between protons and ligands for limited surface sites on the dissolving mineral surface will favor the protons. However, the competition between ligands and protons at near-neutral pH, where proton concentration is comparable or lower than that of the ligand, will favor the ligand and ligand-mediated dissolution. Experimental evidence in this near-neutral pH region, the pH of many natural settings in which weathering occurs, indicates that ligand-mediated dissolution rates can be up to 2 to 10 times higher than rates in the absence of ligands, which reflects the background rate of mineral hydrolysis in the absence of proton- (or hydroxyl-) mediation (Fig. 1; 26).

There is very little experimental evidence for ligand-mediated dissolution in basic solutions, but there are a number of reasons why ligand-mediated dissolution should be less important under alkaline conditions. In the first case, both mineral surfaces and ligands become deprotonated (or hydroxylated) in alkaline solutions. Under these conditions, both the ligand and the surface will be of similar anionic charge and therefore the initial adsorption of the ligand to surface sites, the important initial step in the dissolution reaction, will be electrostatically inhibited. In addition, as the concentration of hydroxyls increases with pH, competition between hydroxyls and ligands for surface sites will favor hydroxyls and the hydroxyl-mediated reaction, similar to the case of proton/ligand competition at lower pH.

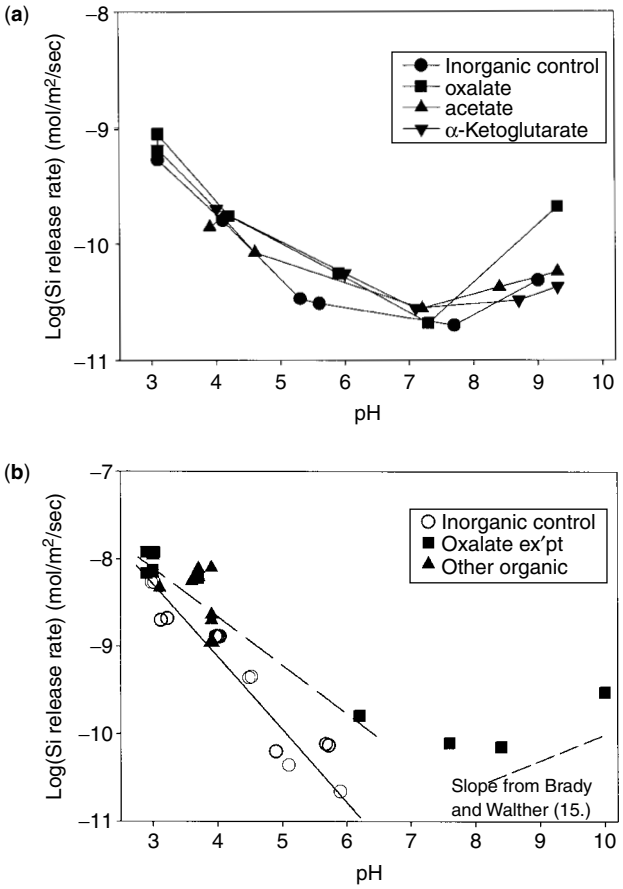

Figure 1. The pH dependence of feldspar dissolution. (**a**) Silicon release rates from two labradorite feldspars ($K_{0.05-0.06}Na_{0.46-0.48}Ca_{0.49}$). The rates of ligand-mediated dissolution follow the same pH dependence as for proton-mediated dissolution alone. Only for oxalate ion, is there evidence for dissolution enhancement at alkaline pH. (**b**) Si release rates from bytownite feldspar ($K_{0.01}Na_{0.23}Ca_{0.77}$). For this calcium-aluminum-rich member of the feldspar series, there is clear evidence of dissolution enhancement throughout the acid pH range with the relative rate of enhancement occurring closest to neutrality. There is clear difference in the slope of ligand-mediated dissolution in the acid pH range (- - -) from proton-mediated dissolution alone (——). At alkaline pH there is no apparent difference between the slope of the pH dependence of ligand-mediated dissolution and of hydroxl-mediated dissolution alone (15) suggesting that ligand-mediated dissolution is less important at alkaline pH. Experimental points taken from S. A. Welch, and W. J. Ullman, *Geochim. Cosmochim. Acta* **57**, 2,725–2,736 (1993).

Ligand Composition

Many low–molecular weight organic ligands that can be produced by bacteria under a variety of circumstances have been shown to enhance mineral dissolution rates over distilled water, dilute-salt, or dilute-acid controls over a range of pH (Table 1). Unfortunately, there are very few experiments in which the relative impacts of ligands of differing molecular weight, functionality, or thermodynamic properties on dissolution rates have been rigorously compared. In one such experiment (26), however, it was found that organic ligands with two or more functional groups (oxalate, salicylate, pyruvate, and citrate) that were capable of forming bidentate metal-organic complexes in solution, and therefore presumably at the mineral surface, had a greater effect on mineral dissolution rates per unit solute concentration than monofunctional ligands (propionate and acetate). Monofunctional ligands, in turn, had a greater impact on dissolution than distilled water, nitric acid, and hydrochloric acid controls. Multifunctional organic ligands were also found to enhance the dissolution of quartz (SiO_2) to a greater extent than monofunctional organic ligands (27). Difunctional aromatic ligands were found to enhance feldspar dissolution rates to a greater extent than more highly substituted aromatics in one study (28). These trends in the degree of dissolution enhancement by the ligand-mediated mechanism correlate weakly with the thermodynamic stability of Al-ligand complexes in solution (as a proxy for the association of ligands with aluminum sites at the feldspar surface). Other factors, however, may also be important including molecular weight and structure, size, and protonation constants of the ligand.

A study of the effect of biopolymers (as analogs of microbial exopolysaccharides) on mineral dissolution rates clearly indicates that polymer composition, functionality, and thermodynamic properties may play a significant role in the mineral weathering process (29). A number of polymers in this study had no effect on overall feldspar dissolution rates even up to concentrations sufficiently high (1 g/L) to change the viscosity of the solution. Alginate and polyaspartate, which are both charged polymers under the experimental conditions used, however, inhibited feldspar dissolution at the highest concentrations. In the case of poly-aspartate, only the solutions containing a high–molecular weight (26kD) form inhibited dissolution; a lower–molecular weight form (6kD) had no measurable effect on dissolution rates. An additional study of the effect of polymers on feldspar dissolution (30) demonstrated that acidic polymers could either enhance or inhibit dissolution rates, depending on pH and the degree of protonation of the acidic functional groups. At neutral pH, these polymers irreversibly adsorbed to the dissolving mineral and thus inhibited dissolution. However, these same polymers greatly enhanced dissolution rates under acidic conditions (Fig. 2). These authors further concluded that the orientation of the functional groups and therefore polymer structure in solution and on surfaces also influenced the degree of dissolution enhancement or inhibition.

There is some evidence for an effect of ligand/ligand competition, analogous to proton/ligand and hydroxyl/ligand competition, discussed earlier, on feldspar dissolution rates. Huang and Longo (31) found that the addition of oxalate to aqueous catechol solutions at 95 °C and pH = 8.5 reduced the effectiveness of dissolution enhancement compared with catechol alone. Because both ions enhance dissolution on their own but to a different degree, this intermediate level of enhancement suggests that competition for adsorption sites on mineral surfaces may affect the overall dissolution rate in mixtures of ligands such as would be expected to be found in nature. A similar observation was made for competition between gluconate and a bacterial exopolysaccharide (29). Further experiments with mixtures of ligands having differing effects on mineral dissolution rates will be needed to determine the extent to which ligands, protons, and other solutes interact at dissolving mineral surfaces and play competing roles in microbially mediated mineral weathering.

Ligand Concentration

Experiments performed at ligand concentrations well above those observed in nature indicate that the rate of feldspar dissolution increases with increasing ligand concentration (when all other variables are held constant). At concentrations up to 1 to 2 mM, the increase can be approximated by a linear function (Fig. 3a). However, above this concentration, the effect of ligand additions appears to be reduced (Fig. 3b). Stillings and coworkers (32,33) suggest that the number of reactive sites on the mineral surface to which the ligand can adsorb and react limits the impact of ligands. Therefore, the overall effect of ligands on the dissolution process should be best represented by an adsorption isotherm with a dependence on free ligand activity with the overall dissolution rate being dependent on the concentration of adsorbed ligand (Fig. 3c). Although this argument and model appear to

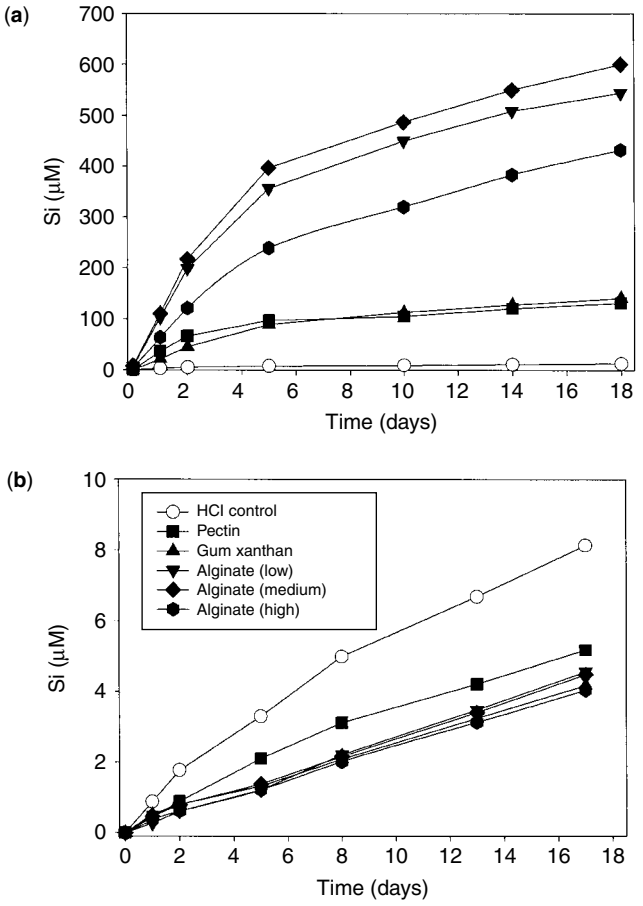

Figure 2. Polymer enhancement and inhibition. A number of the same polymers (pectin, gum xanthan, and alginate of three different molecular weights, low, medium, and high) that enhance feldspar dissolution rates in acidic solutions (**a**) inhibit dissolution at neutral pH (**b**). This difference in polymer impact may be related to changes in polymer charge, adsorption, or conformation with pH. See discussion in the text and in S. A. Welch, W. W. Barker, and J. F. Banfield, *Geochim. Cosmochim. Acta* **63**, 1,405–1,419 (1999).

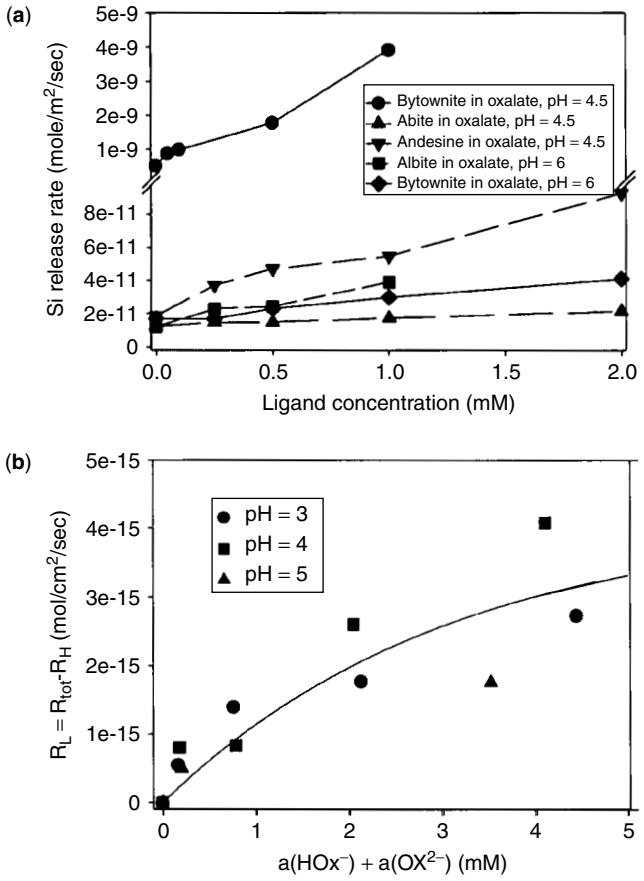

Figure 3. The concentration dependence of ligand-mediated dissolution. (**a**) At low concentration of a dissolution-enhancing ligand, the rate of feldspar dissolution is approximately linearly dependent on total ligand concentration. Examples of a number of experiments involving bytownite ($K_{0.01}Na_{0.23}Ca_{0.77}$), andesine ($K_{0.06}Na_{0.46}Ca_{0.49}$), and albite ($K_{0.09}Na_{0.88}Ca_{0.03}$) are shown. Data from W. J. Ullman and S. A. Welch Water-Rock Interactions, Ore Deposits, and Environmental Geochemistry, A Tribute to David Crerar, in R. Hellmann and S. A. Wood eds., Special Publication 7, The Geochemical Society, St. Louis, Missouri, 2001, (in press). and S. A. Welch and W. J. Ullman, *Geochim. Cosmochim. Acta* **57**, 2,725–2,736 (1993). (**b**) At higher ligand concentration, the dependence of dissolution rate on ligand concentration and activity is nonlinear, perhaps reflecting the saturation of reactive sites on the feldspar surface. (**c**) After taking into account ligand adsorption, the dissolution rate is more linearly proportional to the concentrations of bioxalate (HOx^-) and oxalate (Ox^{2-}) adsorbed on the mineral surface. Data for (**b**) and (**c**) taken from L. L. Stillings et al., *Chem. Geol.* **132**, 79–89 (1996), and L. L. Stillings, J. I. Drever, and S. R. Poulson, *Environ. Sci. Technol.* **32**, 2,856–2,864 (1998).

be well justified on the basis of observation, the linear model is probably sufficient for single ligand or single dominant-ligand experiments, particularly at low ligand concentrations ($\leq$2 mM). The isotherm model may be most useful at higher ligand concentrations and under conditions in which multiple ligands or mixtures of ligands and protons or ligands and hydroxyl groups are reacting with the mineral surface. Under these conditions, this model can incorporate some facets of competition between adsorbates and differences in the effect of adsorbates on dissolution rate. The ability of dissolved ligands to saturate the available reactive sites at the mineral surface is consistent with the idea that mineral dissolution rates are limited by the competition between different mechanisms of dissolution for a limited number of reactive surface sites. These results further suggest that the overall effect of bacteria on mineral dissolution rates in experimental or natural settings should not be a simple linear function of either bacterial numbers or microbial activity except, perhaps, at low abundances and activity.

Temperature

A large number of experiments have demonstrated that the rates of proton-mediated mineral dissolution increase with increasing temperature (34). Within the feldspar group, the temperature dependence of these reactions varies substantially with chemical composition, experimental methods, and pH. The assignment of Arrhenius activation energies, a commonly used exponential

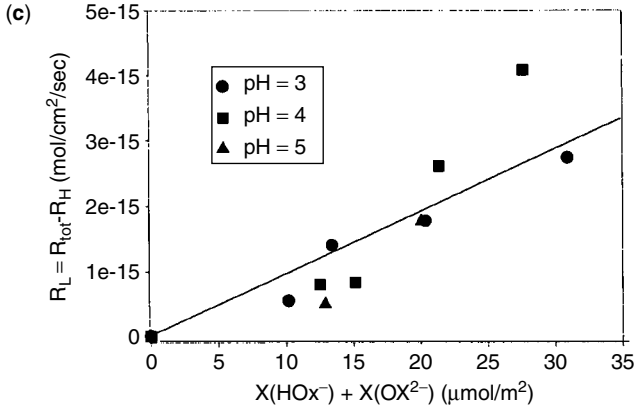

Figure 3. (*Continued*)

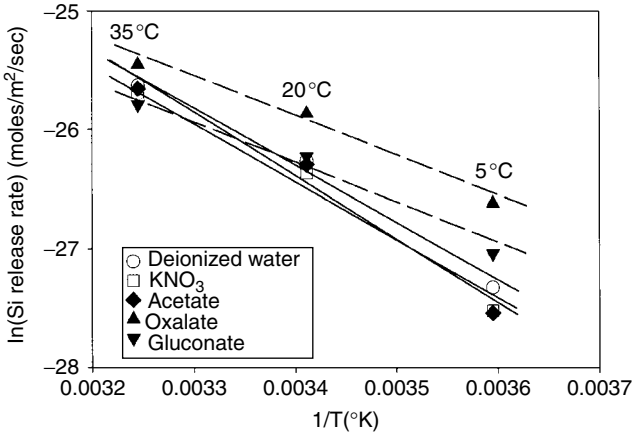

Figure 4. The temperature dependence of ligand-mediated dissolution of bytownite feldspar ($K_{0.01}Na_{0.23}Ca_{0.77}$) isclearly different for ligands that form strong complexes with aluminum in solution and presumably at the mineral surface (oxalate and gluconate; - - -) than for ligands and ions that do not form strong complexes (acetate, deionized water, and KNO3; ——). The apparent activation energy of ligand-mediated dissolution is approximately 3 Kcal/mol less than for the controls, indicating that ligand-mediated dissolution proceeds by a mechanism of dissolution distinct from proton-mediated dissolution. Experimental data from S. A. Welch and W. J. Ullman, *Chem. Geol.* **167**, 337–354 (2000).

expression for the temperature dependence of geochemical reactions, also depends on the kinetic interpretation of the reaction mechanism (34). In one experiment, the temperature dependence of ligand-mediated dissolution at low temperature (5 to 35 °C) and near-neutral pH (and using a pH-independent kinetic expression consistent with the experimental conditions) was evaluated (35). In this experiment, the temperature dependence of dissolution in solutions of acetate, an organic ligand that forms only weak complexes with Al^{3+} in solution and therefore, by analogy, with the Al sites at the feldspar surface, was found to be indistinguishable from that of distilled water and KNO_3 controls. The activation energy of dissolution in the presence of oxalate and gluconate, polyfunctional ligands that form stronger bidentate complexes with Al^{3+}, was significantly less (Fig. 4), clearly indicating the additional catalytic role that ligand mediation plays in the dissolution process under these conditions. What is surprising about these experiments is that the relative enhancement of dissolution due to bacteria and their metabolites was greater at the lower temperature. No similar experiments comparing the impact of ligand- and proton-mediated mechanisms on the temperature dependence of the dissolution of other rock-forming mineral are available, but the expectation is that the same trends will be observed for other mineral systems but with differing absolute values of the activation energies. Additional experiments are needed to determine the interplay between proton-, hydroxyl-, and ligand- mediated mechanisms on the temperature dependence of weathering reactions, under conditions relevant to the weathering environment, to predict the effect of microorganisms on mineral weathering at different temperatures and under different climatic regimes.

Mineral Composition

There are a number of independent lines of evidence that both protons and ligands attack the dissolving feldspar at the limited number of aluminum sites at the mineral surface. These include the correlation of the effectiveness of ligands in ligand-mediated dissolution and the stability of the Al-ligand complexes in solution (discussed earlier). In addition, the rates of dissolution of the calcium-aluminium-rich members of the feldspar series are greater than for the sodium-silicon-rich (Al-poor) members of the series for both proton-mediated and ligand-mediated dissolution (36,37). Furthermore, these observations are consistent with the observations of Goldich (38) that the persistence of feldspars in the soil environment is based on cationic dominance, following the stability sequence K > Na > Na(Ca) > Ca(Na) > Ca. Goldich concluded that feldspar persistence in weathering environments was the result of the thermodynamic stabilities of the minerals in this sequence, but the same result can be obtained independently on the basis of the composition-dependent kinetics of feldspar dissolution rates. Mineral structure and composition can also play a role in the temperature dependence of dissolution. For other classes of minerals, the effect of mineral structure on dissolution rates may dominate over compositional differences.

Biotic Experiments

There are substantially fewer mineral dissolution experiments that have been performed with live and metabolically active cultures than with abiotic solutions mimicking those found in these cultures. As in the case of the abiotic experiments, it is often necessary to perform these experiments under biological and chemical conditions very different than those expected in nature. As a result, these experiments do not alone constitute proof that microbially mediated weathering reactions are important in nature. Typically, higher concentrations of carbon substrate and nutrients are needed to keep cultures alive in the laboratory and to achieve significant experimental results. The microbial population in experimental cultures may also be substantially different than would be expected in nature in

terms of numbers, diversity, and metabolic activity. However, these experiments do provide additional evidence that microbial processes may be important in the weathering process and they give some indication of conditions under which microbial mediation of weathering reactions may be most important in natural settings.

In biotic experiments, it is often difficult or impossible to perform experiments under fully controlled conditions. Thus, the results of these experiments are most often of the qualitative or semiquantitative type. Problems associated with the simultaneous maintenance of both constant microbial numbers and activity as well as constant mineral dissolution rates have often restricted the types and length of experiments that can be performed. Even in relatively short experiments, the microbial culture may respond to the changing geochemical or biogeochemical conditions in the reactor and on the mineral surfaces (associated with dissolution) leading to changes in microbial abundance and metabolic activity. It is difficult to replicate these changes under controlled abiotic conditions or in the absence of mineral substrata. In longer experiments, the culture may also diverge from the original inoculum in both species composition and metabolic activity.

The earliest experiments in which microorganisms were cultured with minerals used a series of acid, oxalate, citrate, and other organic-acid-producing fungal strains isolated from rock surfaces and weathered stones (39). A number of mineral substrata, soils, and soil components were used in these experiments. In all cases examined, ions found in the mineral were released to the culture to a greater extent than in abiotic controls or biotic controls without minerals. The authors attributed this result to acid rather than ligand production following glucose metabolism by their experimental organisms. Subsequent work by this group demonstrated that bacterially produced gluconic acid could similarly solubilize mineral components (40), but there was no basis to assign this effect to proton- or the alternative ligand-mediated reactions. A number of similar qualitative experiments have been reported, principally in the soil science literature, since these earliest efforts. These clearly indicate that microbial processes can affect the solubility and dissolution rates of minerals, rocks, and soil substrata but do not clearly indicate the mechanism by which bacteria and fungi accomplish these results.

More recent experiments have attempted to more quantitatively describe the effect of bacteria and microbial metabolism on mineral dissolution, but many of these suffer from some of the same problems as the earlier qualitative experiments. Vandevivere and coworkers (41) surveyed a range of subsurface bacteria and noted that a number of strains significantly enhanced dissolution relative to bacteria-free controls in glucose-rich/nutrient-poor cultures. Although there was a significant decrease in pH in many of the cultures that enhanced mineral dissolution rates, there were some cultures that enhanced dissolution without acid production. Increases in gluconate, lactate, formate, and some unidentified ketoacids were found in the supranatant at the end of the experiments with acid-producing cultures. In one time-series experiment, microbial abundance, decrease in pH, and increase in gluconate concentration either preceded or co-occurred with the increase in mineral dissolution rate. Studies of building weathering (42) and experiments in which pH variations were minimized by automatic titration (43) similarly demonstrate that enhanced weathering of natural materials by bacteria (and fungi) can occur at neutral pH by the ligand-mediated mechanism.

Welch and Ullman (44) demonstrated that the degree of dissolution enhancement was related to the amount of gluconate production and the subsequent rate of gluconate utilization by a bacterium, and therefore, a function of temperature. Because the temperature dependence of gluconate production from the glucose substrate was larger than either that for gluconate consumption or mineral dissolution, the gluconate concentration attained higher levels at lower temperatures (5 °C) than at higher temperatures (35 °C). The overall rates of gluconate-mediated mineral dissolution were unexpectedly higher at these lower temperatures. In this experiment, however, higher gluconate concentrations co-occurred with lower pHs in the experiments at 5 °C (the buffering due to mineral dissolution was less than the rate of microbial acid production) and therefore it was not clear whether the enhancement of weathering was due to proton- or ligand-mediated processes, or both. At 35 °C, no acid or gluconate accumulated in the experimental cultures as gluconate was consumed (respired) as fast as it was produced and proton consumption by mineral dissolution kept up with metabolic acid production. As a result, the microbial effect on dissolution rate was negligible at 35 °C. Although these results are surprising, similar observations of higher accumulation of volatile fatty acids at lower temperatures have been observed in other settings (45). These results further suggest that microbially mediated weathering may be relatively more important in cold environments than previously thought and there is evidence of high rates of mineral weathering in polar regions (46,47).

Direct Observations

Some of the most interesting and direct evidence for the enhancement of weathering rates and alteration of weathering mechanisms by microorganisms and their metabolites comes from the direct imaging by light and/or electron microscopy and, more recently, by other microanalytical techniques (48,49) of natural and synthetic surfaces colonized by bacteria (Fig. 5). These surfaces may be collected from the field or produced in laboratory experiments; the results from laboratory experiments are subject to the same caveats as for the abiotic and biotic experiments described earlier. The contrasting textures found on surfaces colonized by bacteria and those found on bacteria-free surfaces, however, provide direct evidence of microbially enhanced weathering. Moreover, differences in the chemistry, mineralogy, and textures at these surfaces indicate that bacteria can both moderate the rates and modify the mechanisms of the weathering process.

Callot and others (50) found that two fungi enhanced the rates of etching of preformed microfractures in olivine ($Fe_xMg_{(1-x)}SiO_4$) and a borosilicate waste glass. In contrast to the abiotic controls, the fungal cultures

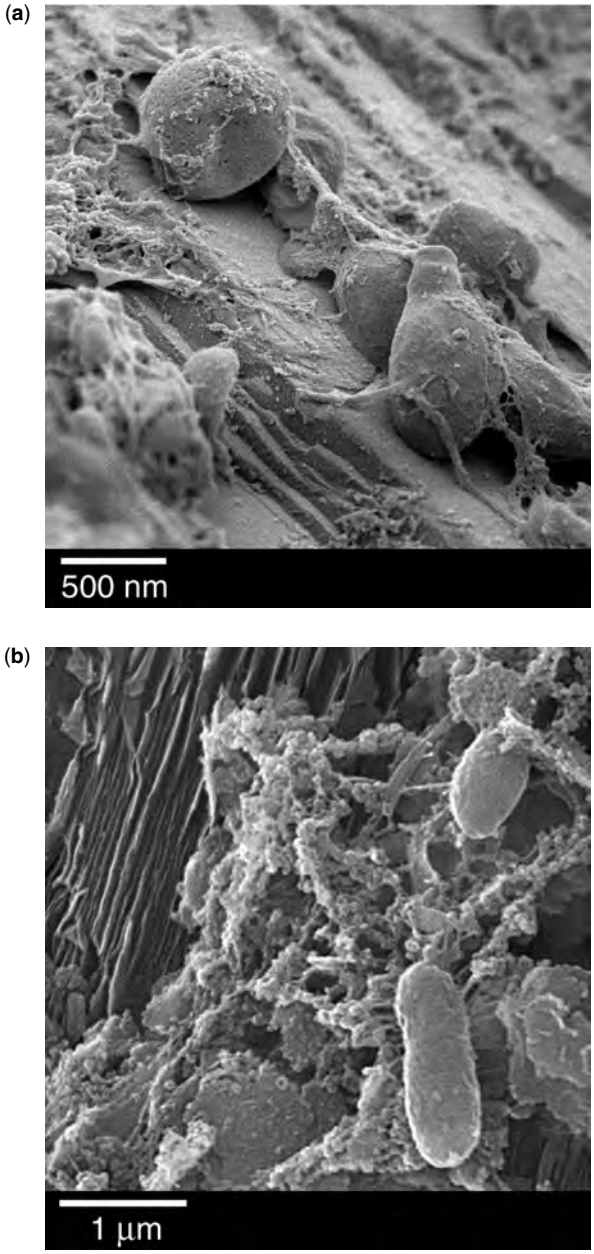

Figure 5. Bacteria and polysaccharides on feldspar surfaces. (**a**) Bacteria on a bytownite feldspar ($K_{0.01}Na_{0.23}Ca_{0.77}$) surface incubated in the laboratory showing bacteria oriented along a cleavage step. The cleavage faces appear rough and the cleavage steps are rounded indicating that dissolution has occurred on these surfaces adjacent to the attached bacteria. Image taken by W. W. Barker, University of Wisconsin. See (23) for the techniques used. (**b**) Bacteria on an anorthoclase feldspar incubated in the field. Striations on the upper left of the image are indicative of crystallographically controlled dissolution of the mineral adjacent to the attached bacteria. Image taken by J. R. Rogers, University of Texas, Austin. See (10) for the techniques used.

enhanced the rates of etching of the microfractures and did not leave a remnant leached-layer on the olivine and only a thin layer on the glass. These cultures also etched the olivine to a greater extent than the glass. In one experiment, one of the fungi was capable of producing siderophores, which strongly complex iron and make it more soluble and bioavailable. This fungus also significantly increased the rate of etching of a normally resistant fused-silica glass that contained no iron. These authors suggested that the increases in etching rate are not related to the production and haphazard excretion of organic acids, but rather that compounds were produced by enzymatic processes in the cell membrane for the express purpose of dissolving the mineral and that contact between the surface and the cell membrane was therefore required for increases in etching to occur. They further suggested that these organisms benefited ecologically by acquiring nutrition from the weathering process. These authors also identified a siderobacterium in a glacial melt-water pond that increased olivine-etching rates in this setting in the same fashion as their experimental fungi. It is intriguing to speculate that the differing temperature dependence of siderophore production and consumption at low temperature could combine to give particularly high levels of these dissolution-enhancing compounds and therefore mineral weathering rates in polar settings. This would be analogous to the high rates of gluconate-mediated dissolution at low temperature discussed earlier. Siderophores have also been implicated as important contributors to mineral weathering on the basis of observations made in a petroleum-contaminated field setting (51) and in the laboratory (52).

On the basis of a study of the naturally weathered basaltic glass, Thorseth and others (53) suggested that the variability in the observed textures and chemistry of the glass surface could only be explained by the existence of a range of chemical microenvironments on the weathering surface. On the basis of observations of cyanobacteria near the surface of the weathering basalt, they concluded that microbial mediation of weathering occurred on these surfaces through proton- and hydroxyl-mediation. The possibility of ligand mediation was not considered. Further experimental work by this group (54) demonstrated that textures and chemistries similar to those found in the previous observational study could develop in relatively short periods (400 days) in an evolving consortium of bacteria grown in an enriched nutrient medium. Thorseth and coworkers have also reported the existence of bacteria deep in basalts in oceanic settings and have inferred, based on of textural and chemical evidence, that microbial weathering of basalt plays a fundamental role in global-scale elemental cycling (55,56). Staudigel and others (57) have shown that substantial biofilms can form on glass surfaces exposed to natural seawater, even in the absence of high-nutrient and substrate levels, and that leaching of glass components from under these films is substantially higher than on biofilm-free surfaces under similar conditions. Staudigel also suggests that microbially mediated weathering of basalts, in which many trace chemical species are at substantially higher concentrations than in seawater, may control the oceanic cycles of a number of trace elements.

Bennett and coworkers have pioneered the use of in situ mineral microcosms to study the influence of bacteria and

microbial metabolism on mineral dissolution in organic-rich groundwater (10,58,59). In this type of experiment, well-characterized mineral and glass samples are inserted into aquifers or zones in aquifers having contrasting water chemistries and biological properties. After a period of time (months to years), these samples are recovered for the recharacterization of the surface and other analyses. This research group demonstrated that mineral dissolution occurred on surfaces even when the bulk groundwater solution was apparently saturated or supersaturated with respect to the dissolving mineral. This result is strong proof that the conditions in the reaction zone under and around bacteria attached to mineral surfaces are significantly different from the bulk solution and that, as suggested by Thorseth and coworkers, weathering occurs primarily in such microenvironments. This group also found that bacteria preferentially colonize and weather some surfaces compared to others, leading to an apparent reversal in the normal (Goldich) sequence of mineral stabilities in weathering environments (see previous text). On the basis of these results, they concluded that the bacteria are benefiting ecologically from the preferential attack of certain surfaces from which they derive needed nutrients (phosphorus, nitrogen, potassium, and/or iron) from the dissolving rock. The mobilization of nutrient elements by mineral dissolution may benefit not only the bacterium able to enhance dissolution rates, but also the whole microbial consortium, particularly in substrate-rich, nutrient-poor groundwater ecosystems in which Bennett and coworkers have worked.

In a high-resolution study of the natural weathering of rocks by lichens, Barker and Banfield (60) found that a polysaccharide gel between the lichen and mineral surfaces played a significant role in mineral leaching and the types of secondary minerals found after dissolution. Leaching did not require direct cell-to-mineral contact as suggested by Callot and others (see earlier discussion). Gradients in the composition and function of the polysaccharide layers with distance from the mineral surface contribute to the patterns of primary dissolution, ionic transport, secondary- product formation under lichen-covered surfaces. On the basis of these and subsequent analyses of the same rock, Barker and Banfield (61) suggested a layered model of the effect of lichens on the weathering of mineral surfaces, which may equally apply to the more general case of weathering by any surface-bound microorganism. In this model (Fig. 6), the production of protons and ligands takes place in a microorganism, which is attached to a mineral surface through a layer of exopolymer. This polymer layer reacts with the surface and secondary mineral phases are precipitated. Below this zone of contact, a third zone is found where the interstitial

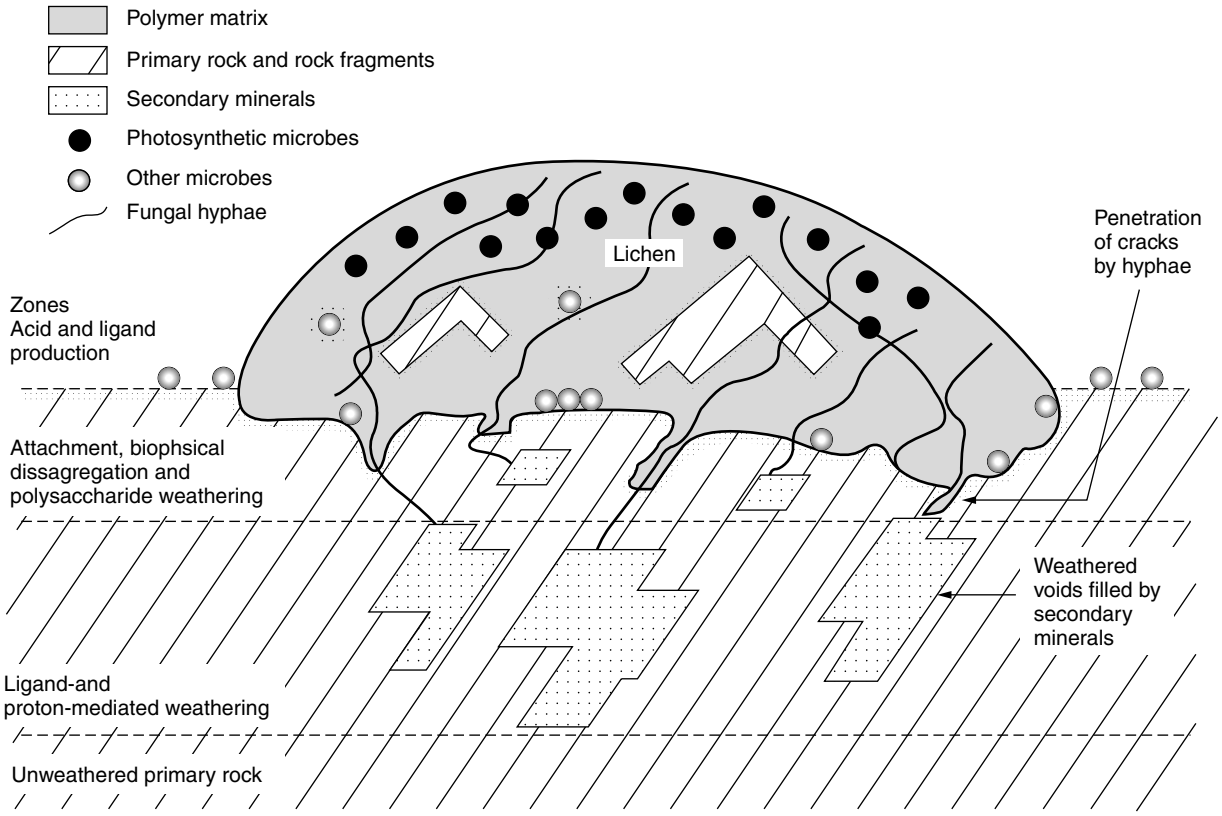

Figure 6. The layered model of Barker and Banfield (61) describing the characteristics of rock weathering by lichens. Although developed to describe the specific characteristics of lichen-mediated weathering, this model could be easily modified and expanded to three-dimensions to encompass the geometry of mineral weathering by other types of attached microorganisms over a range of field conditions.

pore sizes are insufficient to allow organisms or polysaccharides to penetrate, but where some of the soluble acid and ligands produced by the organisms in the upper layer contribute to ligand- and proton-mediated dissolution of the primary mineral. In this zone, secondary products may also be formed but below it the rock is essentially unweathered. In this model, the boundaries between these reaction zones are gradational in character, reflecting the continuity of geochemical and biochemical gradients in which these microbially mediated reactions occur. Although this model is described in a one-dimensional fashion, a similar three-dimensional model of the interfaces and interactions between patches of organisms and mineral surfaces may be more appropriate, given the observed variations in weathering textures and chemistry on two-dimensional surfaces.

GLOBAL GEOCHEMISTRY AND MICROBIALLY MEDIATED WEATHERING

The earlier evidence of the possible mechanisms of microbial mediation of mineral and rock weathering, the ability of these mechanisms to either enhance or inhibit the weathering process, and observational studies of weathered surfaces from the field and from laboratory experiments, document the importance of microbes and microbial metabolism on the weathering cycle. The weathering cycle plays an important role in producing and maintaining the climate and habitability of the earth-surface environment. Thus, microbial processes can be viewed as part of the feedback mechanism by which the regulation of global geochemical cycles occurs, particularly over geologic timescales. It is, therefore, instructive to briefly review the possible influence of microbial processes on two important and interrelated consequences of the global weathering cycle, the regulation of the global greenhouse effect, and the formation and maintenance of soils.

The regulation of atmospheric carbon dioxide concentrations and global climate is related to the weathering of calcium-, magnesium- and aluminum silicate minerals by the following geochemical reactions steps:

$$(Ca,Mg)SiO_3(s) + CO_2(g) + 2H_2O(l) \rightarrow (Ca,Mg)^{2+}(aq) + HCO_3^-(aq) + H_3SiO_4^-(aq) \quad (3)$$

$$(Ca,Mg)^{2+}(aq) + 2HCO_3^-(aq) \rightarrow (Ca,Mg)CO_3(s) + CO_2(g) + H_2O(l) \quad (4)$$

$$CO_2(g) + H_2O(l) \rightarrow H_2CO_3 \rightarrow 2HCO_3^-(aq) + H^+(aq) \quad (5)$$

$$H_3SiO_4^-(aq) + H^+(aq) \rightarrow SiO_2(s) + 2H_2O(l) \quad (6)$$

The overall reaction is often given as:

$$(Ca,Mg)SiO_3(s) + CO_2(g) \rightarrow (Ca,Mg)CO_3(s) + SiO_2(s) \quad (7)$$

In these reactions, $(Ca,Mg)SiO_3(s)$ represents the calcium, magnesium, and silicon components of primary rock-forming minerals (both silicate and aluminosilicate) subject to weathering on land surfaces (Reactions 3 and 7). $(Ca,Mg)CO_3(s)$ (Reactions 4 and 7) and $SiO_2(s)$ (Reactions 6 and 7) represent limestone and silica deposited primarily on the sea floor. The dissolution of limestone on continents (the reverse of Reaction 4) has no effect on the fixation of atmospheric carbon dioxide because Reaction 4 in the ocean removes the same amount of carbon dioxide as is added on the continent.

Reaction 3 is written as a proton-mediated dissolution reaction. However, any reaction that can dissolve a primary calcium-, magnesium-, or aluminosilicate mineral, or that can enhance mineral dissolution rates, can contribute to this process and therefore participate in the regulation of atmospheric composition and global climate. For example, the ligand-mediated dissolution of our model calcium silicate, magnesium silicate, or aluminum silicate mineral is fundamentally identical to Reaction 3 (using oxalate, $(COO)_2^{2-}$, as an example ligand):

$$(Ca,Mg)SiO_3(s) + 2H_2(COO)_2(aq) + H_2O \rightarrow (Ca,Mg)^{2+}(aq) + H(COO)_2^-(aq) + H_3SiO_4^-(aq) \quad (8)$$

when coupled to the biologically mediated reduction of CO_2 and H_2O to form $H_2(COO)_2(aq)$, the protonation and oxidation of $H(COO)_2^-$ (aq) to form CO_2 and H_2O, and Reaction 5. The role of microorganisms in the regulation of climate is therefore related to their contribution to the physical and chemical evolution of soils in which weathering predominantly occurs and their ability to increase the rate of weathering of the primary minerals that participate in carbon dioxide regulation.

In the absence of biological activity early in the evolution of the earth, the primitive "soils" would have consisted of physically and slowly produced proton-mediated weathering products and would have a composition similar to that of the primary rocks. Clays may have been present as a result of the abiotic weathering of the more reactive primary minerals. The pH in these soils would have been dependent on the concentration of atmospheric carbon dioxide, the environmental temperature, and the flux of rainwater through the soils. Therefore, the rates of weathering would have been substantially slower than at present and, as a result, atmospheric carbon dioxide levels would have been substantially higher in the early atmosphere than today (62). The retention of heat in the atmosphere due to carbon dioxide and water would have served to produce an environment warmer than today despite the lower solar heat flux during this period (63). The climate of the steady-state Earth during this period would have been substantially different from that subsequent to the microbial colonization of the continents, the development of soils, and the evolution of higher plants.

The initial colonization by autotrophic and heterotrophic microorganisms would have substantially altered the physics and chemistry of the soil, leading to substantial changes in weathering and carbon dioxide consumption rates and ultimately to a terrestrial climate more like the present. A number of mechanisms and factors could have contributed to the change in weathering patterns (64). These include:

- Residual organic matter from autotrophy would have allowed the soil to better maintain water levels adjacent to reactive mineral surfaces;

- The combination of autotrophy and heterotrophy would have transferred carbon dioxide from the atmosphere to the soil zone leading to a decreased soil pH and increased rates of proton-mediated respiration;
- Microbial production of organic acids and organic ligands would have allowed for ligand-mediated weathering even in the neutral pH range, leading to overall higher weathering rates;
- Microorganisms could have reduced pH to levels lower in the soil zone (by the oxidation of reduced compounds) than those resulting from carbon dioxide equilibria leading to even higher rates of weathering than could be otherwise sustained;
- The physical weathering of the primary rocks, leading to the exposure of new and reactive mineral surfaces for subsequent chemical weathering would have been increased because of freeze-thaw cycles and aided by microbial water retention and, ultimately, by the action of roots and fungal structures; and
- The physical stabilization of the soil by microorganisms and plants would allow sufficient time for the soil components to react with the available solutions.

The initial colonization of soils would have selected for a class of microorganisms that could survive in these primitive soils. These organisms would have had to be able to maintain their water content and to acquire nutrients from the soil material, by physical and chemical extraction. The primitive autotrophs would have had to extract the required nutrients from the mineral solids to produce organic material. Subsequently, organic compounds would have been excreted and respired to enhance the nutrient extraction efficiency, accelerate the rates of physical weathering and fluid transport through the soil zone, and stabilize the soil surface to inhibit further erosion. Thus, it is reasonable to conclude that the inhospitable terrestrial environment would have selected species that were capable of efficiently dissolving minerals and rocks. Microbial mediated weathering, therefore, should be regarded as an important common characteristic of this early terrestrial environment and we should therefore not be surprised that this characteristic ability of microorganisms remains common in the modern terrestrial ecosystem.

The primitive-soil organisms would have added organic matter to the soil, or at least to the surface of the soil, and by increasing the rate of clay production, would have contributed significantly to the ability of the soil to maintain its water content and solutes. This primitive soil would subsequently be able to support increased heterotrophic activity and the activity of larger plants such as those that appeared in the fossil record in the Silurian period and expanded rapidly by Carboniferous time. With colonization by these rooted plants would have come the deepening of the soil layer, the penetration of micro- and, eventually, macroheterotrophs into the soil zone, and the downward development of more modern soil structure. The high rates of organic matter production by the larger plants would have contributed to the higher levels of heterotrophic activity in soils and the maintenance of inorganic and organic acidity necessary for the continued extraction of nutrients and production of mineral particles to maintain soil productivity (65,66).

Thus, it is clear that microbially mediated weathering reactions do not reflect a new biogeochemical process, but rather are among the oldest and most fundamental of biogeochemical processes on the terrestrial surface where most weathering occurs. The role of microorganisms in the development and maintenance of soils is a fundamental geochemical process of global and paleohistorical consequence and remains as important today as in paleohistory.

CONCLUSION

Microorganisms and their metabolic activity can enhance mineral weathering rates and have played an important role in the global weathering cycle and climate moderation throughout geologic time. They accomplish this by a combination of mechanisms that include the regulation of pH and the production of complexing organic ligands in the soil zone, where most weathering occurs. The degree of enhancement of dissolution, the initial step in the sequence of weathering reactions, is dependent on the chemical composition and structure of the mineral substratum, pH, ligand composition and concentration, and temperature. Different primary reactants can affect dissolution rates in different ways, leading to either overall enhancement or inhibition of mineral weathering rates. For aluminum silicate minerals, such as feldspars, the affinity of protons and ligands for a limited number of aluminum sites on the mineral surface leads to a competition between reactive solutes and, therefore, mechanisms of dissolution. Mineral weathering can proceed by still other mechanisms including redox reactions and direct attack at other types of surface sites, in the absence of aluminum. Direct contact between microorganisms and the mineral surface, does not seem to be required for enhanced dissolution rates. However, the attachment of bacteria to surfaces and the formation of microbial microenvironments may create conditions that lead to much higher rates of mineral weathering than would be expected by the composition of the bulk interstitial solutions in soils and aquifers. The distribution of such microenvironments leads to the patchiness that has been observed on weathered surfaces of many types.

Microbially mediated weathering is not an anomalous process. Rather, it represents a fundamental geochemical process that responds to evolving environmental conditions, that evolved early in the history of the earth, and that continues to play an important role in the maintenance of the global environment.

Acknowledgments

Work on the role of microbes and microbial activity on mineral stability at the University of Delaware has been generously supported by the U.S. Department of Energy, Subsurface Science Program (Dr. Frank J. Wobber, Program Director). Since 1997, S.A.W. has received support from grants to Prof. J.F. Banfield from the U.S. Department of Energy, Office of Basic Energy Sciences and by the Geology and Paleontology Program of the National Science Foundation. W.J.U.

was supported, while on sabbatical during 2001 in Adelaide, South Australia, by Flinders University and CSIRO Land and Water. We acknowledge the assistance of L. L. Stillings (USGS, Reno), J. R. Rogers (University of Texas, Austin, and USGS, Denver), and W. W. Barker (University of Wisconsin, Madison) for providing us with data and illustrations for this contribution. Reviews by M. Malavarapu (CSIRO Land and Water, Adelaide) and two anonymous reviewers are gratefully acknowledged. We thank our funding agencies and our colleagues for the many fruitful discussions that are summarized in this review.

WETLANDS. See FLOODED SOILS

WETLANDS AND READBEDS FOR WASTEWATER TREATMENT

ROBERT H. KADLEC
Wetland Management Services
Chelsea, Michigan

Treatment wetlands are a class of natural systems for pollution control. Wetlands are ecologically intermediate between terrestrial and aquatic environments. They therefore occupy a treatment niche between land-based systems, such as infiltration and overland flow, and pond systems, such as facultative lagoons. Although wetlands share characteristics of these wetter and drier counterparts, they also possess unique features of their own. Constructed wastewater treatment wetlands imitate many of the characteristics of natural wetlands, but are designed and focused on water quality improvement as the main goal. Other wetland values, of aquaculture, flood protection, groundwater recharge, and wildlife habitat, are unavoidably present, but less important (1).

All variants of constructed treatment wetlands share common features. A shallow excavated basin, about one meter deep, serves to contain the wetland waters, soils, and biota (2,3) (Fig. 1). The berms of the wetland are formed out of removed soil. An inlet distribution system conveys the wastewater to the basin, and provides for uniform and complete distribution of the water to all portions of the inlet zone. At the outlet end of the wetland, uniform collection is provided, together with water level control and conveyance to the downstream recipient. The receiving water may be surface or groundwater, or another component of the treatment system. The interior of the basin is filled with a layer of either soil, or a porous sand or gravel media. Appropriate wetland plants are seeded or transplanted into the media, and allowed to develop to a mature ecosystem (1,4).

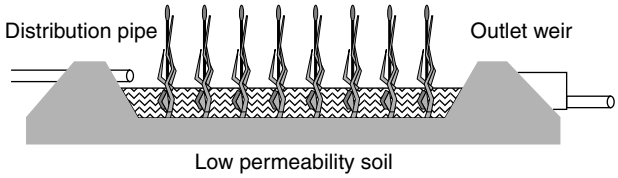

Figure 1. Treatment wetland schematic. See color insert.

Free water surface (FWS) systems (Fig. 2) are patterned after many types of natural wetlands (1,3). The soils used as initial rooting media are most often local topsoils, as a result of ready availability. The desire to maximize the treatment potential of a given land area leads to establishment of a continuously flooded and flowing water regime. Water depths are typically set within the range of 10 to 50 centimeter, which corresponds to the water tolerance of many emergent wetland macrophytes. Floating, submerged, or emergent vegetation may be initially emphasized, but some degree of natural invasion is inevitable (1). Constructed treatment wetlands are most frequently planted with tough emergent macrophytes, such as reeds (*Phragmites* spp.), bulrushes (*Schoenoplectus* spp.), and cattails (*Typha* spp.) because these species are tolerant of a wide variety of water chemistry and hydrology. However, the new wetland is often rapidly colonized by floating plants, such as duckweed (*Lemna* spp.), and by several forms of attached and free microscopic algae. Detritus from dead plant and animal parts forms after a growing season, and become substrates for decomposers. Very large and diverse microbial populations develop, principally on emersed surfaces of live and dead biomass, and sediments, and soils (1,3).

Subsurface flow (SSF) treatment wetlands are based on a water-saturated bed of porous media, for which there is no true analog in the realm of natural wetlands (4,5). A variety of soils, sands, and gravels may be employed, in either vertical or horizontal flow (Fig. 3). The plants are emergent macrophytes, of the same species used in FWS wetlands. In Europe, the plant of choice is the common reed (*Phragmites australis*), and the systems are called reed beds (4,5). The purposes of the media are basically twofold: a microbial substrate for treatment and prevention of exposure to the contaminated water. A portion of the underwater pore space becomes colonized with biofilms that perform many of the observed treatment functions. Comparison of Figures 2 and 3 shows that there are many important ecological distinctions between FWS and SSF systems. Water is not directly exposed to air and is out of potential contact with wildlife and humans. Thus, reaeration is poor, but contact health

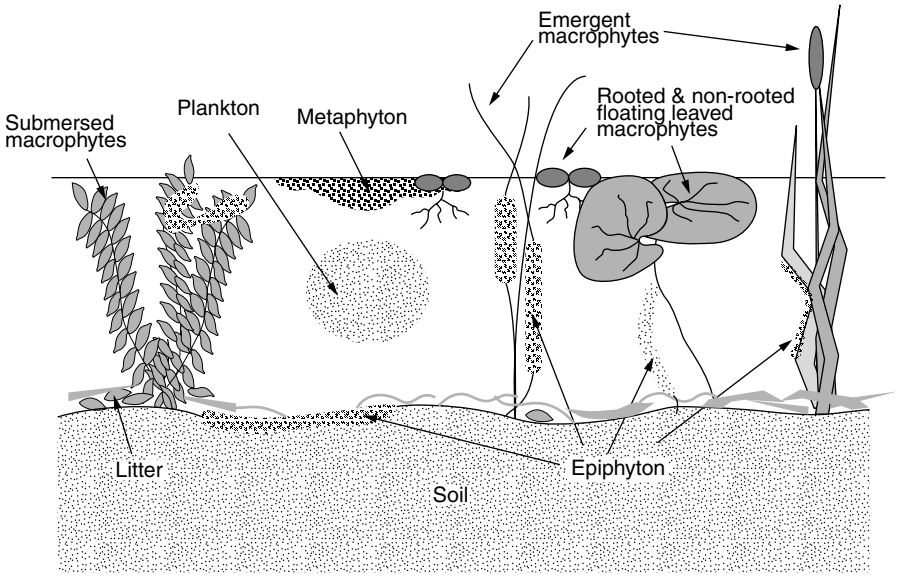

Figure 2. Major macroscopic components of a free water surface wetland.

problems are minimized. Volunteer vegetation is restricted to emergents, which are minimized by poor seedbed conditions. Litter is held above the water column, and decomposition processes have only minimum connection with the belowground water. Vertical intermittent flow may be used with SSF wetlands, thus providing episodic aeration of the drained portions of the bed (4,6).

Treatment wetlands have two unique types of local redox zonation (7). In the macroscopic vertical direction (Fig. 4), the top water layers are often oxygenated (Eh > 300 mv), but there is a sharp demarcation at the sediment–water interface, below which a nitrate reduction zone exists ($300 > Eh > 100$ mv). Below this lie successively more reducing zones: iron reduction ($100 > Eh > -100$ mv), sulfate reduction ($-100 > Eh > -200$ mv), and methanogenesis (Eh < −200 mv). Plants root about 30-cm deep, into one or more of the anaerobic zones, and must possess the ability for self-aeration to survive and respire. Wetland plants use airways (aerenchyma tissues in their stems) to oxygenate the rhizosphere (the immediate microzone surrounding roots and root hairs) and to vent gaseous waste products (8). Oxygen intake must be enough to support root respiration and to maintain an aerobic microzone adjacent to the root (Fig. 5) (8). The result is that aerobic and anaerobic environments exist in close proximity, allowing diffusion of dissolved constituents to and from these two redox environments.

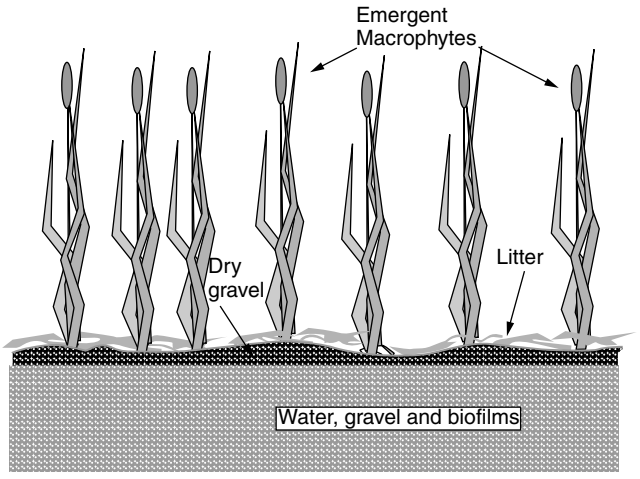

Figure 3. Major macroscopic components of a subsurface flow wetland.

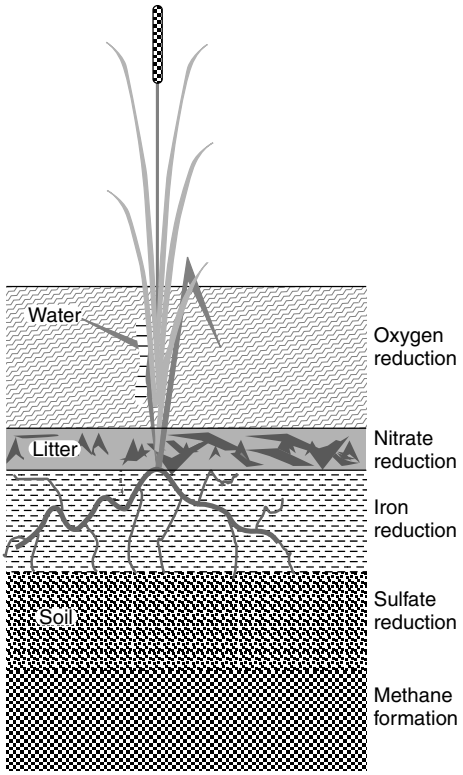

Figure 4. Vertical zonation of a FWS treatment wetland. Redox potential ranges from 300 mv in the water column, to −300 mv in the lower anaerobic zones.

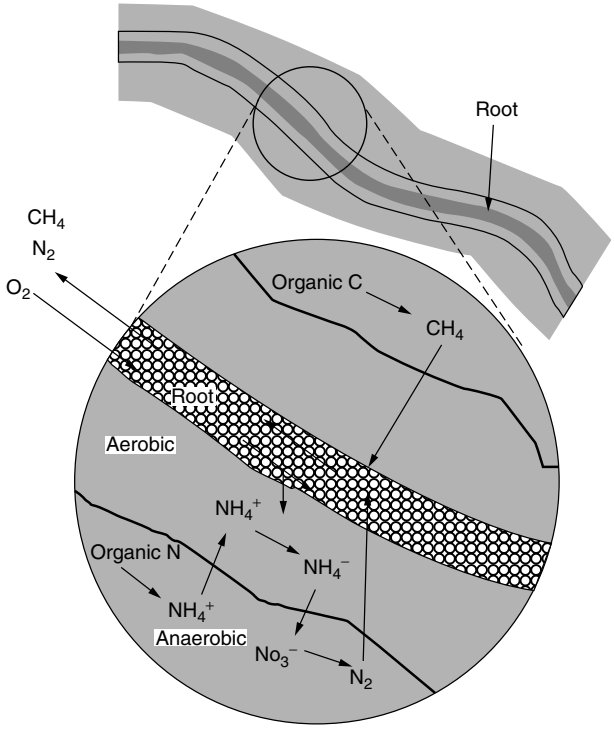

Figure 5. Pathways of carbon and nitrogen transformations in the immediate vicinity of a wetland plant root. (Adapted from Kadlec and Knight, 1996).

A common feature of horizontal flow treatment wetlands is the presence of longitudinal gradients in chemical and biological parameters in the direction of flow. Water flow is often a parallel network of flow paths from inlet to outlet, with varying path transit times (9). As water moves through the system, pollutant reductions and transformations occur, giving rise to longitudinal chemical gradients. Interactions between the vertical, mycorrhizal, and longitudinal spatial scales are provided by diffusional transport, and more importantly by transpiration water flows (10). Above water plant parts transpire water, which is extracted from the root zone, to the air to maintain their thermal balance. Pressure forced flow replenishes the root zone from adjacent and overlying waters.

Seasonal variations are present in many wetland parameters, including physical, chemical, and biological parameters. Water temperature has a critical influence on microbial processes. Solar radiation is a strong determinant of photosynthetic activity. When these environmental variables are combined with the spatial complexity, the resulting effects are beyond simple intuitive understanding. Mechanistic process models may be envisioned and coded, but the calibration data requirements cannot be met. Thus, the present state of performance modeling is limited to removal calculations, with enhancements for spatial and temporal variation, hydrology, and meteorology (1).

MICROBIALLY MEDIATED POLLUTANT REMOVAL

The wide variety of wetland microbial processes provides a unique environment for modifying water quality. Typically, compounds of carbon, nitrogen, sulfur, and iron are altered in the passage of water through wetlands because these are all intimately involved in biogeochemical cycling. The typical end-products of carbon processing are carbon dioxide, water, and methane.

Organic Matter Degradation

The carbon content of the incoming water is usually characterized by carbonaceous biochemical oxygen demand (CBOD), total organic carbon (TOC) or chemical oxygen demand (COD). But there are also both solid and water phase carbon sources in wetlands, in the form of decaying litter and sediments, and soluble hydrocarbons, including many types of organics. Aerobic zones in the wetland contain microbial populations that convert organic matter to carbon dioxide, water, ammonia, and other end-products. The wetland environment contains both aerobic and anaerobic zones, in varying proportions for different treatment wetland types. Methanogenesis has been identified as a major route for CBOD reduction for primary effluents fed to SSF wetlands but not for secondary effluents (11). However, soils of FWS wetlands have been shown to possess potential methane production rates that could consume all CBOD for secondary wastewaters (12).

Microbial populations in wetlands vary seasonally, and with vegetation type (13). Organic compounds in treatment wetlands originate from two sources: added wastewater and internal cycling of biomass, and both may be of importance to the observed performance of the wetland for carbon reduction. Specific organic compounds are oxidized by only a fraction of the aerobic consortia. For instance, only 3 of 30 studied strains of bacteria were found to grow in a glycol-rich environment, but both surface and subsurface flow wetlands remove glycol (14). This and other factors typically contribute to a lag phase in the consumption of individual organic chemicals, such as phenol (15). The result of the complex suite of bacterial carbon processes is the reduction of incoming excesses, down to but not below the natural background created by carbon cycling (1). This background is typically in the range of 5 to 10 mg/L BOD (1). Removal progresses with decreasing rates in the direction of water flow. Extremely wide ranges of BOD have been subjected to wetland treatment, with generally good success (Table 1).

Nitrogen Processing

The nitrogen cycle for wetlands is complex and contains a preponderance of microbially mediated transformations (Fig. 6). The sequential conversions of ammonification, nitrification, and denitrification are all important adjuncts to plant uptake and litter decomposition, the last also being bacterially controlled (1). The natural wetland nitrogen cycle is often shifted to different proportions of the sequential processes of Figure 6 by the introduction of excesses of any of the participating nitrogen species. Fixation is not generally observed in nitrogen-rich systems, but treatment wetlands receiving highly treated domestic effluents, including nitrification and denitrification in the upstream processes, may be deficient in ammonia and also possibly nitrate. By inference, fixation must be a component of the nitrogen supply in those wetlands (1).

Table 1. Example BOD Reductions in Treatment Wetlands

System	Type	Hydraulic Loading cm/d	BOD In mg/L	BOD Out mg/L	Reference
Benton, KY	FWS	6.2	26	10	17
Cannon Beach, OR	FWS	2.5	28	7	17

Oaklands Park, UK	VSF	15	246	14	21
Springe-Eldagsen, GR	VSF	2.7	289	8	22

FWS = **free** water surface, **HSF** = **horizontal** subsurface flow, **VSF** = **vertical** subsurface flow.

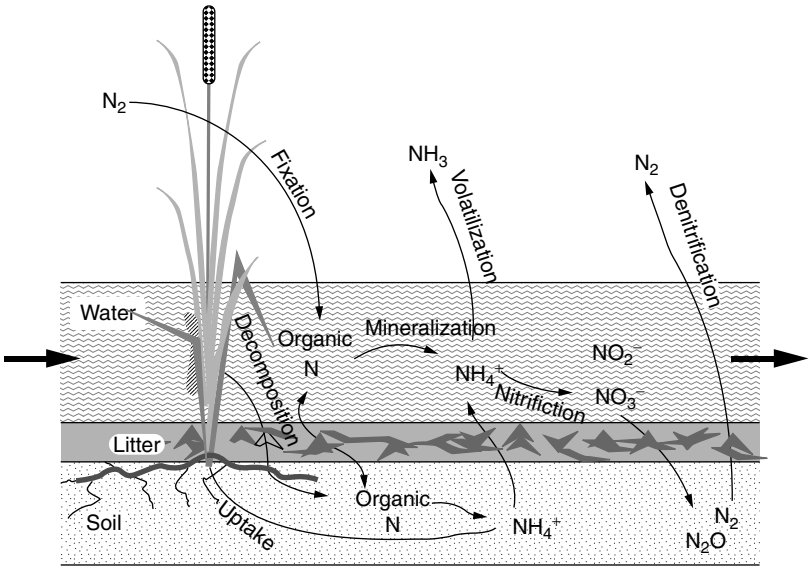

Figure 6. Wetland nitrogen processing. Almost all pathways are microbially mediated.

Mineralization, or ammonification, of organic nitrogen occurs in natural wetlands. For instance, about 50% of the gross mineralization was found to be recycled in a freshwater natural wetland (22). Treatment wetlands that receive large inputs of organic nitrogen produce large amounts of ammonium nitrogen via this pathway. Up to 1,000 gmN/m^2yr have been ammonified in wetlands treating potato wastewater containing 100 mg/L of organic nitrogen (23).

Ammonia reduction is a frequent treatment goal for wetlands. Plant uptake can use ammonia on a seasonal basis, but microbial nitrification is also important (1,4). Theoretically, the microbial reaction requires 4.57 mg of oxygen to nitrify 1.0 mg of NH_4-N, which often exceeds the capability of the wetland environment for aeration of the water column. Nitrification is accompanied by cell synthesis, which utilizes ammonia and reduces the oxygen requirement to 4.3 mgO_2/mgN (24). Wetland data indicate that oxygen transfer limits these processes, especially for horizontal flow reed beds (25). Nitrification competes with respiration for available oxygen, although denitrification supplies some of the joint requirement. Nitrifiers are found in treatment wetland substrates at 10^4 to 10^5 per dry gram in FWS wetlands, and 10^3 to 10^4 in horizontal SSF wetlands (17,26), with lesser numbers in winter.

Denitrification is one of the most efficient wetland processes. The carbon requirement of this reaction is 1.3 gmC/gmN, which must be supplemented by an additional 25% to support cell synthesis. In many treatment wetlands, the carbon source is available in the incoming wastewater (1,4). The wetland environment is ideal for denitrification, because a large renewable carbon source is available from the organic sediments, in an anaerobic zone close to the water column. The decomposition of plant and animal litter can provide up to 10,000 gm/m^2yr of dry detritus, of which about half is carbon that can support denitrification (27). Newly constructed wetlands do not have this source until the biomass cycle fully develops. Organisms are found predominantly on submerged stems and litter, and on the sediment–water interface. Populations in FWS wetlands number approximately 10^6 per gram, with lesser numbers

Table 2. Example Nitrogen Transformations in Treatment Wetlands

		Organic N mg/L	Ammonium mg/L	Nitrate mg/L	Total N mg/L

31	Out	1.02	0.81	1.49	3.32

Grand Lake and NERCC are horizontal subsurface flow; others are free water surface.

in winter (18). Populations develop to larger numbers with continued exposure to oxidized nitrogen.

The end result of the set of nitrogen transformations is a complex removal and respeciation that often prevents simplistic interpretation (1). A wide variety of feed waters produce very different outflow concentrations (Table 2).

Sulfur Processing

Wetlands typically possess a very active, microbially mediated sulfur (S) cycle. Soils may contain up to 0.5% sulfur dry weight, as sulfates, sulfides, and organic and elemental sulfur. Many wastewaters contain abundant sulfates, as does the rain impinging on treatment wetlands. Many interconversions among the four oxidation states of sulfur occur in the different redox zones of wetlands, and most are microbially mediated (31). Depending on the chemical environment, soluble sulfides can form, which are very important in the precipitation of divalent metal cations, such as copper, cadmium, and lead (32). This reduction is favored by warm temperatures, pH > 5, and sulfate greater than about 30 mg/L (33).

Iron Processing

Wetland environments provide appropriate conditions for both iron oxidation and iron reduction. This feature has led to the implementation of hundreds of acid mine drainage treatment wetlands in the United States (34). There are strong interactions between iron processing and sulfur processing within wetlands. Pyrite and elemental sulfur may be oxidized to sulfate by microbial activity. However, the treatment mechanism is most simply described as sulfate reduction producing sulfides that remove dissolved iron to solid iron sulfide minerals (32).

In northern peatlands, ferrous iron in anaerobic groundwater is oxidized to insoluble ferric compounds called bog iron, a commercial ore deposit. Heterotrophic iron-oxidizing bacterial counts reach $> 10^6$ cfu per gram of surface soil in acid mine drainage-treatment wetlands.

Heterotrophic Microbial Activity

Addition of electron acceptors to methanogenic soils causes transition from methanogenesis to utilization of the alternate electron acceptor. In some instances, the transition is slow (days); in other instances it is essentially instantaneous. D'Angelo and Reddy (12) have developed a set of test protocols for wetland soils that assess the rates of various microbial processes under conditions that are not limited by electron acceptor supplies (i.e., NO_3^-, SO_4^{-2}, O_2, Fe^{+2}). Both consumption of the electron acceptor and evolution of CO_2 and CH_4 are measured after stable conditions are achieved. Test results for a northern natural FWS treatment wetland show that microbial consortia exist that can use the various electron acceptors (Table 3). The microbial processes, as assayed in the laboratory, are capable of consuming the incoming BOD, nitrate, and sulfate. Interestingly, ample supplies of either sulfate or ferrous iron in the lab tests do not initially inhibit methanogenesis, but after several days, inhibition is complete (12).

PATHOGEN OCCURRENCE AND REMOVAL

Bacteria

Pathogenic bacteria that enter with wastewater are reduced in treatment wetlands. Mechanisms may include natural die-off, adsorption, ultraviolet radiation kill, chemical toxicity, and grazing by protozoans (35–40). The wetland environment is inimical to many species of pathogenic bacteria, including *Escherichia coli*, *Pseudomonas aeruginosa*, fecal streptococci, and others (Table 4). Both reed beds and free-water wetlands are effective in achieving moderate reductions in numbers, but rarely cause complete elimination. Removals are generally in the range of 0.5 to 3.0 logarithms (base 10), or from 70 to 99.9% (1,4). Inspection of Table 1 shows that there is no difference in this range between FWS and SSF wetlands.

Fecal coliforms are a common indicator group used in regulation of water quality from treatment wetlands,

Table 3. Heterotrophic Activity in a Northern Treatment Peatland at Houghton Lake Michigan

Parameter		Natural Peatland Background Zone	Impacted Peatland Treatment Zone
Soil Parameters			
Total C	mg/gm	432	384
Total N	mg/gm	24.35	25.34
Total P	μg/gm	806	1,643
Bioavailable Fe	mg/gm	4.36	5.08
Microbial biomass C	μg/gm	732	1,164
Bulk density	gm/cc	0.114	0.079
Rates			
Methanogenesis			
Methane C emission	gm/m^{2}d	0.30	0.59
Carbon dioxide C emission	gm/m^{2}d	0.29	0.82
Wetland CBOD carbon loading	gm/m^{2}d		0.09
Oxygen consumption			
Oxygen consumption	gm/m^{2}d	6.09	10.69
Carbon dioxide C emission	gm/m^{2}d	1.55	3.18
Wetland CBOD loading	gm/m^{2}d		0.25
Nitrate reduction			
Nitrate N consumption	gm/m^{2}d	0.27	0.52
Carbon dioxide C emission	gm/m^{2}d	0.82	0.00
Wetland nitrate N loading	gm/m^{2}d		0.02
Sulfate reduction			
Sulfate S consumption	gm/m^{2}d	0.66	2.81
Carbon dioxide C emission	gm/m^{2}d	0.51	0.00
Wetland sulfate S loading	gm/m^{2}d		0.02

The wetland receives aerated lagoon effluent. Rates are for the top ten centimeters of wetland soil, brought to stable conditions in the laboratory (13). Electron acceptor supplies (i.e., NO_3^-, SO_4^{-2}, O_2, Fe^{+2}) were maintained nonlimiting.

especially in the United States (48). In other countries, *E. coli* is the indicator of choice (4). The fecal streptococci group is sometimes used to confirm human fecal contamination, with a high ratio of fecal coliform to fecal streptococcus considered indicative of human origin (24). This test may not be reliable for wetlands as a result of the combined effects of differing removal rates and long wetland detention times. (See also FECAL CONTAMINATION, SOURCES OF, this Encyclopedia.)

Inflow densities of fecal coliforms for surface flow wetlands (Table 5) display a range of eight orders of magnitude, depending on the type of pretreatment before the wetland. Ultra-polishing wetlands, such as Iron Bridge, Florida, receive chlorinated effluent, with essentially no fecal coliforms. Lagoon effluents contain moderate levels of fecal organisms that enter the following wetlands. Animal lagoon wastewaters and minimally pretreated domestic wastewaters may bring 1 to 10 million cfu/100 ml into a treatment wetland. At high numerical input loadings, there is a trend of constant fractional removal for FWS systems. However, at low numerical loadings, there are lower fractional removals, and even additions of fecal coliforms for disinfected influents to the wetland. Replicated side-by-side wetlands (labeled "a" in Table 5) show fairly consistent results. Differences in vegetation (labeled "c") and geometry (labeled "d") have small effects.

At high loadings, SSF wetlands produce the same general reductions as FWS wetlands (Table 6). However, there are no low numerical loadings to be found in the literature, because disinfected effluents are not typically sent to SSF wetlands. Rather, the SSF option is often chosen for untreated wastewaters to prevent contact with the water during treatment. Consequently, some SSF wetlands receive over 10^8 fecal coliforms per 100 ml (Table 6). Replication, vegetation and geometry effects are small, as for FWS systems. However, higher loadings cause less reduction, as indicated for the Hamilton, New Zealand, wetlands (labeled "b" in Table 6).

The progression of removal creates gradients in numbers of organisms in the water along the flow direction (Fig. 7). This decline is sometimes, but not always, characterized by the logarithmic linearity associated with first-order reduction processes. First-order volumetric

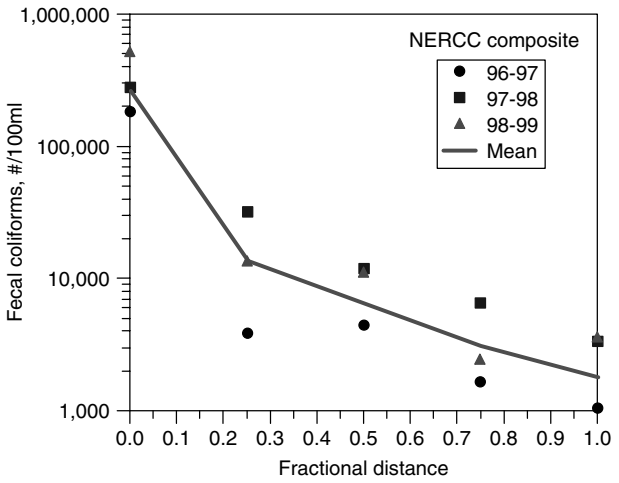

Figure 7. The reduction of fecal coliforms with travel distance in a subsurface flow wetland treating septic tank effluent at the Northeast Regional Corrections Center near Duluth, MN. Data are annual means for three years (30,58). See color insert.

removal rate constants are in the range of 0.2 to 2.0 d^{-1} at 20 °C (1,2). Temperature has been shown to be a factor in pathogen removal at some wetlands, but not others. For example, the NERCC SSF system of Figure 7 displayed a doubling of the removal rate for a 10 °C temperature increase while experiencing a relatively uniform level of incoming organisms (29,57,58).

The microbial populations in wetland waters demonstrate stochastic variability. There are also seasonal cycles in population densities. The cyclic portion of the population time series may be separated from the stochastic portion by detrending several years' data (Fig. 8). For the Grand Lake, Minnesota, SSF wetland, there was no large trend in inflow counts, but a simple sinusoidal trend was observed for densities in the wetland outflow (29). The distribution of individual fecal coliform counts, expressed as a fraction of the trend value, is a unimodal, nearly normal distribution (Fig. 8). The highest outlet values, corresponding to the poorest reduction, occurred in early spring; the lowest counts and best treatment occurred in late summer.

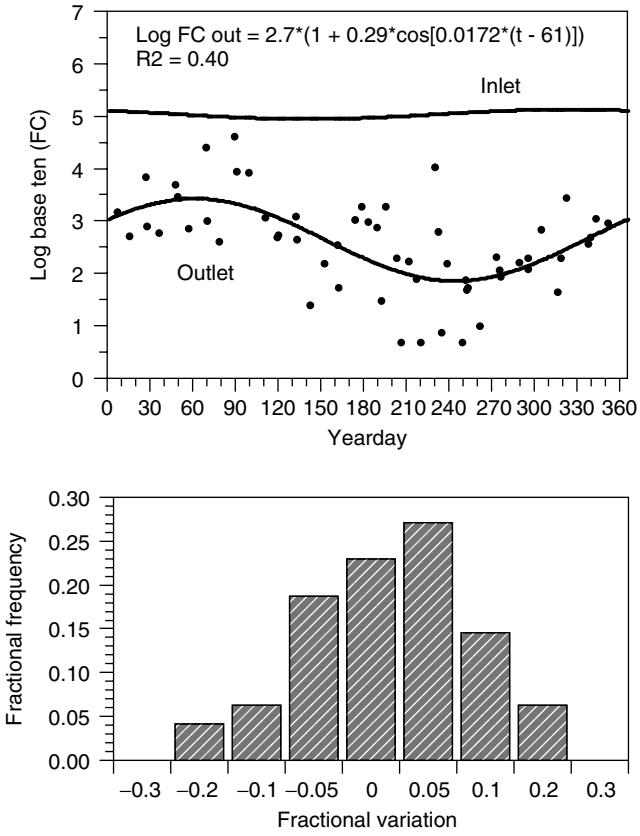

Figure 8. The reduction of fecal coliforms in subsurface flow wetlands treating septic tank effluent at Grand Lake, MN. Data are monthly for three years (30,58). Top: annual trend lines for organisms in the influent and effluent. Influent data points not shown. Bottom: histogram of the fractional stochastic residuals in organism counts. Variability is contained to ±20%. See color insert.

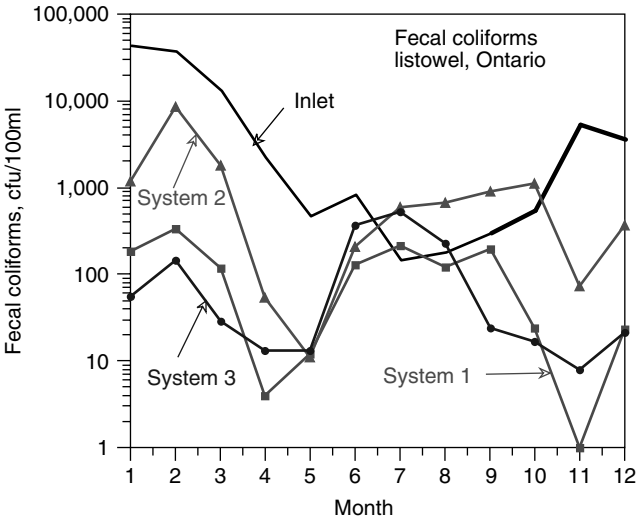

Figure 9. The reduction of fecal coliforms in surface flow wetlands treating lagoon effluent at Listowel, Ontario. Data are means for a given month for three years. The aspect ratio of System 2 was 17 : 1, and 84 : 1 for System 3 (18). See color insert.

Three parallel but geometrically different FWS wetlands at Listowel displayed a different and more complicated seasonal pattern for fecal coliforms (Fig. 9). The lagoon source water at Listowel showed an annual swing of three orders of magnitude in fecal coliform counts, with the highest values in winter, and the lowest in summer. The wetlands outflow count tracked the winter inflow count peak, but also displayed a late summer peak, which exceeded the inflow count for several weeks. Regrowth and desorption were considered possible explanations for the high summer values (17). A first-order reduction model cannot explain these observations because it does not provide for regrowth. Further, a temperature coefficient cannot be assigned, because other factors dominate.

Warm-blooded animals can contribute to populations of fecal organisms in wetlands. FWS wetlands can attract large numbers of birds, in particular, waterfowl and wading birds (1,59). FWS systems also attract rodents, such as muskrats (*Ondatra zibethica*), beavers (*Castor canadensis*) and nutria (*Myocastor copyus*) (1). As a consequence, natural and constructed wetlands have background counts of fecal organisms, in the absence of any introduced bacteria. Background for FWS wetlands has been observed to be in the range of 50 to 500 cfu/100ml (60,61). The Orlando Easterly wetlands in Florida are a well-studied example of this phenomenon (59). Fecal streptococci build in numbers along the flow path until reaching about 100 cfu/100 ml (Fig. 10). Interestingly, populations are lowest in late summer. Presumably, SSF wetlands would have a zero background of fecal organisms, because of the lack of animal interactions.

Viruses

Viruses enter wetlands used for domestic wastewater treatment. The enteroviruses: Polio types one, two,

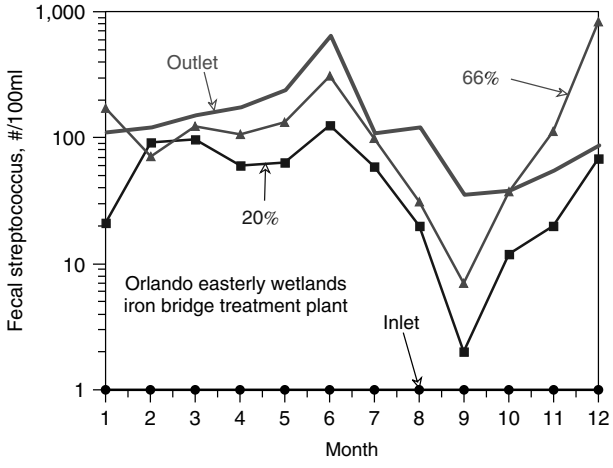

Figure 10. Time series of fecal streptococcus at various travel distances in a surface flow wetland treating tertiary, disinfected effluent from the Orlando Iron Bridge treatment plant. The 482 ha wetland receives zero organisms, but populations grow as the water moves through the system. Data are for 1994, but the seasonal patterns are also typical of other years. The percent labels refer to the fractional distance along the wetland flow path. See color insert.

and three, Echo and Coxsackie; and Reovirus have all been reported in connection with treatment wetlands (43,62–65). Removals of both indigenous and seeded virus are typically one to three logs (Table 7). Biological, chemical, and physical processes are probably all responsible (62).

Suspended solids have been implicated as carriers of virus in wetland waters because of the initial rapid decline in counts along the flow direction (63). Initial first-order reduction rates of 0.06 to 0.18 hr^{-1} were followed by slower rates of about 0.01 hr^{-1} in phage seeding tests in a FWS wetland (63). Decay rates of 0.012 to 0.025 hr^{-1} were found for solid-free water in phage seed testing in a SSF wetland (62). No rapid initial rate was found for the solid-free testing. Somewhat higher removal rate constants were observed for indigenous phages in cypress wetlands, 0.035 to 0.075 hr^{-1} (43,62). These rates are comparable to other pollutant removal rates in wetlands, for easily degraded materials such as nitrate.

The influence of other factors of wetland design is as yet not known. Studies in northern climates under cold-water conditions are not available. Table 7 hints that SSF systems may be more efficient than FWS, but the evidence is not conclusive. Unvegetated SSF beds perform some treatment of virus, but the plants significantly improve removals. It thus appears that rhizosphere processes augment physical adsorption.

Protozoans

Treatment wetlands contain several genera of protozoa and metazoa, and wastewater addition may carry other species into the ecosystem (67) (Table 8). Some of these are human pathogens, such as *Giardia*, *Entamoeba*, and *Cryptosporidium*. Reductions to below detection have been reported for gravel reed beds, for cysts, or trophozoites of *Entamoeba* (37,39,68). Soil-based reed beds showed incomplete removal.

Some protozoa are known to graze on bacteria, thus providing bacterial removal by predation in the wetland (36,38). Twenty-two types of ciliates were found in four reed beds at Audlem, United Kingdom. Two community types were identified: one dominated by aerobic bacterivores (e.g., *Paramecium*) in gravel beds, and the other dominated by microaerophilic species (*Plagiopyla*, *Metopus*) in bare soil beds. Combinations also were found in planted soil beds. Rotifers, nematodes, and free-living amoebae were also observed, which may also have contributed to bacterivory. The numbers of these organisms declined along the flow direction, as did the numbers of bacteria, as indicated by *E. coli*. Ciliates alone

numbered about 600 per ml of water, and grazing at reported rates of 10 to 50 bacteria per ciliate per hour could have accounted for the observed *E. coli* reduction.

Parasite Eggs

Domestic wastewaters can carry propagules of a variety of parasites, particularly in tropical and subtropical climates. These helminths include *Ascaris* (roundworm), *Taenia* (tapeworm), and *Tricuris* (whipworm). The eggs are relatively large (ca. 50 μm), and heavy enough to settle effectively. Consequently, the solids trapping function of treatment wetlands provides removal. Protozoan predation has also been implicated in the removal of *Cryptosporidium* oocysts in constructed wetlands (39).

Both surface and subsurface flow systems have been found to be effective for reducing the numbers of eggs and cysts of parasites (36,68–71). *Ascaris lumbricoides* eggs were reduced from 120 to 220 per gram of solids at the inlet of a gravel–phragmites wetland microcosm, to nil at the outlet, in Mexico City (36). However, reductions were less, 120 to 240 per gram of solids at the inlet of a soil–phragmites wetland microcosm, to 40 at the outlet. Removal of *Ascaris*, *Taenia*, and *Tricuris* was complete in water hyacinth (*Eichhornia crassipes*) wetlands in Morocco (69).

Transect studies (37) showed large percentage reductions in five hours detention in a reed bed dosed with *Ascaris*, *Hymenolepis*, and *Toxocara*. However, longer detention did not remove all eggs, suggesting that some portions of the flow were not treated. Transect studies (70) also showed large percentage reductions in 1.2 to 3.5 hours detention in cross-ditched reed beds, for both Nematodes and Cestodes. Influent counts of four eggs/L were reduced to 0.2 to 1.0 eggs/L, with higher removals at longer retention times and higher temperatures.

Vectors and Wildlife Pathogens

Mosquitoes breed abundantly in wetlands, and can be the carriers of human pathogenic agents. Equine encephalomyelitis and St. Louis encephalitis viruses are among the arboviruses known to be transmitted by mosquitoes, such as *Culex tarsalis* (72). *Anopheles* spp. may carry the blood pathogen *Plasmodium vivax*, which causes malaria. Human health problems are thus associated with wetlands, including treatment wetlands. The incidence of malaria and encephalitis decrease with movement from the tropics to the subtropics to the north temperate climatic zones, and consequently the greatest concern is in warm regions. Treatment wetlands may be

better or worse than natural counterparts with respect to mosquito-borne diseases, but they do constitute additional breeding grounds on the landscape. Control measures include vegetation control, biological control with larvae-consuming mosquito fish, adulticiding and larvaciding. Mosquito-specific bacteria in the genus *Bacillus* may be aerially applied to control mosquito populations (73).

Wildlife pathogens are also potentially associated with treatment wetlands, as they are with natural wetlands. Avian cholera (caused by *Pasteurella multocida*) and avian botulism (caused by *Clostridium botulinum*) have been found in association with sewage lagoons and natural and treatment wetlands (74). Conditions that favor transmission are exposed mud flats, together with stressed and overcrowded bird populations (74). The nematode *Eustronglydes ignotus* has been identified as a potential threat to wading birds that feed and nest near nutrient rich sites. However, extensive research on the fish that are intermediate hosts have shown no potential vector in Florida wetlands treating agricultural runoff (75).

CONCLUSION

Treatment wetlands of many kinds are finding rapidly increasing application in numerous pollutant reduction projects. The wetland environment places water in close contact with soils and biota in both surface flow and subsurface flow designs and environments. The rhizosphere, with its active consortia of microorganisms, is accessible to contaminants and effective in promoting transformations. Large and diverse microbial populations are present, and contribute to biogeochemical cycling of nutrients and other substances. Stratification of redox potential leads to multiple functional zones that can communicate by diffusion. The rates of wetland microbial processing are high, and in many cases can absorb new chemical inputs and provide treatment.

Pathogenic organisms occur naturally in wetlands, and wastewaters may bring different and more numerous organisms into the treatment wetland. The wetland environment is hostile to human enteric pathogens, including viruses, bacteria, parasites, and their eggs. Thus, the technology offers a means to provide reduction in pathogenic organisms, but is not to be viewed as a means of total disinfection.

The challenge facing the researchers and practitioners is to understand the microbiology of these systems to the degree necessary to optimize their performance.

WETLANDS: BIODEGRADATION OF ORGANIC POLLUTANTS

ELISA D'ANGELO
University of Kentucky
Lexington, Kentucky

Wetlands are complex ecosystems that link uplands to aquatic environments (1–3). They are distinguished from other ecosystems by their saturated soil conditions, oxidizing and reducing soil layers, organic matter accumulation, and colonization by vegetation and microbial communities adapted to these conditions. Many pollutant-removal processes are fostered under these conditions (1,4–6).

More than 10 million different organic compounds are known, and humans living in developed nations use over 70,000 of these on a day-to-day basis (7). In this entry, an organic pollutant refers to any chemical that contains at least one carbon-hydrogen linkage that is found at levels higher than background and has adverse effects on the environment. Organic pollutants include pesticides, explosives, dyes, phenols, and petroleum products contained in agricultural, domestic, and industrial effluents. Historically, many of these compounds were referred to as *xenobiotics* (meaning foreign to the biosphere) in an attempt to differentiate synthetic and naturally produced compounds. However, it has been suggested that this

term be discontinued because of the structural similarities between the so-called artificial and biosynthesized organic compounds (7).

The study of organic pollutants in wetlands is important because many constructed wetlands are being used to remediate polluted soil and water, and organic pollution of wetlands poses a threat to human health and wildlife (1,6,8,9). Wetlands receive organic pollutants from various sources, including (*1*) applications of pesticides to control aquatic weeds, algae, and mosquitoes, (*2*) agricultural and urban surface runoff, (*3*) landfill leachate and industrial chemical spillage, (*4*) residual pesticides in agricultural lands converted to wetlands, and (*5*) atmospheric fallout. According to a National Sediment Inventory (10), these sources contaminate 26% of U.S. rivers, streams, lakes, and coastal shoreline sediments at the Tier I level, that is, they pose the greatest health hazard to biota. Pollutants that cause the most concern include polychlorinated biphenyls (PCBs), polyaromatic hydrocarbons (PAHs), and pesticides, mercury, and other heavy metals. Many of these compounds bioaccumulate, and as a result there are over 2,500 fish-consumption advisories in 47 States (11). Organic pollutants interfere with many beneficial wetland functions, including water quality improvement and wildlife habitat utilization (12).

Systems of biotic and abiotic processes govern organic-pollutant removal in wetlands (Fig. 1). Biodegradation is the biologically catalyzed simplification of organic chemicals into its fundamental inorganic constituents, and is generally considered the main detoxification pathway in the environment (13). Biodegradation in wetlands depends on the chemical characteristics of the organic pollutant (water solubility, oxidation state, types of functional groups), and on biogeochemical conditions in the soil-water column (microbial consortia, pH, redox potential, temperature, salinity, nutrient and carbon availability, oxygen and other electron acceptor availability, vegetation type and amount) (14). Biogeochemical conditions can be highly dynamic in wetlands. Predicting organic-pollutant fate and impacts in these ecosystems requires an integration of several disciplines including soil microbial ecology, wetland science, chemistry, physics, engineering, botany, and ecotoxicology. These disciplines are integrated and applied in the field of bioremediation, which is the controlled and practical use of the biodegradative capacity of microorganisms to destroy chemical pollutants to establish safe concentrations (13).

This article covers biogeochemical principles, current biodegradation and fate research, and microbiological transformations of organic pollutants in wetlands. Finally, future directions regarding the study of organic pollutants in wetlands will be addressed. More detailed information about reaction mechanisms of organic pollutant degradation can be found in other entries of this Encyclopedia and other references (7,13,15–18).

WETLAND BIOGEOCHEMISTRY

Between 2 and 6% of the earth's surface is covered by wetlands, which include coastal wetlands (tidal freshwater, estuaries, and mangroves) and inland wetlands (marshes, peatlands, swamps, riparian wetlands, bogs, fens, potholes, pocosins, and floodplains) (2). Wetlands differ from other ecosystems in three main characteristics: periodicity and source of water inundation (i.e., hydrology), presence of hydric soils, and the presence of vegetation and microorganisms adapted to anoxic conditions (3). Hydric soils, as defined by USDA-NRCS and National Technical Committee for Hydric Soils, are... "soils formed under conditions of saturation, flooding, or ponding long enough during the growing season to develop anaerobic conditions in the upper part" (19). Hydric soils can be identified in the field by observing the presence of redoximorphic features, including organic matter accumulation at the surface, and soil zones with alternating dark and light colored areas in the subsurface (Fig. 2). The darker zones, made up of various shades of red, yellow, brown, and black, are indicative of iron and manganese oxides formed under oxidizing conditions; the lighter gray areas are indicative of reduced iron and manganese species formed under anoxic, reducing conditions. Soils containing both color indicators in close

See color insert.

proximity are characteristic of those that experience fluctuating water tables. In some wetlands, which are flooded for longer periods, soils can exhibit a rotten egg odor from hydrogen sulfide, which is generated from the activity of the anaerobic sulfate-reducing bacteria. Wetlands are extremely diverse and dynamic ecosystems, which significantly impact the types and extent of physical, chemical, and biological reactions that occur in these environments.

Perhaps, the two most important factors that distinguish wetland biogeochemical processes from those in other ecosystems are the presence of aerobic and anaerobic interfaces (20) and organic matter accumulation. Aerobic and anaerobic interfaces result from at least three wetland events, namely, hydrologic fluctuations (e.g., rise and fall of water table, flooding/draining), influx/consumption of electron acceptors (e.g., O_2, NO_3^-, Mn^{4+}, Fe^{3+}, SO_4^{2-}, and HCO_3^-), and oxygen transport by plants to the rhizosphere. The occurrence of these events can sometimes be visualized as macroscopic features and chemical gradients in the soil profile (Figs. 2 and 3). They are critical because they dictate the prevailing types of microbial communities and associated metabolic processes.

Wetland soils often undergo cyclic flooding and draining because of seasonal rainfall events. During the dry season, wetland soil pores (about 50% of the soil volume) may be largely filled with air (containing 10 to 21% oxygen). Under these conditions, aerobic microbial processes predominate. Microorganisms use oxygen for two main purposes: (*1*) as terminal electron acceptor during oxidation of organic matter and other energy substrates (electron donors) and (*2*) as a reactant in which oxygen atoms are added to organic molecules to facilitate degradation.

When soils are flooded, water displaces air in the soil pores. Because oxygen diffusion through water is 10,000 times slower than through air-filled soil pores, much of the soil profile rapidly becomes anoxic (devoid of oxygen) as a result of microbial activity (Fig. 3). Oxygen may be depleted in most of the soil in about a day, depending on the temperature and type and amount of materials present that foster oxygen-consuming processes (such as organic matter, sewage effluent, composts, and

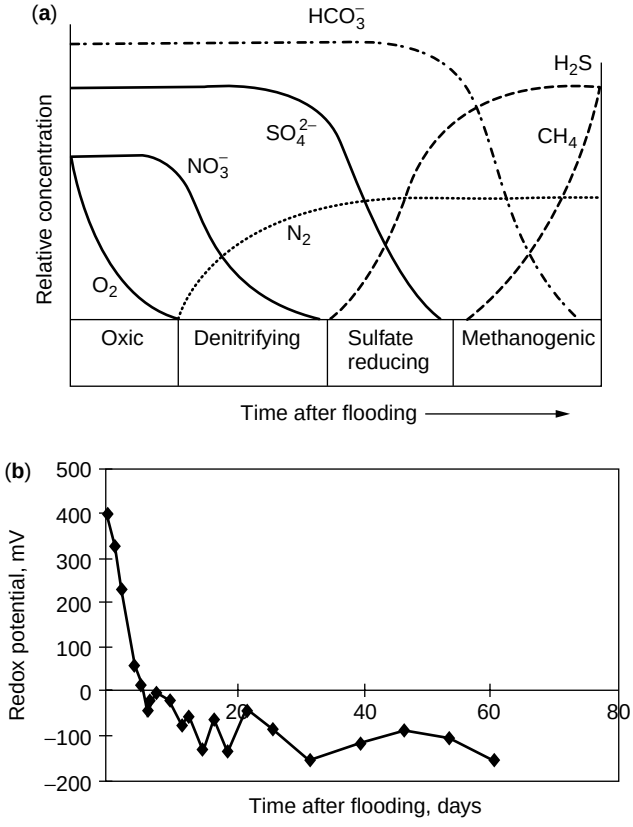

Figure 3. Temporal changes in aerobic and anaerobic processes in wetlands. (**a**) Sequential reduction of electron acceptors as a function of time after flooding, (**b**) Change in redox potential in the subsurface soil horizon after flooding a central Florida marsh soil.

NH_4^+). When oxygen is used up, facultative anaerobic bacteria (e.g., denitrifiers, manganic manganese reducers, ferric iron reducers) and obligate anaerobic microbial groups (e.g., fermenting bacteria, sulfate reducers, and methanogens) take over the transformation of organic matter and pollutants. There are very few examples of anaerobic fungi in wetlands. Anaerobic bacteria use alternate electron acceptors (NO_3^-, Mn^{4+}, Fe^{3+}, SO_4^{2-}, HCO_3^-, and simple organic substrates in the case of fermentation) to oxidize electron donors. Organochlorine and humic substances can also serve as terminal electron acceptors in the metabolism of some bacteria (21,22). These dominant electron acceptors can occur in distinctive patterns in the landscape and give rise to a hierarchy of terminal electron-acceptor processes (TEAPs). Electron acceptors are typically reduced sequentially over time, in accordance with their availability and the relative amount of energy derived from a particular electron acceptor/donor couple. For instance, thermodynamic principles predict that more energy would be gained from the oxidation of a substrate by aerobes using oxygen as compared with anaerobes using alternate electron acceptors. By gaining more energy, aerobes are able to more rapidly reproduce, synthesize new enzymes (including many types not produced by anaerobes), and degrade organic pollutants by outcompeting other groups for available resources. Sequential reduction of electron acceptors is often reflected as increases in the anaerobic decomposition products, including N_2O, NH_4^+, Fe^{2+}, Mn^{2+}, H_2S, and CH_4, and the appearance of redoximorphic features (e.g., change in soil color from red to gray and generation of rotten egg odor).

Sequential TEAPs are also reflected as changes in the redox potential (*Eh*) in the soil-water column (Fig. 3). Redox potential is the tendency of chemical pairs (i.e., electron acceptor and electron donor) to undergo a transfer of electrons, and can be measured in saturated soil using platinum and calomel reference electrodes and a voltmeter. The higher the *Eh*, the greater the tendency of a transfer of electrons from a donor molecule to acceptor molecule, and the greater amount of free energy available for the organism to grow and reproduce. In wetlands, *Eh* values, typically, range between +500 and −300 mV. At *Eh* values exceeding 300 mV, the presence of oxygen and aerobic metabolism are indicated. Lower *Eh* values indicate oxygen-depleted conditions and a shift to anaerobic metabolism, that is, fermentation and microbial utilization of alternate electron acceptors (Mn^{4+}, NO_3^-, Fe^{3+}, SO_4^{2-}, CO_2).

In wetlands flooded for long periods, *Eh* gradients are typically observed as a function of soil depth reflecting changes in the types of metabolic processes (Fig. 4). As expected, *Eh* values are usually greatest at or near the soil surface and in the plant rhizosphere because of oxygen introduction by several processes, including: (*1*) diffusion from the air to floodwater and soil, (*2*) algal production by photosynthesis in the water column, (*3*) burrowing and tunneling of macroinvertebrates in soils, and (*4*) diffusion and mass flow from aerial portions of the aquatic plants to the rhizosphere (Fig. 2b). The thickness of the aerobic zone may expand and contract up to several centimeters in a day because of diurnal fluctuations in light and temperature. Outside the aerobic zones, there is a shift to anaerobic microbial metabolism. Depending on the chemical composition of the water, most flooded wetland soils have several metabolic zones, which are defined by their TEAPs, namely, aerobic (O_2), denitrifying (NO_3^-), sulfate reducing (SO_4^{2-}), and methanogenic (CO_2) (Fig. 4). Freshwater systems are typically dominated by aerobic, iron-, nitrate-, and bicarbonate-reducing conditions, whereas marine systems are dominated by aerobic and sulfate-reducing conditions.

Aerobic and anaerobic interfaces also can be found in the rhizosphere of wetland plants (23,24) (Fig. 2b). Rice (*Oryza sativa*) and other wetland plants have a unique feature in that they transport atmospheric oxygen through the stem and roots. Some of this oxygen diffuses from the root to the adjacent soil layer. Besides oxidizing the reduced microzone around the root surface, the diffused oxygen also stimulates aerobic fungal and bacterial populations, and activity in the wetland plant rhizosphere (25–28). Root oxygen loss from wetland plants has been measured at rates of 13 mg O_2 $plant^{-1}$ day^{-1}, and was used for the oxidation of NH_4^+ and organic carbon substrates (29). Because the bulk soil around the

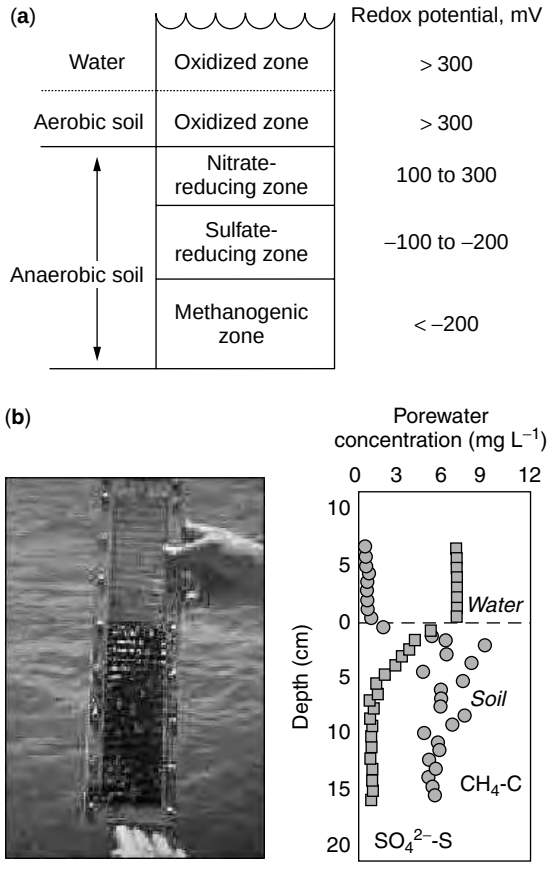

Figure 4. Spatial distribution of aerobic and anaerobic processes in wetlands flooded for extended periods. (**a**) Conceptual diagram showing electron acceptor reducing zones as a function of soil depth, (**b**) Distribution of sulfate reduction and methanogenesis in a central Florida wetland as determined using pore water equilibrators. See color insert.

rhizosphere is mostly anaerobic, the products resulting from aerobic processes to anaerobic zones, diffuse and are transformed by anaerobic microbial processes. This is an important mechanism for nitrogen removal by nitrification-denitrification in flooded soils planted with rice (30).

Aerobic–anaerobic interfaces impact potential rates of organic pollutant degradation. For example, biodegradation of compounds such as octane, benzene, toluene, ethylbenzene, and xylene, and PAHs derived from petroleum and creosote are enhanced under aerobic conditions compared with anaerobic conditions. For other compounds such as pentachlorophenol (PCP), rapid degradation can occur in either aerobic or methanogenic conditions, but is curtailed under denitrifying or sulfate-reducing conditions (31). These observations have obvious implications for the bioremediation of soil contaminated with organic pollutants.

Because wetlands contain redox gradients, there is an additional opportunity for organic pollutant biodegradation. For example, in surface-flow wetlands, pollutants are introduced into the aerobic surface layer where they can be oxygenated to intermediate metabolites and carbon dioxide. Oxygenated products can diffuse to the adjacent anaerobic layers as a result of concentration gradients, where anaerobic processes subsequently transform them. In subsurface-flow wetlands, where pollutants are introduced to anaerobic layers, the order of reactions is reversed. Enhanced transformations by sequential aerobic and anaerobic and diffusion processes have been demonstrated for urea (32) and methane (33). Sequential anaerobic followed by aerobic transformations were found to enhance degradation of the pesticide methoxychlor (34), and may beneficially degrade highly chlorinated compounds such as PCBs and PCP. Sequential biodegradative processes are expected to be more prevalent in wetlands compared with either uplands or permanently flooded aquatic systems because wetlands develop these aerobic and anaerobic interfaces.

The second factor that governs organic-pollutant biodegradation is organic-matter accumulation. Organic matter often accumulates in wetlands because plant and algal productivity are accelerated, stable humic substances are formed, and decomposition rates are slow. External loading may be significant in wetlands receiving domestic and other organic-rich wastes. Organic matter governs organic-pollutant fate through several mechanisms. First, it serves as a carbon and energy source to support the growth of aerobic and anaerobic heterotrophic bacteria and fungi. These groups are primarily responsible for the organic-pollutant biodegradation. Second, organic matter and its degradation intermediates (e.g., hydrogen, cellulose, proteins, fatty acids) facilitate biochemical reduction of organic pollutants in soil under anaerobic conditions. These compounds serve as electron donors for the reductive dehalogenation of organohalogens (e.g., polychlorinated biphenyls, chlorinated phenols, chlorinated ethenes, DDT, toxaphene, and dieldrin) and reduction of nitro groups of certain compounds (e.g., trinitrotoluene and RDX). An additional role of organic matter is sorption, which retards pollutant mobility, bioavailability, and toxicity. On the other hand, pollutant sorption to dissolved organic carbon may enhance mobility and transport out of wetlands (35). An often overlooked mechanism is the oxidative coupling of organic pollutants to humic substances, in which phenol- and aniline-based compounds covalently link to native humic substances (36). Finally, aerobic decomposition of organic matter at the soil surface and the rhizosphere of wetland plants consumes oxygen, causing a shift from aerobic to anaerobic microbial activity. The shift influences the types and extent of biodegradation and other fate processes, as will be discussed in the following sections.

ORGANIC POLLUTANT FATE IN WETLANDS

Several abiotic and biotic processes govern the fate of organic pollutants once they enter the wetlands (Fig. 1). In general, organic pollutants undergo similar processes as natural organic matter. Pollutants introduced into the water column may volatilize to the atmosphere (37), photodegrade (38–40), abiotically degrade (16,41), biodegrade, or interact with colloidal material and settle in the soil (42–63). In the soil and in the plant rhizosphere, organic pollutants may be transformed into intermediate compounds and carbon dioxide by aerobic and anaerobic microorganisms and plants. Organic pollutants may be stored for long periods in the wetland because of sorption and oxidative coupling in soil (64–69), or they may be returned to the water column by diffusion, or by resuspension events, or by the burrowing of macroinvertebrates (35,70). Aquatic plants, crustaceans, fish, and fish-eating birds may accumulate hydrophobic ("water hating") organic pollutants into their waxy and fatty tissues (71–73). Aquatic plants promote volatilization of organic pollutants into the atmosphere by increasing mass transport of constituents toward plant roots and shoots by transpiration, and by translocating chemicals through aerenchyma tissue to the atmosphere (74). Wetlands may attenuate different types of organic pollutants through a combination of some processes, thus reducing the threat to downstream aquatic environments (Tables 1–3).

The extent of many processes can be roughly estimated from the type of organic pollutant and prevailing environmental characteristics (Table 4). For example, a chemical with a high sorption coefficient to organic carbon [e.g., $K_{oc} > 10,000$ mg chemical kg^{-1} organic C $\times$ (mg chemical L^{-1} water)$^{-1}$] would be retained in organic-rich soils, and have limited mobility in the water column. Compounds containing certain types of functional groups are likely to undergo photodegradation, biodegradation, or abiotic reactions in wetlands. Wackett and Herschberger (7) suggested that predicting possible biodegradation routes for the vast number of organic pollutants could be greatly simplified by defining them in terms of their major functional groups. Microbial transformations have been documented in about 58 of the 94 functional groups so far. Environmental factors including organic carbon content of soil, seasonal light and temperature changes, water content, salinity, redox potential, pH, and microbial growth conditions play key

Table 1. Biotransformation of Pesticides in Wetlands and Wetland Microcosms

Pesticides	Sources	Wetland System/Substrate	Experimental Conditions	Rate[†] Sterile	Rate[†] Live	Mechanisms	Notes	Reference
Atrazine (2-chloro-4-ethylamino-6-isopropylamine-1,3,5-triazine)	^{14}C spiked soils	Estuarine sediment microcosm	Aerobic	ND[‡]	15–20 d	Dealkylation, hydroxylation	Sorption accounts for 10–85% loss	42
Atrazine	Spiked soils	Aquatic plant/gravel mesocosm	Aerobic	100% in 41 d	100% in 7–42d	ND; loss of parent compound	Acclimation and rhizosphere enhanced rates; toxicity to plants	43
Atrazine Alachlor (2-chloro-2′,6′-diethyl-N-(methoxymethyl) acetanilide)	Spiked wetland	Riparian forest wetland soils	ND	ND	94% (unspecified period) 59% (unspecified period)	Dilution; other undetermined processes	Dilution accounted for 53% of loss	44
2,4 D (2,4-dichlorophenoxyacetic acid) Atrazine	^{14}C spiked soils	Forested wetland soils	Aerobic	No loss	10–63% in 105 d 6–10% in 105 d	Mineralization	High N inhibits rates, especially in high N soils	45
Dicamba (3,6-dichloro-2-methoxybenzoic acid)	Spiked soil enrichment	Freshwater wetland soil enrichment	Methanogenic	No loss	100% in 30 d	Demethylation, reductive dechlorination	Five member consortia unable to mineralize ring	46
Dicamba Metribuzin (4-amino-6-(1,1-dimethylethyl)-3-(methylthio) 1,2,4-trazine-5-(4H-one)	Spiked soils	Riparian soil microcosms	Denitrifying, methanogenic	No loss	13 to >365 d	Demethylation, deamination	Acclimation enhanced rates	47
p-nitrophenol	^{14}C spiked soils	Everglades soil microcosms	Aerobic	No loss	10–30% in 75 d	Mineralization	High conc. inhibited rates; microbial inoculants enhanced rates	48
Metolachlor (2-chloro-N-(2-ethyl-6-methylphenyl)-N-(2 methoxy-1-methylethyl) acetamide)	Spiked soils	Tidal soil microcosm	Aerobic		0.5% in 84 d	Mineralization	Leaching and sorption greater than mineralization	49

[†]Rates have units of half-life (d) or percentage removal over specified time.
[‡]Not determined.

Table 2. Biotransformation of Hydrocarbons in Wetlands and Wetland Microcosms

Hydrocarbons	Sources	Wetland System/Substrate	Experimental Conditions	Rate†		Mechanisms	Notes	Reference
				Sterile	Live			
Alkanes and Aromatics	Spiked with petroleum oil	Salt marsh plant/soil mesocosms	Diurnal flooding/draining	ND‡	ND	ND	Inorganic fertilizer enhanced plant growth and loss rates; microbial inoculants had no effect	50
Phenanthrene	^{14}C spiked water	Estuarine water microcosms	Aerobic	ND	8–35% in 12 d	Mineralization	Rates enhanced in bulk water compared with air-water microlayer	51
Phenanthrene	^{14}C spiked sediments	Salinity gradient sediment microcosms	Aerobic	No loss	24–384 ng/g/d	Mineralization	Increased salinity enhanced rates	52
Oil and grease	Petroleum and industrial wastes	Treatment wetlands	ND	ND	54–94% (unspecified period)	ND	Rates depend on pollutant-loading	9
Phenols					10–94% (unspecified period)			
Crude oil	Native contamination and spiked soils	In situ and salt marsh soil microcosms	Aerobic	20 d	8–9 d	Volatilization; mineralization	Fertilizer enhanced rates in lab, not in situ	53
Crude oil	Spiked soils	Marine habitats, incl. mangrove and salt marsh	Aerobic and methanogenic	10–37% in 14 d	5–30% in 14 d	Volatilization; mineralization	Oxygen-dependent mineralization; alkanes degraded faster than aromatics; forced aeration and fertilization suggested to bioremediate	54
Surfactants	Pond and laundromat wastewater	Aquatic plant/sediment microcosms	Aerobic	ND	0–40% in 30 d	Mineralization	Rhizosphere enhanced	55

†Rates have units of half-life (d), zero-order rates, or percentage removal over specified time.
‡Not determined.

Table 3. Biotransformation of Industrial Organohalogens and Other Organic Pollutants in Wetlands and Wetland Microcosms

Chlorinated Aliphatics and Aromatics	Sources	Wetland System/Substrate	Experimental Conditions	Rate[†]		Mechanisms	Notes	Reference
				Sterile	Live			
Polychlorinated dibenzo-p-dioxin	Native and spiked	Estuarine sediment microcosms	Anaerobic	No loss	16–54% in 90 d	Reductive dechlorination	Electron donors (esp H_2) enhanced rates	56
Pentachlorophenol	Spiked	Wetland soil microcosms	Varied electron acceptors/ donors and PCP levels	No loss	0–100% in 30 d	Reductive dechlorination	Aerobic, methanogenic conditions enhance rates; toxicity, denitrification inhibits	31
Pentachlorophenol	Native and ^{14}C spiked	Estuarine sediments	Varied pH/redox	ND[‡]	0.3–68% in 34 d	Mineralization	High redox and pH 6–8 enhance rates	57
Chlorine disinfection byproducts (THM, HAA, TOX)	Tertiary treated domestic waste	Treatment wetland	ND	ND	13–97% (unspecified period)	ND	Potential for chlorination of wetland dissolved organic C	58
Tetrachloroethane	Native and spiked	In situ freshwater tidal wetlands and microcosms	Methanogenic	79% in 35 d	100% in 16 d	Volatilization; Dichloroelimination; reductive dechlorination	50% loss by vol. in 1 d; toxic intermediates produced biotically and abiotically	59
Mono halogenated benzoates	Spiked	Estuarine wetland and river inocula	Denitrifying, aerobic, sulfate reducing	No loss	0–100% in 12 d	Dehalogenation; mineralization	Denitrifying conditions enhance rates with most compounds	60
Other								
TNT (2,4,6 trinitrotoluene)	^{14}C spiked	Submerged plant hydroponic mesocosms	Aerobic	No loss	90% in 12 d	Plant uptake, alkyl, aromatic oxidation, nitro reduction, conjugation	Significant extracellular release of toxic plant root metabolites	61
TNT (2,4,6 trinitrotoluene)	Contaminated groundwater and ^{14}C spiked	Aquatic plant/sediment mesocosms	Aerobic	No loss	0.04–0.2% in 7 d	Mineralization	Plant uptake, sediment sorption responsible for 2–80% removal	62
RDX (hexahydro 1,3,5 trinitro1,3,5 triazine)				No loss	0.5–10% in 13 d			
22 organic compounds (alcohols, alkanes, nitro and chlorophenols, surfactants)	Spiked	Forest wetland soil microcosms	Methanogenic	ND	0 to >75% in 56 d	ND	Compound dependant; nitrophenol toxicity inhibits rates	63

[†]Rates have units of half-life (d) or percentage removal in specified time.
[‡]Not determined.

Table 4. General Guide for Predicting Transformations, Partitioning, and Transport of Organic Pollutants Based on Chemical and Environmental Characteristics (16,75)

Pathway	Organic Pollutant Characteristics that Promote Process	Environmental Regulators
	Abiotic transformation	
P hotodecomposition	Chemicals with chromophoric functional groups (e.g., aromatic rings, C=C, C=O, C−NO_2, C−OH, C−NH_2 groups)	Light penetration depth, pH, photoquenching and photoactivation agents
Nucleophilic substitution	Chemicals with electron-deficient center atoms (e.g., S,P,C atoms bonded to electron withdrawing groups, e.g., oxygen, halogens, ester, ether, amide, phosphoester, thioester groups, etc.)	Nucleophile concentration (e.g., pH, sulfide, amines, etc.)
	Novel Catabolic Enzyme Reactions	
Oxidoreductases		
Monooxygenases and dioxygenases	Chemicals with electron-dense center atoms (e.g., carbon atoms of alkanes, alkenes, aromatic compounds)	Presence of O_2 (indicated by $Eh > 300$ mV); affected by organic substrates, nutrients
Phenoloxidases and peroxidases	Chemicals with phenolic and aniline based structures can oxidatively couple with humic substances	Presence of O_2; humic substance concentration
Reductases	Chemicals with electron-deficient center atoms (e.g., carbon atoms bonded to electron withdrawing groups, e.g., NO_2, halogens, etc)	Reductive dehalogenation typically occurs under anaerobic conditions (e.g., $Eh < 300$ mV); affected by supply of electron donors and acceptors
Hydrolases	Similar chemicals as for nucleophilic substitution	pH, water content, temperature
	Partitioning	
Sorption	Chemicals with elevated organic C normalized sorption coefficients [$K_{oc} > 10,000\ mg\,kg^{-1}$ OC $\times$ $(mg\,L^{-1}H_2O)^{-1}$]; ionic compounds can be held by exchange processes	Soil pH and organic carbon content (>1%); soils with high ion exchange capacity, metal oxide reactive surfaces
Bioaccumulation	Chemicals with elevated octanol: water partitioning coefficients [$K_{ow} > 500\ mg\,L^{-1}$ octanol $\times$ $(mg\,L^{-1}\ H_2O)^{-1}$]	Food chain characteristics
	Transport	
Volatilization	Chemicals with high Henrys Law constant [$K_h > 0.01$ atm $\times$ $(mol/L)^{-1}$]	Temperature, pH, wind speed, concentration in air and water
Mobility in water	Chemicals with high water solubility ($>30\ mg\,L^{-1}$)	Hydraulic conductivity, diffusion coefficient, concentration, and matric-potential gradients

roles in the fate of organic pollutants. Several models predicting organic pollutant fate according to these factors are available (16,75); however, they have not been validated in wetland ecosystems.

Experiments that examine the environmental fate of organic pollutants in wetlands typically involve monitoring the concentration of the parent compound, or metabolic products in contaminated microcosms, mesocosms, or in situ wetlands (Tables 1–3). Microcosm and mesocosm studies have an advantage in that environmental conditions can be more carefully controlled, so that the influence of individual factors on the rate and mechanisms of organic pollutant removal can be more effectively described. For example, microcosm studies that include sterile controls can distinguish between losses from biochemical and abiotic reactions. Microcosm experiments employing stable- or radioactive-carbon labeled organic pollutants can distinguish between partial transformations to intermediate by-products and mineralization to carbon dioxide. These studies are most useful when devising pollutant-amelioration strategies in wetlands. On the other hand, these studies do not reflect the complexity of the wetland soil-water-plant environment, and so may not accurately reflect the pollutant-removal potential of wetlands. To date, few studies have attempted to integrate different scale experiments to explain organic pollutant fate in wetlands.

The fate of selected agricultural pesticides including atrazine, 2,4 D, dicamba, metolachlor, and metribuzin have been evaluated in wetlands (Table 1) (42–49). Surface runoff is the dominant source bringing agricultural pesticides to wetlands. Recent evidence suggests, however, that air deposition from agricultural areas may be an important source (76). After deposition into wetlands, pesticides are lost at variable rates, depending largely on the type of compound and environmental conditions. For example, metolachlor was lost at a rate of 0.5% in 84 days in microcosms constructed with tidal

wetland soil (49), whereas atrazine was lost at a rate of 100% in 7 days from mesocosms constructed from aquatic plants and gravel materials (43). In both studies, abiotic processes (volatilization, leaching, sorption) were the dominant loss mechanisms. Mineralization played a less important role; however, rates depended strongly on environmental conditions. Factors showing positive effects on pesticide biodegradation included microbial acclimation, inoculation of contaminated samples with adapted microorganisms, presence of a plant rhizosphere, and nitrogen availability. Inhibitory factors included toxicity and high nitrogen concentrations. Several pesticides were transformed to intermediates by numerous degradative mechanisms. The fate and toxicity of pesticide metabolites to wetland biota is largely unstudied. Most pesticide-fate studies have been conducted under aerobic conditions, although several TEAPs occur in wetlands. Hence, it is not yet possible to adequately predict the fate or ecological consequences of many organic pollutants in wetlands.

Several hydrocarbon-fate studies have been conducted in both coastal and inland wetlands (Table 2) (9,50–55). This is probably attributed to the frequency of wetland contamination by this class of pollutant from oil spills and leaking underground storage tanks. Crude oil components include a mixture of long- and short-chain alkanes, and mono- and polyaromatic hydrocarbons (PAHs). Significant hydrocarbon loss has been observed, as with pesticides. In microcosm studies, rates of loss were between 5% in 14 days (54) and 50% in 8 days (53). A literature review of hydrocarbon losses in treatment wetlands revealed between 10 and 94% during one retention period, typically less than two weeks (9). Several variables and processes influenced hydrocarbon loss. Those with positive effects included nitrogen and phosphorus fertilizers, salinity, and oxygen. Amending contaminated soils with hydrocarbon-adapted microorganisms played a minimal role, suggesting that indigenous hydrocarbon degraders may have inhabited the soil (50).

Extensive hydrocarbon loading and inadequate wetland mixing may have deleterious impacts on loss rates. Toxicity may affect the degrading populations. Extensive loading may also influence the oxygen status of the wetland. For instance, high loading rates would rapidly consume oxygen in the wetland soil-water profile. Under anoxic conditions, hydrocarbon mineralization is highly restricted (54). Volatilization is also a major hydrocarbon-removal mechanism in wetlands, accounting for up to 37% loss in 14 days for volatile oil components (54).

The fate of many organohalide industrial chemicals including polychlorinated dioxins, chlorophenols, trichloromethane, trichloroethane, and chlorobenzoates have been investigated in diverse wetlands (Table 3). Sources bringing these chemicals to wetlands include industrial waste disposal, landfill leachate, domestic wastewater, accidental spillage, contaminated groundwater, and residual pesticides in agricultural lands converted to wetlands. Organochlorine compounds are also generated in wetlands with high amounts of natural organic matter that receive chlorine-disinfected, tertiary treated wastewater (58).

Rates and mechanisms of organochlorine loss are highly compound and site-specific. Rates of parent compound loss range from zero to 100% in 12 days (Table 3). The dominant mechanisms of parent compound transformation/removal included mineralization, reductive dechlorination, and volatilization. Reductive dechlorination involves the replacement of a Cl^- ion with two electrons and a proton (H^+), which is catalyzed by bacterial reductase enzymes or other biological reductants (discussed in following section). Although reductive dechlorination results in less chlorinated intermediates, these are sometimes as toxic or more toxic than the parent compound. The major factors controlling reductive dechlorination are electron donor and acceptor availability because these serve as sources and alternative sinks of electron equivalents. Organic matter amendments may help to promote reductive dechlorination in the environment. Other factors such as pH and toxicity also play major regulatory roles (31).

The fate of munition wastes, 2,4,6-trinitrotoluene (TNT), and RDX have been evaluated in planted wetland mesocosms under aerobic conditions (61,62) (Table 3). In these two studies, the predominant sources of these wastes were surface runoff and groundwater. Loss rates were up to 90% in 12 days, and were predominantly caused by sorption and plant uptake. Biodegradation, which occurred through a series of oxidation, reduction, and conjugation pathways, played a less important role over the course of these two studies. In addition to uptake, plants played a further role on TNT fate by excreting toxic-degradation intermediates into the root zone (61).

The various studies indicate that several wetland processes play major roles in decreasing organic-pollutant concentration from wastewater. These included dilution, vegetative uptake, volatilization, sorption, and biodegradation. Except for biodegradation, the other processes may not represent detoxification mechanisms because they simply transfer pollutants from one wetland component to another, which may be later released to the environment. Therefore, one must be cognizant of the difference between parent compound removal and detoxification by the wetland.

MICROBIOLOGICAL TRANSFORMATION REACTIONS

The purpose of this section is to provide an overview of the processes in the external and internal cell environment, leading to the degradation of organic pollutants in wetland soils (Fig. 5). More detailed description of individual processes can be found in other entries of this Encyclopedia and other reference materials (7,13,15–18).

Microbiological transformations of organic pollutants are important because many abiotic reactions, although thermodynamically favorable, occur extremely slowly because of kinetic limitations. Microorganisms accelerate reaction rates by employing enzymes, which are special proteins sometimes linked with nonprotein coenzymes, and metallic and organometallic cofactors. Enzymes often increase reaction rates by 10^8 to 10^{20} times. Enzymes increase reaction rates by bringing chemical reactants together, converting them to reactive species, and holding them in the correct position for specific types of chemical

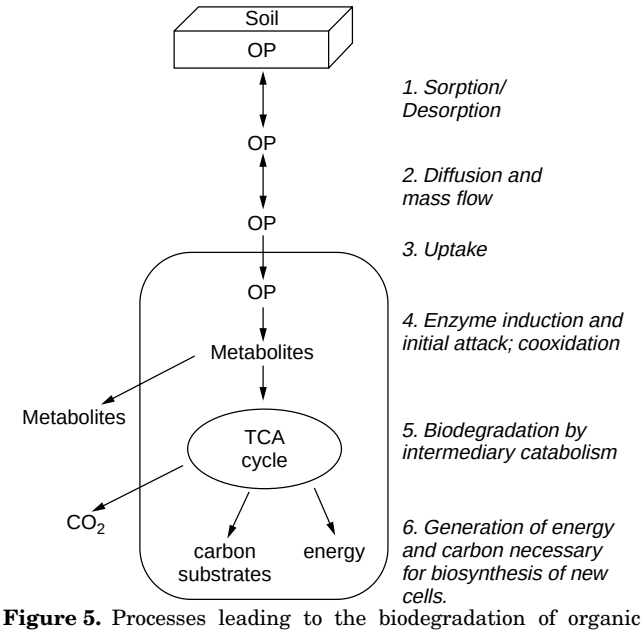

Figure 5. Processes leading to the biodegradation of organic pollutants (OP) in a soil type environment. [1 and 2. Desorption and migration of OP required for optimum microbial–OP interactions. 3. Microbial uptake of OP by passive and active transport mechanisms; 4. Induction of enzymes that either catalyze cooxidation (OP does not serve as carbon or energy source) or catalyze the production of common central metabolites that can enter into intermediary metabolic pathways. Key enzymes include those in oxidoreductase and hydrolase classes. 5. Biodegradation using common intermediary catabolic pathways, such as β-oxidation and the tricarboxylic acid (TCA) cycle. 6. Cell biosynthesis using energy and carbon generated from catabolic reactions].

reactions to take place. Because enzymes are regenerated after catalyzing a chemical reaction, they can repeat the process hundreds or thousands of times before losing activity. Most degradation enzyme reactions are intracellular, that is, they are conducted inside microbial cells.

Unfortunately, in wetlands and other soil environments, processes outside the cell may limit the overall degradation rate of organic pollutants (Fig. 5) (77). Perhaps the most important processes controlling microbial uptake and transformation of organic pollutants are sorption and desorption in the soil. Sorption is defined as physical and chemical interactions between a contaminant and the solid phase (e.g., soil minerals and organic matter) that reduce contaminant concentration in the dissolved pool. Sorption consists of several mechanisms that can be generally grouped into adsorption and absorption. Adsorption generally refers to two-dimensional surface phenomena and absorption consists of three-dimensional interactions between the soil (sorbent) and contaminant (sorbate). Sorption is the result of physical and chemical reactions with the solid phase including London-van der Waals forces, ion exchange, hydrogen bonding, ligand exchange, chemisorption, and hydrophobic interactions. The latter interaction occurs when hydrophobic contaminants get separated from the aqueous phase into the hydrophobic regions in the soil (e.g., organic matter). Combinations of adsorption and absorption phenomena occur in soil depending on the characteristics of the organic pollutant and soil. A common value used to quantitatively describe the extent of sorption is the equilibrium sorption coefficient, which is usually determined experimentally from sorption isotherms. For chemicals with high equilibrium sorption coefficients, greater amounts of chemical are associated with the solid phase compared with the dissolved phase. Desorption rates are typically slower for chemicals with higher sorption coefficients (78). Many microorganisms can enhance desorption by producing a variety of emulsifiers, or biosurfactants (7 and references therein). In addition, microbial organic–pollutant interactions can be dependent on the diffusive or convective migration of chemical toward the degrading microorganism. Sometimes these processes can limit overall degradation kinetics in contaminated environments.

In wetland environments, heterotrophic bacteria and fungi are primarily responsible for transforming or metabolizing organic pollutants. Metabolism refers to enzyme-catalyzed reactions occurring in living cells that synthesize new chemical structures for cellular growth (anabolism or biosynthesis) or break down chemicals to derive energy for cellular growth (catabolism). It is primarily through catabolism that organic pollutants are biodegraded in the environment.

Catabolism can be generally grouped into two categories, namely, central intermediary catabolism and peripheral (or novel) catabolic reactions. Intermediary catabolic pathways consist of core processes such as the tricarboxylic acid cycle and glycolysis, which are common to most living things, from human beings to microorganisms. Intermediary catabolic enzymes are typically constitutive, that is, they are always active in the living microbial cell. Peripheral catabolic reactions are rare processes, probably not ubiquitous in the microbial world, which organisms use to initiate organic-pollutant transformations. Typically, in the absence of the pollutant, a peripheral catabolic enzyme is not synthesized or its activity is repressed. Enzyme induction and derepression occur when the pollutant or another molecule is introduced. This may account for a lag period, or interval of time, before degradation is observed. Typically, a small subset of the total microbial population may be capable of carrying out the enzymatic reactions that initiate pollutant metabolism.

The main strategy used by organisms to degrade organic pollutants is to employ one or more catabolic enzymatic reactions, to yield common metabolites that feed into the existing intermediary catabolic pathways (Fig. 5). After desorption and migration of pollutants to microbial cells, peripheral catabolic reactions are often the biochemical rate-limiting steps to pollutant degradation, and will be the focus of the remainder of this section.

Enzymes are currently grouped into six classes by the Enzyme Commission (EC), including oxidoreductases, transferases, hydrolases, lyases, isomerases, and ligases (see Nomenclature Committee of the International Union of Biochemistry and Molecular Biology Enzyme Nomenclature, *http://www.chem.qmw.ac.uk/iubmb/enzyme/* and The University of Minnesota Biocatalysis/Biodegradation Database, *http://umbbd.ahc.umn.edu/index.html*). Enzyme classes are primarily distinguished by the type of

reactions that they catalyze. Of the six enzyme classes, the oxidoreductases and hydrolases are most frequently involved in novel catabolic pathways. The enzymes and their activity depend on the type of organism (e.g., fungi, bacteria, aerobe, anaerobe), type of compound (e.g., the types of functional groups), and environmental conditions (e.g., pH, temperature, availability of oxygen and other electron acceptors) (Table 4).

Oxidoreductases catalyze redox reactions in which hydrogen atoms, oxygen atoms, or electrons are transferred between molecules. Oxidoreductases are divided into subclasses, and are named based on the type of donor and acceptor molecule and the entity that is transferred. For example, dehydrogenases or reductases transfer hydride ions, oxidases transfer electrons to diatomic oxygen, peroxidases transfer electrons to hydrogen peroxide, and oxygenases transfer oxygen atom(s) from diatomic oxygen. Oxidoreductases are the largest class of enzymes, and act on an enormous variety of organic pollutants. Except for those catalyzed by the dehydrogenases (reductases), all oxidoreductase reactions, directly or indirectly, require oxygen and so occur in aerobic environments.

Some of the most important examples of oxidoreductases involved in the initial phases of pollutant degradation are the oxygenases (see OXYGENASE ENZYMES: ROLE IN BIODEGRADATION, this Encyclopedia) (Fig. 6). Oxygenases are enzymes that catalyze reactions between diatomic oxygen (O_2) and organic or inorganic substrates, which results in products that contain one or both of the oxygen atoms. Oxygen atoms are usually incorporated at locations in the molecule with the most readily available electrons, which often include aromatic rings, double bonds, alkyl groups, and nonbonded sulfur and nitrogen structures. Chemicals containing electron-deficient central atoms, such as highly chlorinated polychlorinated–biphenyls, -phenols, and -aliphatics, are often resistant to oxidation by oxygenases, peroxidases, and phenoloxidases (79,80). These compounds may be more readily transformed by dehydrogenases or reductases of the oxidoreductase class (see discussion that follows).

There are two main types of oxygenases, namely, monooxygenases and dioxygenases (Fig. 6). The monooxygenases incorporate one atom of oxygen into organic molecules, either as a hydroxyl group to one of the central atoms (hydroxylase-type monooxygenase), or an oxygen atom between a carbon–carbon bond (Baeyer Villiger monoxygenase). Dioxygenases insert two atoms of oxygen into organic molecules, either as two hydroxyl groups on carbons that lack hydroxyl groups (hydroxylase-type dioxygenase), or as two oxygen atoms of an aromatic ring already containing two hydroxyl groups (ring cleavage type dioxygenase).

Over a hundred different oxygenases are known and many are produced by heterotrophic bacteria and fungal species to facilitate the extraction of carbon and energy from organic substrates, such as lignin and cellulose in plant litter. Common examples of bacterial genera that transform organic pollutants using oxygenases include *Pseudomonas, Alcaligenes, Sphingomonas, Rhodococcus*, and *Mycobacterium*. Some oxygenases are relatively nonspecific with respect to the types of compounds that they transform; for example, naphthalene 1,2-dioxygenase reacts with at least 72 different substrates (81). In some cases, oxygenases intended for one compound also transform other organic pollutants. The term *cooxidation* applies to situations when the enzyme-producing organism does not gain carbon or energy from the reaction using the nonintended molecule. However, in an assemblage of several different microbial groups, other members may complete biodegradation of the cooxidation products. Two or more microbial groups acting together in a community in such a manner, is known as a *microbial consortium*.

By incorporating oxygen atoms, oxygenases chemically activate inert compounds and cleave cyclic rings (Fig. 6). Oxygenase reactions are essential early steps in aerobic mineralization of many compounds, consisting of only carbon and hydrogen, such as alkanes (e.g., octane in gasoline), alkenes, benzene, biphenyl, and PAHs. In the absence of oxygenase activity, these compounds are transformed much more slowly. Products of oxygenase reactions include alcohols, aldehydes, ketones, esters, epoxides, phenols, and carboxylic acids. Oxygenase reactions often lead to the replacement of halogen substituents and other functional groups of organic pollutants with hydroxyl groups. For example, both membrane-bound flavoprotein monooxygenases of *Flavobacterium* and *Arthrobacter* species and cytochrome P_{450} monooxygenase of *Mycobacterium* species para-hydroxylate pentachlorophenol (PCP)-producing tetrachlorohydroquinone (82–84). Oxygenase reactions often yield common metabolites that are biodegraded through intermediary catabolic steps, such as β-oxidation and the tricarboxylic acid cycle.

Other types of oxidoreductases, including peroxidases and phenoloxidases, are involved in the oxidative coupling reactions between certain types of organic pollutants and humic substances in the soil (36) (Fig. 6). These enzymes catalyze one-electron transfer from aniline-based and phenolic compounds to acceptor molecules of hydrogen peroxide and oxygen. One-electron oxidation of these organopollutants generates free radicals that react with other free radicals (e.g., from native humic substances) to form large molecular weight polymers. Polymerization of phenols can also be abiotically catalyzed by Mn(IV), Fe(III), and Al and Si oxides (85). Oxidative coupling is thought to be analogous to the humification process, and may benefit organisms by removing pollutants from the bioavailable pool (69,86).

Aerobic fungi and bacteria that produce oxidative-coupling enzymes have been discovered in wetland soils and plant rhizosphere, suggesting that oxidative coupling may be prevalent in the oxic zones of these environments (27,87,88). The production and activities of these enzymes may be promoted by manipulating the types of carbon substrates, pH, nitrogen, copper, manganese, and oxygen availability. Because of the requirement of oxygen (or hydrogen peroxide), oxygenase, peroxidase, and phenoloxidase reactions are restricted to the oxic soil–water interface and oxidized rhizosphere in flooded wetlands. On the basis of this understanding, it would be possible to control many oxidoreductase reactions by manipulating wetland hydrology.

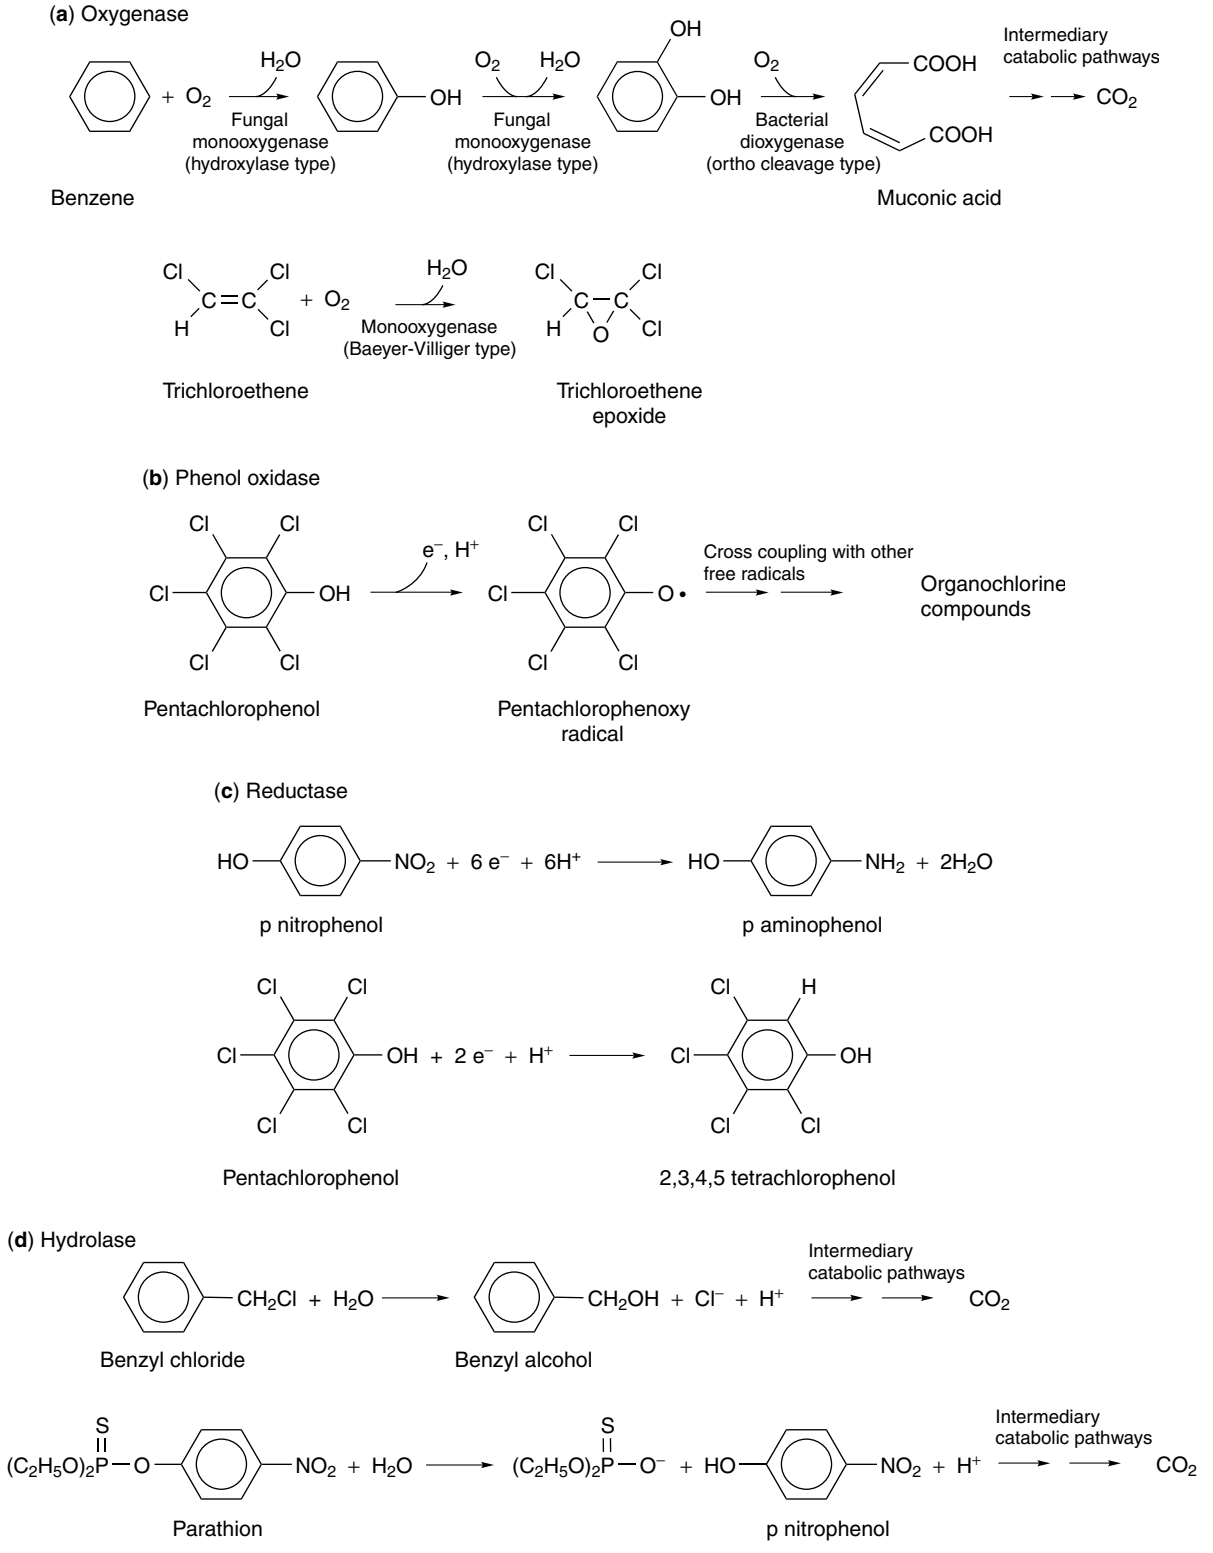

Figure 6. Some microbially mediated organic pollutant transformations by catabolic enzymes. (**a**) Oxygenases, (**b**) Phenol oxidase, (**c**) Reductases, and (**d**) Hydrolases.

Reductases are important examples of oxidoreductases involved in the peripheral catabolism of many organic pollutants (Fig. 6). These enzymes catalyze the transfer of hydride ($H:^-$) from donor to acceptor molecules. Donor molecules typically include NAD[P]H and other biological reductants generated from oxidation of organic compounds. Hydride atoms are usually incorporated at locations of the pollutant molecule containing oxidized (i.e., electron-deficient) central atoms, including those attached with electron-withdrawing functional groups. Examples of electron-withdrawing groups include hydroxyl, carbonyl, nitro, sulfoxide, sulfone, and halides.

Reductive dehalogenation is an important example of a reduction reaction that commonly occurs in anaerobic environments, including wetland soils (see Reductive Dehalogenation of Haloorganics, this Encyclopedia) (Table 3). Reductive dehalogenation involves the replacement of a halogen substituent of an organic pollutant with two electrons and a proton (Fig. 6). Electrons are, directly or indirectly, derived from the oxidation of organic substrates and hydrogen, and protons are derived from the dissociation of water. Dehalogenation reductases, known as *dehalogenases*, have been isolated from both microbial membranes and cytoplasm. Dehalogenases often contain reduced transition metal cofactors (e.g., Fe-S, heme, corrinoid groups) that are involved in electron transfer. Reductive dehalogenation has been observed for a multitude of alkyl halides (DDT, chloroform, PCE, TCE, lindane) and aryl halides (PCBs, chlorobenzoates, chlorophenols, chlorobenzenes).

Several organisms (e.g., *Desulfomonile tiedjei, Desulfitobacterium chlororespirans*, and others) gain energy for growth by coupling the oxidation of organic compounds to the reduction of organohalogens (89,90). This process is known as *halorespiration*, and is conceptually similar to the respiratory processes using oxygen or alternative electron acceptors (91,92). Many organohalogens have reduction potentials at par with Mn^{4+}, NO_3^-, and Fe^{3+}, and greater than SO_4^{2-} and HCO_3^-. Therefore, organisms conducting halorespiration gain a significant amount of energy from the reaction, and perhaps, outcompete other groups. Halorespiration is important because it means that the organohalide respiring bacteria can proliferate in contaminated environments, and so may facilitate the degradation process.

The presence of alternate electron acceptors such as O_2, NO_3^-, Fe^{3+}, and even other chlorinated organic pollutants typically inhibit reductive dechlorination of highly chlorinated compounds, presumably because they divert electrons away from the pollutant molecule (31). Also, less chlorinated compounds often do not undergo reductive dechlorination as rapidly as highly chlorinated ones, presumably because they are less effective electron acceptors (i.e., have lower reduction potentials). Hence, reductive dechlorination commonly results in the accumulation of toxic intermediates.

Several polyhalogenated organic pollutants are reductively dehalogenated by various metallo-porphyrins, including cytochrome P_{450} containing Fe^{2+}, vitamin B_{12}, and other corrinoids containing Co^{1+}, and cofactor F_{430} containing Ni^{1+} (93,94). The reduced metal ions donate one electron to alkyl halide (e.g., tetrachoroethene, carbon tetrachloride) and aryl halide (hexachlorobenzene) acceptors, resulting in dehalogenated products. Reduced metalloporphyrins are produced by many anaerobic bacteria, including acetogens, sulfate reducers, and methanogens. It is thought that these reactions do not generate significant amounts of energy for the microorganisms.

Reductive dehalogenation carried out by dehalogenases or metalloporphyrins frequently renders molecules more susceptible to aerobic and anaerobic catabolic breakdown. Because lesser halogenated products are amenable to aerobic degradation, it has been suggested that sequential anaerobic-aerobic microbial processes may be effective at detoxifying these chemicals. Wetlands provide a unique environment to promote these sequential reactions because they contain aerobic and anaerobic interfaces. For example, reductive dechlorination of an organohalide such as pentachlorophenol (PCP) to lower chlorinated congeners under anaerobic conditions (perhaps induced by soil flooding) could be subsequently oxidized to carbon dioxide under aerobic conditions (induced by soil draining). Alternatively, lower chlorinated congeners produced through reductive dechlorination in anaerobic soil layers in a flooded soil system may diffuse to aerobic zones (e.g., the soil–water interface or rhizosphere), and subsequently be metabolized to carbon dioxide. Regulating water table depth and flooding duration, establishing wetlands with macrophytes with high oxygen transport capacities, amending soil with electron donors, and controlling inputs of alternative electron acceptors can artificially control these processes.

In addition to the oxidoreductases described in the previous paragraphs, enzymes in the hydrolase class are extremely important in peripheral catabolic steps of many organic pollutants. Hydrolases catalyze the hydrolytic cleavage of ester, ether, anhydride, amide, and halogen bonds associated with organic pollutants such as organophosphates, phenoxyacetates, phenylureas, acid anilides, phenylcarbamates, and alkyl halides (Fig. 6). In hydrolytic reactions, the oxygen atom of water replaces hydrogen, chloride, phosphate, sulfate, and amino groups of the organic pollutants. The oxygen atom is usually inserted at similar positions in the molecule as the hydride atom catalyzed by reductases, that is, at electron-deficient central atoms. The products of hydrolytic reactions often resemble the oxidation products generated by oxygenases; however, the incorporated oxygen atoms are derived from water instead of diatomic oxygen. Hydrolytic reactions typically have wide specificity, are constitutive (i.e., always present in the cell), and are active in both aerobic and anaerobic environments. For many organic pollutants in anaerobic environments, hydrolysis is a critical mechanism because the addition of the oxygen atom activates the molecule for further catabolic breakdown, or facilitates expulsion of toxic compounds from the microbial cell. Many hydrolytic enzymes are excreted and catalyze organic pollutant reactions in the extracellular environment, resulting in by-products that may be taken up for microbial use. Heterotrophic aerobic and anaerobic microorganisms produce hydrolytic enzymes as a response to nutrients, suggesting that it

may be possible to manipulate this process through soil amendments (95,96).

CONCLUSION

Wetlands are effective treatment alternatives for conventional pollutants such as nutrients, organic carbon, and total suspended solids (1,8). In recent years, there has been increasing interest in wetland processing of organic pollutants, largely because of the extent of contamination from several point and nonpoint sources. Although excessive nutrient pollution causes eutrophication of wetlands and aquatic ecosystems, organic pollutants can result in additional acute and chronic toxicological effects (12). Organic pollution can be especially tragic because wetlands attract many fish and wildlife species. Documented cases of organic pollutant effects on wetland functioning include the disruption of the aquatic food chain (97–101), bioaccumulation of toxaphene and other chlorinated compounds in turtles, ducks, and fish (102–108), reproductive disorders in alligators from DDT contamination (106), and massive mortality of white pelicans from organochlorine pollution (110). These events emphasize the importance of taking a comprehensive, ecological-based risk assessment approach when attempting to use wetlands to treat organic pollutants (111). Wetland treatment of organic pollutants may be incompatible with the value of wetlands as wildlife habitats (112).

The dominant organic pollutant removal processes in wetlands are sorption to soil and sediment, volatilization through plants and from the water surface, uptake in the plant biomass, and biodegradation by soil microorganisms. Pollutant removal through these processes is highly variable, and depends on the type of compound and environmental conditions in the wetland, such as the extent of organic matter accumulation, nutrient availability, presence of oxygen and electron acceptors, and redox interfaces. However, one set of wetland conditions may be optimum to remove one type of compound, and inhibitory for the removal of another. Therefore, a successful bioremediation strategy must consider the type of wastes, and how mitigation actions might affect other biogeochemical processes in the wetland (e.g., fertilization effects on eutrophication).

Experiments using laboratory microcosms have proved invaluable in elucidating potential detoxification mechanisms in environmental samples. From these results, scientists and engineers have postulated and implemented several remediation strategies. However, several basic questions remain unanswered with respect to understanding organic pollutant biodegradation in wetlands: What microorganisms are involved in degradation? What are the mechanisms and regulators of these processes? What criteria should be used to define when wetland contaminants no longer pose an ecological risk? (113,114). Difficulties in addressing these issues are largely methodological ones. Traditional methods do not contend well with quantifying diverse biochemical processes occurring at microbial scales (1 to 100 μm) in the landscape. Encouragingly, several methods have recently been developed to improve our ability to characterize microbial populations and their activities in the environment (113). Examples of these new methods include extraction and analysis of genetic and other microbial biomarkers (e.g., DNA, mRNA, microbial lipids) and enzyme activities (e.g., laccases, reductases, oxygenases, hydrolytic enzymes). Selective chemical extractants (115) and biosensors (116,117) (genetically engineered microorganisms that respond to environmental pollutants) are being developed to quantify the bioavailability and toxicity of pollutants. These methods are yet to be applied in wetlands or other field habitats. Results obtained using these approaches will probably prove fruitful in establishing process-based remediation, and monitoring programs for contaminated environments in the next decade.

INDEX

A
ABC bacteria, 2471
Abies, ectendomycorrhizal fungi, 2125–2126
Abrasion, biofilms vs., 547
Absicisic acid, 344
Absorption (See also Sorption), biofiltration, 590–591
Acacia, 2785
Acanthamoeba, 2594–2604
  Antarctic soils and, 1026
  biofilms and, 2342–2356
  bottled water and, 800
  desert environment and, 1579
  endosymbiosis and, 1123
  meningoencephalitis and, 1343–1350
  in source water, 2968, 2969–2978
  in spas and hot tubs, 2980–2984
  in wastewater/sewage, 2329–2337
  in water treatment systems, 1718
Acantharian, 2617
Acartia, 972
Acaryochloris, 964
Acaulospora, mycorrhizae, 2120–2124
Acclimation of microorganisms, 713, 2386
Accumulation vs. nonaccumulation, soil salinity, 2781
Acenaphthene, biodegradation, 2403–2416
Acenaphthylene, 696–712, 2403–2416
Acenapthalene, bioremediation, 696–712
Acetalglucosame, 458
Acetate, 2172
  activated sludge and, 741–748
  anaerobic granulation and, 235, 236
Acetic acid, 3147–3155
Acetobacter
  nitrogen fixation and, 2193–2201, 2938
  petroleum reservoirs and, 2430
Acetogenesis, acetogenic microbes
  activated sludge and, 741–748
  biofilms and, 83
  petroleum reservoirs and, 2430
  soil microorganisms and, 2892
Acetohalobium, 1514–1529
Acetoin, alkaliphiles, 228
Acetyl coenzyme A (CoA), 21–26, 683–692
Acetylcholine (ACh), 847
Acetylcholinesterase (AchE), 847
in wastewater/sewage, 3170
Acetylene reduction assay (See Nitrogen fixation in soils)
Achnanthes, 1053, 1054, 1055, 1057–1063
  periphyton and, 2357
  subaerial communities and, 3057–3065
Achromacia, 1337
Achromatium, 3111–3116
Achromobacter, 1200
  biodegradation and, 2386
  granular activated carbon (GAC) filters and, 1490
  heterotrophic bacteria and, 1541–1552
  rhizosphere and, 2717
Acid–base (AB) surface energies, hydrophobicity, 1600–1601
Acid–base levels (See pH levels)
Acid degradation in biodeterioration of mineral materials, 517
Acid mine drainage (See also Biomineralization), 828–832
  acidophilic chemolithotrophs, 677
  algae biotechnology and, 199–200
  biofilms and, 84
  bioleaching and, 633, 640, 642–650
  biomineralization and, 677
  bioremediation and, 709
Acid rain, 2679
Acidaminobacter, activated sludge, 744–748
Acidianus, 1235, 1629–1646, 3144–3147
  Archaea and, 298
  bioleaching and, 632–642, 645–650
Acidic lipids in biosurfactants/bioemulsions, 756–757
Acidification, nitrogen cycle, 2942–2943
Acidimicrobium
  activated sludge foaming and, 3–7
  bioleaching and, 645–650
Acidiphilium, bioleaching, 644–650
Acidithiobacillus
  biodeterioration of mineral materials and, 524
  bioleaching and, 632–650
  weathering, bioweathering and, 3366
Acidobacterium
  desert environment and, 1578
  flooded soils and, 1320
  soil microorganism and diversity in, 533, 538, 539
Acidophiles (See also Extremeophiles), 677, 1235, 2889, 3129
Acidophilic chemolithotrophs, 677
Acidothiobacillus, 881–882
Acidovorax, 3314–3319
  activated sludge and, 71
  granular activated carbon (GAC) filters and, 1490
Acineria, 2595–2604, 2606
Acinetobacter, 499, 757, 1196, 1197, 1855, 1302–1306, 3314–3319
  activated sludge and, 38, 71
  bacterial counts using, 27–29
  biodegradation and, 2407
  biofilms and, 566, 572, 579, 2342–2356
  bioremediation and, 715
  biosurfactants/bioemulsions and, 714–715, 750–770, 1129–1130
  desert environment and, 1578
  extracellular polymeric substances (EPS) and, 1230
  fluorescent studies of, 1835
  gene transfer and, 1413–1415, 1417
  granular activated carbon (GAC) filters and, 1490, 1569–1570
  in groundwater, 1671
  heterotrophic bacteria and, 1541–1552
  infectious airborne bacteria and, 1694–1695
  nosocomial infections and, 2236–2250
  resistance in, 607
  streams and, 3019
  subsurface microbial communities and, 2035, 3065–3071
  in drinking water, 944, 945
Acquired genes, 1446
Acrasiomycota, 2912
Acremonium
  in allergies and illness, 1367–1372
  cold-adapted microorganisms and, 881
  in drinking water, 945
Acridine orange (AO), 1676, 1776–1778, 1949, 2653, 3196
Acrylacylamidase, in soil, 2903–2910
Acrylonitrile, bioremediation, 707
Actinides, 671, 1902
Actinobacteria
  bacterioplankton and, 2524–2526

Actinobacteria (*continued*)
flooded soils and, 1320
soil microorganism and diversity in, 533
Actinocyclus, 1866–1869
Actinomycetes (See also Soil microorganisms), 1, 458, 2549, 2882, 2912
activated sludge foaming and, 1–7,26–43
airborne, 1
Antarctic soils and, 1027
biofilms and, 1083, 2342
desert environment and, 1577
filamentous forms of, in activated sludge, 1293–1306
granular activated carbon (GAC) filters and, 1490
halophiles and, 1506–1512
mycolic acid containing, 3
nonfilamentous, 4
soil microorganisms and, 2889
soil salinity and, 2775
in drinking water, 946
Actinopoda, 2605, 2618
Actinopolyspora, 1506–1512
Actinorhizal Frankia symbiosis, 2208–2209
Actinorhizal symbiosis (See Nitrogen fixation in soils)
Actinorhizosphere, 2714
Activated carbon (See also Granulated activated carbon)
activated sludge and, 44
biofiltration and, 590
biologically active carbon (BAC), 1489, 1491
granular activated carbon (GAC) filters in, 315, 1489–1496
Activated sludge, 738
aeration/oxygenation in, 46, 74–77, 739
aerobic processes in, 44, 46, 77, 79
algal blooms in, 77
amino acids and, 743–744
amoeba in, 2605
anaerobic ammonium oxidation (anammox) in, 11–14, 38, 71
anaerobic processes in, 1313–1314
anaerobic/aerobic storage in EBPR process and, 3011–3013
anoxic processes in, 77, 79, 1313–1314, 3011
astroviruses and detection, 334
ATV guidelines for, 49
bacteria counts in, 69, 70–71, 738–739
bacteriophages and, 360, 381
bacteriovorous ciliates in, 2611
balanced growth conditions in, 3007
Bardenpro reactor for, 77
bioaugmentation in, 40
biofilms and, 44, 51–52, 54, 58
biogas yield from, improving, 746–748
biological nutrient removal (BNR) and, 1313–1314
biological oxygen demand (BOD) in, 49, 50, 745–746
biomass in, 72, 74, 739, 1311, 1315
biosolids and, 738–750
bulking in, 1287–1306, 1306–1315, 2002, 3008–3011
capsular polymers in, 740
carbon dioxide and, 738
cell death and cell lysis in, 745–746
chemical oxygen demand (COD) for, 14–26, 49, 50
chemical pretreatment of, 747–748
ciliates in, 2605–2607, 2610–2611
clarification of, 59
community composition of, 26–43, 68–74, 75
completely mixed batch reactor (CMBR) for, 44, 75–76
completely mixed flow reactor (CMFR) for, 44, 45, 75–76
composting of, 738
configurations systems for, 75–77
contact stabilization in, 76–77
contact zones, contact times in, 1313
contaminants and, 44–45, 46
culturing, 69
Deep Shaft process in, 76–77
denitrification of, 34–38, 49, 58, 77–78
design parameters for, 1313–1314
dewatering of, 54, 59–60, 748
dissolved oxygen (DO) in, 1311
enhanced biological nutrient removal (EBNR) in, 70
enhanced biological phosphorus removal (EBPR), 15, 26, 32, 38–40, 62, 64–67, 78–80, 1311, 1313, 3005, 3011–3013
eutrophication in, 77
exopolymeric compounds in, 739–740
extracellular polymeric substances (EPS) in flocs of, 54
fatty acids in, 741, 744
fermentation in, 741
filamentous bacteria in (See also Filamentous bacteria; Filamentous bulking), 1–7, 69, 70, 1287–1287
flagellates in, 2605, 2611
floc formation in, 5–7, 44, 54–61, 68, 73, 75, 1288–1306, 1306–1315, 2002
foaming in, 1–7, 75, 1287–1306, 2002, 3008–3011
food chain within, 72
functional microorganism groups in, 32–40
G bacteria in, 40, 57, 61–68, 71
glycogen in, 73, 3005
growth rate of microorganisms in, 72
hepatitis viruses and, 1534
history of, 74–75
hydraulic residence time (HRT) in, 49
hydrophobic particles in, 44
hydroxyalkanoates in, 73
identifying microbes in, 70
improvements to, 50–51, 80
improving performance of, 73
International Water Association (IWA) model for, 49
kinetic (internal) induction and, 3007–3008
lipids in, 741
Ludzack Ettiger process for, 78
measuring bacterial activity in, 3342–3345
mechanical pretreatment of, 746–747
metabolic (external) induction and, 3006–3007
methane and methanogenesis in, 738, 740–748
mixed liquid suspended solid (MLSS) ratio in, 54
models of, microbiological basis for, 14–26, 14
Modified UCT process (MUCT) process for, 79–80
nitrification in, 49, 74, 76
nitrifying bacteria in, 34–35
nitrogen removal from, microbiology of, 8–14
nonaqueous phase liquids (NAPLs) in, 44
nucleic acids in, 741, 744
nutrient content of sludge following, 75, 1311
Opercularia in, 2611
oxic contact zone in, 1313
parasitic protozoa in, 2607
pathogenic protozoa in, 2607

pH levels and, 72, 1311
phases of operation in, 46–47
phosphorus removal in (See also Enhanced biological phosphorus removal), 38–40, 77
plant configuration and, 1312–1313
plug flow reactor (PFR) for, 44, 75–76
plug flow reactor with dispersion (PFDR) for, 44, 75–76
polyhydroxyalkanoates (PHA) in, 21–26, 78–80, 3005
polyphosphate accumulating bacteria (PAB), 64–67, 78
polyphosphates in, 73, 3005
polysaccharides in, 741–743
powdered activated carbon (PAC) and, 44
process of, 74–80
proteins in, 741
protozoa and, 2332, 2605–2612
purines in, 741
pyrimidines in, 741
return activated sludge (RAS) in, 75, 79
sampling in, 68–69
sequencing batch biofilm reactor (SBBR) for, 51–52
sequencing batch reactors (SBR) for, 43–54, 75, 2002
settling in, 59, 75, 1306–1315
simultaneous nitrification/denitrification (SND) in, 77
sizing of SBR plants in, 48–49
sludge biotic index (SBI) and, 2609–2611
sludge volume index (SVI) for, 1288
slurry systems for, 51–52
soil slurry sequencing batch reactor (SS-SBR) for, 51–52
solids retention time (SRT) and, 2006
specific bacterial growth rates in, 3344–3345
stabilization of, 738
storage polymers in, 3004–3014
structure of, 738–740
sugars in, 741–743
syntrophic degradation in, 744–745
temperature and, 1311
testate amoeba and, 2610
thermal pretreatment of, 747
total extended filament length (TEFL) in, 1307
toxic chemicals and heavy metals in, 72, 75
unbalanced growth conditions, 3006–3008
University of Cape Town (UCT) process for, 79–80
upflow anaerobic sludge blanket (UASB), 2002
viruses in, 70
volumetric bacterial growth rates in, 3344
waste activated sludge (WAS) in, 738
wastewater/sewage treatment plants and, 739
water in, 740
Wuhrmann process in, 77
zone settling velocity (ZSV) in, 1307
Activity testing, fluorescent probes and, 1783–1784
Acute exposure, toxicity testing, 3220–3221
Acute hemorrhagic conjunctivitis (AHC), 1151
Acute hemorrhagic cystitis, 93–100
Acute respiratory disease (ARD), 93–100
Acutiphycin, 976
Acylated homoseriine lactone (AHL), 567
Acyrthosiphon, 1114–1115
Adamsite (See Chemical warfare)
Adaptation
biochemical, 1195
evolution and, genetic adaptation, 1195
polluted environment and, 1194–1195
soil microorganisms and, 2057
Adenosine diphosphate (ADP), 1125
aerobic respiration and, 149–151
biomass estimation and, 2654
subsurface microorganisms and, 2022
Adenosine triphosphate (ATP), 89, 1125
activated sludge denitrification and, 9–14
aerobic respiration and, 149–151, 154, 157–158
alkaliphiles and, 138–139
assimilable organic carbon (AOC) and, 323
bacterioplankton and, 2521
biodegradation and, 2931
biofilms and formation of, 82, 83
bioluminescence and, 657–663
biomass estimation and, 2654
metal biodegradation and, 1878
oligotrophic bacteria and, 2273
soil microorganisms and, 2883–2884, 2889, 2948
subsurface microorganisms and, 2022
sulfate-reducing bacteria (SRB) and, 3087
wastewater/sewage treatment and, 3338–3339
Adenoviridae, 93
Adenovirus, 92–100, 2745
in spas and hot tubs, 2980–2984
in source water, 2969–2978
Adenylate energy charge (AEC), 2022
Adhesion (See also Biofilms), 113–132
acid–base interactions and, 104–105
adsorption and, 114
atomic force microscopy (AFM) and, 125, 126, 128–129
batch and packed bed systems to study, 118–119
biofilms and, 100–113, 560–561, 612–613, 628–629
bioleaching and, 635–636
boundary layers and, 114
Brownian motion and, 114, 115
centrifugation vs., 116–117
colloidal particles and, 127–128
conditioning films and, 101, 127, 938–939
deposition and, 114, 117–118
Derjaguin Landau Verwey Overbeen (DLVO) theory of, 102–104, 119–122, 124, 561, 2004–2005
diatoms and, 1052–1053
electrostatic interactions in, 103–104,
extracellular polymeric substances (EPS) and, 1224–1225
free energy of adhesion in, 101
heterogeneity of cell and substratum in, 128
hydrodynamic testing for, 117–118
hydrophilic microorganisms and, 100
hydrophobic microorganisms and, 100, 1599–1604
interfacial free energies in, 122–124
ionic strength and, 121–122
laminar flow and, 117
Lifshitz-van der Waals forces in, 101–104, 123, 124, 936, 938
macromolecule formation at interface in, 125–127
marine biotechnology and, 1855–1856
microsphere attachment and, 128

Adhesion (See also Biofilms), (*continued*)
pH levels and, 100, 104–105, 121–122
physicochemical aspects of, 119–124
Reynolds number and, 114
Robbins device for, 118
secondary minimum in, 104
sedimentation and, 114–116
shear stress and, 117
soil microorganisms and, 2062–2063, 2926
static systems for, 115–116
strength of, evaluating, 116–117
study of, methods for, 114–119
substratum interfaces and, 124–129
surface conditions vs., 124–129
surface modification vs., 120–121
van der Waals forces, 119–120, 124
Young equation in, 122–123
zeta potentials and, 100, 119
Adsorption (See also Adhesion; Sorption)
adhesion in biofilms and, 114
aggregates and consortia in, 162
bacteriophages and, into soil, 358, 389
biofiltration and, 590–591
conditioning films and, 937
enteroviruses and, 1169–1170
floc formation and, 57
home water treatment systems using, 1566
Aeolosoma, 1722
Aequorea (See also Green fluorescent protein), 559, 1341,1430, 1831
Aeration/oxygenation, 5–7, 74–77, 2017, 2266
Aerobacter
bioaerosols and, 3321
floc formation and, 2006
heterotrophic bacteria and, 1541–1552
Aerobic alkaliphiles, 133–140
Aerobic bacteria, bioaugmentation and bioremediation, 435
Aerobic bacteriochlorophyll containing (ABC) bacteria, 2471
Aerobic denitrification, activated sludge denitrification, 14
Aerobic endospores, 140–149
Aerobic processes
activated sludge and, 44, 46, 77, 79
aerobic storage in EBPR process and, 3011–3013
aggregates and consortia in, 161
biodegradation and, 2930–2932
explosives biodegradation using, 1987
flooded soils and, 1328
hydrocarbon degradation and, 2404–2411
hyperthermophiles and, 1633
oxygen and, 2277
petroleum reservoirs and, 2427
wetlands and, 3403–3405
soil microorganisms and, 2888
municipal solid waste landfills and, 1759–1762
Aerobic respiration, 149–160
adenosine diphosphate (ADP) in, 149–151
adenosine triphosphate (ATP) and, 149–151, 154, 157–158
chemiosmosis in, 149–151
conservation of energy in, 149–151
cytochromes, cytochrome c pathway in, 153
detoxification in, 151
diversity of respiratory chains and, 155–157
electrogenic protein complexes in, 150
electron transfer and charge separation in, 151, 153–154
F1F0 ATP synthase and, 157–158
Gibbs equation in, 149
heme copper oxidases in, 155
iron–sulfur centers in, 152–153
lipids and, 151–152
lithotrophs and, 151, 157
NADH in, 149–154, 156, 157
nitrifiers and, 151
oxidases in, 154–155
oxidative phosphorylation and, 149–151
oxygen sensing regulatory proteins in, 158
porphyrins in, 153
proton motive force (PMF) in, 150
pyrroles in, 153
Q loop in, 153
quinones and Q pool in, 151–153, 156, 157
regulation of, 158–159
succinate dehydrogenase and, 153, 154
Aeromicrobiology, 3320–3330
Aeromonas, 313, 386, 1091–1099
activated sludge and, 71
biocontrols and, 458
biofilms and, 1209, 2341–2356
bioplastics and, 684–692
bottled water and, 800
as cold-adapted microorganism, 872–885
fecal contamination and, 1271
gene transfer and, 1416
granular activated carbon (GAC) filters and, 1490–1492, 1569–1570
as heterotrophic bacteria, 1541–1552
neuston microbiology and, 2139
in source water, 2969
metal biodegradation and, 1885
Aerophitic microorganisms, 835–843
Aeropyrum, 1234, 3129, 1442, 1629–1646
Aerosol (See Bioaerosols)
Afipia, 1345
Aflatoxins, 182–189, 1375
Agar, 88, 192
Agaricus, 1384, 1983
Agent T (See Chemical warfare)
Aggregates and consortia, 160–181
anaerobic granulation and, 240–241
anoxic processes in, 166
bioaugmentation and bioremediation in, 437
biofilms and, 1213
biofouling and, 601–609
biogeochemical processes, 161, 165–166
carbon dioxide and, 175
characterizing structure and function of, 175–178
coagulation theory and, 162
community composition of, assessment methods for, 175–176
cyanobacteria and, 164–165, 166–168, 170–181
denitrification and, 166
dimethylurea (DMCU) and, 175
dissolved organic matter (DOM) and, 175
ecological roles of, 166
expopolysaccharides (EPS) and, 166
filamentous bacteria and, 164–165
floc formation and, 2001–2002
formation of, 162–166
hypersaline lakes and, 173
hyperthermophiles and, 1642
ice and, 174–175
microbial mats and, 161, 165–166, 170–173
microbial modification of, 164–165
nitrogen fixing bacteria and, 166, 167–181
oxygen and, 175
pH levels and, 175
photosynthesis and, 175

sea and lake ice, 164
sedimentation in, 164–165
soil microorganisms and, 2924–2925
stromatolitic mats and, 172–173
subtropical and tropical oceanic, 168–170
sulfate-reducing bacteria (SRB), 165–166
in surface waters, 928, 928
surficial and benthic habitats, 164
suspended and solid surfaces as microenvironment for, 161, 162–164
temperate marine ecosystems, 170–172
Agriculture, agricultural biotechnology
cold-adapted microorganisms and, 881
coliform bacteria and, 902
enzymes and, 3215
nitrogen fixation and, 2188–2211
rhizosphere and, productivity and, 2722–2723
sustainable, 3116–3126
Agrobacterium, 1385–1392, 3110
biocontrol use of, 425–455, 462, 2700, 2704
biodegradation and, 2396
biofilms and, 1209
bioluminescence in, 1831
floc formation and, 2006
genetically engineered microorganisms (GEMs) and, 1279
microbial insecticides using, 1710
rhizosphere and, 2717
soil salinity and, 2775, 2779–2789
stress response and, 3048
subsurface microbial communities and, 2035, 3067–3071
toxic solvents and, 3151
Agrocybe, explosives biodegradation, 1983
Agroterrorism (See also Bioterrorism), 181, 780–781
Ahermatypic corals, 1117
AIDS/HIV, 1690
activated sludge and, 70
algae biotechnology and, 195
amoebic meningoencephalitis and, 1343–1350
Cryptosporidium and, 652
heterotrophic bacteria and, 1545, 1548
Mycobacterium avium complex (MAC) and, 2114–2120
nosocomial infections and, 2242
Air-handling systems (See also Bioaerosols)
biofiltration and, 593–601
odor control in, 593–601
Air pollution, 181, 588, 782–795
Air sampling, 181
Air sparging, 695
Air stripping, 695
Air–water interface (See also Neuston microbiology), 3274–3275
neuston microbiology, 2133–2144
Airborne microorganism (See Bioaerosols)
Aircraft deicing fluid (ADF), biodegradation, 2930
Alaninebetaine, soil salinity, 2778–2789
Alasan, bioremediation, 715
Albacausuarina, 2124–2132
Alcaligenes, 1058, 1200, 2942, 3110, 3160
activated sludge and, 13–14, 35–38, 3006
bacterial counts of, 32
biocontrols and, 455
biodegradation and, 2386, 2387–2393
biofilms and, 572, 577, 579, 580, 581, 2342–2356
bioluminescence in, 1831
bioplastics and, 689–692
bioremediation and, 705
biosurfactants/bioemulsions and, 714–715, 750–770, 1129–1130
cold-adapted microorganisms in, 872–885
genetically modified microorganisms (GMMs) and, 1431
granular activated carbon (GAC) filters and, 1490
heterotrophic bacteria and, 1541–1552
metal biodegradation and, 1882, 1885, 1889, 1890, 1894
as microbial tracer in groundwater, 3172
municipal solid waste landfills and, 1766
subsurface microbial communities and, 3065–3071
toxic solvents and, 3151
in drinking water, 944
Alcalignin, 1882
Alcanivorax, biosurfactants/bioemulsions, 756
Alcoholic beverages
cold-adapted microorganisms and, 880
Alcohols, 929, 1760, 3147–3155, 3412
activated sludge and, 741–748
alkaliphiles and, 228
biofilms and, 85–86, 582
composting of, 916–917
enzymes and, for fuels, 1185–1186
fungi and production of, 1369, 1385
microbial protection from, 432
ALCOL model, biodegradable dissolved organic carbon (BDOC), 503
Aldehyde, 929, 1046, 3412
Aldehyde-based biocides, biofouling vs., 605
Aldolases, 928
aldoses, biofilms, 85–86
ALEXA dyes, 1676
Alexandrium, harm/in harmful algal blooms (HABs) and red tides, 2686–2693
Algae (See also Algal blooms), 189–205
algal solid phase assay (ASPA) in, 3227–3228
algal turf scrubbing (ATS) and, 213–219
biodeterioration of mineral materials and, 519–522, 524–525
biofilms and, 88, 612–613
bioluminescence in, 657–663
biomass of, 1190
bioremediation and, 196–200
biosorption in, 200
biotechnology, 196–200
blooms of (See Algal blooms)
blue-green (See Cyanobacteria)
cold-adapted microorganisms in, 872–885
culture technology for, 191–192
desert environment and, 1576, 1579
endosymbiosis and, 1115–1116, 1126–1128
eutrophication in, 1189–1194
food products from, 196, 1851, 1857, 2516
grazing vs., 1193–1194
halophiles, 1501–1512
harmful algal blooms (HABs), 2685–2693
high-rate algae ponds vs., 2333
loss functions in, 1193–1194
macrofouling from spores of, 615–616
nitrogen cycle and, 2183
nitrogen fixation and, 1191

Algae (See also Algal blooms), (*continued*)
nutrient concentrations and, 1190, 1191–1194
oxygen and, 2277
paleolimnology of, 2301–2306
periphyton, 2357–2367
Pfiesteria and toxic Pfiesteria complex (TPC), 2431–2447
pH levels and, 1191
phosphorus and, 1190
photoautotrophic, in low-light habitats, 836–843
photosynthetic pigments of, marine, 2453–2470
pigments in, 2306–2317
plankton and, 2502–2518
red tides and, 2685–2693
salt production and, 2805
sedimentation vs., 1193–1194
soil salinity and, 2775
solar radiation and, 1192–1193
streams and, 3020, 3021–3022
subaerial communities and, 3056–3065
temperature and, 1193
toxicity assays using, 3172–3173, 3219–3230
trophic state in, 1190–1191
in wastewater stabilization ponds (WSBs), 3331–3332
water turnover vs., 1193–1194
weathering and, 3364–3389
algal blooms (See also Harmful algal blooms and red tides), 204–213, 2685–2693
activated sludge and, 77
adsorption of by products from, 212
blue-green algae in, 206
causes of, 206–207
control of, 211–212
dinoflagellates in, 205
green algae in, 205
hepatatoxins in, 207
impact of, on water treatment, 207–210
nitrogen and, 206–207
phosphorus and, 206–207
preoxidation vs., 207–208
presedimentation vs., 207
yellow green or golden brown algae in, 206
Algal mats, nitrogen cycle, 2183
Algal solid phase assay (ASPA), 3227–3228
Algal toxicity assays, 3172–3173
Algal turf scrubbing (ATS), 213–219
Alginate lyase, 1211–1223
Alicyclobacillus, bioleaching, 645–650
Alkali environments, alkaliphiles, 219–231, 1235–1236, 1510, 3127–3140
aerobic, 133–140
alkalithermophiles, 3127–3140
ATP synthesis and, 138–139
auxotrophy and antibiotic resistance in, 137
Bacillus as, 220–231
cell wall makeup in, 137
cyanobacteria, 136
flagella and sodium ions in, 138
haloalkaliphiles, 135–136
lipid composition in, 137–138
membrane transport in, 138
pH regulation and, 138, 221
sodium/hydrogen antiporters in, 138
thermoalkaliphiles, 136
yeast and fungi in, 136
Alkaline degradation in biodeterioration of mineral materials, 517–518
Alkaline saline habitats, 1510
Alkalis, 1902
Alkalithermophiles, 3127–3140
Alkalitolerant microorganisms, 133–140
Alkaloids, 195, 975
Alkanes biodegradation, 697–713, 928, 2402–2404, 2411–2412, 3147–3155, 3412
Alkenes biodegradation, 2407–2408, 3412
Alklybenzes bioremediation, 713
Alkoxysiloxanes, in biodeterioration of mineral materials, 518
Alkylaromatics biodegradation, 1423–1429
Alkylbenzene composting, 916–917
Alkypyridines bioremediation, 707
Allergic bronchopulmonary aspergillosis (ABPA), 1363
Allergies and allergens (See also Bioaerosols; Spores and spore dispersal), 338
antibodies and, 1359–1366
enzyme linked immunoassay (ELISA) and, 1361
fungal, 1359–1383
immunoglobulin E (IgE) and, 1359–1366
major histocompatiblity class (MHC) and, 1360
radioallergosorbent (RAST) assay and, 1361
sensitization in, 1360, 1368–1369
T helper cells and, 1359–1366
volative organic compounds (VOCs) and, 1366–1383
Allochromatium, 2476
Allochthonous (See also Oligotrophic bacteria), 2268, 2347–2353, 2428
Allolevivirus, 364–374
Allorhizobium
endosymbiosis and, 1120
nitrogen fixation and, 2201–2211
soil salinity and, 2775, 2785
Alloxanthin, in paleolimnology, 2307–2317
Alnus, 2912
mycorrhizae and, 2124–2132
nitrogen fixation and, 2208, 2209
Alpha amylases, alkaliphiles, 223–224
Alphaglycerylglucose, 518
Alternaria, 1650, 1651, 1653
in allergies and illness, 1361–1366, 1367–1372
bioaersols and, 404–405
desert environment and, 1579
explosives biodegradation and, 1983
metal biodegradation and, 1885
in permafrost, 2369
spores and spore dispersal in, 405, 408, 409–510
subaerial communities and, 3057–3065
Alteromonas, 1610, 1851, 2550
Altrose, biosurfactants/bioemulsions, 756
Aluminum, 928, 1880–1893
Alvinella, 1118, 1609–1610, 1619–1620, 3090–3096
Amanita, 2124–2132
Amaricoccus, 61–63, 66
Ambient temperature catalytic oxidation, biofiltration, 587
Amebiasis, Entamoeba, 1136–1146
Americium, 1879–1893
Amidase, in soil, 2903–2910
Amides, 929
biomineralization and, 671
conditioning films and, 937–938
in surface waters, 928
Amidohydrolases, 1185
Amines, 671, 929
Amino acids, 2716
activated sludge and, 743–748
biofilms and, 85–86
microbial protection from, 432
soil salinity and, 2778–2789
Aminobenzene biodegradation, 2297–2300
Aminocyclopropane (ACC) biocontrols, 455
Aminohexanoate bioremediation, 693
Aminomethylcoumarin, 1676
Aminophenol biodegradation, 3413
Amitrole bioremediation, 705–712

Ammonia/ammonium, 1760
activated sludge denitrification and, 8–14, 20
activated sludge processing and, 24–26
anaerobic ammonium oxidation (anammox) in, 11–13, 24, 38, 71, 2146, 3145
anaerobic ammonium oxidizing bacteria in, 38
anoxi metabolism of, 9–11
bioaugmentation and bioremediation in, 435
biofilms vs., 582
biofiltration vs., 598
bioremediation and, 694, 707–708
heterotrophic ammonia oxidation, 13
in marine/ocean environment, 1698–1701
nitrification and, 2144–67, 2167–2176
nitrifying bacteria in, 34–35
nitrogen cycle and, 2176–2188, 2939
nitrogen fixation and, 2188–2221
oxidation of, 9
in wastewater stabilization ponds (WSBs), 3332
water treatment systems and, 2167–2176, 2167
weathering, bioweathering and, 3367–3368
Ammonia monooxygenase (AMO), 2145–2167
Ammonia oxidizing bacteria (AOB), 2144, 2167–2176
Ammonification, 2939
Ammonium nitrogen, activated sludge denitrification, 8–14
Amnesic shellfish poisoning (ASP), 2687
Amoeba (See also Protozoa), 2594, 2605
biofilms and, 2342
bottled water and, 800
desert environment and, 1579
Entamoeba and, 1136–1146
free-living, 1343–1350
heterotrophic bacteria and, 1540
lobose, 2616, 2617
marine/ocean environment and, 2616, 2617
meningoencephalitis and, 1343–1350
testate, 2610
Amoebobacter, 2527
Ampelomyces, 452, 454
Amphidinium, 1126, 2805–2809
Amphileptus, 2606
Amphipods, algal turf scrubbing (ATS), 215
Amphiphora, 1058, 2839
Amphora, 1053, 1055–1063
biofilms and, 612
salt production and, 2805–2809
Amplification fragment length polymorphism (AFLP), 443
Amplified rDNA restriction analysis (ARDRA), 299, 536–537, 2737–2738, 2920
Amylase, 223–224, 1177–1189, 2903–2910, 3170, 3207–3210
Amylopectin, 1181
Anabaena, 206, 207, 210, 961, 966, 972, 973, 980, 984–995, 1191, 1193
aggregates and consortia in, 167–168
meroplankton and, 1868–1869
metal biodegradation and, 1879
nitrogen fixation and, 2193–2201, 2201–2211, 2214–2221
paleolimnology of, 2302–2306
in permafrost, 2369
in wastewater/sewage, 3172
Anabolic processes, biofilms, 81
Anacystis, 972
algae biotechnology and, 196
cold-shock response and, 888–895
metal biodegradation and, 1879
Anaerobic ammonium oxidation (anammox) 11–13, 24, 38, 71, 2146, 3145
Anaerobic ammonium oxidizing bacteria, activated sludge, 38
Anaerobic bacteria
activated sludge foaming and, 6–7
bioaugmentation and bioremediation in, 435, 439
Clostridium and, 861–871
cyanobacteria and, 965–966
halophiles and, 1512–1529
sampling of, 827–828
subsurface microbial communities and, 3069–3070
Anaerobic granulation, 232–245
chemical oxygen demand (COD), 243
colonization and, 241–243
consortia in, 240–241
extracellular polymers (ECP) and, 238, 242–243
fermenting bacteria and, 239–240
filamentous bacteria in, 240
hydrophobicity in, 238, 241
layered structures in, 234–237
metabolic activity zones in, 238
methanogens and, 238
microbial composition of, 232–234
microcolonies in, 237–238
nonlayered structure in, 237
nuclei in, 238–241
sludge structure and, 234–238
species specific interaction in, 241–242
start-up procedures for, 243–244
syntrophy in, 240–241
volatile fatty acids (VFA) and, 235, 242–243
Anaerobic migrating bed reactor (AMBR), 232–245
Anaerobic oxidation, activated sludge denitrification, 10–14
Anaerobic oxidation of methane (AOM), 288–289
Anaerobic processes
activated sludge and, 21–26, 1313–1314
aggregates and consortia in, 161
anoxic storage in nitrogen removal processes and, 3011
biodegradation and, 2932–2933
explosives biodegradation using, 1983, 1985–1987
flooded soils and, 1319–1321, 1327–1328
granulation (See Anaerobic granulation), 232–245
hydrocarbon degradation and, 2411–2413
hyperthermophiles and, 1633
municipal solid waste landfills and, 1759–1762
nitrification and, 2146–2147
oxygen and, 2277
petroleum reservoirs and, 2427
in sediments and sedimentation, 2844–2845
soil microorganisms and, 2888, 2891–2893
sulfate-reducing bacteria (SRB) and, 3092
wetlands and, 3403–3405
Anaerobic respiration, 149
cold-adapted microorganisms, 872–885
Anaerobic sequencing bed reactor (ASBR), 232–245
Anaerobranca, 1236, 3130, 3132, 3134–3135
Anammox, 11–13, 24, 38, 71, 2146, 3145
Anatoxin, 976, 987–995, 2340
Ancylonema, 2835–2844
Ancylostoma, 3333–3334
Anaerobic respiration, 149
Anhydrobiosis (See also Desiccation), 245, 1030–1031
Animal and Plant Health Inspection Service (APHIS), 2704–2707

Animal feed, enzymes, 1188
Anisakis, in food, 3277–3287
Anisonema, 2841
Ankistrodesmus, 205
Annelida, 1117, 1722
Annotation, in genomic sequencing, 1442–1443
Anodic depolarization, sulfate-reducing bacteria (SRB), 472–475
Anodontia, 1606
Anolytes, biofouling, 604
Anopheles, 3399
Anoxic environments/processes
  activated sludge and, 77, 79, 1313–1314
  activated sludge and, 77, 79
  aggregates and consortia in, 166
  metabolism in, activated sludge denitrification and, 9–14
  protozoa and, 2596
Anoxygenic bacteria, 2892
Anoxygenic photosynthesis, 2280–2282
Antagonism, in biofiltration, 591
Antarctica
  cold-adapted microorganisms and, 1103
  cyclic climatic events and, 2558–2559
  endolithic microorganisms in, 1100–07
  hypersaline lakes in, 1510
  lichens in, 1101–1106
  marine/ocean environment of, 2557–2558
  mineral resources of, 1026
  nitrogen cycle and, 2182
  organic matter in soils of, 1025
  ozone hole and, 2564–2565
  permafrost and, 2367–2385
  physical characteristics of, 1023–1025
  psychrophilic bacteria and, 2639–2646
  salt content of soils in, 1027
  sea ice microorganisms, 2833–2844
  soil composition in, 1024–1025, 1104
  soil microbes in, 1023–1029
  solar radiation and, 1025, 1103
  temperatures in, 1103
  water and, 1024, 1104
"Antenna effect," biofilms, 560
Anthomedusa, 1116
Anthozoa, 1116
Anthracene biodegradation, 696–712, 917, 2404
Anthrax (See also Bioterrorism), 245, 771–782, 1689–1697
Antibiosis, biocontrols, 456
Antibiotics (See also Resistant bacteria)
  alkaliphiles vs., 137, 228
  bacteria-produced, 456–457
  biocontrols and, 456–458
  fungal produced, 457–458
  fungi and production of, 1369
  microbial protection from, 432
  microgravity and, 3001
  neuston microbiology and, 2139
  resistance to (See Heterotrophic bacteria; Nosocomial infections; Fecal contamination; Resistant bacteria)
  rhizosphere and soil microbes in, 347–348
Antibodies
  in allergies and illness and, 1359–1366
  fluorescent probes and, 1781
  rhizosphere and soil microbes in, 351
Anticancer agents, fungi production, 1369
Antifoam agents, for activated sludge, 6–7
"Antifreeze" Pseudomonas, 2694–2695
Antimicrobials, 195, 556–557

Aplysiatoxin, 976
Aposymbiosis, 1113
Appendages, in soil microorganisms, 2885–2886
Apple scab spore dispersal, 413
Aquabacterium, 572
Aquaculture, 1850, 1856–1857, 1859, 3215
Aquareovirus, 2753–2773
Aquaspirillum
  activated sludge and, 3009
  nitrogen fixation and, 2193–2201
  psychrophilic, 2640–2646
Aquatic biofilms, 1216
Aquatic ecosystems (See also Marine/ocean environment; Surface waters)
  bioremediation and, 712–722
  Enterococci in, 1264–1278
  fecal contamination in, 1256–1264
  lipid biomarkers of and, 1821
  nitrification in, 2144–2167
  proteomes and proteins in, 306–307
  Streptococci in, 1264–1278
Aquifers, 245
  Atlantic Coastal Plain, 2028–2042
  bioaugmentation and bioremediation in, 440–441, 507, 695
  lipid biomarkers of, 1821
  microbial communities of, 1661–1673
  protozoa and, 2595–2596, 2599–2602
  sparging, 695
Aquifex, 1233, 1235, 1442, 1512–1529, 1629–1646, 3128–3140, 3143–3147
Aquificales, 1512–1529, 1614, 1629–1646, 3143–3147
Arabidopsis
  bioplastics and, 689–692
  genomic studies and, 1442
  microarray study of, 1973
Arabinases, 1187
Arabinose, 2716
Arachidonic acid (AA), cold-adapted microorganisms, 880–881
Arbuscular mycorrhizae (See also Mycorrhizae), 245, 2120, 2126
arbutoid mycorrhizae, 2126
Arbutus, 2124–2132,
Arcella, 2605
Archaea, 246–259, 2552
  biodeterioration of mineral materials and, 523
  bioleaching and, 634–642
  genomic studies and, 1440
  sulfate-reducing bacteria (SRB) and, 467–475
  Amplified ribosomal DNA restriction analysis (ARDRA), 299
  anaerobic granulation and, 236–245
  anaerobic oxidation of methane (AOM) and, 288–289
  autotrophism in, 266
  bacterial artificial chromosome (BAC) and, 299

bacterioplankton and, 2519
biocatalysis and, 259–276
biomass estimation and, 266, 2658
biomining and metal ion extraction using, 274
biotechnology using, 259–276, 290–291
cell envelope of, 248–256
cell wall structure of, 248
coenzymes and, 256–257
compatible solutes and, 273
culturing of, 246–247
denaturing gradient gel electrophoresis (DGGE) and, 278, 299
desert environment and, 1578
detection of, 246–259, 278–288
diversity of habitats for, 260–262, 276–285
ecophysiological attributes of, 288–280
Entner-Doudoroff pathway and, 262
enzymes and, 259–276
extraction and processing of, 252
fermentation and, 259–276
fluorescent in situ hybridization (FISH) and, 279, 301
Fourier transform infrared (FTIR) spectroscopy and, 257
gas chromatography (GC) and, 253–255
genome sequencing of, 263–266, 290–291, 1443–1446
in groundwater, 1671
halophiles as, 246–259, 262, 277–293, 297–298, 1512–1529
heteropolysaccharides in, 249
high performance liquid chromatography (HPLC) and, 252–253
hydrogen production and, 273–274
at hydrothermal vents, 278, 287–289, 293, 1611, 1622–1628
hyperthermophiles as, 246–259, 266, 277–293, 1629–1646
lipids and, 249–259, 271–272, 279–293
marine environment and, 276–283, 289–290
marine sediments containing, 285–287
metal biodegradation and, 1890
methane and, 256, 259–276, 296–297
methanochondroitin in, 248–249
methanogens as, 246–259, 262, 263, 277–293, 296–297, 1913–1914, 1916
molecular culturing techniques for, 247–248
nanotechnology and, 273
nitrogen fixation and, 2212–2221
noncultured approaches to sampling in, 299
oligotrophic bacteria and, 2268
origins and evolution of, 291
phospholipid ether liquid (PLEL) in, 252
photosynthetic pigments in, 2464
phylogenetics of, 259–260, 295
plankton and, 279–285, 288
proteins of, 263
pseudomurein in, 248
psychrophiles as, 246–259, 262
quinones and, 256
rhizosphere and, 300–301
seasonal variation in marine environment, 281–285
single-strand conformational polymorphism (SSCP), 299
small subunit ribosomal RNA (SSU rRNA) and, 278, 295, 301
soil habitats of, 293–305, 2880–2886
soil salinity and, 2776
stress response in, 3024–3034
sulfate-reducing (See Sulfate-reducing bacteria)
sulfolobales and, 298–299
sulfur dependent anaerobic methane oxidation and, 288–289
supercritical fluid chromatography (SFC) and, 255–256
surface (S) layers in, 248, 272–273
taxonomy of, 295
temperature gradient gel electrophoresis (TGGE), 299
terminal fragment length polymorphism (T-RFLP) and, 278, 299
thermoacidophiles as, 246–259, 261
thermophiles as, 246–259, 277–293, 3140–3147
thermoplasmales and, 297
thermoproteales in, 298
thin layer chromatography (TLC) and, 251
uncultured, accessing genomes of, 262–263, 299–301
Archaebacteria, 246–259
Archaeoglobales, 287, 1614, 1630–1646
Archaeoglobus, 1233, 1235, 1622–1628, 1630–1646, 3114–3116, 3144–3147
genetically altered, in biotechnology, 1448
hydrothermal vents and, 1611
metal biodegradation and, 1905
sulfate-reducing bacteria (SRB) and, 467–475, 3090–3096
Archezoa hypothesis, endosymbiosis, 1124–1125
Archianium, 1578
Arcobacter
diazotrophy in, 2541–2547
disinfection and, 1065
hydrothermal vents and, 1609–1610
Arctic and Arctic Ocean, 2556–2558
cyclic climatic events and, 2558–2559
permafrost and, 2367–2385
sea ice microorganisms, 2833–2844

Arsenic
algae biotechnology and, 196
biomineralization and, 671–681
bioremediation and, 694, 708
metal biodegradation and, 1888
microbial methylation of, 1885–1886
Arsenite bioremediation, 708
Arsenophonus, 1115
Artemia, 1031, 1513–1529, 2805–2809
Arthrobacter, 757, 1102–1106, 2549, 3314–3319
activated sludge and, 3009
biodegradation and, 1044, 1047–1048, 1996, 2387–2394, 3412
biofilms and, 572
biomineralization and, 675
biosurfactants/bioemulsions and, 714–715, 750–770, 1129–1130
cold-adapted microorganisms in, 872–885

Arthrobacter, (*continued*)
cold-shock response and, 892
desert environment and, 1578, 1580–1584
genetically engineered microorganisms (GEMs) and, 1425
granular activated carbon (GAC) filters and, 1490
identification of isolates in, 1964
metal biodegradation and, 1890, 1904
oligotrophic bacteria and, 2269, 2272
subaerial communities and, 3057–3065
subsurface microbial communities and, 2023, 3065–3071
Arthrobotyris, 455, 2913, 3360
Arthroconidia, 1647
Arthrospira, 170–172
Artificial neural network (ANN) (See also Neural networks), 1008–1009
Artificial recharge, vadose zone microbiology, 3242
Artificial substrata, periphyton, 2358
Artificial wetlands, 2333, 3389–3401
Aryl halide biodegradation, 1238–1252
Arylesterase, in soil, 2903–2910
Arylsulfatase, in soil, 2903–2910
Arylthioallkymaleimides, 605–606
Ascaris
in food, 3277–3287
in wastewater stabilization ponds (WSBs), 3333–3334
in water treatment systems, 1718
in wetlands for wastewater treatment, 3399
Ascomycetes, 406, 1359, 1394–1400
Ascomycota, 1367–1372, 1647, 2913–2914, 3353–3364
Ascomycotina, 2124–2132
Ascophyllum, 198, 199–200
Ascospores, 412–414, 1647
Asellus, asellidae, 1722–1723, 3021
Asenophonus, 1122
Aseptic meningitis, enteroviruses, 1151
Asparaginase, in soil, 2903–2910
Aspartame, 1185
Aspergillus, 182–189, 423, 1130, 1647, 1648, 1650, 1651, 1653–1654, 2649
in allergies and illness, 1359, 1362–1383
bioaerosols and, 3325
biocontrol use of, 2703, 2705
biodegradation and, 2386
biofilms and, 580, 1177, 2342–2356
bioleaching and, 635
cold-adapted microorganisms and, 880
composting and, 916
desert environment and, 1579
detection of, 1133
explosives biodegradation and, 1983
metal biodegradation and, 1886
mineral materials biodegradation and, 518
municipal solid waste landfills and, 1766
nitrification and, 2149
nosocomial infections and, 2245
radioactive waste degradation and, 2666–2674
rhizosphere and, 2718
soil microorganisms and, 2881
spores and spore dispersal in, 408, 412, 418, 421, 422
subaerial communities and, 3057–3065
in drinking water, 945
Asphaltene biodegradation, 696–712, 2403–2416
Aspidisca, 2608, 2595–2604, 3173
Assimilable organic carbon (AOC), 312–327, 485–507
adenosine triphosphate (ATP) and, 323
BDOC vs., 323–324
biodegradable dissolved organic carbon (BDOC) and, 485–507
biofilm formation rate (BFR) and, 324–325
biofilms and, 88
biological stability of, 323–325
concentration of, in water, 319–323
filtration vs., 321–322
growth measurement and calibration curves in, 318–319
heterotrophic plate count (HPC) for, 322–323
materials in contact with water and, 325
in source water, 2972
storage of water and, 322–323
tests for, 316–319
water treatment assessment of, 312–327, 1729
Assimilatory sulfate reduction, 3087, 3107
Associative symbiosis, nitrogen fixation as, 344, 2199–2200
Astaxanthin, 193, 1852, 2307–2317, 2307
Asterionella, 206, 210
Asterionellopsis, 2506
Asthma, fungal allergens, 1359–1366
Astraeus, 2124–2132
Astroviruses, 327–337
in source water, 2969–2978
in spas and hot tubs, 2980–2984
streams and, 3017
Atlantic Coastal Plain
aquifers of, 2028–2042
subsurface microbial communities of, 3065–3066
Atmosphere and microbes, 2061, 3183–3194
Atomic force microscopy (AFM)
adhesion in biofilms and, 125, 126, 125, 128–129
bioleaching and, 635
conditioning films and, 935–936
floc formation and, 2008
ATP-based assays, in wastewater/sewage, 3171
ATP binding cassette (ABC), 1208, 2781
ATPases, in wastewater/sewage, 3170
Atractella, photoautotrophic, in low-light habitats, 838–843
Atrazine biodegradation, biodegradation, 705–712, 921–922, 2289–2300, 2391–2396
Atriplex, 1511, 1577
Attachment, biofilms, 2088
Attachment system, filtration, for microbes, 2708
ATV guidelines, activated sludge, 49
Aulacoseira, 1864–1869
Aureobasidium, 121, 422, 2649, 3057–3065, 3360
Aureococcus, harm/in harmful algal blooms (HABs) and red tides, 2689–2693
Auricula, 1055
Auroeumbra, harm/in harmful algal blooms (HABs) and red tides, 2689–2693
Auto-associative neural networks, 1007
Autochthonous microorganisms, 1583, 2342–2343
Autotransporter pathway, 1208–1210
Autotrophs
activated sludge and, 18–26
Archaea and, 266
bacterioplankton and, 2521
biodeterioration of mineral materials and, 523

biofilms and, 81–82, 2341
hyperthermophiles and, 1633
nitrification and, 2144–2145, 2940–2941
Auxins, 344, 454
Auxotrophy, alkaliphiles, 137
Available dissolved organic carbon (ADOC), biofilms, 1086–1087
Aviadenovirus, 93
Axial filaments, 2885
Axinella, 539
Axisymmetric drop shape analysis, in biosurfactants/bioemulsions, 762
Azoarcus, 2282
bacterial counts of, 32
flooded soils and, 1328
nitrification and, 2149
nitrogen fixation and, 2193–2201
subsurface microorganisms and, 2035
Azobacter
aerobic respiration and, 151, 154
aggregates and consortia in, 164
nitrogen fixation and, 2212–2221
Azocarbonamide, 1186
Azogreen wheat, 351
Azolla, 973, 1119, 2196, 2201–2211, 2938
Azorhizobium, 2720
endosymbiosis and, 1120
nitrogen fixation and, 2201–2211
soil salinity and, 2775
Azospirillum, 345–354, 1118, 2720
flooded soils and, 1318
genetically modified microorganisms (GMMs) and, 1431
metal biodegradation and, 1880
nitrogen fixation and, 344, 2193–2201, 2938
resistant bacterial strains in, stress response, 349
soil salinity and, 2775, 2779–2789
subsurface microbial communities and, 3067–3071
Azotobacter, 347, 1924–1936, 2282, 2720
biofilms and, 1221
diazotrophy in, 2541–2547
floc formation and, 2006
nitrogen fixation and, 344, 2190–2191, 2193–2201, 2938
resistant bacterial strains in, stress response, 349
rhizosphere and, 2717
soil salinity and, 2775, 2779–2789
subaerial communities and, 3057–3065
Azpoarcus, nitrogen fixation, 2193–2201

B

Bacillariophyceae, 206
photoautotrophic, in low-light habitats, 837–843
photosynthetic pigments in, 2467
polar phytoplankton and, 2556

activated sludge and, 35–38
aggregates and consortia in, 166
alkaliphiles and, 133, 134, 135, 137, 139, 220–231
alkalithermophiles and, 3127
bioaerosols and, 3325
biochips, biochip testing, 449
biocontrols and, 452, 455, 457, 462, 2700, 2703
biodegradation and, 1045
biodeterioration of mineral materials and, 518, 523
biofilms and, 82, 577, 579, 580, 1177, 1209, 1210, 1215, 2342–2356, 2960, 2962, 2963
bioleaching and, 635
bioluminescence in, 1831
biomineralization and, 673, 674
bioplastics and, 683–692
biosurfactants/bioemulsions and, 757–759, 766
bioterrorism and (See Anthrax)
cold-adapted microorganisms in, 872–885
cold-shock response and, 885–895
composting and, 915
desert environment and, 1578, 1580, 1583
desiccation and, 1033–1041
detection of, 1133, 1134
enzyme activity and, 2902
extracellular polymeric substances (EPS) and, 1229
flooded soils and, 1319
fluorescent studies of, 1834
gene transfer and, 1409, 1413–1415
genetically modified microorganisms (GMMs) and, 1431, 1447
genomic studies and, 1448
glutaraldehyde vs., 605
granular activated carbon (GAC) filters and, 1490
in groundwater, 1671
halophiles and, 1505–1512, 1505
high hydrostatic pressure (HHP) vs., 1559–1563
hydrothermal vents and, 1611, 1620–1628
infectious airborne bacteria and, 1689–1697
measurement of, using aerobic endospores, 143–149
metal biodegradation and, 1881, 1884, 1886, 1890, 1897, 1905, 1908
as microbial tracer in groundwater, 3198
microbial insecticides using, 1710, 1711–1712
microgravity and, 2998, 3002
municipal solid waste landfills and, 1766
nitrification and, 2146, 2149
nitrogen fixation and, 2214–2221
oligotrophic bacteria and, 2270
radiation and, 2987, 2992–2995
resistant bacterial strains in, stress response, 349, 607
rhizosphere and soil microbes in, 346
soil microorganism and diversity in, 533
soil salinity and, 2775, 2779–2789
stress response and, 3048, 3050–3051
subaerial communities and, 3057–3065
subsurface microbial communities and, 2024, 2032, 2035, 3067–3071
toxic solvents and, 3151
ultraviolet light and, 3231
viable but not culturable (VBNC) phenomenon and, 3251
in wastewater/sewage, 3172, 3173
in drinking water, 945, 946, 2266
in wetlands for wastewater treatment, 3400
Bacillus pertussis, biochips, biochip testing, 448
Bacillus thuringiensis, 417, 449, 450, 1279, 1434, 1437, 1448, 1710–1717, 2058, 2693, 2699, 2700, 2701
Back siphon, cyanobacteria, 943
Backwash water
biodegradable dissolved organic carbon (BDOC) and, 496
filtration and, 2707

Backwash water (*continued*)
protozoa remaining in, 2262–2267
BacTech process, for bioleaching, 647–648
Bacteria
activated sludge and 70–71,75
antibiotics produced by, 456–457
as biocontrol agents, 454–455
biodegradation and, 2386
biodeterioration of mineral materials and, 523
biofilms and, 551–559
bioluminescence in, 657–663
bottled water and, 795–801
cold-adapted microorganisms in, 872–885
desert environment and, 1577
hydrothermal vents and, 1620–1622
infectious airborne bacteria as, 1689–1697
lytic enzymes produced by, 458
in metal stressed environment, 1893–1901
as microbial tracers in groundwater, 3194–3202
microbial insecticides using, 1711–1712
photosynthetic pigments of, marine, 2453–2470
salt production and, 2805–2809
sea ice and, 2838
snow/in snow and ice environments, 2874
soil microorganisms and, 664–665
soil salinity and, 2775
in spas and hot tubs, 2979
streams and, 3017–3020
stress response and, 3034–3046
subaerial communities and, 3057–3065
in wastewater/sewage treatment, 3337
in wastewater stabilization ponds (WSBs), 3330–3331, 3334–3336
water purifiers vs., 1572–1573
weathering and, 3364–3389
Bacteria
bacterioplankton and, 2519, 2524–2526
bioleaching and, 634–642
halophiles and, 1514–1529

disinfection and, 341–342
fungal contamination and, 342
general living areas, 340
hazard analysis and critical control point (HACCP) concept, 342
home water treatment units and, 1573–1575
hygiene practices vs., 342
illness studies and, 341
kitchens and, 338–340
pathogens in, 340
sampling techniques for, 338
species found in, 338, 339
sponges, rags, fabrics, 340
viral contamination and, 342
Bacterial counts, 26–43, 2653
activated sludge and water treatment plants, 26–43, 69
aerobic endospores used in, 141–149
biofilms and, 565–566
flow cytometry and, 1948–1950
subsurface microorganisms and, 2031
wastewater/sewage treatment and, 3338
Bacterial phytostimulators (See Phytostimulators, bacterial; Rhizosphere)
Bacteriastrum, 2506
Bactericides, biofouling vs., 602–609
Bacteriochlorophylls, 2453–2470, 2473
Bacteriogenic iron oxides (BIOS), 1407
Bacteriome, 1114
Bacterioneustons, 2133, 2135–2140
Bacteriophages and coliphages, 363–374, 379–380, 384–385, 914, 2101
activated sludge and, 70, 360, 381
adsorption into soil of, 358, 389
aerosol samples and, 382
aggregation of virus particles and, 389
bacterioplankton vs., 2531–2532
Bacteroides fragilis-infecting bacteriophages as, 356–358, 378–379
biofilms and, 2342
biology of, 363–374
capsid of, 364
coliphages as, 363, 379–380, 384–385
colorimetric detection of, 381
detection methods for, 359–360, 374–384
ecology of, 385–387
enteric bacteria and, 384–392
enteroviruses and, 363–364, 384–385
F-specific RNA bacteriophages as, 356
fecal contamination and, 1257
gene amplification detection in, 383
genetics of, 363–374, 382–383
groundwater and, 375–377
heat treatment vs., 361, 387
inactivation of, 358–359
index use of, 356–358
indicator organism use of, 354–363
Information Collection Rule (ICR) protocol for, 376
ISO method for, 376–378
lambdoid phage, 370–373
lytic vs. lysogenic state in, 371–373
membrane filtration (MF) method for, 375–376
as microbial tracers in groundwater, 3194–3202
microbial activity vs., 387
molecular detection methods for, 382–383
MS2, 368–370, 387, 389–390
nucleocapsid of, 364
organic matter vs., 389–390
pathogen transport models and, 385
pathogenesis of, 366–367
persistence of, in environment, 387–390
pH levels and, 387–389
pollution index use of, 357–358
radiation vs., 360–361
removal and inactivation of, in nature, 358–359
RNA and DNA of, 367–373
salt levels vs., 389
sampling of, 376–381
sedimentation and, 358
in shellfish, 361, 382
soil properties vs., 389
soil recovery of, 381

somatic coliphages, 355–356, 377–378
in source water, 2974
structural units of, 364
taxonomy of, 364–366
temperatures vs., 387
U.S. EPA sampling methods for, 379–380
viral index use of, 357
virion of, 364
virus type vs., 389
wastewater treatment vs., 359
water treatment systems and, 359–360, 375–377
Bacterioplankton (See also Plankton and phytoplankton), 392, 2519–2539
abundance of, 2528–2530
adenosine triphosphate (ATP) and, 2521
Archaea in, 2526
autotrophs in, 2521
Bacteria of, 2524–2526
binary fission reproduction in, 2519
biodiversity of, 2524, 2526–2528
biomass of, 2520, 2528–2530
carbon fixation in, 2521–2523, 2533
cell wall in, 2519
chemoautotrophs in, 2521
chemolithoautotrophs in, 2522
colonies in, 2520
distribution of, spatial and temporal, 2526–2528
DNA/RNA analysis of, 2523–2524
ecological significance of, 2532–2534
electron use in, 2522
energy conservation in, 2521–2523
extreme environment and, 2526
flagella in, 2520
fluorescent in situ hybridization (FISH), 2524
food web and, 2534–2535
grazing in, 2531–2532
growth rate of, 2529–2531
habitats for, 2520–2521
heterotrophs in, 2521
light and solar radiation in, 2520
lipids in, 2519
metabolism in, 2526–2528
mortality in, 2531–2532
nitrogen cycle and, 2525, 2533–2534
nucleoid in, 2519
nutrients use by, 2520, 2521–2523, 2530–2531, 2532–2534
organic matter and, 2530–2531
oxygen use by, 2520, 2521–2522, 2530–2531
oxygenic photoautotrophy in, 2522
phosphorus cycle and, 2534
photoheterotrophs in, 2522
photolithoautotrophy in, 2522
photosynthesis in, 2521
polymerase chain reaction (PCR) and, 2523
predators of, 2531–2532
research questions/issues in, 2535–2536
salinity of water and, 2520
sixteen/16S RNA and, 2523–2524
taxonomy of, 2523–2524, 2526–2528
temperature and, 2520–2521, 2531
transduction and, 2532
viruses and bacteriophages vs., 2531–2532
Bacteriorhodopsins, 1505, 2464, 2470
Bacteriostatic filters, 1570–1572
Bacteriovorous ciliates, 2611
Bacterium, 2386
Bacterium salmonicida (See Aeromonas)
Bacteroides
cold-adapted microorganisms in, 872–885
coliform bacteria, 895–905
endosymbiosis and, 1122
fecal contamination and, 1256–1257
filamentous forms of, in activated sludge, 1302–1306
flooded soils and, 1320
halophiles and, 1506–1512
municipal solid waste landfills and, 1766
soil microorganism and diversity in, 533, 539
subsurface microorganisms and, 2035
Bacteroides fragilis-infecting bacteriophages, 356–358, 374–384
Baetis, 3020
Baeyer–Villiger monooxygenase (BVMO), 2290
Bailers, 2815
Balamuthia, meningoencephalitis, 1343–1350
Balantidium, 2712, 2980–2984
Balanus, biofilms, 614
Bank infiltration, 2014–2015
Bardenpro reactor for activated sludge, 77
Barron, George, 2914
Basaltic rock
lithotrophs and, 1826–1828
subsurface microbial communities and, 3065
Basidiomycetes, 1027, 2646–2647
Basidiomycota, 1367–1372, 1647, 2914, 3353–3364
Basidiomycotina, 2124–2132
Basidiospores, 412–414, 1647
Batch reactors for bioremediation, 695
Batch systems, adhesion in biofilms and testing, 118–119
Bathrooms, bacteria in home/residential environment, 340
Bathymodiolus, 1606, 1619
Bdellovibrio, 561, 1084
Beauveria
alkaliphiles and, 227–228
in allergies and illness, 1368–1372
microbial insecticides using, 1710
Beetles, bioluminescence, 657–663
Beggiatoa, 2284–2285, 3098–3104, 3111–3116
Archaea and, 286
filamentous forms of, in activated sludge, 1301–1306, 1310
hydrothermal vents and, 1610, 1618–1628
salt production and, 2805–2809
sulfate-reducing bacteria (SRB) and, 3091
Beijerinckia
nitrogen fixation and, 2193–2201
subaerial communities and, 3057–3065
Benchmark values, in water treatment systems, 1729–1730
Benthic algae (See Meroplankton)
Benthic-associated primary production (See also Primary production), 392, 2573
Benthic fauna, in sediments and sedimentation, 2852
Benthic habitats, aggregates and consortia, 164
Benthic pelagic coupling, nitrogen cycle, 2180–2188
Bentonite, activated sludge foaming, 6–7
Benzanthracene bioremediation, 696–712
Benzene biodegradation, 700, 714, 916–917, 1423–1429, 1763, 1994–2000, 2412, 2931, 3147–3155, 3405, 3412, 3413
Benzisothiazolinone (BIT), 605
Benzofluoranthene bioremediation, 697–712

Benzoperylene bioremediation, 697–712
Benzopyrene biodegradation, 697–712, 714, 917, 2403–2416
Benzothiophenes, desulfurization, 1047–1048
Benzyl alcohol biodegradation, 3413
Benzyl chloride biodegradation, 3413
Berkeleya, 2837–2844
Beta carotene, 2516
Beta cyclodextrin, 1185
Beta D glucans, 417
Betaine, 518, 2778–2789
Betula, ectendomycorrhizal fungi, 2125–2126
Bicarbonate, in activated sludge, 741–748
Bifidobacterium, 895–905, 1257
Biguanides, biofouling vs., 604–605
Bile acids, 1257
Binary fission, in bacterioplankton, 2519
Binary image enhancement, 1682–1683
Binuclearia, 1025
Bio Green, 881
Bioacidification, metal biodegradation, 1881
Bioactive barrier, 695
Bioactive zone, 695
Bioaerosol sampling (See also Bioaerosols), 392–404
  analysis of samples in, 400
  biochemical assay in, 402
  calibration of sampler in, 399–400
  collection time for, 399
  culturing in, 400–401
  data analysis for, 402
  efficiency of, 397–398
  electrostatic precipitation type, 397
  filtration type, 396–397
  gravity sampling in, 397
  identification in, 401
  immunoassay in, 401–402
  impaction type, 393–396
  liquid impingement type, 396
  microscopy in, 401
  number of samples in, 399
  polymerase chain reaction (PCR) in, 402
Bioaerosols (See also Bioaerosol sampling), 182, 392
  actinomyces, 1
  active dispersal mechanisms in, 405–407
  agricultural and outdoor settings, 404–416
  apple scab spores in, 413
  ascospores in, 412–414
  atmospheric transport of, 407
  bacterial pathogens, 182
  bacteriophages and, 382
  basidiospores in, 412–414
  bioassays of, 1130–1131
  biosensors and, 1132
  biotechnology and, 417–419
  bioterrorism and, 425, 780
  blue mold spores in, 414–415
  Buller's drop and, 406
  death rate of, 2110
  deposition of, 407, 428
  detection of, 1130–1136
  diffusion rates for, 427
  dispersal mechanisms in, 405–407, 425–427, 2108–2112
  dry air spora in, 408–414
  electrochemiluminescence in, 1132
  enzyme immunoassay (EIA) in, 1131
  enzyme linked immunosorbent assay (ELISA) in, 1131
  exponential decay in, 2108
  exposure recommendations for (NIOSH, OSHA, etc.), 420–423
  fate of, survivability and, 425, 428–432
  flow cyclometry (FCM) in, 1132
  food processing and, as byproduct of, 423
  fungi and fungal spores in, 182, 404–405, 407–415, 1359–1366, 1647–1661
  Fusarium spores in, 413–414
  gas chromatography MS in, 1132
  Gaussian plume dispersion model for, 2108–2110
  gram-negative bacteria, 429
  gram-positive bacteria, 429
  immunoassays in, 1131–1132
  industrial settings for, 416–425
  infectious airborne bacteria as, 1689–1697
  kinetic limulus assay with resistant/parallel line estimation (KLARE) in, 1131
  landfill spreading associated with, 3324–3325
  late blight of potato spores in, 414
  Legionella as, 1788–1806
  limulus amebocyte lysate assay (LAL) in, 1130–1131
  machining and, as byproduct of, 419–420
  mass spectrometry and, 1132
  matrix assisted laser desorption ionization mass spectrometry (MALDI MS), 1132
  microchip-based PCR for, 1134
  modeling of, 2107–2112
  moist air spora in, 412–414
  molds, 1647–1661
  molecular beacons and, 1134
  mycobacteria and, 416–417
  open air factor (OAF) and, 430–431
  organic dust toxic syndrome (ODTS) and, 422
  oxygen inactivation in, 430
  ozone vs., 430–431
  particle tracking model for, 2110–2112
  passive dispersal mechanisms in, 405
  plume height vs. dispersion of, 2110
  pollutants vs., 430
  polymerase chain reaction (PCR) in, 1132–1134
  protection of microbes in, 431–432
  regression decay in, 2108
  relative humidity vs., 428–430
  repair of microbes in, 431
  respiratory diseases and, 422
  rust spores in, 411–412
  sampling of, 392–404, 2818–2820
  saphrophytes and, 416
  smut spores in, 410–411
  solid waste management as source of, 3320–3330
  spores as (See also Fungi and fungal spores, above), 183–184
  sprinkler systems using wastewater, generation of, 3323–3324
  survival models for, 2108
  temperature vs., 431
  textile industry and, as by-product of, 422–423
  toxigenic molds, 182–189
  transport of, 425–432
  ultraviolet radiation vs., 431
  uredospores in, 411–412
  viruses in, 3255–3260
  waste treatment and, 420–421
  wastewater treatment as source of, 3320–3330
  wind speed vs. dispersion of, 2110
  wood processing and, as byproduct of, 421–422
  yeast spores, 405
Bioassays, 1130–31
Bioaugmentation and bioremediation (See also Biodecomposition), 434–442, 695, 2395–2397

activated sludge and, 6–7, 40
anaerobic bacteria in, 439
aquifer treatment using, 440
biofiltration using, in situ, 439–440
bioremediation and, 713
cold-adapted microorganisms and, 3212
constitutive degradative activity in, 435–436
desert environment and, 1584
energy enrichment for, 436–437
enhanced transport for, 436
hierarchy for, 434–435
improving organisms used in, 435
metal biodegradation and, 1886
as microbial tracer in groundwater, 3200
mixed cultures and consortia in, 437
organisms used in, 435
polybetahydroxybutyric acid (PHB) in, 436–437
in septic tank systems, 2862
survival of introduced bacteria in, 438–439
type 1, 437–439
type 2, 439–441
Bioavailability, 87–88, 725
Biocatalysis
Archaea and, 259–276, 271
cold-adapted microorganisms and, 881
enzymes and, 1185
Biochemical adaptation, 1195
Biochemical assay, 402
Biochemical fossils, 2307
Biochemical methane potential (BMP), 1760
Biochemical oxygen demand (BOD), 2972, 3168
Biochips (gene chips) (See also Microarrays), 443–450, 1448–1449
applications for, 447–449
classification of, passive vs. active, 444
detection by, 445–446
electrophoresis and, 445–446
hybridization techniques and, 446
micrototal analysis in, 446–447
nitrifying bacteria typing using, 448
oligonucleotide microarray analysis using, 449
reactions in, 445
rifampin resistance testing and, 448–449
sample preparation for, 444–445
Biocides
biofilms vs., 556–557
biofouling vs., 602–609, 625–626
enzymatic degradation of, 608
extracellular polymeric substances (EPS) vs., 1228
surface embedded, 606
Biocompatibility, bioplastics, 687–692
Biocontrols (See also Genetically modified microorganisms), 450–465
bacteria as, 454–455
biosurfactants/bioemulsions and, 766
cell wall lysis and, 458
combined usage of, 461–462
delivery of, 461
direct control through, 456–459
formulation of, 461
fungi as, 451–454, 1385
genetically modified microorganisms (GMMs) and, 1437
improvement of, molecular approaches to, 462–463
indirect control using, 459–460
integrated pest management (IPM) and, 462
mechanisms of, 456–461
microbial insecticides, 1709–1717
nematodes vs., 455–456
plant growth promoting rhizobacteria (PGPR) and, 454–455, 2722
regulation of, 2693–2707
selection of, 460–461
siderophores as, 454
Biocorrosion (See also Microbially induced corrosion), 464–475, 2423–2424
biofouling and, 621
cyanobacteria vs., 942–943
extracellular polymeric substances (EPS) and, 1227–1228
marine biotechnology and, 1855–1856
sulfate-reducing bacteria (SRB) and, 3092–3093
Biodegradable dissolved organic carbon (BDOC), 484–507
assimilable organic carbon (AOC) vs., 323–324, 485–507
biodegradable organic matter (BOM) estimation and 486–504
biofilm formation and, 88, 499–504, 572
bioreactors for, 487–488
dissolved organic carbon (DOC) and, 485–507
identification of, 485–486
measurement of, 485–493
nutrient levels in water and, 489
organic carbon transformation and, 494–499
parameters affecting, 489–491
particulate organic carbon (POC) and, 485–507
refractory dissolved organic carbon (RDOC) and, 487
regrowth of bacteria and, 499–504
removal of, 493–499
sand-attached bacteria and, 487
specific UV absorbance (SUVA) testing, 485
suspended bacteria and, 487
total organic carbon (TOC) and, 485–507
in water treatment systems, 1729
Biodegradable organic matter (BOM) estimation, 486–504
Biodegradation (See also Metal biodegradation), 475–484, 507–516, 1895, 2929–2930
accelerated degradation in, 2386
acclimation in, 2386
adenosine triphosphate (ATP) and, 2931
aerobic processes in, 2404–2411, 2930–2932
anaerobic processes in, 2411–2413, 2932–2933
aryl halides, 1238–1252
assessment of, 475–484
benzothiophenes and, 1047–1048
bioaugmentation and, 2395–97
biochemical adaption of microorganisms in, 1195
bioplastics and, 683–692
bioreactors for, 1942
bioremediation and, 478–482, 514, 2395–2397
biostimulation, 695, 714, 750, 2395–2397, 3211–3212
biosurfactants/bioemulsions and, 714–715, 750–770, 1129–1130
bromophenol utilization in, 512
carbon/energy cycle and, limitations to, 1872–1876
catabolic pathways and, 1197–1199, 1203–1204
catabolite repression in, mixed substrates, 1872
chemical warfare and, 846–847
chlorinated compounds, 3410
chlorinated methane and trichloroacetate utilization in, 511–512
chloroethene utilization in, 510–511

Biodegradation (See also Metal biodegradation), (*continued*)
chlorophenol utilization in, 512
cold-adapted microorganisms and, 3210–3215
cometabolic reductive dechlorination, 508–509
cometabolism in, 2386–2387
compost and, 914–927
contaminant levels vs., 2930
definition of, 475–476
dehalogenation in, 3414
desert environment and, 1583–1584
diauxic growth vs. mixed substrate growth in, 1870–1872
dibenzothiophene and, 1042–1049
dioxygenases in, 3412
enzymes and, 1875–1876
explosives, 1498, 1978–1993, 3410
fertilizer application to aid, 699, 714, 724, 2931
fuel oxygenates, 1994–2000
fungi and, 1390–1392, 2911–2912,
genetically engineered microorganisms (GEMs) and, 1420–1429
genetics of, 2387
growth kinetics and, 1874–1875
halogenated compounds and, 702, 703–704, 1195, 1238–1252, 1447, 3405–3410, 3414
halorespiration in, 3414
herbicides and, 2385–2393
hydrocarbons and, 694–697, 2402–2416, 3211–3215, 3405–3410
hydrogen peroxide and, 2932
IS1071 insertion element and, 1200
metabolic pathway evolution for, 1194–1207
metal (See also Metal biodegradation), 1878–1883, 1895, 3045, 3216
mineralization and, 2386, 2931
mixed microbial populations used in, 512–513
mixed organic pollutants and, 1869–1877
mixed substrate growth in, 1870
monitored natural attenuation (MNA) in, 1941–1942
monooxygenases in, 3412
municipal solid waste landfills and, 1759–1763
natural attenuation, 1238
neuston microbiology and, 2137–2139
nicotinamide adenine dinucleotide (NAD) and, 2931
nitrilotriacetate (NTA), 1871, 1875–1876
nitrogen and, 707–708, 2930, 2931, 2932–2933
nuclear wastes and, 250–260, 2661–2674, 3045
oil spills and (See Oil spills)
oxidative phosphorylation in, 2931
oxidoreductases in, 3412
oxygen and, 2930–2932
oxygenase enzymes in, 2288–2300
pesticides and, 2385–2402, 3121–3122, 3405–3410
petroleum and, 2402–2416
phosphorus and, 2930
plasmid borne degradation genes and, 2387
primary and ultimate, 2394–2395
protozoa and, 2594
in pulp and paper industry, 2646–2651
radioactive wastes and, 250–260, 2661–2674, 3045
reductases in, 3414
reductive dechlorination and dehalorespiration in, 509–510, 513–514
sampling for, 476–478
seagrass detritus and, 2829–2831
in septic tank systems, 2860–2861
soil adaptation and, 2386, 2923–2936
stress response and, 3043–3045
subaerial communities and, 3061–3062
subsurface microorganisms and, 2033
surfactants in, 714–715, 750–770, 1129–1130, 2411
terminal electron accepting processes (TEAP) in, 2932
toxic chemicals, 2650, 3153
triazine herbicides and, 2391–2393
water fungi and, 3353–3364
weathering and, 3364–3389
wetlands and, 3401–3417
wood and, 2646–2647
xenobiotics and, 1195
Biodesulfurization, hydrocarbons, 2414
Biodeterioration of mineral materials (See Weathering)
Biodiversity
bacterioplankton and, 2524, 2526–2528
desert environment and, 1577–1580
fungi and, 3354–3355
genomic studies and, 1450–1452
in groundwater, 1671–1672
hydrothermal vents, 1604–1628, 1625
marine biotechnology and, 1850
mycorrhizae and, 2127
permafrost and, 2367–2385
petroleum reservoirs and, 2426–2431
in sediments and sedimentation, 2848–2849
soil microorganisms and, 528–544, 2925–2926
subaerial communities and, 3055
subsurface microbial communities and, 2034–2036, 3314–3315
sustainable agriculture and, 3116–3126
thermophiles and, 3141–3142
wastewater/sewage treatment and, 3337
Bioemulsifiers, 750–770
Biofertilizers, 351
Biofilm Accumulation Model (BAM), 502
Biofilm formation rate (BFR), 1729
Biofilm reactor, 695
Biofilms (See also Adhesion; Biofouling; Conditioning films), 100, 551–559
abrasion vs., 547
accumulation of, 545
acetogenesis in, 83
actinomycetes and, 1083, 2342
activated sludge and, 44, 51–52, 54, 58
activity and carbon transformations in, 81–92
adenosine triphosphate (ATP) formation in, 82, 83, 89
adhesion and, 100–132, 560–561, 612–613, 628–629, 938–939
adsorption of macromolecules in, 937
aggregates and consortia in, 160–181, 1213
algae in, 88, 612–613
allochthonous pathogens in, 2347–2353
amides in, 937–938
amoebas in, 2342
analysis of, 624–625, 2006–2008, 2340
"antenna effect" in, 560

anthropogenic carbon sources for, 86–87
antimicrobials vs., 556–557
aquatic, 1216
architecture of (See Structure of)
assimilable organic carbon (AOC) and, formation rates (BFR), 88, 324–325
attachment of, 2088
autochthonous microorganisms in, 2342–2343
autotrophs in, 81–82, 2341
available dissolved organic carbon (ADOC) and, 1086–1087
bacterial counts for, 565–566
bacterial-fungal, 551–559
bacteriophages and, 2342
bioavailability concepts for, in carbon assimilation, 87–88
biocides vs., 556–557
biodegradable dissolved organic carbon (BDOC) and, 572, 499–504, 572
biodeterioration of mineral materials and, 516
biofilm formation rate (BFR) in, 1729
biofouling and, 601–609
biological weathering and, 517
blooms of, 2340
Brownian motion and, 936
carbohydrates in, 85–86
carbon dioxide and, 83–84, 87, 89–91, 1083
carbon metabolism in, 81–83, 559
carbon substrate sources for, DOC and POC, 84–87, 89
catabolic vs. anabolic reactions in, 81
catabolite repression in, 89
in caves and mines, 830–831, 842
cell signaling in, 567
cell walls and, 2959–2960
chain elasticity in, 937
characterization of, 553–554
charge neutralization in, 2004–2005
chemical weathering and, 516–517
chemoautotrophs in, 81–82
chemoorganotrophs in, 81–82
classification of, 81
coliform bacteria and, 907–909
colloidal particles and, 127–128, 2964–2965
colonization in, 611–612, 1083
composition of, 937–938
computer simulation of, 2089
conditioning films and, 101, 127, 559, 611, 928–941
confocal scanning laser microscopy (CLSM) to study, 558, 570
consortia and (See Aggregates and consortia)
control of, 556–557, 623–630
cooling systems and, 579
cultivation of, 563–564
cyanobacteria in, 83, 568–569, 1083
cytoplasm and, 2960
demethylation in, 2963
denaturing gradient gel electrophoresis (DGGE) and, 563
density of, 548–549
deposition of, 114, 938
Derjaguin Landau Verwey Overbeen (DLVO) theory of adhesion in, 102–104, 106, 119–122, 124, 561, 2004–2005
desorption limitation in, 88
detachment of, 544–550, 561, 2087–2088
detection of, 580, 624
development of, 551–553
diatoms in, 612–613, 1051–1063
direct viable count (DVC) in, 565
directed evolution and, 1176–1177
disinfection vs., 580–582, 625–628
dispersal of, 561, 606, 626–628
dissolved combined amino acids (DCAA) in, 85
dissolved components in, 2088
dissolved free amino acids (DFAA) in, 85
dissolved organic carbon (DOC) and, 569, 1086–1087
dissolved organic matter (DOM) and, 569
dissolved oxygen (DO) and, 2005–2006
disturbance of, ecological impact of, 1088
DNA analysis of, 565–566
ecological selection in, 546
electrostatic interactions in, 103–104, 120, 606, 936, 2004
environmental, 555–556
enzyme activity in, 1214–1221
equivalent spherical diameter (ESD) measurement in, 2006
eukaryotes and bacteria interaction in, 567–568
exogenous isolation and, 1410
exopolymers in, 561, 1083–1084
extracellular enzymes and, 560, 1207–1223
extracellular polymeric substances (EPS) in, 81, 89, 546, 548, 560, 569, 571, 628, 1081, 1083–1084, 1207–1223, 1408, 2000–2012, 2959, 2961, 2964
extracellular survival in, 2353
factors affecting, 2005–2006
facultative anaerobes in, 82
fecal pollution and, 2347–2350
fermentation and, 82
filamentous bacteria, 1083
floc formation and, 58, 89, 2000–2012
fluid in, 2089
fluorescence in situ hybridization (FISH) studies of, 570, 571
food industry and, 577–587
formation of, 554–556, 560–563, 611–613, 620–623, 936–937, 1082–1083, 2004–2005
fractionation of, 1213
free energy of adhesion in, 101
fungi in, 613, 2342
Gallionella in, 1406
gene exchange/gene transfer in, 567, 1408–1420
genetics of, 561–563
glycoproteins in, 937–938
gradients in metabolism of, 1085
gram-negative bacteria and, 2960
gram-positive bacteria in, 2959–2960
granular activated carbon (GAC) and, 1489–1496
grazing in, 2342
green fluorescent protein (GFP) markers for, 558–559, 1498
growth rate of, 545–546, 549, 558
hazard analysis and critical control point (HACCP) concept, 583
heterogeneity of, 549
heterotrophs in, 81–82, 2341
humic substances and, 86–88, 114
hydrogel matrix of, 81
hydrolysis in, 87
hydrophilic/hydrophobic forces in, 2004, 2005, 2007–2008
hyperthermophiles and, 1642
immobilization in (See also Adhesion), 100, 105–111
industrial, 555–556, 582–584, 619–632
intracellular survival in, 2353
iron and, 1085–1086

Biofilms (See also Adhesion; Biofouling; Conditioning films), (*continued*)
lectins and, 570
Lifshitz-van der Waals forces in, 101, 102–104, 123, 124, 936, 938
lipids in, 85–86, 2960
lipopolysaccharides and, 2960
lithotrophs in, 81–82
macrofouling and, algal spores in, 615–616
macrofouling and, invertebrate larvae in, 613–615
marine biotechnology and, 1855–1856
"marine snow" and, 89
marine/ocean environment and, 1081–1091
mass balance equations for, 2088–2089
mass transfer in, 2087
matrix of, 547–548
measuring transformations and activity in, 89–91
medical uses for, 554–555
metabolic activities of, 565–566
metals in, 2960–2963
methanogenesis in, 83, 87, 2963
methanotrophs in, 82–83
microautoradiographic studies of, 565
microbial mats and, 568–569
microbial transforms in substrates of, 88–89
microdomains in, 1215
microscopic analysis of, 2008
mineralization and biomineralization in, 82, 2961–2962
modeling of, 587, 2083–2094, 2340
Modified Robbins Device (MRD) to study, 557–558
nicotinamide adenine dinucleotide phosphate (NADPH) in, 83
nitrogen and, 1085–1086, 2005
nutrients in, for bacteria, 939–940
organic substances in, 2963–2964
oxygen and, 83–84, 1083, 2005, 2962
ozonation and, 87
particulate organic carbon (POC) and, 1086–1087
particulates in, 2088
pathogens in, 587, 621, 2339–2356
periphyton and, 2357–2367
pH levels and, 100, 104–105, 121–22, 1085–1086
phosphorus and, 1085–1086, 2005
phosphorylation in, 82–83
photoautotrophs in, 81–82
photoheterotrophic bacteria in, 1087–1088
photosynthesis in, 84
phototrophy and photoautotrophy in, 83
physiology of, 548–549
plankton and, 81, 82, 88, 114, 611–612, 1082–1083
polar interactions in, 937
polymer bridging in, 2005
polymerase chain reaction (PCR) to study, 558–559
polysaccharides in, 937–938
precipitation in, 2962
prevention of, 628–630
proteins in, 85–86, 937–938
pseudomonads in, 2343–44
in pulp and paper industry, 580, 2650
quorum sensing in, 549, 1220
redox and, 2960–2963
reduction and, 2962
remobilization in, 2965
resistance of bacteria in, 608
respiration in, 82–83, 565
restriction fragment length polymorphism (RFLP) in, 563
retention of microbes in, 111
"river snow" and, 570–571
riverine, 569–572
RNA analysis of, 565–566
rotating annular bioreactors (RAB) studies for, 570
saccharolytic enzymes vs., 606
Salmonella in, 2793
salt bridging in, 2005
sampling of, 624, 830–831, 2006–2008, 2814
settling in, 2007
shear rates and, 2341
sloughing in, 1083
sorption properties of, 587, 2958–2967
spalling, 517
steric forces in, 2004
stoichiometric matrix in, 2086–2087
stress and strain forces on, failure of, 547–548
structure and architecture, 553, 560–563, 1083–1084, 2341–2342, 2341
substratum properties for, 546, 938
sulfate-reducing bacteria (SRB) and, 82, 2962, 3091–3092
sulfur and, 82, 1085–1086
surface charge and, 2008
surface thermodynamics and, 2005
survival of, 2353–2354
suspended, 587
syntrophy and antagonism in, 83–84
terminal fragment length polymorphism (T-RFLP), 563
terrestrial, 1216
thickness of, 1083, 2088–2089
transfer processes in, 2087–2088
transformation processes in, 2086
transport processes in, 2087
turbulence vs., 547
van der Waals forces in, 119–129, 124, 552, 1083, 2004
ventilation and air handling systems and, 579–580
verocytotoxigenic E. coli (VTEC) and, 2349–2350
viable but nonculturable cells (VBNC) in, 565
viruses and, 2342, 2353
wastewater/sewage treatment and, 3346–3347
in drinking water, 560–575, 620–622, 945–947, 2960
weathering, bioweathering and, 3367
zeta potentials and, 100, 119
Biofilters, 587–593, 695
activated carbon in, 590
adsorption and absorption in, 590–591
ambient temperature catalytic oxidation in, 587
ammonia vs., 598
applications for, 588–589
bioaugmentation and bioremediation in, 439–440
bioodors and, 593–601
bioremediation and, 693
bioscrubbers in, 587
biotrickling filters in, 587, 782–795
chemical potential/chemical activity in, 592
chromatographic effect in, 590
compost as, 592, 914–927
compound specificity in, 589
degradation rates in, 590
destruction/removal efficiency (DRE) in, 587, 590
economics of, 589
granular activated carbon (GAC) filters and, 1491–1492

hydrogen sulfide vs., 598, 599–600
hydrophilic materials in, 591–592
hydrophobic materials in, 591–592
mechanism of, 589–591
media for, 591–592
microbial activity in, 598–599
moisture and, 592–593
organic media in, 591–592
physical potential (hydraulic head, water tension, suction) in, 592
POTWs vs., 598
synthetic media in, 592
temperature vs., 593
toxicity and antagonism in, 591
volatile organic compounds (VOCs) vs., 598
water films in, 590–591
Biofluffing, 695
Biofouling (See also Biofilms; Microbially influenced corrosion), 601–609
adhesion and, 612–613, 628–629
algae in, 612–613
analysis of, 624–625
bactericides vs., 602–609
biocides vs., 625–626
biofilm formation and, 611–613
colonization in, 611–612
conditioning films and, 611, 928–941
corrosion and, 621
countermeasures and control of, 623–630
detection of, 624
diatoms in, 612–613, 1051, 1058–1059
disinfection vs., 625–628
dispersants vs., 606
efficacy of treatment, factors affecting, 606–608
electrochemically activate water vs., 603–604
extracellular polymeric substances (EPS), 628, 1227–1228
formation or occurrence of, 620–623
fungi in, 613
heat exchangers and, 622–623
industrial, 619–632
macrofouling and, algal spores in, 615–616
macrofouling and, invertebrate larvae in, 613–615
marine biotechnology and, 1856
marine environment and, 610–619, 623,
microbially influenced corrosion (MIC) and, 623
molecular level, 611
oil industry and, 623
organic fouling in, 619
particle fouling in, 619
pathogens in, 621
prevention of, 628–630
removal or dispersal of, 626–628
resistance of bacteria in, 607–608, 625
saccharolytic enzymes vs., 606
sampling in, 624
scaling or mineral fouling in, 619
sequence of processes in, 610–611
ship hulls and, 623
sulfate-reducing bacteria (SRB) and, 3091
water treatment systems and, 602–609, 620–622
Biogas (See Activated sludge; Methane and methanogenesis)
Biogenic acids, bioleaching, 632–642
Biogenic trace gases (See Trace gases)
Biogeochemical cycles
aggregates and consortia in, 161, 165–166
flooded soils and, 1316–1318
nitrogen cycle and, 2180–2188
in sediments and sedimentation, 2844–2848
Bioherbicides, 1385
Biohydrometallurgy (See also Bioleaching), 632, 881–882
Bioindicator
protozoa and, 2630–2631
soil quality and, interpretation of, 2950–2951, 2953–2954
Bioinformatics, 1449–1450
Bioinsecticides, 1385
Bioleaching, 632–650, 695
applications for, 638–640
attachment of bacteria to mineral surfaces in, 635–636
BacTech process for, 647–648
biomining and, 638–639
biooxidation in, 648–649
BIOX process for, 647
chemoorganoheterotrophic microorganisms in, 635
chemotaxis in, 635–636
cold-adapted microorganisms and, 881–882
commercial practice of, 647–648
environmental problems and, 640
extracellular polysaccharide (EPS) and, 644
galvanic influence in, 637
heap vs. dump leaching in, 642, 648, 649
history of, 642–643
hydrogen sulfide pathway in, 637
iron and, 637–638, 643, 646
metal biodegradation and, 1881
metal sulfide dissolution in, microbiological, 635–638
metal sulfide oxidizing bacteria in, 634–635
microorganisms of, 634–647
minerals affected by, 633–634
polysulfide pathways in, 637
pyrite and, 638
sphalerite and, 637–638
thiosulfate pathways in, 636–637
weathering, bioweathering and, 3366
BIOLOG, 1961–1962
Biological fluidized bed, 695
Biological mat, in septic tank systems, 2858
Biological nutrient plants (BNR)
activated sludge and, 1313–1314
Microthrix parvicella and, 3
wastewater/sewage treatment and, 3337, 3338–3339
Biological oxygen demand (BOD)
activated sludge and, 49, 50, 745–746
algal turf scrubbing (ATS) and, 216
in wastewater stabilization ponds (WSBs), 3336
Biological plug, 695, 707
Biological pulping process, fungi, 2647
Biological soil crusts (BSCs), 1019–1023
Biological trickling filters, 74
Biological warfare (See Bioterrorism)
Biological weathering, 517
Biologically active carbon (BAC), 1489, 1491
Biologically controlled mineralization (BCM) (See also Biomineralization), 671
Biologically induced mineralization (BIM) (See also Biomineralization), 671
Bioluminescence, 657–663, 1830–1838
Biomarkers, lipids (See Lipid biomarkers)
Biomass, 2565
acridine orange and, 2653
activated sludge and, 22–26, 72, 74, 739, 1311, 1315
adenine nucleotides in, ATP, ADP, 2654
algal (See Plankton and photoplankton)

Biomass, (*continued*)
algal turf scrubbing (ATS) and, 213–219
Archaea and, 266, 2658
bacterial counts and, 2653
bacterioplankton, 663, 2520, 2528–2530
in biotrickling filters, 786–795
biochemical constituents of, 2654–2657
biofilms and, 81
cell wall analysis in, 2657
chloroform fumigation incubation/extraction (CFI/E) for, 2653
desert environment and, 1576, 1577, 1579
diamindino phenylindol (DAPI) and, 2653
DNA/RNA analysis of, 2656–2657
endolithic microorganisms and, 1104–1105
enzymes and, 1186
epifluorescence and, 2653
estimation techniques for, 2653
fatty acid methyl ester (FAME) and, 2656
fatty acids and, 2654–2656
flow cytometry and, 2653
fungal, 1397, 2657–2658
harmful algal blooms (HABs) and red tides, 2690
lipid biomarkers of, 1818–1819
marine biotechnology and, 1851
mass spectrometry for, 2656
metal bioadsorption by, 1879–1880
nucleic acid–based testing of, 2656–2657
periphyton and, 2357, 2359
phospholipid bound phosphate (PLP) and, 2654–2656
phospholipid fatty acids (PLFA) and, 2654–2656
phospholipids in, 2654–2656
photosynthetic pigment analysis in, 2657
plankton and phytoplankton, 2516, 2559–2560, 2653
polar phytoplankton and, 2559–2560
primary production (marine) and, 2566–2575
proteins in, cellular, 2654
protozoa and, 2628–2629
quantification of, 2652–2660
sea ice microorganisms and, 2841
soil (See also Soil microorganisms), 294–295, 663–670, 2895, 2948
subaerial communities and, 3061
subsurface microorganisms and, 1076, 1077–1078, 1080
toxicity testing and, in soils, 3158–3159
Biomaterials, 1850, 1853
Biomineralization (See also Mineralization; Sulfate-reducing bacteria), 670–681
biofilms and, 82
biologically controlled mineralization (BCM) and, 671
biologically induced mineralization (BIM) and, 671
bioremediation and, 679
carbonates, 672
cyanobacteria in, 672
freshwater lakes and rivers and, 677–678
geologic evidence of, 676–678
hydrothermal environment, 678
ionotrophy and, 672
iron and, 674–679
magnetotactic bacteria and, 678
manganese and, 675–676
redox transformations and, 673–675
significance of, 678–679
silicates, 672–673
stromatolites and, 678
sulfate-reducing bacteria (SRB) in, 672
Biomining (See also Metal ion extraction), 274, 682, 638–639
Biomonitoring
periphyton and, 2365
in wastewater/sewage, 3168
Bioodors
biofiltration and, 593–601
biotrickling filters, 782–795
Biooxidation, bioleaching, 648–649
Biopesticides (See Insecticides)
Biopile, 695, 914–927, 914
Biopitting, 518
Bioplastics, 682–692
Biopolaris, 1651
Biopolymers
biomineralization and, 671
bioplastics and, 682–692
marine biotechnology and, 1853
Bioprocess engineering, marine biotechnology, 1850, 1855–1856, 1858–1861
Bioprocessing, hydrocarbons, 2414
Bioreactors, 487–488, 1942
Bioremediation and detoxification (See also Biodegradation; Composting), 692–712, 1446–1447, 2402
acclimation of microorganisms in, 713
acid mine drainage and, 709
aerobic respiration and, 151
algae biotechnology and, 189–204
ammonium, 707–708
aquatic ecosystems and, 712–722
bacteria used in, 713
bioaugmentation and, 434–442, 713, 2395–2397
bioavailability of contaminants vs., 725
biodegradation and (See Biodegradation)
biofiltration and, 693
biomineralization and, 679
bioreactors for, 1942
biostimulation in, 695, 714, 750, 2395–2397, 3211–3212
biosurfactants in, 714–715, 750–770, 1129–1130
carbon and, 714, 724
case studies in, 734
closed loop, 695
cold-adapted microorganisms and, 882–883, 3210–3215
cold-adapted microorganisms and, 3215
commercial applications of, revenues from, 693
composting and, 693, 695, 914–927
concentration of contaminants vs., 725
ecology and, 693–694
electron acceptors for, 714, 724
encapsulation of microbial cells for, 730
enhanced, 712
ex situ, 695
explosives biodegradation and, 1988–1990
fertilizer application to aid, 699, 714, 724, 2931
fungi and, 1390–1392
genetic engineering and, 729–730
genetically engineered microorganisms (GEMs) in, 726, 729–730
groundwater pollution and, 699–700, 702–703, 705–708, 1447
halogenated compounds and solvents, 693, 701–705
heavy metals, 1855
herbicides and, 705–706
hydrocarbons and, 694–701, 713–719, 2414
inorganic contaminants and, 707–708
intrinsic, 695

lipid biomarkers of, 1822
marine bacterial isolate (MBI), 715
marine biotechnology and, 1850, 1855
marine/ocean environment and, 712–722
metal biodegradation and, 1886
metals and metalloids in, 708–709
methanogenesis, marine, 1921
methanotrophic bacteria in, 1936–1944
as microbial tracer in groundwater, 3200
military chemicals and, 706–707
mixed organic pollutants and, 1869–1877
moisture content (of soils) in, 723–724
monitored natural attenuation (MNA) in, 1941–1942
nitrogen compounds and, 707–708, 714, 724
oil spills and, 693–701, 713, 715–719
options for, 734–735
oxygen and, 714, 724
pesticide degradation and, 705–706, 2395–2397
pH levels and, 713–714, 724
phosphorus and, 714, 724
phytoremediation and, 709, 731–734
plant assisted microbial bioremediation, 1424–1425
polychlorinated biphenyl (PCBs) in, 726–735
pulsed, 695
rate monitoring in, 730–731
rhizofiltration and, 709
rhizoremediation, 695, 1424–1425
rivers and ponds, 705
soil contamination and, 700–707, 722–737
solubility of contaminants vs., 725
sorption characteristics of contaminants vs., 725
sulfate-reducing bacteria (SRBs) in, 708
surface water, 708,712–722
technology for, 694
temperatures vs., 713, 723
toxicity of contaminant vs., 724–725
vadose zone microbiology and, 3242–3243
vapors of halogenated compounds, 702
vapors of hydrocarbons and, 697–698
verification of, 478–482
wastewater/sewage treatment and, 693
xenobiotics, 693
Biorestoration (See Bioremediation)
Bioscrubbers, 587
Biosensors, 1132, 3172
Bioslurping, 695
Biosolids (See also Activated sludge), 420, 738–750
bioaerosols released from, 3320–3330
Biosorbents, metal, 750
Biosorption, algae biotechnology, 200
Biosparging, 695
Biosphere, soil biosphere, 294–295
Biostability of drinking water (See Assimilable organic carbon)
Biostimulation (See also Bioremediation), 695, 714, 750, 2395–2397, 3211–3212
Biosurfactants/bioemulsions, 714–715, 750–770, 1129–1130
acidic lipids in, 756–757
applications for, 763–766
biocontrols, 766
biodegradation and, 764
bioremediation and, 763–765
chemical production using, 766
critical micelle concentration (CMC) in, 751
emulsan in, 761
emulsion index for, 762–763
extracellular polymeric substances (EPS) and, 1129–1130
fengycin in, 757–759
flushing agent use of, 764
glucose lipids in, 756
glycolipids in, 752
iturin in, 757–759
lichenysin in, 759
lipoproteins in, 757–760
mannosylerythritol lipids in, 755–756
medical applications for, 765–766
neutral lipids, 756–757
phospholipids in, 756–757
polymeric, 760–762
rhamnolipids in, 752–753, 764–765
screening for activity in, 762–763
sophorolipids in, 753–755
surfactin in, 757–759
trehalose lipids in, 753
turbidity assay for, 763
Biosynthesis in cold-adapted microorganisms, 875–876
Biotechnology (See also Genetically engineered microorganisms), 1176–1189
algae in, 189–204
aquaculture and, 3215
Archaea and, 259–276, 290–291
bioaugmentation and, 3212
biodegradation and, 3210–3215
bioremediation and, 3210–3215
biostimulation and, 3211–3212
cloning and, 3203–3206
cold active enzymes and, 3206–3210
cold-adapted microorganisms and, 879–883, 3203–3219
enzymes in, 1176–1189
extracellular polymeric substances (EPS) and, 1229
field release of GEMs and, 1278–1287
fungi in, 771, 1384–1394
genetically modified microorganisms (GMMs) in, 1429–1440
intellectual property rights and, 1861
legal issues of, 1861
marine, 1850–1863
methanogenesis and, 771, 1920–1921, 1933
microbial insecticides using, 1710
petroleum reservoirs and, 2424–2425
plankton and phytoplankton, 2516
plant growth promoting rhizobacteria (PGPR), 351–352
protein engineering and, 3208–3209
psychrophiles and, 3203–3219
recombinant DNA and, 2693–2694
regulation of, 2693–2707
salt production using, 2804–2809
spores and spore dispersion in, 417–419
technology transfer issues and, 1861
Toxic Substances Control Act (TSCA) and, 1280
Biotechnology Science Coordinating Committee (BSCC), 2695–2707
Bioten, 1334
Bioterrorism (See also Bioaerosols; Toxicity testing), 771–782
aerosolization in, 780
agroterrorism and, 181, 780–781
anthrax in, 771–782
bioaersols and, 425
botulism in, 778

Bioterrorism (See also Bioaerosols; Toxicity testing), (*continued*)
brucellosis in, 775–776
characteristics of, 773–779
chemical weapons vs., 773–775
cholera and, 776, 853–861
combating, through detection and preparedness, 781
dispersion methods for, 779–789
dose response assessment in, 2745–2747
Ebola virus in, 777–778
glanders in, 771, 776
hemorrhagic fevers in, 777–778
history of, 771–773
Marburg virus in, 777–778
plague in, 776–777
ricin in, 778
sampling for, 781
smallpox in, 777
Staphylococcus aureus enterotoxin (B/SEB) in, 778
toxicity of, 773–775, 778–779
tularemia in, 777
Venezuelan equine encephalitis (VEE) in, 777
viruses for, 777–778
yellow rain in, 778–779
Biotoxins (See also Cyanobacteria; Harmful algal blooms and red tide)
Biotransformation, 695
Biotrickling filters, 587, 695, 782–795
Bioventing, 695
Biowall, 695
Bioweathering, extracellular polymeric substances (EPS), 1227–1228
BIOX bioleaching, 647
Biphenyl biodegradation, 2289–2300, 3412
Bipolaris, 408, 410, 1020–1023, 1650, 1654
Bis phthalate bioremediation, 707
Bisphenol, 605
Bivalvia, endosymbiosis, 1117
Bjerkandera, 1385, 2649
Black Sea, phototropism, 2476
Black water, 3099
Blackley, C.H., 404
Blastocladiella, 972
Blastoconidia, 1647
Blastomyces fungi, 1368
Blattabacterium, 1122
Bleaching samples, 1785–1786
Bleaching, biological, fungi, 2647–2648
Blister agents (See Chemical warfare)
Blood plasma sampling technique, 824
Blooms (See Harmful algal blooms and red tides)
Blue-green algae (See Cyanobacteria)
Blue mold, 414–415
Bodo, 2605, 2608, 2594–2604
Bodonids, 2619
Boletus, mycorrhizae, 2124–2132
Bombyx, microsporidia vs., 2065–2083
Bordetella, 1209, 3325
Boreal waters, nitrogen cycle, 2182
Borehole bioreactor, 695
Borellia, 1906
Bornholm disease, enteroviruses, 1152
Borodinella, 1109
Borrelia, 555, 1701, 1838–1849
Borreliosis (See Lyme borreliosis)
Botryococcus, 1854, 2302–2306
algae biotechnology, 199–200
Botrytis, 405, 412, 451
Bottled water, 795–802
artificial inoculation of, with bacteria, 799
bacteria in, 795–801
carbonated vs. noncarbonated, 799
Clostridium and, 866–871
contact lens cleaning and, 800
containers for, 798
dispensers for, 800
endotoxins in, 800
fluoridation of, 800
heterotrophic bacteria and, 1549–1550
mineral water and, 796
nomenclature of, 798
Pseudomonas and, 1549–1550, 2632–2639
storage of, 789–799
treatment of, 797–798
Bottom-up exploratory data analysis, 1005
Botulinum, botulism, 182–189
bioterrorism and, 778
Clostridium and, 862–871
high hydrostatic pressure (HHP) vs., 1559–1563
in wetlands for wastewater treatment, 3400
Bound effect concentration (BEC), 3163
Bound water, biofilms, 2960
Boundary layers, adhesion in biofilms, 114
Bovine astrovirus infection, 332
Brachiola, 2066–2083
Brachymonas, 32
Brackish water, aggregates and consortia, 166–168
Bradyrhizobium, 2720
biocontrol use of, 2703, 2704
endosymbiosis and, 1120
nitrogen fixation and, 2188–2211, 2188
soil salinity and, 2775, 2779–2789
stress response and, 3048
subsurface microbial communities and, 3067–3071
Bremia, 2895
Brevibacter, 753, 756, 1044, 1102–1106, 2387, 2394
Brevipalpus, 1122
Brewing and distilling, 1187, 1384
Brickwork, weathering, bioweathering, 3371–3372
Bridging, 2005
Brine fly, salt production, 2805–2809
Brine shrimp, salt production, 2805–2809
Bromine, 3184, 3266–3267
biofiltration and, 589
biofouling vs., 603
in spas and hot tubs, 2979
Bromophenol biodegradation, 512
Bromus, 1989
Bronopol, 605
Brown algae, 2467, 2504–2518
Brown rot fungi (See also Pulp and paper industry), 801, 1388–1389, 2646–2647
Brown tides (See also Harmful algal blooms and red tides), 801, 2689
Brownian motion
adhesion in biofilms and, 114, 115
aggregates and consortia in, 162
conditioning films and, 936
Brucella, 772, 775–776, 1689–1697
Brucellosis, 775–776, 1689–1697
Bryophtyes, 2504–2518, 3056–3065
Bryum, 1025
BTEX compound biodegradation, 699, 1994–2000, 2412, 2594, 2930, 2933
Buchnera, 1123
Buffering capacity, 1749
Bugula, 614
Building related disease (See Sick building syndrome)

biofilms and, 90
granular activated carbon (GAC) filters and, 1490
oligotrophic bacteria and, 2268, 2271–2272
stress response and, 3048
viable but not culturable (VBNC) phenomenon and, 3247, 3251
Causarina, nitrogen fixation, 2202
Caves and mines (See also Acid mine drainage; Subsurface microbial communities), 835
aerophitic photoautotrophic microorganisms in, 835–843
air-filled, 822–825
anaerobic bacteria in, 827–828
biofilms in, 830–831, 842
blood plasma sampling technique in, 824
chasmoendolithic microbes in, 842
cold-adapted microorganisms in, 872–885
endolithic microbes in, 842
epiendolithic microbes in, 842
gases in, 823
"green sickness" of, 841–843
habitats in, 822–823
kick-plate boundary in, 829
microbes in, 823–825
microbiological sampling in, 821–835
minerals in, 823
on-site observations in, 827
permits and legal restrictions on, 832–833
pH levels in, 842
protection of, 832–833
rock sampling in, 829–830
safety in, 833
subaerial communities and, 3059
subsurface microbial communities and, 1076, 1078–1079, 3067–3068
surfaces in, 821
underground mines and, 828–832
volcanic tuffs, subsurface microbiology of, 3110–3119
water and moisture in, 821–835
water filled, 825–828
Cell–cell interactions, biofilms, 1056–1058
Cell membranes and stress response, 3031
Cell signaling in biofilms, 567
Cell sorting, 1944–1958
Cell surface hydrophobicity, activated sludge foaming, 5–7
Cell viability (See Laser scanning microscopy)
Cell wall structures
alkaliphiles and, 137
Archaea and, 248
bacterioplankton and, 2519
biofilms and, 2959–2960
biomass estimation and, 2657
cold-adapted microorganisms and, 874
desiccation and, 1029
lysis of, through biocontrols, 458–459
metal sorption to, 1879, 1895–1896
oligotrophic bacteria and, 2274–2275
plankton and phytoplankton, 2509

polar phytoplankton and, 2555
soil microorganisms and, 2882
toxic solvents and, 3153
Cellobiose, 756, 2899
Cellobiose dehydrogenase (CDH), 1387–1388
Cellubiase, 2899, 3021
Cellulase, 226, 1177–1189, 1388, 2903–2910
Cellulitis, Aeromonas, 1091–1099
Cellulomonas, 1583
Cellulose, 85–88, 682–693, 1210, 1760
Cellulosome, 1447
Cement, biodeterioration of mineral materials, 523–525
Cenarchaeum
Archaea and, 289–290
biotechnology and, 3204
soil microorganism and diversity in, 539
Centrifugal impactor type bioaerosol sampler, 395–396
Centrifugation, adhesion in biofilms vs., 116–117
Centropyxis, 2605
Cephaleuoros, 3056–3065
Cephalosporin, 1366, 1369, 1852
Cephalosporium, 2705
Ceramics, weathering, bioweathering, 3371–3372
Ceratium, 205, 1864–1869
Ceratocorys, 2507
Ceratocystis, 2648–2650
Cercocarpus, 2124–2132
Cercomonas, 1126, 2594–2605, 2608
Cercospora, 413
Ceriporiopsis, 1385, 2647
Ceroidaphnia, biomonitoring, 3169
Certaium, 2507
Cesium, 1879–1893
Chaetoceros, 1058, 2506
Chaetogaster, 1722
Chaetomium, 1650, 1654–1655, 3144–3147
in allergies and illness, 1367–1372, 1374–1383
biocontrols and, 457–458
composting and, 916
desert environment and, 1579
Chaetosphaeria, 3359
Chain elasticity, conditioning films, 937
Chalcopyrite bioleaching, 633
Chaperone machine, molecular (See also Heat shock; Stress response), 843, 3028, 3048, 3050, 3052
Chaperonins, 3028–3029, 3048, 3052
Chara, Charales, paleolimnology, 2304–2306
Charge separation, aerobic respiration, 151
Charophytes, 2504–2518
Chasmoendolithic microbes, 842, 1100–1112
Chattonella, 2467, 2508, 2686–2693
Cheilobus, 1721
Chelation, 517, 1881–1882, 2717
Chelatobacter, 1871, 1875
Chemical controls, biocontrol vs., 450–465
Chemical oxygen demand (COD)
activated sludge and, 14–26, 49, 50
algal turf scrubbing (ATS) and, 216
anaerobic granulation and, 243
in source water, 2972
in wetlands for wastewater treatment, 3391
Chemical potential/chemical activity, in biofiltration, 592
Chemical production
biosurfactants/bioemulsions and, 766
cold-adapted microorganisms and, 881
enzymes and, 1185
Chemical transformations in wastewater/sewage treatment, 3337
Chemical warfare (See also Bioterrorism), 844–852
biodegradation of, 846–847
blister agents in, 844
destruction of, 844–845
immobilized cell reactors for, 847
isopropyl methylphosphonate (IMPA) vs., 850
nerve agents in, 844
organophosphorus acid anhydrolases (OPAA) vs., 848
organophosphorus hydrolase (OPH)., 848–850
sequencing batch reactors (SBR) for, 847
stockpiles of, 844–845
toxicity characteristic leachate protocol (TCLP) analysis of, 846
VX agents in, 844
bioterrorism vs., 773–775
bioremediation and, 706–707
Chemical weathering, 516–517
Chemiosmosis in aerobic respiration, 149–151
Chemoautotrophs
activated sludge and, 71
bacterioplankton and, 2521
biofilms and, 81–82
hydrothermal vents and, 1606–1609
soil microorganisms and, 2889, 2891–2892
sulfur cycle and, 3110
Chemoheterotrophs, 71, 3110
Chemokines, in allergies and illness, 1360
Chemolithoautotrophs, 1075, 1455, 1824–1826, 2522, 3141–3144
Chemolithotrophs, 677, 1075, 1455
metal biodegradation and, 1880
weathering, bioweathering and, 3365–3366
Chemoorganoheterotrophic microorganisms
bioleaching and, 635
biodeterioration of mineral materials and, 525
cold-adapted microorganisms in, 872–885
Chemoorganotrophs
biofilms and, 81–82
weathering, bioweathering and, 3365
Chemosensing, diatoms, in biofilms, 1052–1053
Chemotaxis bioleaching, 635–636
Chemotrophs
biodeterioration of mineral materials and, 523
soil microorganisms and, 2887
Chemtax analysis, photosynthetic pigments, 2468
Chenodeoxycholic acid, alkaliphiles, 228
Chenopodium, 1435
Chironomids, algal turf scrubbing (ATS), 215
Chitin, 1210, 1447
Chitinase, 227–228, 458, 1211–1223
Chitinolytic enzymes, 458
Chitobiase, 3021
Chitobiosidase, 1212–1223
Chladysporium, 2342–2356
Chlamydia, 1345
genomic studies and, 1446
infectious airborne bacteria and, 1689–1697
Chlamydiamicrovirus, 364–374
Chlamydoconidia, 1647
Chlamydomonas, 206
algae biotechnology and, 196
sea ice and, 2835–2844
snow/in snow and ice environments, 2873, 2876
toxicity testing and, 3221–3230
in wastewater stabilization ponds (WSBs), 3331, 3332
in wastewater/sewage, 3172
Chloramines, 1069

Chloramphenicol (CAP), 3160
Chlorarachniophyta, 237–243, 2465, 2467
Chlorararchnion, 2467
Chlorbenzoates biodegradation, 1421–1429
Chlorbiaceae, 2471
Chlorella, 205, 1851, 1853
algae biotechnology and, 189–204, 196, 198
biodeterioration of mineral materials and, 519
endosymbiosis and, 1117
photoautotrophic, in low-light habitats, 840–843
polar phytoplankton and, 2556
sea ice and, 2835–2844
subaerial communities and, 3056–3065
toxicity testing and, 3221–3230
in wastewater stabilization ponds (WSBs), 3331
in wastewater/sewage, 3172
Chlorhexidine, 604–606
Chlorides, soil salinity, 2774
Chloridium, 2125–2126
Chlorinate volatile organic compounds (CVOCs), 434–442
Chlorinated compound biodegradation, 507–16, 916–917, 1421, 2289–2300, 2931, 3410
Chlorinated solvents, bioremediation, 713, 714
Chlorine, chlorination (See also Disinfection), 607, 1063–67, 1069, 2333–2334, 3184
activated sludge foaming and, 6–7
adenoviruses vs., 96
bacteriophages vs., 360
biodegradable dissolved organic carbon (BDOC) and, 498
biofilms vs., 582, 589
biofouling vs., 603, 625–626
enteroviruses and, 1172
in marine/ocean environment, 1707
ozone layer destruction and, 3184
in spas and hot tubs, 2979
viruses vs., 3265–3267
Chlorine dioxide, 1063–1067, 1069–1070
Chlorobactene, 2459, 2465
Chlorobenzene biodegradation, 1763
Chlorobenzoate biodegradation, 2932
Chlorobenzoic acid biodegradation, 1238–1252
Chlorobiaceae, 2455, 2458, 2459, 2465
flooded soils and, 1320
phototropism in, 2471, 2474, 2476, 2481, 2483
in wastewater stabilization ponds (WSBs), 3332–3333
Chlorobiphenol biodegradation, 1195
Chlorobiphenyl biodegradation, 1422–1429
Chlorobium, 2282, 3088–3096, 3111–3116, 3142–3147
biofilms and, 83
biomineralization and, 675
nitrogen fixation and, 2193–2201
in paleolimnology, 2312
phototropism in, 2474, 2479–2489
Chlorococcales, 1109, 2301, 2369, 3056–3065
Chloroethene biodegradation, 510–511
Chloroflexaceae, 83, 511, 2278, 2471, 3142–3147
Chlorofluorocarbons (CFCs), 3183, 3184, 3188–3189
Chloroform (CF), 434–442, 511–514
Chloroform fumigation incubation/extraction method (CFI/EM), 666–667
Chlorogloae, 840–843
Chlorogloeopsis, 962
Chloroherpeton, 2479–2489
Chloromethylisothiazolinone (CMIT), 605
Chloromonas, 838–843, 2873
Chlorophenol biodegradation, 512, 605, 921–922, 1421, 3147–3155
Chlorophtya, 2467, 2837–2844
Chlorophyll, 2453–2480, 2504, 2512
cyanobacteria and, 964
in paleolimnology, 2307–2317
Prochlorococcus, 2576–2593
soil biosphere and, 204
in wastewater stabilization ponds (WSBs), 3332–3333
Chlorophyta, 205
Antarctic soils and, 1025
periphyton and, 2357
photoautotrophic, in low-light habitats, 837–840
plankton and phytoplankton, 2503
polar phytoplankton and, 2556
Chloroplasts, plankton and phytoplankton, 2509–2510
Chlorosarcinopsis, 1109
Chlorotoluene biodegradation, 1421–1429
Chlorsalicylate biodegradation, 1421
Choanoflagellates, 2617, 2618–2619
Cholera, 776, 853–861, 3320
Cholesterol, 1257
Cholic acids, alkaliphiles, 228
Choline sulfate, soil salinity, 2778–2789
Chondrilla, 974
Chondromyces, desert environment, 1578
Chrionomidae, in water treatment systems, 1723
Chromate, 606–608, 1878, 1894
Chromatium/Chromatiaceae (See also Halochromatium), 2282, 2455, 2458, 2465, 3111–3116, 3142–3147
aggregates and consortia in, 173
biofilms and, 83
nitrogen fixation and, 2193–2201, 2214–2221
in paleolimnology, 2312
phototropism in, 2471, 2477–2482
salt production and, 2805–2809
in wastewater stabilization ponds (WSBs), 3332–3333
Chromatographic effect, biofiltration, 590
Chromium (See also Heavy metals), 671–681, 694, 708, 1883–1884, 1888–1889, 3089
Chromobacterium
granular activated carbon (GAC) filters and, 1490
heterotrophic bacteria and, 1541–1552
infectious airborne bacteria and, 1696
in drinking water, 945
Chromohalobacter, 1506–1512
Chromophytes, 2504–2518
Chromulina, 2317–2327
Chronic exposure, toxicity testing, 3220–3221
Chroococcales, periphyton, 2357
Chroococcidiopsis, 963, 964, 1102–1106
Antarctic soils and, 1025
desert environment and, 1579, 1582, 1584
photoautotrophic, in low-light habitats, 839–843
subaerial communities and, 3056–3065
Chroococcus, 963, 1507–1512
alkaliphiles and, 134
photoautotrophic, in low-light habitats, 840–843
subaerial communities and, 3056–3065
Chroomonas, photosynthetic pigments, 2467
Chrysene biodegradation, 694, 696–712, 2403–2416

Chrysochromulina, 2508
Chrysodidymus, 2317
Chrysolykos, sea ice, 2835–2844
Chrysomonads, 2619
Chrysophtyes (See also Paleolimnology), 861, 2301–2306, 2317–2327, 2504–2518
Chrysophycea, 206
in paleolimnology, 861, 2301–2306, 2317–2327, 2504–2518
photoautotrophic, in low-light habitats, 837–843
photosynthetic pigments in, 2467
polar phytoplankton and, 2556
sea ice and, 2837–2844
Chrysosphaerella, 2317–2327
Chrysosporium, in allergies and illness, 1368–1372
Chymosin, 1186–1187
Chymotrypsin, 2899
Chyseobacterium, 1302–1306
Chytridiomycota, 1367–1372, 2913, 3353–3364
Chytridium, 972
Chytrids, 2913
Ciguateratoxin, 976
Ciliated protozoa (See also Protozoa), 861, 2594, 2605–2607, 2610–2611, 2617
bacteriovorous, 2611
biodegradation and, 2626–2632
marine/ocean environment and, 2619–2620
Ciliophora (See also Protozoa), 2594, 2605
Cinetochilum, 2595–2604
Ciona, 614
Cisterns (See also Rainwater catchment systems), 861, 903, 2677–2680
Citrate, 88
Citric acid, 417, 632–642
Citrobacter
biomineralization and, 675
bioremediation and, 708
coliform bacteria and, 896–905, 906–914, 906
endosymbiosis and, 1118
explosives biodegradation and, 1985
granular activated carbon (GAC) filters and, 1491, 1571–1572
high hydrostatic pressure (HHP) vs., 1556–1563
infectious airborne bacteria and, 1694–1695
metal biodegradation and, 1890
municipal solid waste landfills and, 1766
nitrogen fixation and, 2193–2201
in drinking water, 944, 946
CL20, biodegradation, 1979–1993
Clades, 2524
Cladochytrium, 2552
Cladophora, 205
algal turf scrubbing (ATS) and, 215
paleolimnology of, 2305–2306
periphyton and, 2357, 2362, 2364
Cladosporium, 423, 1650, 1655, 3360
in allergies and illness, 1361–1366, 1367–1372, 1374–1383
bioaersols and, 404–405
cold-adapted microorganisms in, 872–885
desert environment and, 1579
spores and spore dispersal in, 405, 408–409
subaerial communities and, 3057–3065
in drinking water, 945
Cladothrix, 1401
Clarification
activated sludge and, 59
algal blooms vs., 209
water treatment systems and, high-rate, 2017
Clavibacter
biocontrol use of, 2705
genetically engineered microorganisms (GEMs) and, 1279
subsurface microbial communities and, 2035, 3067–3071
Clays
biofilms and, 88
soil microorganisms and, 2058–2059
weathering, bioweathering and, 3371
Clean Water Act (CWA), 2975, 3169
Clethrionomys, 2127
Climacodium, 2506
Climate change (See also Paleolimnology), 861, 3184
cyclic climatic events and, 2558–2559
desulfurization of fossil fuels, 1041–1051
greenhouse effect and, 3184
nitrogen cycle and, 2943
paleolimnologic studies of, 2312–2313, 2324–2325
periphyton and, 2365, 2380–2382
plankton and phytoplankton, 2515–2516
polar phytoplankton and, 2558–2559, 2564–2565
protozoa and, 2630–2631
rhizosphere and, 2721–2722
Clinorotation, simulated microgravity, 3000
Clitocybe, explosives biodegradation, 1983
Clone library screening, 2734
Cloning, 861, 2492–2494, 2524, 2732–2733
Archaea and, 247
cold-adapted microorganisms and, 3203–3206
soil genetic ecology, 2920–2921
stress response and, 3026
Clonothrix, 3101
Closed loop bioremediation, 695
Clostridia, 1236, 2551
Clostridiales, halophiles, 1515–1529
Clostridium, 136, 182–189, 861–871, 1233, 1854, 3129, 3102, 3130, 3131–33, 3145–3147
activated sludge and, 742–748
anaerobic granulation and, 232–245
bacteriophages and, 359
bioaerosols and, 455, 3324–3325
biodegradation and, 509
biofilms and, 82
bioremediation and, 706
biotechnology and, 3206
bioterrorism and (See Botulism)
cold-adapted microorganisms in, 872–885
cold-shock response and, 886–895
desert environment and, 1578
diazotrophy in, 2541–2547
endosymbiosis and, 1118
fecal contamination and, 1257, 1269
filtration and, 2709
gene transfer and, 1409
genetically altered, in biotechnology, 1447
halophiles and, 1521–1529
high hydrostatic pressure (HHP) vs., 1559–1563
hydrothermal vents and, 1622
metal biodegradation and, 1886
microbial insecticides using, 1714
municipal solid waste landfills and, 1760, 1766
nitrogen fixation and, 2193–2201, 2212–2221, 2938
oxygen and, 2278
psychrophilic, 2640–2646
rain/in rainwater roof catchment systems, 2680, 2682
sampling of, 2813
in source water, 2974
toxic solvents and, 3153
in wastewater/sewage, 3173

Clostridium, (*continued*)
water treatment systems and, 2015, 2266
in wetlands for wastewater treatment, 3400
Club root, 2913
Cluster analysis, 310–311, 1005–1006
Clyindrospermopsin, 987–995
Coagulation, 871
aggregates and consortia in, 162
algal blooms and, 208, 209
biodegradable dissolved organic carbon (BDOC) and, 494, 495
water treatment systems and, 2015–2018
Coal, 677, 1049
Coal gas biodegradation, 916–917, 2404
Coal tar bioremediation, 694, 2404
Coastal waters, nitrogen fixation, 2218
Cobalt (See also Heavy metals), 1879–1894, 2961
algae biotechnology and, 199
bioleaching and, 632–642
resistance of bacteria to, 608
soil microorganisms and, 2887
Coccachloris, 972
Cocci, 2882
Coccidioides, fungi, 1368
Coccidiosis, 1734–1737
Coccoliths, 2509, 2515
Cochaperones, stress response, 3030
Cochilobolus, 410, 2913
Cochlodinium, 195
Codakia, 1606, 1609
Codium, harm/in harmful algal blooms (HABs) and red tides, 2689–2693
Coelenterates, bioluminescence, 657–663, 1830
Coelenterazine, 1830
Coelomycetes, 3353–3364
Coenzymes, Archaea, 256–257
COG, 1450
Cohesion, extracellular polymeric substances (EPS), 1224–1225
Cold-active enzymes, 871, 3206–3210
Cold-adapted microorganisms (See also Psychrophilic bacteria), 871–885, 2639
agricultural biotechnology using, 881
in Antarctica, 2557–2558
aquaculture and, 3215
in Arctic Ocean, 2556–2558
bioaugmentation and, 3212
biocatalysis using, 881
biodegradation and, 3210–3215
biohydrometallurgy, 881–882
bioremediation using, 882–883, 3210–3215
biostimulation and, 3211–3212
biosynthesis in, 875–876
biotechnology and, 879–883, 3203–3219
cellular adaptations in, 874
cloning and, 3203–06
cold-shock proteins in, 874, 885–895
cold-shock response and, 874, 885–895
Csps and cold-shock response in, 888–892
cyanobacteria and, 963
cyclic climatic events and, 2558–2559
detergents and, 881
ecology of, 872–873
endothilic microorganisms and, 1103
enzymes and, 876–879, 3206–3210
extremeophiles and, 1232–1237
fatty acids and, 875–876, 888
food processing and, 879–881
genetic compatibility among, 3204–3205
growth characteristics of, 873
homeophasic theory in, 875
homeoviscous adaptation theory in, 875, 887
intracellular vs. extracellular enzymes in, 876
limits of adaptation in, 879
lipids in, 874–876, 887–888
membranes in, 874–876
metal degradation and, 3216
molecular biology and, 883
nucleic level cold-shock response and, 888
permafrost and, 2367–2385
phytoplankton of polar seas as, 2554–2565
polyunsaturated fatty acids (PUFA) in, 3215
protein engineering and, 3208–3209
proteins and, 874, 883, 888–893
psychrophiles as, 871–885, 2639–2646
psychrotrophs as, 871–885
ribosomal level cold-shock response and, 888
sea ice microorganisms, 2833–2844
snow and ice environments, 2872–2880
soil microorganisms and, 2889
subaerial communities and, 3061
subsurface microorganisms and, 2025
thermal regulation in, 875–876
wastewater/sewage treatment using, 882
Cold desert environment, soil microorganisms, 1023–1029
Cold extraction, 924
Cold-shock proteins, 874, 885–895
Cold-shock response, 874, 885–895
Cold-tolerant enzymes, Archaea, 268
Colds, 338
Coleophoma, 1579
Coleps, 2606
Coliform bacteria, 895–905
assimilable organic carbon (AOC) and, 312–327
bioaerosols and, 3327
biofilms and, 621, 907–909
bottled water and, 796
control of, 905–914
distribution case studies in, 909–913
fecal, 896–898
granular activated carbon (GAC) filters and, 1490–1491
heterotrophic bacteria and, 1541–1552
municipal solid waste landfills and, 1766
occurrence of, in U.S., 907
opportunistic, 898–899
pathogenic, 898–899
regrowth of (See Biodegradable dissolved organic carbon)
sampling for, 899
in source water, 2973
sources of, in drinking water, 906
Total Coliform Rule (TCR) and, 905, 906–907
in wastewater stabilization ponds (WSBs), 3334–3336
in drinking water, 895–914, 944, 946–951, 946
in wetlands for wastewater treatment, 3393–3397
Coliphage (See Bacteriophages; Somatic coliphages)
Colitis, Clostridium, 862–871
Collar, 2321
Collectotrichum, 405, 413
Collision frequency, kinetics of growth, 1741–1745
Colloidal particles, 928
adhesion in biofilms and, 127–128, 2964–2965
floc formation and, 2002
virus filtration and, 2097
Colonization
anaerobic granulation and, 241–243

bacterioplankton and, 2520
biofilms and, 1083
biofouling and, 611–612
heterotrophic bacteria and, 1546
subaerial communities and, 3061
Colorimetry, 381, 762
Colorless sulfur bacteria, 3097–3098
Colpidium, 2595–2604, 2607, 2626–2632, 3173
Colpoda, 3173
Coltivirus, 2753–2773
Colwellia
biotechnology and, 3204, 3205
cold-adapted microorganisms and, 875
hydrothermal vents and, 1610
psychrophilic, 2640–2646
Comamonas, 1200, 3110
filamentous forms of, in activated sludge, 1300–1306
spores and spore dispersion in, 420
subsurface microbial communities and, 2035, 3065–3071
Cometabolic reductive dechlorination, 508–509
Cometabolism, 914, 2386–2387
Commercial use of microorganisms (See Regulation of commercial uses)
Communicable diseases, 1690
Community analysis, subsurface microorganisms, 2030–2040
Community composition, lipid biomarkers, 1819
Community genome arrays (CGAs), 1977
Community level physiological profile (CLPP), 1580
Comparative genomics, 1450
Compatible solutes, Archaea, 273
Competition, biocontrols, 456
Complement fixation (CF), adenoviruses, 98
Completely autotrophic N removal over nitrite (CANON), 11–14
Completely mixed batch reactor (CMBR), 44, 75–76
Completely mixed flow reactor (CMFR), 44, 45, 75–76, 75
Complexation of heavy metals, 1894, 1902–1913
Composite transposons, 1200
Compost (See also Bioremediation), 914–927
activated sludge and, 738
biodegradation in, 914–927
biofiltration and, 592, 914–927
biopiling and, 914–927
bioremediation and, 693, 695, 914–927
cold extraction and, 924
cool down period in, 915
detoxification using, 916–917
enteroviruses and, 1173
explosives and, 922–924, 1988
fungi and, 2911–2912
halogenated compounds and, 919–920
humic substances in, 915
hydrocarbons and, 917–919
lipid biomarkers of, 1822
mesophilic microorganisms in, 915–916
microorganisms in, 915–916
military chemicals, 916–917, 922–924
municipal solid waste landfills and, 1759–1762
nutrients and, 915
organic matter and, 915–927
organic pollutants and, 924–925
pesticides and, 921–922
petroleum products and, 917–919
pH levels vs., 915
polycyclic aromatic hydrocarbons (PAH) and, 916–919
principles of, 915–916
soil contamination and, 921–922
Soxhlet extraction and, 924
stabilization and maturation period in, 915
temperature vs., 915–916
thermophilic microorganisms in, 915–916
total petroleum hydrocarbons (TPH) and, 916–919
Comprehensive microbial resource (CMR), 1449–1450
Computer simulation of biofilms, 2089
Concentration rate, 1008
Concrete, biodeterioration, 523–525, 3370–3371
Conditioning films (See also Biofilms), 101, 127, 559, 611, 928–941
adhesion and, 938–939
adsorption of macromolecules in, 937
amides in, 937–938
analysis of, 929–936
Brownian motion and, 936
chain elasticity in, 937
composition of, 937–938
contact angle analysis of, 930–932
deposition of, 938
electrokinetic analysis of, 933
electrospray ionization (EI) analysis of, 934
electrostatic interactions in, 936
ellipsometric analysis of, 935
filters for, 929
formation of, 936–937
Fourier transform infrared spectrometric (FTIR) analysis of, 934–935
Fourier transform Raman spectroscopic analysis of, 935
fragmentation analysis of, 932–933
glycoproteins in, 937–938
mass spectrometry (MS) analysis of, 933–934
mercury drop electrode analysis of, 932
near field optical microscopic analysis of, 935
nutrients in, for bacteria, 939–940
organic and inorganic components of, 928
polar interactions in, 937
polysaccharides in, 937–938
proteins in, 937–938
sampling of, 928–928
scanning probe microscopic (SPM)analysis of, 935–936
substratum surface and, modification by, 938
surface enhanced Raman spectroscopy (SERS) analysis of, 935
thickness of, 929
X ray photoelectron spectroscopic (ESCA) analysis of, 934
Confocal laser scanning microscopy (CLSM) (See also Image analysis), 56–57, 558, 570, 1335, 1338, 1416, 1675, 1772–1788
Conidia, 1647
Coniothyrium, 453, 454
Conjugaphyta, paleolimnology, 2302–2306
Conjugation, 1409–1413
Conjugative transposons, 1202–1203
Conjunctivitis, adenoviruses, 92–100
Connate water, 2418
Conservation of energy, aerobic respiration, 149–151
Conservation reserve programs, quality of soils, 2951–2952
Consortia (See Aggregates and consortia)
Constant denaturant capillary electrophoresis (CDCD), 814
Constants, kinetic, as measure of S, 1740–1741

Constructed Wetland Continuous Stirred Tank Reactor (CSTR), 695
Contact angle analysis/measurement (CAM), 2007–2008
  conditioning films and, 930–932
  hydrophobicity and, 1600–1601
Contact lens cleaning, bottled water, 800
Contact stabilization, in activated sludge, 76–77
Contact time, 495, 1069
Contact zones, activated sludge foaming, 5–7
Contagious diseases, 1690
Contrast, image, 1679
Conventional filtration, 2708
Conventional optical microscopy (COM), 2008
Cool down period in composting, 915
Cooling systems, biofilms, 579
Cooxidation, 2292
Copiotroph (See also Oligotrophic bacteria), 2268, 2271
Copper (See also Heavy metals), 1878–1894, 1902–1913, 2961
  algae biotechnology and, 196, 200
  cyanobacteria and, 969
  in marine/ocean environment, 1706
  municipal solid waste landfills and, 1763–1764
  resistance of bacteria to, 608
  soil microorganisms and, 2887
Coprinus, 916, 1983
Coprostannone, 1257
Coprostanol, 1257
Coprosterol, 1257
Coral bleaching, 1117
Coral reefs
  endosymbiosis and, 1116–1117
  nitrogen cycle and, 2183, 2219
Corbicula, 3019
Cordyceps, 2913
Corethron, 2506
Coriaria, 2209
Coronavirus, in spas and hot tubs, 2980–2984
Corrosion (See Biocorrosion; Microbially induced corrosion)
Corticium, 916
Corticoviridae/Corticovirus, 365–374
Cortinarius, 2124–2132
Corynebacterium
  activated sludge foaming and, 5–7, 5
  alkaliphiles and, 228
  biodegradation and, 1874, 2291–2300
  biofilms and, 2342–2356
  biosurfactants/bioemulsions and, 753, 756
  desert environment and, 1578
  granular activated carbon (GAC) filters and, 1490
  heterotrophic bacteria and, 1541–1552
  metal biodegradation and, 1885, 1890
  soil salinity and, 2779–2789
  subsurface microbial communities and, 3067–3071
  in drinking water, 945
Coryneform, adhesion in biofilms, 123
Cosmarium, 2304–2306
Cosmetics (See also Biosurfactants), 189–204, 952
Cosmic radiation, space microbiology, 2985
Coxiella, 772, 1689–1697
Coxsackievirus, 1152, 2743, 2745
  biodegradation and, 3289–3300
  soil/in soil, 3273–3276
  in source water, 2969–2978
  in spas and hot tubs, 2979, 2980–2984
  subsurface microorganisms and, 2025
  in wetlands for wastewater treatment, 3398
Crenarchaeota
  Archaea and, 246–259, 277, 280–285, 295, 299–301
  bacterioplankton and, 2526
  desert environment and, 1578
  halophiles and, 1515–1529
  nitrogen fixation and, 2212–2221
  tomato roots and, 301
Crenothrix, 676, 3101
Creosote biodegradation, 694, 2404
Cresol biodegradation, 605, 1763
Cretaceous shales and sandstones of Southwestern U.S., 2042–2047
Crinipellis, 2914
Critical micelle concentration (CMC), biosurfactants/bioemulsions, 751
Cropping systems, enzyme activity, 2907
Cross connections, cyanobacteria, 943
Crotonobetaine, soil salinity, 2778–2789
Crude oil (See also Hydrocarbons; Oil spills), 952
  biodegradation of, 2402–2404, 2930
  desulfurization of, 1048–1049
Crustacea
  endosymbiosis and, 1117
  hydrothermal vents and, 1619
  in water treatment systems, 1722–1723
Cry toxins, microbial insecticides using, 1712–1717
Cryconite, 963
Cryothecomonas, sea ice, 2835–2844
Cryptaulax, 2594–2604
Cryptobiosis, 2021
Cryptococcus, 1102–1106, 1890
  Antarctic soils and, 1025, 1027–1028
  cold-adapted microorganisms in, 872–885
  fungi and, 1368
  in permafrost, 2369
Cryptoendolithic microorganisms, 1100–1112
Cryptomonada, 2467
Cryptonectria, biocontrol use, 2705
Cryptoperidiniopsis, 2431
Cryptophtyes, 2453–70, 2505–2518
  periphyton and, 2357
  photoautotrophic, in low-light habitats, 837–843
  photosynthetic pigments in, 2467
  polar phytoplankton and, 2556
Cryptosporidium, 650–657, 903, 2598, 2079–2080, 2607
  activated sludge and, 72
  aquatic sediments and, 1252–1256
  biofilms and, 2341–2356
  bottled water and, 796
  Clostridium and, 868–871
  disinfection and, 360, 1067–1073
  filtration and, 2709
  flow cytometric studies of, 1951, 1952
  in food, 3277–3287
  granular activated carbon (GAC) filters and, 1493
  heterotrophic bacteria and, 1548
  high hydrostatic pressure (HHP) vs., 1561
  measurement of, using aerobic endospores, 141–149
  rain/in rainwater roof catchment systems, 2680
  sampling of, 2813
  in source water, 2968, 2969–2978
  in spas and hot tubs, 2979, 2980–2984
  streams and, 3021
  subsurface microorganisms and, 2025
  ultraviolet light and, 3231–3235
  in wastewater stabilization ponds (WSBs), 3334
  in wastewater/sewage, 2329–2337

water purifiers vs., 1572–1573
water treatment systems and, 1719, 1727, 2013–2019, 2262–2266, 3199
in wetlands for wastewater treatment, 3398–3399
Cryptostroma, 422
Crysophyceans, periphyton, 2357
Crystallolithus, 2508
Csps and cold-shock response, cold-adapted microorganisms, 888–892
CT concept, in disinfection, 1064–1065
Culex, in wetlands for wastewater treatment, 3399
Culturable subsurface microbial communities (See Subsurface microbial communities)
Culturable vs. unculturable organisms, 1113
Culturing
activated sludge and, 69
algae biotechnology and, 191–192
Archaea and, 246–247
astroviruses and, 333
bioaersol samples, 400–401
chloroform fumigation incubation in, 666–667
fungi and, 1648, 1652–1653
heterotrophic bacteria and, 1542–1544
hydrothermal vents and, 1611–1614
hyperthermophiles and, 1628–1633
plankton and phytoplankton, 2516
protozoa and, 2594
psychrophilic bacteria and, 2641–2642
ribosomal RNA targeted oligonucleotide probes and, 1339–1340
space microbiology and, 3000
subsurface microorganisms and, 1079
vadose zone microorganisms and, 3241–3242
Cunningham, D.D., 404
Cunninghamella, 459, 2410, 2649

Cyanobacteria and blue-green algae, 136, 206, 952–995, 1853, 2453–2470, 2549
aggregates and consortia in, 161, 164–165, 166–168, 170–181
algae biotechnology and, 189–204
algal blooms and, 204–213
Antarctic soils and, 1025
bacterioplankton and, 2524–2526
biodeterioration of mineral materials and, 519–522, 524–525
biofilms and, 83, 568–569, 1083
biomineralization and, 672
cold-adapted, 963
cold-shock response and, 887–895
desert/in desert soils and biological soil crust (BSC), 1020–1023, 1020, 1576, 1579
disinfection of, 991–992
endolithic habitats for, 963–964, 1100–1112
endosymbiosis and, 1115, 1118–1119, 1126–1128
filamentous forms of, in activated sludge, 1312
floc formation and, 992
halophiles and, 1507–1512, 1513–1529
heterotrophy in, 966
hypersaline environment and, 963
meroplankton and, 1863–1869
metal biodegradation and, 1879–1880
microbial mats and, 568–569, 966–967
nitrogen and, 967–968, 2181, 2189
nitrogen fixation and, 2189, 2212–2221
oxidation vs., 992
oxygen and, 2277–2278
oxygenic photosynthesis in, 965–966
paleolimnology of, 2304–2306
pathogenic, 972–973
periphyton and, 2357, 2358
in permafrost, 2369
phosphorus cycling and, 969, 2450
photoautotrophic, in low-light habitats, 836–843
photosynthetic pigments in, 964–965, 2466
phototropism in, 2471, 2472
plankton blooms and, 970–972, 975–981, 989–990, 2503
polar phytoplankton and, 2555, 2556
predators of, 972–973
Prochlorococcus as, 2576–2593
research in, 980–981
safety and health guidelines for, in drinking water, 990–991
salt production and, 2805–2809
snow/in snow and ice environments, 2874, 2876
soil microorganisms and, 2890–2891
in source water, 2969–2978
subaerial communities and, 3056–3065
sulfur and, 969
symbiosis in, 973–975
toxins and, 975–980, 982–995
trace metals and, 969–970
ultraviolet resistance in, 963
vertical migration in water column by, 970–972
in wastewater stabilization ponds (WSBs), 3331
water treatment systems and, 982–995
Cyanobacterial mats (See Biofilms)
Cyanochlorontans, cyanobacteria (See also Blue-green algae), 952–982

  Wards method of, in cluster analysis, 1006
Databases, genomic, 1449–1450
Datsica, nitrogen fixation, 2209
DDT biodegradation, 507–516, 703–712, 1238–1252, 1421, 2297–2300, 2933, 2963, 3415
Dead Sea, 1509
Death of bacteria, 3253–3254
Death rate, bioaerosols, 2110
Debromoaplysiatroxn, 976
Decarboxylase, in soil, 2903–2910
Decay, activated sludge processing, 23–26
Dechlorination
  cometabolic reductive, 508–509
  reductive dechlorination and dehalorespiration in, 509–510, 513–514
Deconvolution, image analysis, 1679–1681
Deep sea euryarcaheotic group (DSEG), 1611
Deep Shaft process, activated sludge, 76–77
Deferribacter, 1515–1529, 2429–2431
Defluvicoccus, 63
Degrading systems, quality of soils, 2952–2954
Dehalobacter, 511–513
Dehalococcoides, 511–513
Dehalogenation (See also Biodegradation), 507–516, 3414
Dehalorespiration, 435, 509–510
Dehalospirillum, 511, 513, 514
Dehydration (See Desiccation)
Dehydrogenase, 3170, 3207–3210, 3338
Deinococcus, 1102–1106, 1204, 2874, 3216
  bioremediation and, 1446
  desert environment and, 1582, 1584
  desiccation and, 1033–1041
  genetically altered, in biotechnology, 1446
  genomic studies and, 1442
  metal biodegradation and, 1883
  radiation and, 2987–2995
  radioactive waste degradation and, 2666–2674
Deleterious rhizobacteria (DRB), 2717, 2722
Deleya, 614, 2214–2221
Demethoxycylindrospermopisn, 977
Demethylation in biofilms, 2963
Demethylsulfonium propionate (DMSP), 3192–3193, 3192
Denatured gradient gel electrophoresis (DGGE), 28–29, 71, 247, 278, 299, 563, 1010, 1974, 2732, 2494–2496, 2735–2737, 2921
  activated sludge and, 71
  Archaea and, 247, 278, 299
  bacterial counts using, 28–29
  biofilms and, 563
  methanotrophic bacteria and study, 1931–1932
  microarray study of vs., 1974
  Spartina, 2545
Denaturing high performance liquid chromatography (DHPLC), 814
Denitrification (See also Nitrification; Nitrogen cycle), 2150, 2941–2942, 3189–3192
  activated sludge and, 8–14, 19–20, 34–38, 49, 58, 77–78
  aggregates and consortia in, 166
  algal turf scrubbing (ATS) and, 217–218
  anoxic storage in nitrogen removal processes and, 3011
  bacteria for, 1012–1013, 2891
  carbon and, 1013–1014
  controls of, 1013–1014
  desert soils and, 1022
  floc formation and, 58
  marine/ocean environment and, 1010–1019
  nitrogen cycle and, 2184
  oxygen and, 1013–1014, 2282–2283
  oxygen minimum zones (OMZs) vs., in marine environment, 1016

patterns of, in marine environment, 1016–1017
pH levels and, 1013–1014
Pseudomonas, 2632–39
quantification of, rates and, 1015–1016
sampling in, 1015–1016
in septic tank systems, 2860
temperature vs., in marine environment, 1016–1017
toxicity testing and, in soils, 3160
wetlands and, 3404
Dense nonaqueous liquids (DNAPLs), bioremediation, 436, 507–516
Deodorants, algae biotechnology, 195
Deoxythymidine diphosphate (dTDP), 3340–3341
Deoxythymidine triphosphate (dTTP), 3339–3342
Deoxyuridine monophosphate (dUMP), 3340–3341
Depolymerization, biodeterioration of mineral materials, 518
Deposition, adhesion in biofilms, 114
Derjaguin–Landau–Verwey–Overbeen (DLVO) theory of adhesion, 57, 102–106, 119–122, 124, 561, 2004
Derxia, nitrogen fixation, 2193–2201
Desert environment (See also Desiccation), 1019–1029
actinomycetes in, 1577
adaptations to, 1580–1583
algae in, 1576, 1579
amoebas in, 1579
Antarctica as, soil microbes and, 1023–1029
Archaea in soil of, 1578
autochthony in, 1583
bacteria in soil of, 1577, 1578
bioaugmentation in, 1584
biodegradation of pollutants in, 1583–1584
biological soil crusts (BSCs) and, 1019–1023
biomass of, 1576, 1577, 1579
carbon and, 1577, 1582
cold deserts, soil microbes in, 1023–1029
cyanobacteria in, 1576, 1579
desiccation and, 1029–1041, 1580–1582
diversity of microbes in, 1577–1580
dwarfing of bacteria in, 1582
endolithic microorganisms in, 1100–1112
environmental impact and conservation in, 1022
extracellular polysaccharides (EPS) and, 1577, 1581
extremeophiles and, 1232–1237
fungi in, 1576, 1577, 1578–1579
heat-shock response/proteins and, 1583
hot deserts, 1576–1586
hot deserts, endolithic microorganisms and, 1107–1110
microbial abundance in, 1577
nitrification and denitrification in, 1022
nitrogen and, 1577
nutrients and, 1576, 1582–1583
oxygen and, in soils, 1021–1022
pH levels and, 1576
phospholipid fatty acid (PLFA) profiles in, 1578, 1579
protozoa in, 1579
reclamation efforts in, plant-microbe symbiosis for, 1583
salinity of, 1576–1577, 1580–1582
soil microorganisms of, 1576–1586
solar radiation and, 1021–1022
spatial and temporal distribution of microbes in, 1577
temperature and, 1576, 1583
total organic carbon (TOC) and, 1577
water and, 1021–1022, 1576–1577, 1580–1582
Desert varnish, 963, 1103
Desiccation and dehydration, 1029–1041
aggregates and consortia in, ice embedded, 174
anhydrobiosis, 1030–31
damage by environmental agents and, 1033–1035
desert conditions and, survival under, 1039–1040
desert environment and, 1580–1582
DNA and, 1032–1041
dormancy and, 1029, 1030–1031
dynamic vacuum drying and, 1035–1036
enteroviruses and, 1174
extremeophiles and, 1232–1237
fluorescent probes and, 1335
freeze drying and, 1030, 1035, 1350–1359
fungi and, 1029, 1031
growth limits and, 1030
molecular events induced by, 1031–1035
panspermia theory and, 1029, 1037
removal of hydrate water in, 1032–1035
removal of liquid cell water in, 1031–1032
secondary reactions to, 1033–1035
space exploration and, 1035–1039
spores and, 1029, 1031, 1037–1041
subaerial communities and, 3060–3061
survival at, 1035–1039
Desmidaceae, 2301, 2302–2306, 2302
Desmids, snow/in snow and ice environments, 2874
Desmococcus, 840–843, 1107–1112, 3056–3065
Desorption limitation, biofilms, 88
Destruction/removal efficiency (DRE), biofiltration, 587, 590
Desulfacinum, petroleum reservoirs and, 2429–2431
Desulfobacter, 2849–2851, 3088–3096, 3114–3116, 3143–3147, 3193, 3414
biodegradation and, 511–514
biofilms and, 82
halophiles and, 1519–1529
nitrogen fixation and, 2214–2221
petroleum reservoirs and, 2429–2431
Desulfobotulus, flooded soils, 1326
Desulfobulbus, 2551, 3090–3096, 3114–3116
activated sludge and, 742–748
anaerobic granulation and, 232–245
flooded soils and, 1326
Desulfocella, halophiles, 1519–1529
Desulfococcus, 3090–3096, 3114–3116
Desulfofaba, psychrophilic, 2640–2646
Desulfofrigus, psychrophilic, 2640–46
Desulfohabdus, flooded soils, 1326
Desulfohalobium, 1514–1529, 3090–3096
Desulfolobus, 2429–2431, 2429
Desulfomaculum, 510, 2278, 2419, 3089–3096, 3111–3116, 3137, 3193
Desulfomicrobium, 3114–3116, 3090–3096
desulfurization and, 1047
in groundwater, 1671
halophiles and, 1519–1529
petroleum reservoirs and, 2429–2431
Desulfomonas, 3090–3096, 3111–3116

Desulfomonile, 509–510, 512, 513, 3114–3116, 3414
Desulfonatrobonovibrio, 134, 1519–1529
Desulfonema, 2851, 3114–3116
Desulfosarcina, 3090–3096, 3114–3116, 3193
Desulfosporosinus, biodegradation, 511
Desulfotalea, psychrophilic, 2640–2646
Desulfotomaculum, 1520–1529, 2054, 2848–2851, 3099–3104, 3114–3116, 3130
  biofilms and, 2962
  flooded soils and, 1326
  halophiles and, 1519–1529
  petroleum reservoirs and, 2429–2431
  sulfate-reducing bacteria (SRB) and, 467–475
Desulfovibrio, 1514–1529, 1672, 2285–2286, 2551, 2552, 2848–2851, 3087–3096, 3099–3104, 3111–3116
  anaerobic granulation and, 232–245
  biocontrols and, 455
  biodegradation and, 512, 1044
  biofilms and, 82, 2962
  biomineralization and, 672, 674
  diazotrophy in, 2541–2547
  flooded soils and, 1326
  genomic studies and, 1448
  in groundwater, 1671
  halophiles and, 1519–1529
  hydrothermal vents and, 1610
  metal biodegradation and, 1883, 1886, 1897, 1902, 1903, 1908
  nitrogen fixation and, 2193–2201, 2212–2221
  oxygen and, 2278
  petroleum reservoirs and, 2419, 2429–2431
  radioactive waste degradation and, 2666–2674
  sulfate-reducing bacteria (SRB) and, 467–475
Desulfurization of fossil fuels, 1041–1051
  benzothiophenes and, 1047–1048
  coal, 1049
  Desulfomicrobium and, 1047
  Desulfovibrio and, 1044
  diesel or crude oils, 1048
  enzymes and, 1046
  genes for, 1045–1046
  hydrocarbons and, 1046–47, 2414
  hydrodesulfurization (HDS) in, 1042
  microbial degradation and, of dibenzothiophene, 1042–1049
  monooxygenase system for, 1046
  oil–water emulsions and, 1047
  Sulfolobus and, 1045
  thermophilic microbes and, 1045
Desulfurobacterium, 1614, 1620–1628
Desulfurobolobus, Archaea, 298
Desulfurococcales, 1629–1646
Desulfurococcus, 298, 1233, 1234, 1611, 1624–1646
Desulfuromonas, 82, 511, 512, 2474, 3193
Detachment of biofilms, 2087–2088
Detergents, 1176
  alkaliphiles and, 220, 226
  alkalithermophiles and, 3127
  biofouling vs., 604
  cold-adapted microorganisms and, 881
  enzymes and, 1178–1180, 3209–3210
Detoxification (See Bioremediation and detoxification)
Deuteromycota, 1367–1372, 3353–3364
  in allergies and illness, 1359
  soil microorganisms and, 2913–2914
Dewatering of activated sludge, 54, 59–60, 748
Dextran sulfate, algae biotechnology, 195
Dextransucrase, in soil, 2903–2910
Diabetes, enteroviruses and, 1151–1152
Diacetylphloroglucinol (Phl), 457
Diadesmis, 840–843
Diadinoxanthin, 2307–2317, 2512
Diadochism, in minerals, 633
Diagenesis, subsurface microorganisms, 1074
Diamidinophenylindole (DAPI), 1068, 1676, 1776–1778, 1949, 2596, 2653, 3196
Diarrheal diseases and gastroenteritis, 93–100, 338, 2743, 3288–3300
  Aeromonas and, 1091–1099
  astroviruses, 327–337
  Campylobacter and, 803–811
  cholera and, 853–861
  Cryptosporidium and, 650–657
  Cyclospora and, 995–1001
  disinfection and, 1067
  Escherichia coli and, 2337–2339
  in food, 3277–3287
  Giardia and, 1469–1489
  human caliciviruses and, 1586–1598
  Isospora and coccidiosis, 1734–1737
  Norwalk-like viruses (NLVs) and, 2221–2235
  rotavirus and, 2743, 2753
  Salmonella and, 2789–2802
  Shigella and, 2865–2871
Diatomaceous earth, 204
Diatomae, 206, 2467
Diatomophyceae, harm/in harmful algal blooms (HABs) and red tides, 2685–2693
Diatoms, 204, 1051–1053, 2504–2518
  algal turf scrubbing (ATS) and, 215
  Antarctic soils and, 1025
  biofilms and, 612–613, 1051–1063
  biofouling by, 1051, 1058–1059
  calcium and, 1053, 1055
  carbon metabolism in, 1052
  cell–cell interactions in biofilms of, 1056–1058
  cell structure and taxonomy of, 1052
  dissolved organic carbon (DOC) and, 1061
  extracellular carbohydrate polymers in, 1053–1055
  extracellular matrix (ECM) and, 1054, 1058
  extracellular mucilage (ECM) in, 1053
  extracellular polysaccharide (EPS), 1060–1061
  footpads or footprints of, 1053–1055
  frustule associated components (FACs) and, 1054
  frustulins and, 1055
  harm/in harmful algal blooms (HABs) and red tides, 2685–2693
  meroplankton and, 1863–1869
  motility, adhesion, and chemosensing in, 1052–1053
  in paleolimnology, 2301–2306
  periphyton and, 2358
  photoautotrophic, in low-light habitats, 840–843
  photosynthesis in, 1060
  phycosphere of, 1056–1057
  salt production and, 2805–2809
  sedimentation and, 1059–1061
  snow/in snow and ice environments, 2874
  subaerial communities and, 3056–3065

surface energy of substratum and, 1055–1056
Diatoxanthin, 2453–2470
Diauxic growth vs. mixed substrate growth, 1870–1872
Diazinon bioremediation, 705–712, 921–922
Diazotrophic bacteria (See also Nitrogen fixation), 1063, 2541–2547, 2550–2551
Dibenzathrancene bioremediation, 696–712
Dibenzofurans biodegradation, 1421
Dibenzoparadioxin biodegradation, 2297–2300
Dibenzothiophene (DBT) biodegradation, 1042–1049
Dibenzothiophene biodegradation, 696–712, 2297–2300, 2403–2416
Dibromo chloropropane (DBCP) biodegradation, 2933
Dibutylphthalate (DBP), 882–883
Dicamba, composting, 921–922
Dichlorobenzene biodegradation, 1763
Dichlorodiphenyl chlororoethane (DDE) biodegradation, 1238–52
Dichlorodiphenyl trichloroethane (See DDT)
Dichloroethane (DCA) biodegradation, 434–442, 512–513, 919–920, 1763
Dichloroethylene (DCE), 434–442, 1937–44
Dichloromethane (DCM) biodegradation, 511–514, 919–920
Dichlorophenol, 3147–55
Dichlorophenoxyacetic acid (2,4D) biodegradation, 507–516, 1421, 2385–2393, 2931
Dichlorophenoxylacetate bioremediation, 703–712
Dichloroztriazin aminofluorescein (DTAF), 1676
Dictyocha, 2467, 2508
Dictyostelium, 1055, 1952, 2912
Didenium, 975, 2474, 2614
Didymella, spores and spore dispersal, 406, 413
Didymohelix (See also Gallionella), 1401
Dielectrophoresis, 820
Diesel fuel biodegradation (See also Hydrocarbons), 916–917, 1048–1049, 2930
Diethers, Archaea, 249–259
Diethylhexyl phthalate (DEHP), 1822
Dietzia, 3–7
Difference imagery, 1683–1684
Differential display (DD) technique, 538
Differential interference contrast (DIC) microscopy, 1675
Diffusion of bioaerosols, 427
Diffusion of gases through soil, 1749
Diffusion of solutes through soil, 1748–1749
Digester, 695
Digital cameras, 1676
Digitaria, nitrogen fixation, 2199
Diglyceride fatty acid (DGFA), subsurface microorganisms, 1079, 2030
Digoxigenin, 1334
Dihalogens, biofiltration, 589
Diisopropanolamine bioremediation, 707
Diisopropyl ether (DIPE) biodegradation, 1994–2000
Diisopropyl fluorophosphates (DTPs), 848
Dimefuron, composting, 921–922
Dimethyl sulfide (DMS), 3192
Dimethyldisulfide (DMDS), 2645
Dimethylhydrazine bioremediation, 706–712
Dimethyloxazoline (DMOX), psychrophilic bacteria, 2645
Dimethylsufonioacetate (DMSA), soil salinity, 2778–2789
Dimethylsulfide (DMS), 1701, 3192
Dimethylsulfoniopropionate (DMSP), 1701, 2778–2789
Dimethylurea (DMCU), 175
Dinitrogen, 8–14, 1010–1019, 2176–2188
Dinitrogenase (See also Nitrogen fixation), 1063, 2205
Dinitrotoluene (DNT) biodegradation, 1979–1993
Dinoaxanthin, in paleolimnology, 2307–2317
Dinobryon, 210, 2556
Dinoflagellates (See also Pfiesteria), 205, 2504–2518, 2617, 2618
  bioluminescence in, 1830
  harm/in harmful algal blooms (HABs) and red tides, 2685–2693
  meroplankton and, 1863–1869
  Pfiesteria and toxic Pfiesteria complex (TPC), 2431–2447
  photosynthetic pigments in, 2466
  salt production and, 2805–2809
Dinophyceae, 2466, 2685–2693
Dinophysis, 2461, 2507, 2686–2693
Dinophyta, 837–843, 2357
Dinoseb bioremediation, 705–712
Dioporeia, meroplankton, 1867–1869
Dioxin biodegradation, 507–516, 1238–1252, 1421, 2297–2300
Dioxin bioremediation, 713
Dioxygenases (See also Oxygenase enzymes), 1063, 2289–2300, 3412
Dipeptides, soil salinity, 2778–2789
Diphenyl, 605
Diplogaster, 1720
Diptera, in water treatment systems, 1723
Dipyridyl, microbial protection from, 432
Direct filtration, 2708
Direct viable count (DVC), biofilms, 565
Directed evolution in biofilms, 1176–1177
Disaccharides, 432, 1350–1351, 2716
Discaria, nitrogen fixation, 2208
Discoloration of materials, bioweathering, 3367
Discosphaera, 2508
Discriminant data analysis, 1007–1009
Disease resistance, plant, 2722–2723
Disinfection, 359–361, 1063–1073
  aerobic endospores and, in measuring effectiveness, 140–149
  algal blooms vs., 209
  algal turf scrubbing (ATS) and, 216–217
  analysis of, 1068–1069
  assimilable organic carbon (AOC) and, 313–327
  bacteria in home/residential environment and, 341–342
  bacteriophages and, 359–360
  biofilms and, 580–582, 625–628
  biofouling vs., 625–628
  bottled water and, 797–798
  bromine as, 3266–3267
  by-products (DBP) of, 1066
  chloramines in, 1069
  chlorine as, chlorine, 6–7, 96, 360, 498, 582, 589, 603, 607, 625–626, 1063–1067, 1069, 1172, 1707, 2333–2334, 2979, 3184, 3265–3267
  chlorine dioxide in, 1063–1070
  Clostridium, 867–871
  concentration in, 1069
  contact time and, 1069
  CT concept in, 1064–1065
  cyanobacteria and, 991–992
  diamidinopheylindole (DAPI) in, 1068
  enteroviruses and, 1172
  factors influencing, 1067–1069

Disinfection, (*continued*)
filtration and (See Filtration)
fluorescein diacetate (FDA) in, 1068
granular activated carbon (GAC) filters and, 1493–1494
heat/thermal, 361, 387, 1174, 3264
heterotrophic bacteria and, 1541–1552
home water treatment systems using, 1567
iodine as, 3266–3267
ionization as, 3264–3265
Legionella vs., 1803
metal ions as, 3267
monochloramine in, 1063–1066, 1069
nitrification vs., in water treatment systems, 2172–2175
ozonation in, 6–7, 87, 273, 430–431, 496–497, 603, 797–798, 1067, 1070–1071, 1172, 2334, 2979, 3262
propidium iodide (PI) in, 1068
protozoa vs., 1066–1073, 2333–2334
Pseudomonas vs., 2632–2639
rain/in rainwater roof catchment systems, 2681–2683
risk assessment and, 2749
sampling in, 1068–1069
solar powered, in RRCS, 2682–2683
in spas and hot tubs, 2979
synergistic effects of disinfectants in, 1071
ultraviolet light in (See also Ultraviolet radiation), 1071, 1173, 2334, 3230–3235
viability testing and, 1068–1069
viral, 3260–3268
virus transport and removal in subsurface, 2094–2107
in water treatment systems, 1729, 2266
Dispersants, biofilms vs., 606
Dispersion
of bioaerosols and, 2108–2112
of viruses, 2101
Dissimilatory sulfate reduction, 3087
Dissolved air floation (DAF), 2017, 2266
Dissolved combined amino acids (DCAA), 85, 928
Dissolved free amino acids (DFAA), 85, 928
Dissolved organic carbon (DOC), 485–507
biofilms and, 84–87, 89, 569, 1086–1087
conditioning films and, 928
diatoms and, 1061
in groundwater, 1665
landfill leachate and, 1768
protozoa and, 2596
streams and, 3017
subsurface microorganisms and, 1074
Dissolved organic material (DOM)
aggregates and consortia in, 175
biofilms and, 569
sea ice and, 2838
subsurface microbial communities and, 1455
Dissolved organic nitrogen (DON), 2176–2188
Dissolved inorganic phosphorus (DIP), 2448–2453
Dissolved organic phosphorus (DOP), 2448–2453
Dissolved oxygen (DO)
activated sludge and, 1311
biofilms and, 2005–2006
floc formation and, 2005–2006
in source water, 2972
Distillation, home water treatment systems using, 1567
Distribution system for water, 941–952
antibiotic resistant bacteria in, 944
back siphon in, 943
biofilms in, 945–947
bird habitation in storage tanks for, 950–951
breaks and repairs in, 943, 949
coliform bacteria in, 944, 946–951
corrosion and, 942–943
cross connections in, 943
granular activated carbon (GAC) filters and, 1494
heterotrophic bacteria and, 1546–1548
illegal taps in to, 949–950
macroinvertebrates in, 945
microbial flora in, 943–945
microorganisms in, 1725
monitoring microbial activity in, 947–948
opportunistic pathogens in, 944–945
pathogenic bacteria in, case studies in, 948–951
pigmented bacteria in, 945
pipes in, service life of, 942
pressure interruptions in, 949–950
quality control in, 941–952
quality management for, 943
sampling of, 2813
stability of water in, 947
sulfate-reducing bacteria (SRB) in, 3102
sulfur bacteria and, 3101–3103
turbidity and, 944
ultramicrobacteria in, 945
Disturbance of soils, 3122
Dithiocarbamates, 607
Ditylum, 2506
Diuron, diatoms vs., 1060
Diversity (See Biodiversity)
Diving techniques and equipment, in water-filled caves, 825–826
DNA chips (See Biochips)
DNA type microarray, 1969
DNA/RNA analysis and genetics, 1195, 1858, 2269
acquired genes and, 1446
amplified rDNA restriction analysis (ARDRA) in, 2737–2738, 2920
bacterioplankton and, 2523–2524
biodegradation and, 2387
biofilms and, 565–566
bioinformatics, 1449–1450
biomass estimation and, 2656–2657
capillary electrophoresis and, 811–821
captured megaplasmids in, 1446
catabolic pathways in, 1203–1204
clades, 2524
clone library screening in, 2734
cloning and, 2492–2494, 2524, 2732–2733
cold-adapted microorganisms and, 3203–3206
cold-shock response and, 888
community genome arrays (CGAs), 1977
comparative genomics and, 1450
composite transposons and, 1200
conjugation and, 1409–1413
conjugative transposons and, 1202–1203
denatured gradient gel electrophoresis (DGGE), 28–29, 71, 247, 278, 299, 563, 1010, 1974, 2494–2496, 2732, 2735–2737, 2921
desiccation and, 1032–1041
directed evolution and, 1176–1177
DNA rearrangement and, 1200
DNA-based phylogeny in, 2492–2496
enzyme inactivation and, 1196–1197
evolution and, 1195
exogenous isolation and, 1410

fecal contamination and, 1258
fingerprinting techniques in, 2734–2735, 2739
fluorescent probes and, 1333–1343
forward sample array hybridization, 2731–2732
functional gene arrays (FGAs), 1974–1996
functional genomics and, 1448–1449
gene activation and inactivation in, 1199–1200
gene capture in, 1200
gene chips and, 1448–1449
gene clusters, 2524
gene exchange in biofilms and, 1408–1420
gene expression and, using microarrays, 1971–1974
gene transfer techniques in, 1280, 1285
genetic engineering and, 1449
genetically engineered microorganisms (GEMs) (See Genetically engineered microorganisms)
genetically modified microorganisms (GMMs) in, 1429–1440
homologous recombination in, 1197–1199
horizontal gene transfer and, 1195, 1201–1203, 1446
hybridization in, 2922
identification of isolates in, 1960–1961, 1964–1965
insertion elements for, 1199
integrons and, 1201
IS1071 insertion element, 1200
knockout studies in, 1449
microarray analysis in, 1968–1979
microgravity and, 3001
mRNA detection in, 2499
mushroom culture and, 1384–1385
mutations, radiation induced, 2993
naked DNA uptake, 1203, 1280
oligonucleotide probe hybridization in, 2497–2499
oligotrophic bacteria and, 2273
orthologs and, 1450
phages and, 1202
phylogenetic oligonucleotide arrays (POAs), 1976–1977
phylogenetics, 2489–2501
phylotypes, 2524
plasmids and, 1201–1202
polymerase chain reaction (PCR), 1853, 2492–2494, 2730, 2733–2739
radiation effects and, 1986–1994
rearrangement and gene capture in, 1200
recombinant DNA in, 1176–1178
regulation of, 1204
regulatory functions in, 1197
replication and repair systems in, 1195–1196
replicative transposons and, 1201
retrotransfer in, 1201–1202, 1413, 1427
reverse transcription polymerase chain reaction (RT PCR) in, 1162–1164, 2500
ribosomal intergenic spacer analysis (RISA), 2738–2739
ribosomal RNA-based phylogeny in, 2491–2492
ribotyping, 2728–2741
RNA-based methods of phylogeny in, 2496–2499
sequencing in, 2491
shotgun cloning in, 2732–2733
single-strand conformational polymorphism (SSCP) in, 28–29, 299, 536–537, 813, 2737
soil genetic ecology, 2918–2923
soil microorganism and diversity in, 528–544
subsurface microorganisms and, 2035
subtractive hybridization and, 1451–1452
temperature gradient gel electrophoresis (TGGE), 299, 536–537, 818–819, 2735–2737
temporal temperature gradient electrophoresis (TTGE), 2735–2737
terminal fragment length polymorphism (T-RFLP) in, 28–29, 71, 177–178, 278, 299, 536–537, 563, 829, 1974, 2496, 2737–2738, 2921
transcription in, 1199–1200, 1637–1639, 2489–2491
transduction in, 1415–16
transformation in, 1413–1415
translation in, 1637–1639, 2489–2491
transposition and integration in, 1199
transposons in, 1280
viruses as gene transfer tools, 3205, 3308
wastewater/sewage treatment and, 3339–3342
Dobson units, 2565
Docosahexaenoic acid (DHA), cold-adapted microorganisms, 880–881
Dolomite, subsurface microbial communities, 1464–1466
Domestic microbiology (See Residential environment, bacteria in)
Dormancy, desiccation, 1029, 1030–1031
Dose response, toxicity testing, 2745–2747, 3162–3164
Doubling time, bacterioplankton, 2529
Drain fields, septic tank, 2855, 2858, 2859
Drancunculus, in water treatment systems, 1718
Drechsler, Charles, 2914
Drechslera, 405, 408, 410, 1651
Drinking water (See Water treatment systems)
Drop collapse test, biosurfactants/bioemulsions, 762
Drop shape analysis, biosurfactants/bioemulsions, 762
Drosophila
endosymbiosis and, 1121–1122
genomic studies and, 1442
stress response and, 3047
Drugs, biotechnology, 1447–1448
Dry air spora, 405, 408–414
Dryas, nitrogen fixation, 2209
Dual media filtration, 2707
Dunaliella, 1507–1529, 1851, 1853, 1854, 2508
algae biotechnology and, 189–204
salt production and, 2805–2809
Dust, bioleaching, 640
Dwarfing of bacteria, in desert environment, 1582
Dyes, microbial protection from, 432
Dynamic vacuum drying, 1035–1036
Dysentery (See also Diarrheal diseases), Shigella, 338, 2865–2871

E

Eadie–Hofstee transformation, 2901
Earthworm Toxicity Test, 725
Ebola virus, 777–778
Echinenone, in paleolimnology, 2307–2317
Echovirus, 389, 2743, 2745
bioaerosols and, 3327
biodegradation and, 3289–3300

Echovirus, (*continued*)
municipal solid waste landfills and, 1766
soil/in soil, 3271–3276
in source water, 2969–2978
in spas and hot tubs, 2979, 2980–2984
in wetlands for wastewater treatment, 3398
Ecocyc, 1450
Ecological selection in biofilms, 546
Ecology, bioremediation, 693–694
Ectenagena, 1606
Ectendomycorrhizal fungi, 2125–2126
Ecthyma gangrenosum, Aeromonas, 1091–1099
Ectoenzymes, 1210, 2451
Ectoine, soil salinity, 2778–2789
Ectomycorrhizal fungi (See Mycorrhizae)
Ectosymbionts or ectobionts, 1113
Ectothiorhodospira, 2482, 3111–3116
alkaliphiles and, 134
halophiles and, 1517–1529
phototropism in, 2471, 2472, 2477–2489
soil salinity and, 2777
in wastewater stabilization ponds (WSBs), 3332–3333
Ectothiospira, nitrogen fixation, 2193–2201
Edgeworthia, 227
EEO, 820
Effective concentration (ECx), 3163
Eicosapentaenoic acid (EPA), 880–881, 3215
Eimeriina, 650
Einstein unit, 2565
El Nino, 1040, 2558
Elaphomyces, 2124–2132
Eleagnus, nitrogen fixation, 2209
Electrical fields vs. biofilms, 606
Electrochemically activated water, biofouling vs., 603–604
Electrochemiluminescence, detection, 1132
Electrogenic protein complexes in aerobic respiration, 150
Electrokinetic analysis, conditioning films, 933
Electromagnetic radiation, soil microorganisms, 2061
Electron acceptors, bioremediation, 714, 724
Electron capture detector (ECD), 3160
Electron microscopy (EM), rotaviruses, 2765, 2767
Electron transfer, aerobic respiration, 151, 153–154
Electron transport system (ETS), 1783–1784, 2884
Electron use, bacterioplankton, 2522
Electronegative filters, enteroviruses and, 1156–1159
Electrophoresis (See Capillary electrophoresis)
Electroporation, freeze drying, 1355–1356
Electropositive filters, 1159–1160
Electrospray ionization mass spectrometry (ESI MS), 309, 820
Electrospray ionization (EI) analysis, conditioning films, 934
Electrostatic forces
adhesion in biofilms and, 103–104, 120
biofilms and, 2004
conditioning films and, 936
floc formation and, 57, 2004
hydrophobicity and, 1599
Electrostatic precipitators, bioaerosol samplers using, 397
Eliminases, 1210
Ellipsometry, conditioning films, 935
Elminius, biofilms, 614
Elongation factor 2, 3207–3210
Embden–Meyerhof (EM) pathway, hyperthermophiles, 1633
Embedment, fluorescent probes, 1335
Embellisia, desert/in desert soils and biological soil crust (BSC), 1020–1023
Emergency water supplies, heterotrophic bacteria, 1550
Emergent plants, marine/ocean environment and (See also Spartina), 2539–2549
Emericella, 1647
Emiliana, 1854, 2508
Empty bed contact time (EBCT), biodegradable dissolved organic carbon (BDOC), 495
Emulsan, biosurfactants/bioemulsions, 761
Emulsion index, 762–763
Emulsions, desulfurization, 1047
Encapsulation of microbial cells, bioremediation, 730
Encephalitis, 1343–1350, 3399
Encephalitozoon, 2065–2083, 2329–2337, 2969–2978
Endocellulase, 1211–1223, 3021
Endogenous respiration, activated sludge processing, 23–26
Endogone, mycorrhizae, 2124–2132
Endolimax, 1136
Endolithic microorganisms, 842, 1100–1112
Antarctica and, 1100–1107
biodeterioration of mineral materials and, 517–528,
biomass of, 1104–1105
cyanobacteria and, 963–964
extinction and fossilization of, 1106
growth of, 1105–1106
hot arid regions and, 1107–1110
Paleoclimate indicators and, 1108
weathering and, 1105
zonation and, 1104
Endomycorrhiza, 2120
Endonucleases, Archaea, 271
Endoplasm, 1115
Endorhizosphere, 2714
Endosphere, marine/ocean environment, 2548–2549, 2552
Endospores
aerobic, 140–149
high hydrostatic pressure (HHP) vs., 1559–1563
soil microorganisms and, 2886
Endosymbiosis, 1112–1130
algae and, 1126–1128
amoebas, free-living pathogenic, 1345, 1347
aposymbiosis in, 1113
Archezoa hypothesis and, 1124–1125
bacteriome in, 1114
culturable vs. unculturable organisms in, 1113
ectosymbionts or ectobionts in, 1113
endosymbionts or endobionts in, 1113
epixenosomes and, 1123
eukaryote cell origin and, 1123–1126
evolution and, 1123–1128
extracellular endosymbiont/extrasymbiont, 1113
horizontal or environmental infection in, 1118
host in, 1113
hydrothermal vents and, 1117–1118, 1606–1609
hyperparasitoids in, 1115
insects and, 1114–1115
intracellular endosymbiont/intracytobiont, 1113
Karyomastigont and, 1124
male-killing bacteria in, 1122
marine/ocean environment and, 1115–1116
methane rich waters and, 1117–1118
mitochondrial origin and, 1125

mutualism in, 1113
nitrogen fixation and, 1118–1120
obligate intracytobionts, 1113
obligate symbiosis in, 1123
parasitism in, 1113
parasitophorus vacuole or inclusion, 1113
parthenogenesis and, 1122–1123
pathogen emergence and, 1123
photoautotrophy and, 1115–1117
plastic origins and cyanobacteria in, 1126–1128
primary vs. secondary symbionts in, 1114–1115
reproductive parasites and, 1120–1123
Rhizobium/legume, 1119–1120
Serial Endosymbiosis Theory (SET), 1123–1126
sulfur rich waters and, 1117–1118
symbiont in, 1113
symbiosome, 1113
symbitotrophic systems in, 1113–1120
syntrophy in, 1113–1120
transovarial infection and, 1118
Endotoxins, 417, 421, 977, 1690
bioaerosols and, 3328
bottled water and, 800
Energy production, marine biotechnology, 1850, 1853–1855
Energy recovery from landfill gases, 1767
Energy sources (See also Methane/methanogenesis), 1921–1922
Enhalus, 2549, 2823–2833
Enhanced biological nutrient removal (EBNR), 70
Enhanced biological phosphorus removal (EBPR), 15–26, 38–40, 62–67, 78–80, 1311, 1313, 3005, 3011–3013
Enolic hydrogen, 929
Entamoeba, 1136–1146
biofilms and, 89
disinfection and, 1067, 1069
endosymbiosis and, 1125
in food, 3277–3287
high hydrostatic pressure (HHP) vs., 1561
in source water, 2969–2978
in spas and hot tubs, 2980–2984
subsurface microorganisms and, 2025
in wastewater stabilization ponds (WSBs), 3334
in wastewater/sewage, 2329–2337
in water treatment systems, 1718
in wetlands for wastewater treatment, 3398–3399
Entamoeba dispar, 1136–1146
Entamoeba histolytica, 1136–1146
Enteric adenoviruses (See Adenoviruses)
Enteric bacteria, bacteriophages and, 384–392
Enteric cytopathogenic human orphan (ECHO) viruses, 1147
Enteric viruses (See also Adenoviruses), 388, 1252–1256
Enterobacter, 499, 1345, 2596, 3102
bioaerosols and, 3322
biocontrols and, 455, 457, 462
biodegradation and, 511
biofilms and, 577, 580, 581, 2342–2356
bioluminescence in, 658–662
cold-shock response and, 885–895
coliform bacteria and, 895–914
disinfection and, 1065
endosymbiosis and, 1118
fecal contamination and, 1258, 1272
fluorescent studies of, 1835
genetically altered, in biotechnology, 1448
granular activated carbon (GAC) filters and, 1491, 1571–1572
heterotrophic bacteria and, 1545, 1550
infectious airborne bacteria and, 1689–1697
metal biodegradation and, 1883, 1885, 1886
as microbial tracer in groundwater, 3195
municipal solid waste landfills and, 1766
nitrogen fixation and, 2193–2201
O serogrouping, 1259–1260
rhizosphere and soil microbes in, 346
Salmonella and, 2789–2802
soil microorganisms and, 2896
in drinking water, 944, 946
Enterococci, 1264–1278, 1297
biofilms and, 556
cold-shock response and, 886–895, 892
gene transfer and, 1409
metal biodegradation and, 1889
municipal solid waste landfills and, 1766
nosocomial infections and, 2236–2250
in source water, 2974
Enterocytozoon, 2066–2083, 2329–2337, 2969–2978
Enterohemorrhagic E. coli (EHEC), 1146, 2338
Enteroinvasive E. coli (EIEC), 1146, 2339
Enteromorpha, macrofouling, 616
Enterotoxigenic E. coli (ETEC), 1146, 2339
Enterotoxin (B/SEB), bioterrorism, 778
Enteroviruses, 1146–1156, 1167–1175
bacteriophages vs., 363–364, 384–385
biodegradation and, 3289–3300
biofilms and, 2353
in spas and hot tubs, 2980–2984
streams and, 3017
in wastewater stabilization ponds (WSBs), 3334
Entner–Doudoroff (ED) pathway, 262, 1633
Entomopathogens (See also Insecticides, microbial), 1175, 1710
Entomopox viruses (EPV), 1711
Entomorphthora, microbial insecticides using, 1710
Entophysalis, 1507–1512
Entrophospora, mycorrhizae, 2120–2124
Environmental Directorate (DGXI), 2706–2707
Environmental genomics (See Soil genetic ecology)
Environmental impact of landfills, 1765–1769
Environmental infection, 1118
Environmental Protection Agency (EPA), 2695–2707, 3164, 3169
Environmental scanning electron microscopy (ESEM), 2008
Enzymatic toxicity tests (See Toxicity testing)
Enzyme electrophoresis, 309
Enzyme immunoassay (EIA), 97, 98, 333, 1131
Enzyme linked immunoassay (ELISA)
adenoviruses and, 97
in allergies and illness, 1361
astroviruses and, 333
detection of, 1131
nitrifying bacteria and, 2169
proteomes and proteins, 309
rotaviruses and, 2765, 2767–2769
Enzyme linked lectinsorbent assay (ELLA), 1061
Enzymes, 1176–1189, 1850, 1852
activity of, determining, 1210–1214
activity of, in biofilms, 1214–1216

Enzymes, (*continued*)
activity of, in municipal solid waste landfills and, 1760
activity of, in soil, 2906–2909
agriculture and, 3215
alkaliphiles and, 220, 221–223
Archaea and, 259–276, 1175
Arrhenius equation in, 2900
assays of, in soil, 2903–2904
ATP binding cassette (ABC) pathway in, 1208
autotransporter pathway in, 1208–1210
Baeyer Villiger monooxygenase (BVMO), 2290
bioaugmentation and bioremediation in, 435
biocide degradation and, 608
biodegradation and, 1875–1876
bioluminescence in, 657–663
biomass conversion, 1186
biotechnology and, 1176–1189
bleaching, fungal, 2647–2648
brewing and distilling, 1187
chemical synthesis and, 1185
cofactors and, 2900–2001
cold active, 268, 3206–3210
cold-adapted microorganisms and, 871–885
concentrations of, in soil, 2904–2906
cropping systems vs., in soils, 2907
dairy products and, 1186–1187
desulfurization and, 1046
detergents and, 1178–1180, 3209–3210
distribution of, in soils, 2907
Eadie–Hofstee transformation and, 2901
ecto-, 1210
environmental factors vs. activity of, 1216–1217
extracellular enzymes and, 1750
extracellular polymeric substances (EPS), 1207–1223
extremeophiles and, 1232–1237
in fat and oil processing, 1187–1188
in feeds for animals, 1188
fermentation, 1177–1178
fertilizer and, 2906
in fiberboard production, 1185
flooded soils and, 2906
fluorescent probes and, to trace activity of, 1784
food additives, 1186–1188
food processing and, 3209
formulation of, 1178
in fruits, juices, wines, 1187–1188
in fuel alcohols, 1185–1186
functions of, in biofilms, 1220–1221
fungal, 1369, 1385–1388, 2647–2648
genetically altered, in biotechnology and, 1447
halotolerant, 268
Hanes–Wolf transformation and, 2901
hydrogen peroxide generating, 1387
immobilization of, 2903
inactivation of, in genetic evolution, 1196–1197
industrial production of, 1176–1178
inhibition of, in soil, 2901–2902
ionic environment and, 2900–2901
leather processing, 1183
Linweaver–Burk transformation and, 2901
marine biotechnology and, 1853
market for, 1178
Michaelis–Menten equation and, 2901
molecular biology and, 3210
mycorrhizae and, 2129
nitrogen fixation and, 2189–2195
oil and gas drilling, 1185
organic solvent tolerant, 268
oxygenases, in biodegradation, 2288–2300
personal care products and, 1185
pesticides and, 2909
pH levels and, 2900, 2906, 2908–2909
phosphorus cycling and, 2450–2452
pressure tolerant, 269
in pulp and paper industry, 1183–1185
recombinant DNA in, 1176–1178
in recycling of paper, 1184–1185
regulation of, in biofilms, 1217–1220
secretion mechanisms in, 1207–1210
secretons in, 1209
soil microorganisms and, 2899–2910, 2949
sources of, in soils, 2902
in starches, 1180–1183
state of, in soils, 2902–2903
streams and, 3021
substrate concentration and, 2901
technical type, 1178–1186
temperature and, 2900
in textile processing, 1181–1183
thermostable, 267–269, 1852
tillage and residue management and, 2908
toxic metals and, 2909
in toxicity testing, 3155–3168
in wastewater/sewage, 3169–3171
weathering, bioweathering and, 3368
wetlands and, 3410–3415
Eo70, 3039–3040
Eosinophils, in allergies and illness, 1360
EPANET model, biodegradable dissolved organic carbon (BDOC), 502
Ephemera, streams, 3019, 3020
Ephydra, salt production, 2805–2809
Epibionts, hydrothermal vents, 1609–1610
Epichloe, spores and spore dispersal, 406
Epicoccum, 405, 408, 412, 1367–1372, 1650, 1655–1657, 3360
Epidemiological studies, municipal solid waste landfills, 1765
Epidermophyton, 1368, 1373–1383
Epiendolithic microbes, 842
Epifluorescence (EF), 1336–1338, 2340, 2653
Epifluorescence microscopy (See also Image analysis), 1189, 1675
Epilithic microorganisms (See also Subaerial communities), 517–528, 1189
Epiphytes, subaerial communities, 3056–3065
Episcopic differential interference contrast (EDIC), 2340
Epistylis, 2608
Epixenosomes, 1123
Epoxides, 3412
Epoxytrichothecenes, 1375
Equalization
filtration and, 2265–2266
image analysis and, 1679
Equivalent spherical diameter (ESD), floc formation and biofilms, 2006
Ergosterol, 1818–1824
Erwinia, 2723
cold-adapted microorganisms in, 872–885
detection of, 1134
soil salinity and, 2775
subaerial communities and, 3057–3065
in wastewater stabilization ponds (WSBs), 3334

Erysiphe, 454
Erythema migrans, 1838
Erythomicrobium, 2035, 2522
Escarpia, 1606
Escherichia coli, 314, 332, 339, 340, 386, 499, 539, 1132, 1345
adhesion in biofilms and, 123
aerobic respiration and, 155–157
alkaliphiles and, 223
bacteriophages and, 355–356, 374–384
bioaerosols and, 431, 3321, 3322–27
biochips, biochip testing sample, 444, 447, 449
biocontrol use of, 2703
biodegradation and, 513, 1874
biofilms and, 562, 567, 577, 581, 582, 621, 1209, 2341–2356, 2960
bioleaching and, 643
bioluminescence in, 658–662
biomineralization and, 674
biotechnology and, 3203–3204
bottled water and, 796, 799
Clostridium and, 868–871
cold-adapted microorganisms in, 872–885
cold-shock response and, 885–895
coliform bacteria and, 895–914
desert environment and, 1581
desiccation and, 1032–1035
disinfection and, 1065, 1066
enterohemorrhagic E. coli (EHEC), 1164, 2338
enteroinvasive E. coli (EIEC), 1164, 2339
enterotoxigenic E. coli (ETEC), 1164, 2339
fecal contamination and, 1257, 1269, 1272
flow cytometric studies of, 1951, 1952
fluorescent studies of, 1834, 1835
gene transfer and, 1409, 1413–1415
genetically modified microorganisms (GMMs) and, 1437
genomic studies and, 1446
granular activated carbon (GAC) filters and, 1489–1496
green fluorescent protein (GFP) studies for, 1498
heterotrophic bacteria and, 1541–1552
high hydrostatic pressure (HHP) vs., 1555–1563
identification of isolates in, 1964
immobilization of, 110
in marine/ocean environment, 1706
metal biodegradation and, 1880, 1886, 1890
microarray study of, 1971
as microbial tracer in groundwater, 3195
microgravity and, 2998, 3001
municipal solid waste landfills and, 1766
nitrogen fixation and, 2193–2201
nosocomial infections and, 2236–2250
O serogrouping, 1259–1260
oligotrophic bacteria and, 2269, 2270, 2272–2275
pathogenic, 899, 1164, 2337–2339
peroxide vs., 603
phosphorus cycling and, 2448–2451
pulsed field gel electrophoresis (PFGE), 1260–1261
radiation and, 2987
rain/in rainwater roof catchment systems, 2682
resistance in, 607–608
ribotyping of, 1261–1263
soil salinity and, 2781
in source water, 2968, 2969–2978
in spas and hot tubs, 2980–2084
spores and spore dispersion in, 421
streams and, 3019
stress response and, 3048, 3050–3051
subsurface microorganisms and, 2025
toxic solvents and, 3149, 3150, 3151, 3153
ultraviolet light and, 3230
verocytotoxigenic E. coli (VTEC) and, 2349–2350
viable but not culturable (VBNC) phenomenon and, 3249, 3250
in wastewater/sewage, 3171
in drinking water, 944, 945, 949, 2013, 3199
in wetlands for wastewater treatment, 3393–3397
Esterase, 1212–1223, 3021, 3170, 3207–3210
Esters, 928–929, 3412
Estrogen mimics, biodegradation, 507–516
Estuarines (See Marine/ocean environment)
Ethacrylate bioremediation, 707
Ethane, 2426
Ethanol, 699, 3147–3155
activated sludge and, 742–748
alkaliphiles and, 228
biodegradation and, 2410
Ethene (ETH) biodegradation, 510–514
Ether, 929
Etheylbenzene, 700
Ethyl alcohol (EtOH) biodegradation, 1994–2000
Ethyl ester, in surface waters, 928
Ethyl t-butyl ether (ETBE) biodegradation, 1994–2000
Ethylbenzene biodegradation, 714, 917, 1763, 1994–2000, 2412, 3147–3155, 3405
Ethylene, 344
Ethylene diamine tetraacetic acid (EDTA), 196–199
Ethylene glycol dinitrate (EGDN) biodegradation, 1979–1993
Ethylphenol biodegradation, 1763
Eubacteria, 744–748, 1440, 1443–1446
Eucalyptus, 2124–2132, 2649, 2911

Fluorescein isothiocyanate (FITC), 570, 1334, 1676
Fluorescence in situ hybridization (FISH), 812, 1333–1334, 1416
activated sludge bacteria counts using, 30–43, 62–63, 69
anaerobic granulation and, 235
Archaea and, 247, 279, 301
bacterial counts using, 30–43, 62–63, 69
bacterioplankton and, 2524
biofilms and, 570, 571
floc microbiology and, 56–57
methanotrophic bacteria and, 1931–1932
soil microorganism and diversity in, 529, 538
Fluorescence microscopy (See Laser scanning microscopy)
Fluorescent focus assay (FFA), rotaviruses, 2766–2767
Fluorescent probes, 1333–1343
activity testing using, 1783–1784
antibody identification using, 1781
attachment to, 1334
confocal laser scanning microscopy (CLSM), 1335, 1338, 1772–1788
confocal microscopy and, 1338
dehydration and embedding for, 1335
enzyme activity using, 1784
epifluorescence in, 1336–1338, 1336
extracellular polymeric substances (EPS), 1778–1781
fixation for, 1335
flow cytometry and, 1945–1958
fluorescent labels and, 1334
fluorescent proteins as reporters in, 1341–1342
green fluorescent protein (GFP), 558–559, 659, 1341–1342, 1412, 1496–1500, 1676, 1781, 1830–1838
hybridization techniques for, 1335–1336
labels for, 1676
laser scanning microscopy and, 1772–1788
luciferase, 1830–1838
as microbial tracer in groundwater, 3196
microenvironment testing using, 1784
molecular approaches to, 1339–1342
mounting and washing for, 1335
nucleic acid databases and, 1333–1334
red fluorescent protein (RFP), 1835–1836
reporter gene detection using, 1783–1784
ribosomal RNA targeted oligonucleotide probes and, 1339–1340
RNA targeting using, 1781, 1784
sample preparation for, 1334–1335
sectioning for whole cell hybridization and, 1334–1335
viability testing using, 1783
virus tracers and, 3305
Fluorescent proteins, as reporters, 1341–1342
Fluorescent recovery after photobleaching (FRAP), 1784
Fluoridation, bottled water, 800
Fluorochromes (See also Laser scanning microscopy), 1343,1676, 1786, 3196
Fluorometry, pigment analysis, 2462–2463
Flushing agents, biosurfactants/bioemulsions and as, 764
Flushing reactors, municipal solid waste landfills, 1769–1770
Foaming in activated sludge, 1–7, 75, 1287–1306, 1343, 2002, 3008–3011
Folliculitis, in spas and hot tubs, 2980–2984
Folsomia, 2915
Fomes, 1983, 2647
Fomitopsis, 2647
Food additives, 1176, 1850, 1852–1853, 2516
Archaea and, 259–276
enzymes and, 1186–1188
Food and Drug Administration (FDA), 2694–2707
Foodborne disease, 338–340
Aeromonas and, 1094–1099
astroviruses and, 331
biofilms and, 577–587
bioterrorism and, 779
Campylobacter, 803–811
Clostridium and, 862–871
cold-shock response and, 886–895
Cryptosporidium and, 650–657
Cyclospora and, 995–1001
Entamoeba and, 1136–1146
Enterococci in, 1264–1278
enteroviruses and, 1146–1156
Escherichia coli and, 2337–2339
Giardia and, 1469–1489
hepatitis viruses and, 1534
high hydrostatic pressure (HHP) vs., 1561
human caliciviruses and, 1586–1598
Norwalk-like viruses (NLVs) and, 2221–2235
protozoa and, 3276–3287
Pseudomonas, 2632–2639
risk assessment and, 2749
rotavirus, 2753–2573
Salmonella and, 2789–2802
Shigella and, 2865–2871
Streptococci in, 1264–1278
viruses and, 3276–3287
Food industry, 1343
algae as, 2516
aquaculture and, 1856–1857
bioaerosols and, as byproduct of, 423
biofilms in, 577–587
biofiltration and in, 588
cold-adapted microorganisms and, 879–881
coliform bacteria and, 901
contamination of food in, 1343
enzymes and, 3209
hepatitis viruses and, 1534
high hydrostatic pressure (HHP) vs. microbial inactivation, 1552–1563
marine biotechnology and, 1850, 1851–1853, 1857
preservation of foods and, 1343
protozoa and, 3276–3287
salting, halophiles and, 1511
viruses and, 3276–3287
Food sources
algae biotechnology and, 189–204
cyanobacteria and, 980
cold-adapted microorganisms and, 880–881
Food web
bacterioplankton and, 2534–2535
mycorrhizae and, 2127

Food web (*continued*)
periphyton and, 2360–2361
polar phytoplankton and, 2563–2564
protozoa and, 2620–2622, 2630
in sediments and sedimentation, 2844–2845
stream microbiology and, 3015–3024
viruses and, 3306–3307
Footpads or footprints, diatoms, 1053–1055
Foraminifera, 2613, 2616–2617
Forestry, mycorrhizae, 2129–2130
Formaldehyde, 605, 608, 625
Formaldehyde dehydrogenase (FdDH), 1927–1936
Formate, 741–748, 2172, 3062
Formate dehydrogenase (FDH), methanotrophic bacteria and, 1927–1936
Formation water, 2418
Formic acid, alkaliphiles, 228
Forward angle light scatter (FALS), flow cytometry, 1945
Forward sample array hybridization, 2731–2732
Forward scatter, flow cytometry, 1945
Fossil fuels (See also Hydrocarbons), 1343, 1850
desulfurization of, 1041–1051
Fossil infusorian, 1401
Fossilization
endolithic microorganisms and, 1106
in paleolimnology, 2301–2306
Fourier transform infrared spectrometry (FTIR), 257, 934–935
Fourier transform Raman spectroscopic analysis, 935
Fowler, Gilber, 74
Fractionation
activated sludge processing, 14–26
biofilms and, 1213
subsurface microbial communities and, isotopic, 1461
Fragillaria, 206
Fragmentation analysis, conditioning films, 932–933
Francisella (See also Tularemia), 432, 772, 777, 1123
Frankia, 1118
endosymbiosis and, 1119–1120, 1119
nitrogen fixation and, 2188–2211, 2939
plant growth promoting rhizobacteria (PGPR) inoculation and, 350
soil microorganisms and, 2912
Free energy balance, hydrophobicity, 1600–1601
Free energy of adhesion, 101
Free-living amoebas, meningoencephalitis, 1343–1350
Free water, 2418, 2960
Freeze drying, 1030, 1035, 1350–1359
artificial trehalose introduction in, 1355–1357
chemical permeability and electroporation in, 1355–1356
disaccharides in, 1350–1351
genetic biosynthesis of sugars in, 1356–1357
lipid phase transitions in, 1356
microbial protection from, 432
pore proteins and trehalose introduction, 1357
sugar glasses and stabilization in, 1351–1354
trehalose and, 1353–1357
Freshwater bodies (See Aquatic ecosystems; Surface waters)
Friedmanniella, 64, 1026, 1028
Frontia, 972
Frucose, 2716
Fructose, 1185, 1186
Fruit juices, enzymes, 1187–1188
Frustule associated components (FACs), diatoms, 1054
Frustulins, diatoms, 1055
Fucose, biosurfactants/bioemulsions, 756
Fucoxanthin, 2307–2317, 2453–2470, 2504, 2512
Fucus, algae biotechnology, 199–200
Fuel alcohols, 1185–1186
Fuel oxygenates, 1994, 2410
Full-cycle RNA approach, bacterial counts using, 29–34
Fulvic acid, in surface waters, 928
Fumarate, 3062
Fumonisins (See also Bioaerosols), 182–189, 1359, 1375
Funalia, 2649
Functional gene arrays (FGAs), 1974–1996
Functional genomics, 34, 1448–1449
Fungi (See also Bioaerosols; Mycorrhizae; Spores and spore dispersal), 338, 417, 1366–1400, 2910–2918, 3353–3364
actinomycetes and, 2912
activated sludge and, 71–72
airborne, 1647–1661
alkaliphiles and, 136
allergies and allergens of, 1359–1366
antibiotics produced by, 457–458
arbuscular mycorrhizae, 2126
arbutoid mycorrhizae and, 2126
Ascomycota in, 2913–2914
asexual vs. sexual forms, 1647
bacteria in home/residential environment and, 342
Basidiomycota in, 2914
beneficial chemicals from, 1369
as biocontrol agents, 451–454
bioaerosols and, 404–416
biodegradation and, 2386, 2911–2912, 3390–3392, 3412
biodeterioration of mineral materials and, 518–519, 524
biodiversity in, 3354–3355
biofilms and, 551–559, 2342
biofouling and, 613
biological bleaching and, 2647–2648
biological pulping process in, 2647
biomass estimation and, 2657–2658
bioremediation and, 1390–1392
biotechnology and, 1384–1394
brewing and distilling, 1384
brown rot, 1388–1389, 2646–2647
cellobiose dehydrogenase (CDH) and, 1387–1388
chytrids in, 2913
classification of, 1647
cold-adapted microorganisms in, 872–885
common species of, 1653–1661
conidia of, 1647–1648
control of spores from, 1370–1371
culturing of, 1648, 1652–1653
decomposition and, 1385–1389, 2646–2647, 3358–3359
desert environment and, 1576, 1577, 1578–1579
desiccation and, 1029, 1031
diseases caused by, 1366–1383
distribution of, 3354–3355
dry air spora in, 408–414
ectendomycorrhizal, 2125–2126
ectomycorrhizal, 2124–2132
enzymes produced by, 1385–1388, 2647–2648
explosives biodegradation using, 1983–1985, 1989
fermentation and, 1384
genetic manipulation of, 1389–1390

habitats of, 1648
hydrocarbon degradation and, 2405
hydrogen peroxide-generation from, 1387
hypersensitivity pneumonitis (HP), 1369, 1374–1375
hyphae and, 2646–2647
identification of, 1649–1653
infections caused by, 1368, 1372–1374
irritations caused by, 1369, 1375
leaf litter decomposers in, 3355–3358
lichens and, 2914
lignin degrading, 1385
lytic enzymes produced by, 458–459
marine/ocean environment and, 1394–1400, 2539–2540
marshes, decomposer fungi in, 3359–3360
methylation and, 1388
micro-, 1367
microbial insecticides using, 1710, 1711
microbial volatile organic compounds (MVOCs) and, 1372–1383
mildews and, 1647
moisture and, 1367–1368
monotropoid mycorrhizae and, 2126
municipal solid waste landfills and, 1766
mushroom culture and, 1384–1385
mycelial growth in decomposition, 3355
mycorrhizae and, 1385, 2120–2132, 2911–2912
mycotoxicosis and, 1369, 1378–1379
mycotoxins and, 1366–1383
nutrients and, 1648
organic dust toxic syndrome (ODTS) and, 1369, 1374–1375
organoosmotrophy, 3354
periphyton and, 2357–2367
pitch (wood sap) degradation in, 2648–2650
predatory role of, 2914–2915
pyroloid mycorrhizae and, 2126
residential environment and, 1372–1383
rusts, 411–412
safety in handling spores of, 1651
sampling of, 1369–1370, 1650–1651
sensitization to, 1368–1369
sick building syndrome (SBS) and, 1372
slime molds and, 2912–2913
smuts, 410–411
soft rot, 1389
soil microorganisms and, 664–665, 2910–2918
soil salinity and, 2775
solar radiation and, 1368
spore prints in, 1652
spores and spore dispersal in, 405–415, 1366–1383, 1647–1653, 3354–3355
staining of wood by, 2648–2650
streams and, 3021
subaerial communities and, 3057–3065
symbiosis in, 1367
taxonomy of, 3354
transmembrane redox potential in, 1388
trophic links between, 2914–2915
volatile organic compounds (VOCs) and, 1366–1383
in drinking water, 945
water fungi and, 3353–3364
water molds and, 2912
water purifiers vs., 1572–1573
weathering and, 3364–3389
wetlands and, 3412
white rot, 1385–1386, 2646–2647
wood degradation and, 1385–1389, 2646–2647, 3358–3359
yeasts and, 1647, 1661, 2913–2914
Zygomycota in, 2913
Fungi imperfecti, in allergies and illness, 1359
Fungicides, biocontrol vs., 450–465
Furan biodegradation, 1238–1252
Fusarium, 182–189, 1657
in allergies and illness, 1367–1372, 1378–1383
biocontrols and, 450, 451, 453, 454, 455, 460, 2705
bioterrorism and, 779
desert environment and, 1579
explosives biodegradation and, 1983
rhizosphere and, 2718
soil microorganisms and, 2913
spores and spore dispersal in, 405, 408, 413–414
subaerial communities and, 3057–3065
Fusobacterium, 555

Gene capture, 1200
Gene chips (See Biochips)
Gene clusters, 2524
Gene expression, 1971–1974, 2205
Gene probes (See also Laser scanning microscopy), 1974–1975, 2036
Gene transfer
biofilms/ in biofilms, 567, 1408–1420

Gene transfer (*continued*)
conjugation and, 1409–1413
exogenous isolation and, 1410
frequency of, in situ, 1416–1417
genetically engineered microorganisms (GEMs) and, 1280, 1285
horizontal gene transfer in, 1446
retrotransfer in, 1413
Reynolds number and, 1416–1417
transduction in, 1415–1416
transformation in, 1413–1415
to unknown organisms, 1416
viruses for, 3205, 3308
GeneChip system for proteomes and proteins, 310
General rate constant, kinetics of growth, 1741–1742
General stress resistance (GSR), 3038–3043
Genetic ecology of soil (See Soil genetic ecology)
Genetic engineering (See also DNA/RNA analysis), 1449, 1850
aquaculture and, 1856–1857
bioremediation and, 729–730
desulfurization and, microbial, 1045–1046
fungi and, 1389–1390
marine biotechnology and, 1856, 1858
trehalose production and freeze drying, 1356–1357
Genetic fingerprinting, 1887
Genetically engineered microorganisms (GEMs) (See also Genetically modified microorganisms), 726, 729–730, 1278–1287, 1420–1429
containment of, 1283–1284
ecosystem alteration from, 1282
field release of, 1278–1287
gene transfer techniques in, 1280, 1285
monitoring of, 1282–1285
persistence in environment, 1280–1281
plant assisted microbial bioremediation, 1424–1425
polymerase chain reaction (PCR) monitoring of, 1284–1285
propagation of, 1425–1426
regulation of, 2693–2707
retrotransfer in, 1427
rhizoremediation, 1424–1425
risk management for, 1283–1285
stability of, 1425–1426
survival of, 1425–1426
target microcosms and, 1426
Toxic Substances Control Act (TSCA) and, 1280
tracking of, 1425–1427
transfer of rDNA from Pseudomonas to other microorganisms and, 1426–1427
transport of, in environment, 1281–1282
xenobiotics and, 1420–1421
Genetically modified microorganism (GMMs) (See also Genetically engineered microorganisms), 1429–1440, 1429
biocontrols using, 1437
construction of, 1430–1431
containment of, 1430–1431
fate of, factors affecting, 1432
genetic impact of release of, 1436–1437
indigenous soil populations vs., 1434–1437
introduced soil populations of, 1431–1432
nitrogen fixation and, 1431, 1434–1437
plant growth and, 1434–1437
polymerase chain reaction (PCR) and, 1433–1434
reporter genes and, 1430–1431
sampling, 1432–1434
survival of, 1431–1432
tracking of, 1432–1434
Genetics (See DNA/RNA analysis and genetics)
Genome sequencing, 263–266, 290–291, 1442–141443
Genomics and genomic studies (See also DNA/RNA analysis), 1440–1453
acquired genes and, 1446
application of, 1443–1446
biodegradation of halogenated compounds and, 1447
bioinformatics applications for, 1449–1450
bioremediation and 1446–1447
captured megaplasmids in, 1446
comparative genomics and, 1450
databases of, 1449–1450
diversity of microbes and, 1450–1452
environmental modeling systems using, 1448
functional genomics and, 1448–1449
gene chips and, 1448–1449
genetic engineering and, 1449
in groundwater, 1671–1672
horizontal gene transfer in, 1446
hyperthermophiles and, 1637–1641
industrial applications for, 1447–1448
knockout studies, 1449
metal oxidation/reduction and, 1446–1447
microbial genome sequencing and annotation in, 1442–1443
nuclear magnetic resonance (NMR) in, 1449
open reading frames (ORFs) and, 1443
orthologs and, 1450
pathogenesis and, 1448
phylogeny and evolution in, 1446
physical gaps in, 1443
polymerase chain reaction (PCR) and, 1443
subtractive hybridization and, 1451–1452
unknown and conserved hypotheticals in, 1450
X ray crystallography in, 1449
Genotyping, rotaviruses, 2770–2771
Gentisic acid, biodegradation, 2295–2300
Geobacter
activated sludge and, 71
biomineralization and, 674
genetically altered, in biotechnology, 1447
metal biodegradation and, 1882, 1884, 1905
Geochemicals, subsurface microbial communities, 1453–1468
Geodermatophilous, 523, 1102–1106, 3057–3065
Geology, subsurface microbial communities, 1453–1468
Geometric increase in population, 1738
Geosiphon, 1118, 2120–2124
Geosmin, 210, 980, 2889
Geospirillum, metal biodegradation, 1905, 1908
Geostatics (See Soil distribution of microorganisms)
Geothermal environments (See also Hydrothermal vents)
biofilms and, 84
cyanobacteria and, 961–963
extremeophiles and, 1233–1235
high temperature subsurface environment, 2047–2057
Microthrix parvicella and, 3
thermophiles and, 3140–3147
Geothrix, 533, 1905
Geotoga, 1515–1529, 2420
Geotrichum, 916
Geovibrio, 1905

Gerdermatophilus, 1578
Germicidal wavelengths, 3231
Giardia, 903, 1469–1489, 2598, 2607
activated sludge and, 72
aquatic sediments and, 1252–1256
bioaerosols and, 3327
bottled water and, 796
Clostridium and, 868–871
disinfection vs., 360, 1065, 1066, 1067–1073
endosymbiosis and, 1124, 1125
filtration and, 2709
flow cytometric studies of, 1952
in food, 3277–3287
heterotrophic bacteria and, 1548
high hydrostatic pressure (HHP) vs., 1561
measurement of, using aerobic endospores, 141–149
rain/in rainwater roof catchment systems, 2680
sampling of, 2813
in source water, 2968, 2969–2978
in spas and hot tubs, 2979, 2980–2984
streams and, 3021
ultraviolet light vs., 3231–3235
in wastewater stabilization ponds (WSBs), 3334
in wastewater/sewage, 2329–2337
water purifiers vs., 1572–1573
water treatment systems and, 1719, 1727, 2013–2019, 2262–2266, 3199
in wetlands for wastewater treatment, 3398–99
Gibberelins, 344
Gibbs equation, aerobic respiration, 149
Giberella, 2913
Gigaspora, 455, 2120–2124
Glacial ice, 1024, 2873–2875
Glacieocola, 2640–2646
Glactosidase, 3170
Glanders, bioterrorism, 771, 776
Glass, weathering, bioweathering, 3372
Glasses, sugar glasses and stabilization, 1351–1354
Glaucocystophyta, 837–843
Glaucomys, 2127, 2595–2604
Gliocladium, 451–459, 461, 462, 1885, 2649
Gliotoxins, 1375
Global warming (See Climate change)
Globigerinoides, 1115–1116
Globodera, 455, 458
Gloeocapsa, 1102–1112
Antarctic soils and, 1025
biodeterioration of mineral materials and, 519
photoautotrophic, in low-light habitats, 840–843
subaerial communities and, 3056–3065
Gloeocystis, 840–843
Gloeosphera (See also Gallionella), 1401
Gloeothece, 2193–2201
Gloeotrichia, 1863–1869, 2302–2306
Glomus, 455, 1579, 2120–2124, 3121
Glucanase, 1187, 1188, 2903–2910, 3207–3210
Glucanotransferase, 1185
Glucoamylase, 1185, 1187
Gluconate, 3062
Glucosaminidase, 1211–1223
Glucose, 2716, 2899
activated sludge and, 742–748
anaerobic granulation and, 235–237
biofilms and, 88
flooded soils and, 1320
Glucose bacteria (See G bacteria)
Glucose isomerase, 1177–1189
Glucose lipids, biosurfactants/bioemulsions, 756
Glucose oxidase, 1185, 2903–2910
Glucosidase, 1211–1223, 2903–2910, 3021, 3170
Glucosylglycerol, soil salinity, 2778–2789
Glucuronidase, 1212–1223
Glutamate dehydrogenase (GDH), 1698–1701
Glutamate, soil salinity, 2778–2789
Glutaminase, in soil, 2903–2910
Glutamine, 2716
Glutamine synthetase (GS), 1698–1701
Glutaraldehyde, biofouling vs., 605
Glyceria, 2548
Glycerol, 518, 741–748
Glycidyl azide polymer (GAP), biodegradation, 1979–1993
Glycine, 2716, 2778–2789
Glycogen, 21–26, 40, 73, 2270, 3005
Glycogen accumulating organisms (GAOs), 40, 67
Glycolic acid, 607
Glycolipids, bioremediation, 715, 752, 1817–1824
Glycoproteins
Archaea and, 248
conditioning films and, 937–938
Glycosides, 2129
Glycosyl hydrolases, 269
Glyphosphate, bioremediation, 705–712
Gold, 1902–1913, 2961
algae biotechnology and, 199
biomineralization and, 671–681
metal biodegradation and, 1881
Golden-brown algae, 206
Gomphidius, 2124–2132
Gomphosphaeria, 972, 2805–2809
Goniomonas, 2594–2604
Gonyaulax, bioluminescence, 1830
Gordonia, 3314–3319
activated sludge and, 3–7, 3009
biosurfactants/bioemulsions and, 753
desulfurization and, 1048
filamentous forms of, in activated sludge, 1288–1306, 1312
Gordonia amarae-like organisms (GALO), 3–7
Grab samples, 2812
Gracilaria, 1857, 2689–2693
Gradients of metabolism, biofilms, 1085
Gram-negative bacteria, 1781–1783
bioaerosols and, 429
biodegradation and, 1996
biofilms and, 2960
G bacteria and activated sludge processes, 61–68
immobilization of, 109
infectious airborne bacteria and, 1694–1695
metal biodegradation and, 1895–1896
nosocomial infections and, 2236–2250
in permafrost, 2369
Salmonella and, 2789–2802
Shigella and, 2865–2871
soil microorganisms and, 2881–2886
soil salinity and, 2783–2786
Gram-positive bacteria, 1781–1783
activated sludge and, 38
alkaliphiles and, 133
bacterial counts using, 31
bioaerosols and, 429
biodegradation and, 1996
biofilms and, 2959–2960
genomic studies and, 1442
immobilization of, 109
nitrogen fixation and, 2214–2221
oligotrophic bacteria and, 2272
in permafrost, 2369
soil microorganisms and, 2881–2886
soil salinity and, 2781–2783
stress response and, 3048
subsurface microbial communities and, 3065–3071

Gram-positive bacteria, (*continued*)
viable but not culturable (VBNC) phenomenon and, 3253
Gram staining, 1781–1783
Granitic rocks, subsurface microbial communities, 3068
Granular activated carbon (GAC), 315, 1489–1495, 1541–1552, 1563–1575, 2707
Granular high-rate filtration, 2707–2713
Granular sludge (See Anaerobic granules)
Granulosis viruses (GV), 1711
Graphium, 422
Grass–bacteria association, nitrogen fixation, 2199–2200
Gravity (See Microgravity; Space microbiology)
Gravity sampling, bioaerosol samplers using, 397
Grazing
algae vs., 1193–1194
bacterioplankton and, 2531–2532
biofilms and, 2342
periphyton and, 2359, 2364
photosynthetic pigments in, 2455
plankton and phytoplankton, 2514
protozoa and, 2599–2601
sea ice microorganisms and, 2841
Great Salt Lake, 1509–1510
Green algae, 205, 2504–2518
paleolimnology of, 2302–2306
in permafrost, 2369
photoautotrophic, in low-light habitats, 837–843
photosynthetic pigments in, 2467
Green bacteria, 2470–2480, 2992–2993
Green fluorescent protein (GFP), 558–559, 659, 1341–1342, 1412, 1496–1500, 1676, 1781, 1830–1838
Green rust, subsurface microbial communities, 1464–1466
"Green sickness" of caves, 841–843
Green sulfur bacteria, 1515–1529, 2455, 2458, 3097–3104
Greenhouse effect (See Climate changes)
Greigite, biomineralization, 671
Groundwater
Atlantic Coastal Plain aquifers and, 2028–2042
bacteriophages and, 375–377
biodegradation of contaminants in, 507
bioremediation and, 699–700, 702–705, 707, 708, 1447
carbon transformation in, 1669–1671
Clostridium and, 865–871
coliform bacteria and, 903
dissolved organic carbon (DOC) in, 1665
diversity of microorganisms in, 1671–1672
environment of, 1665–1666
fecal contamination in, 1256–1264
Gallionella in, 1401–1408
genomic studies of, 1671–1672
halogenated compounds in, 702–703, 705
heavy metals in, 1768
heterotrophic bacteria and, 1541–1552
high temperature subsurface environment, 2051–2057
hydrocarbons in, 699–700
hydrogen dependency in, 1672
hydrologic studies and, 3198–3199
iron reducing bacteria (IRB) in, 1665, 1667–1669
isotope activity in, 1669–1671
leachate from landfills and, 1768
light nonaqueous phase liquids (LNAPLs) in (PICKUP), 507–516, 699
lipid biomarkers of, 1821
lithotrophs and, 1827
microbial communities of, 1661–1673, 1723–1724
microbial numbers in, 1666–1669
microbial tracers in, 3194–3202
military chemicals in, 707
nitrates, nitrates in, 708
nonaqueous phase liquids (NAPLs) in (PICKUP), 44, 699
oxygen in, 1665
pathogens in, 2025, 2971–2972
permafrost and, 2367–2385
pesticide contamination of, 706, 2398–2399
pH levels in, 1665
public health studies and, 3199–3200
sampling of, 1664–1665, 2815, 3073, 3077–3079
in source water, 2971–2972
subsurface microbial communities and, 1076, 1079, 1454–1468, 2025, 2028–2042, 3068
sulfate-reducing bacteria (SRB) in, 1665, 1667–1669
vadose zone microbiology and, 3236–3246
virus transport and removal in subsurface, 2094–2107
viruses and, 3288–3300
Growth factors, soil microorganisms, 2060
Growth inhibition assays, in wastewater/sewage, 3171–3172
Growth kinetics (See Kinetics of growth)
Growth rates, 1745
cold-adapted microorganisms and, 873
microgravity and, 2999–3000
protozoa and, 2615
Guinardia, 2506
Gunnera, 974, 975, 1118
Gutters and downspouts, in RRCS, 2677
Gymnodinium, 1058, 2431, 2507, 2686–2693
Gymnostoma, 2209
Gymodinium, 2805–2809
Gyrodinium, photosynthetic pigments, 2466

H

Haber–Bosch process (See Nitrogen fixation)
Haematococcus, 189–204, 1853, 1859
Haemophilus, 1413–1415, 1440, 1973
Hafnia, 1491, 1545
Halanaerobiales, 1515–1529
Haldule, 2551
Halfnia, 1766
Haliscomenobacter, 4–7, 1302–1306, 1310
Haloalkaliphiles, 135–136
Haloarcula, 135–136, 298, 1237, 1503–1512, 3146
Halobacteriaceae, 135–136, 246–259, 270, 295, 298, 1233, 1236–1237, 1501–1512, 2419, 2666–2674, 2776, 2806–2809
Halobaculum, 1503–1512
Halocarbons, 3183
Halocella, 1520–1529

Harmanella, 2594–2604
Harmful algal blooms (HABs) and red tides, 1529, 2002, 2340, 2565, 2685–2693
cyanobacteria and, 970–972, 975–980, 989–990
harmful algal blooms (HABs), 2685–2693
Pfiesteria and toxic Pfiesteria complex (TPC), 2431–2447
red tides and, 2685–2693
Hartmanella, 1123, 2342–2356, 2605
Hazard analysis and critical control point (HACCP), 342, 583
Hazard identification, in risk assessment, 2742
Hazardous wastes (See also Radioactive/nuclear wastes)
in municipal solid waste landfills, 1765
toxicity testing and, 3225–3227
vadose zone microbiology and, 3243–3244
Heap bioleaching, 642, 648, 649
Heat exchangers, biofouling, 622–623
Heat-shock response/proteins (hsp70) (See also Stress response), 1529, 1583, 3026–3028, 3024–3034, 3046–3055
Heat treatment/disinfection, 361, 387, 1174, 3264
bacteriophages vs., 361, 387
enteroviruses and, 1174
viruses vs., 3264
Heavy metals, 1529, 1878–1894, 2340
activated sludge and, 72
algae biotechnology and, 196–200
biodegradation and, 1855, 3402
bioleaching and, 648
biomineralization of, bacterial, 670–681
enzyme activity and, 2909
metal biodegradation and, 1886–1891
neuston microbiology and, 2137–2139
periphyton and, 2364–2365
resistance of bacteria to, 608
soil salinity and, 2774
sulfate-reducing bacteria (SRB) and, 3089–3090
toxicity testing and, in soils, 3162
Hebeloma, 2124–2132, 2914
Hedysarum, 2785
Heinrich sediments, 2314
Helicase, 3207–3210
Helicobacter
biochips, biochip testing, 447
biofilms and, 563, 1209, 2341–2356, 2351–2352
disinfection and, 1065
genomic studies and, 1451–1452
hydrothermal vents and, 1609–1610
phototropism in, 2471
in source water, 2969–2978
Helicobacter pylori, in gastric ulcer, 1529–1530
Heliothis, microbial insecticides using, 1710
Heliozoan, 2617
Heliscus, 3358
Helium, 3183
Helminthosporium, 410, 1579
Helminths, in wastewater stabilization ponds (WSBs), 3333–3334
Hemagglutination inhibition (HI), adenoviruses, 98
Heme copper oxidases, aerobic respiration, 155
Hemerocampa, microbial insecticides using, 1710
Hemiaulus, 2506
Hemicellulase, 1186
Hemicellulose, 85–86, 1760
Hemichloris, 1025, 1026, 1102–1106, 3061
Hemiselmis, 2508
Hemolysis of red blood cells, biosurfactants/bioemulsions, 762
Hemorrhagic fevers, bioterrorism, 777–778
Hepatitis, hepatitis viruses A and E (HAV/HEV), 95, 360, 1162, 1384, 1530–1540, 2743, 2744–2745, 2747
biodegradation and, 3288–3300
in food, 3277–3287
soil/in soil, 3271–3276
in source water, 2969–2978
in spas and hot tubs, 2979, 2980–2984
streams and, 3017
subsurface microorganisms and, 2025
Hepatotoxins, 207, 986–995, 2340
Hepatophyta, 837–843
Hepetosiphon, 1303–1306
Heptamethylnonane, biodegradation, 2407
Herbaspirillum, nitrogen fixation, 2193–2201
Herbicides
biocontrol vs., 450–465
biodegradation and, 693, 705–706, 916–917, 1421, 2385–2393
biofilms and, 88
biofiltration and, 591
groundwater pollution by, 706
regulation of, 2693–2707
soil contamination by, 706
Hermatypic corals, endosymbiosis, 1116–1117
Herpangina, 1150–1151
Herpes simplex, algae biotechnology, 195
Herpyzonema, 838–843

Heterduplex DNA analysis (HPA), 813
Heterobasidium, 451, 2646–2647
Heterococcus, 1102–1106
Heterocysts, 836–843, 2891
Heterodera, 455
Heterokonta, 837–843, 2912
Heterolobosea, 2912
Heteropolysaccharides, Archaea, 249
Heterorhabditis, biocontrol use, 2705
Heterosigma, 199–200, 2686–2693
Heterotrophic ammonia oxidation, activated sludge denitrification, 13–14
Heterotrophic bacteria, 1540–1552
  activated sludge and, 18–26
  algal turf scrubbing (ATS) and, 213–219
  antibiotic resistance in, 1545
  bacterioplankton and, 2521
  biodeterioration of mineral materials and, 523
  biofilms and, 81–82, 2341
  bottled water and, 1549–1550
  cultivation of, 1542–1544
  cyanobacteria and, 966
  genera of, 1541–1542
  indigenous bacteria as, 1544
  nitrification and, 2145–2146, 2941
  origins of, 1544–1545
  pathogenic, 1545
  phosphorus cycling and, 2450
  soil microorganisms and, 2889, 2891
  subaerial communities and, 3057–3065
  sulfur cycle and, 3110
  thermophiles and, 3141–3142, 3144–3146
  transient bacteria as, 1544
  in wetlands for wastewater treatment, 3393
Heterotrophic plate count (HPC), assimilable organic carbon (AOC), 322–323
Hexachlorobenzene (HCB) biodegradation, 1238–1252, 2963
Hexachlorocyclohexane (HCH) biodegradation, 1238–1252
Hexachlorodimethylsulfone, 605–606
Hexachlorophene bioremediation, 703–712
Hexacorallia, 1116
Hexadecane biodegradation, 2403–2416, 3147–3155
Hexahydrotrinitriotriazine (RDX) biodegradation, 706–712, 916–917, 923–924, 1979–1993, 3410
Hexanitrohexaazaisowurtzitane biodegradation, 1979–1993
Hexoses, 2716
High hydrostatic pressure (HHP) vs. microbial inactivation, 1552–1563
High Melting Explosive (HMX), 706–712, 923–924
High performance liquid chromatography (HPLC), 252–253, 1853, 2359, 2463
High-rate algae ponds, protozoa vs., 2333
High-rate clarification, 2017
High temperature subsurface environment, 2047–2057
Hippea, 1517–1529
Hippophae, 2209
Hirsutella, 1710
Histogram equalization, image analysis, 1679
Histoplasma, fungi, 1368
HIV (See AIDS/HIV)
Hoffman modulation contrast microscopy, 1675
Holoenzymes, 3039
Holophaga, 533, 539, 1320, 2549
Holosticha, 2595–2604
Home water treatment devices, 1550–1551, 1563–1575
Homeophasic theory, cold-adapted microorganisms, 875
Homeoviscous adaptation theory, cold-adapted microorganisms, 875, 887
Homoacetic acid, activated sludge, 741–748
Homoacetogenesis, flooded soils, 1320–1321
Homoanatoxins, 977
Homologous recombination, 1197–1199
Homoserine, 2716
Hopane biodegradation, 696–712, 2403–2416, 2403
Hopanoids, 1818–1824
Horizontal gene transfer, 1195, 1201–1203, 1446
Horizontal or environmental infection, 1118
Hormone herbicides, biodegradation, 2385–2393
Hormothamnin, 977, 1852
Host, 1113
Hot environments (See also Desert environment), 1576
  high temperature subsurface environment, 2047–2057
Hot tubs (See Spa and hot tub microbes)
Human bacterial flora, Clostridium, 861–871
Human caliciviruses, 1586–1598
Human health outcomes, in risk assessment, 2742–2744
Human rotavirus (HRV), 95
Humic acid, humic substances, 1750
  biofilms and, 86, 87, 88, 114
  composting and, 915
  floc formation and, 57
  in surface waters, 928, 928
Humicola (See also Thermomyces), 881, 3002
Humin, in surface waters, 928
Hyalella, 1065
Hyandtoinases, 1185
Hybridization, 2922
  activated sludge foam monitoring and, 4–7
  adenoviruses and, 97
  Archaea and, 247, 279
  astroviruses and, 333–334
  bacterial counts using, 29–31
  biochips, biochip testing and, 446
  fluorescence in situ (See Fluorescence in situ hybridization)
  fluorescent probes and, 1335–1336
  forward sample array, 2731–2732
  microarrays for, 1970–1971
  oligonucleotide probe, 2497–2499
  rotaviruses and, 2769–2770
  rRNA targeted probes for, 29–34
  subtractive, 1451–1452
Hydgenophaga, 1490
Hydraulic head, water tension, suction, biofiltration, 592
Hydraulic residence time (HRT), 49, 2857
Hydrocarbons
  aerobic degradation in, 2404–2411
  anaerobic degradation of, 2411–2413
  bacterial genera to degrade, 2404
  biodegradation of, 694–701, 713–719, 2289–2300, 2402–2416, 2930, 3211–3215, 3405–3410
  cold-adapted microorganisms in, 872–885
  composting and, 917–919
  desulfurization and, 1046–1047
  fuel oxygenate biodegradation, 1994–2000
  fungal genera to degrade, 2405
  high temperature subsurface environment and, 2055
  hydrophobicity and, 1599–1604
  marine sources for, 1853–1855

marine/ocean environments and, 715–719
microbially enhanced oil recovery (MEOR), 2421, 2424–2425
microbially influenced corrosion (MIC) and, 2423–2424
mousses of, for biodegradation, 2413
neuston microbiology and, 2137–2139
petroleum reservoirs and, 2416–2426
sampling of, 3073
soil contamination and, 700–735
sulfate-reducing bacteria (SRB) in, 2419–2420, 2422–2424, 2428–2429
in surface waters, 928
surfactants vs., 2411
toxic solvents and, 3147–3155
vapors of, bioremediation in, 697–698
wetlands and, 3405–3410
Hydrochlorofluorocarbons (HCFCs), 3188–3189
Hydrodesulfurization (HDS), 1042
Hydrodynamic testing, adhesion in biofilms, 117–118
Hydrodynamics of periphyton, 2363
Hydrogel matrix of biofilms, 81
Hydrogen (See also Nutrients and energy sources)
activated sludge and, 741–748
Archaea and to produce, 273–274
in groundwater, 1672
hydrothermal vents and, 1611, 1618
hyperthermophiles and, 1633
in marine/ocean environment and, 1697–1709, 1854–1855
municipal solid waste landfills and, 1760
subsurface microbial communities and, 1454–1455, 1464–1466
Hydrogen cyanide (HCN), 457
Hydrogen oxidizing soil microorganisms, 2890
Hydrogen peroxide, 582, 603, 1387, 2932
Hydrogen sulfide, 2427, 3193
biofiltration vs., 589, 598, 599–600
bioleaching and pathway in, 637
bioremediation and, 708
in caves and mines, 823
hydrothermal vents and, 1618
municipal solid waste landfills and, 1763–1764
phototropism in, 2473
sulfate-reducing bacteria (SRB) and, 3092
Hydrogenases, sulfate-reducing bacteria (SRB), 468–475
Hydrogenobacter, 3111–3116, 3143–3147
Hydrogenophaga, 439, 1996, 3314–3319
Hydrolases, 269, 1210, 2273, 2903–2910
Hydrologic studies, microbial tracers in groundwater, 3198–3199
Hydrolysis
activated sludge processing and, 22–26
biofilms and, 87
flooded soils and, 1319–1320
phosphorus cycling and, 2450–2452
Hydrophilic forces, 2004
Hydrophilic materials, biofiltration, 591–592
Hydrophilic microorganisms, adhesion in biofilms, 100
Hydrophobic materials, biofiltration, 591–592
Hydrophobic microorganisms, adhesion in biofilms, 100
Hydrophobicity, 1599–1604
acid–base (AB) surface energies in, 1600–1601
activated sludge and, 1–7, 44
anaerobic granulation and, 238, 241
assay methods to measure, 1599
biofilms and, 2004, 2005, 2007–2008
contact angle measurement for, 1600–1601
electrostatic forces in, 1599–1604
floc formation and, 57, 2004, 2005, 2007–2008
free energy balance in, 1600–1601
Lifshitz van der Waals forces and, 1600–1601
microbial adhesion to hydrocarbons (MATH) for, 1599–1600, 1601–1604, 2007–2008
microbial adhesion to solvents (MATS) for, 1600, 1601–1604
thermodynamic analysis of, 1600–1604
viruses in soil and, 2098
Hydrostatic pressure (See also High hydrostatic pressure), hydrothermal vents, 1626
Hydrothermal vents (See also Geothermal environments), 289, 1604–1628
abundance and distribution of microorganisms at, 1620
Archaea and, 278, 287–288
bacteria at, 1620–1622
bacterial mats and, 1618
biomineralization and, 678
carbon dioxide and, 1611
chemoautotrophs and, 1606–1609
crustaceans and, 1619
cultivation and isolation of microbes from, 1611–1614
deep sea euryarcaheotic group (DSEG) and, 1611
distribution of vent fields of, 1618
diversity of, 1625
endosymbionts and, 1606–1609
endosymbiosis and, 1117–1118
epibionts and, 1609–1610
fluid composition at, 1618
genera and species of, 1619
genetic elements and, 1625–1626
hydrogen and, 1611
hydrostatic pressures and, 1626
hydrothermal processes in, 1618
hyperthermophiles and, 1628–1646
inert surfaces of, 1618
invertebrate-associated bacteria of, 1619
low temperature habitats and, 1610–1611
marine benthic group (MGIII) and, 1611
marine crearchaeotic group I (MGI) and, 1611
marine euryarchaeotic group (MGII) and, 1611
marine hydrothermal vent groups (MHVGs), 1614
methanogenesis in, 1920
methanotrophs and, 1606–1609
minerals and, 1618
miscellaneous euryarchaeotic group (MEG) and, 1611
molluscs and, 1619
nonsymbiotic mesophiles in, 1618–1619
nutrients and, 1618
oxygen and, 1610
pH levels and, 1618
phylogenic analysis of, 1614
Polychaetes and, 1619–1620
prokaryotes in, 1617–1628
psychrophilic bacteria and, 1617–1628
subvent biosphere of, 1614–1615
sulfur oxidizing bacteria in, 1610
surrounding waters, mesophiles in, 1618
temperature and, 1619–1620
thermophiles and, 3140–3147

Hydrothermal vents (See also Geothermal environments), (*continued*)
thioautotrophs and, 1606
tungsten and, 1706–1707
Vestimentifera symbionts and, 1619
Hydroxides, biomineralization, bacterial, 670–681
Hydroxy carboxy muconic semialdehyde, biodegradation, 2295–2300
Hydroxy formylbenzothiophene (HFBT), 1043–1045
Hydroxyalkanoates, activated sludge, 73
Hydroxybenzoic acid, biodegradation, 2295–2300
Hydroxyl radicals, 2278, 3183
Hydroxylamine oxidoreductase (HAO), 9–14
Hydroxylaminobenzoate, biodegradation, 1423–1429
Hydroxylase, 435, 2290, 2297–2300
Hydroxylation, 2293–2300
Hydroxyls, biomineralization, 671
Hydroxymuconic semialdehyde, biodegradation, 2295–2300
Hydrozoa, 1116
Hydrurus, 2362
Hygiene, bacteria in home/residential environment, 342
Hymenobacter, 1026, 1028
Hymenogaster, 2124–2132
Hymenolepis, 3399
Hymenoscyphus, 2913, 2915
Hyocholic acids, 1257
Hyodeoxycholic acids, 1257
Hyperparasitoids, 1115
Hypersaline environments (See also Halophiles), 1512–1529
aggregates and consortia in microbial mats, 173
alkaline saline habitats and, 1510
Antarctic hypersaline lakes, 1510
Antarctic soils and, 1027
Archaea and, 262, 276–293
bacteriophages and, 389
cyanobacteria and, 963
Dead Sea, 1509
desert environment and, 1576–1577, 1580–1582
enteroviruses and, 1170
extremeophiles and, 1232–1237
fermentation in, 1525
Great Salt Lake, 1509–1510
halophiles and, 1501–1529
methanogenesis in, 1525
microbial ecology of, 1514–1515
organic matter in, 1513–1514
osmotic adaptations to, phototrophic bacteria, 2483–2486
pH levels in, 1513
purple and green phototrophic bacteria in, 2470–2480
salt deposits, evaporites, rock salts, 1510–1511
salted foods, 1511
solar lakes, sabkhas, pools and lagoons of Sinai, 1509
solar salterns, 1508–1509, 1511
Hypersensitivity pneumonitis (HP), fungi, 1369, 1374–1375
Hyperthermophiles, 1233–1235, 1628–1646
aerobic processes and, 1633
aggregates and consortia in, 1642
anaerobic processes and, 1633
Archaea and, 246–259, 266, 277–293
autotrophs as, 1633
biofilms and, 1642
carbohydrates and, 1641–1642
carbon and, 1633
carbon dioxide and, 1633
cultivation of, 1628–1633
ecology of, 1641–1642
Embden–Meyerhof (EM) pathway in, 1633
Entner–Doudoroff (ED) pathway in, 1633
genetic elements of, 1639–1641
hydrogen and, 1633
hydrothermal vents and, 1604–1628
interspecies interaction at high temperatures and, 1642
isolation of, 1628–1633
lithotrophs as, 1633
metabolism in, 1633–1637
nutrients and, 1633
pH levels and, 1628
polysaccharides and, 1641–1642
sulfate-reducing bacteria (SRB) and, 3090–3091
sulfur and, 1633
temperatures and, 1642
transcription and translation in, 1637–1639
tricarboxylic acid (TCA) and, 1633
tungsten and, 1706–1707
Hyperthermus, 1630–1646
Hyphae, 2646–2647, 2889
Hyphochytriomycota, 2912, 3353–3364
Hyphoderma, 2914
Hypholoma, 2915
Hyphomicrobium, 3111–3116
activated sludge and, 35–38, 71
biofilms and, 90, 572
identification of isolates in, 1958
metal biodegradation and, 1884, 1907
Hyphomonas, 90, 2549
Hyphomycetes, 3353–3364
Hysterangium, mycorrhizae, 2124–2132

I

Ice (See Snow and ice environments)
Identifying microbial isolates, 1958–1967
BIOLOG and, 1961–1962
DNA analysis and, 1960–1961, 1964–1965
extracellular polysaccharides (EPS) and, 1960
fatty acid methyl ester (FAME) analysis in, 1962
genetic analysis in, 1964–1965
most probable number (MPN) technique in, 1959
obtaining isolates for, 1959–1961
physiological/metabolic testing in, 1961–1962
structural components and, 1962–1964
viable but nonculturable (VBNC), 1960
visual traits and, 1961
Idiopathic pulmonary hemosiderosis (IPH), 185–186
Igneococcales, 1233, 1614, 1629–1646
Igneous rock
lithotrophs and, 1826
microbial communities of, 1661–1673
Image analysis, 1674–1688
acquisition of image in, 1677
analysis of image in, 1676–1677
applications for, 1685–1687
binary image enhancement in, 1682–1683
biofilms and, 2340
calibration of, 1684–1685
cameras for, video, digital, 1676
contrast in, 1679
deconvolution in, 1679–1681
difference imagery in, 1683–1684
field and object parameters for, 1684
filtration in, 1679
flow cytometry and, 1944–1958
fluorescent probes/labels in, 1676
histogram equalization in, 1679
microscopy in, 1674–1675
presegmentation processing in, 1677–1681
primary image in, 1677

processing of image in, 1676–1677
replication and sampling intensity in, 1685
resolution in, 1785
restoration of image in, 1785
segmentation/thresholding in, 1681–1682
shading corrections in, 1677–1689
Image processing systems, 1676–1677
Immobilization (See also Adhesion), 105–111
Archaea and, 273
biofilms and, 100
Derjaguin–Landau–Verwey–Overbeen (DLVO) theory of, 106
enzyme activity and, 2903
motile bacteria and, 110–111
polymers and, 109–110
remobilization in, 2965
rhizosphere and, 2719–2720
soil microorganisms and, 2887
substrata makeup vs. 106–109
sulfur cycle and, 3107–3108
Immobilized cell reactors, chemical warfare and, 847
Immune disorders (See also AIDS/HIV), 1152, 2065–2083
Immune electron microscopy (IEM), rotaviruses and, 2765, 2767
Immunity, viral, 2747
Immunoassay and, 401–402, 1131–1132
Immunofluorescence
activated sludge foam monitoring and, 4–7
adenoviruses and, 98
bacterial counts using, 27–29
proteomes and proteins, 309
Immunoglobulin E (IgE), in allergies and illness and, 1359–1366
Immunomagnetic capture (IMC), rotaviruses and, 2771
Immunosuppressive drugs, fungi and production of, 1369
Impaction type bioaerosol samplers, 393–396
In-line coagulation, water treatment systems and, 2018
In-well bioreactor, 695
Inanidrilus, 1118
Inclusions in soil microorganisms and, 2884–2885
Incubation, chloroform fumigation type, 666–667
Indenopyrene bioremediation and, 697–712
Indexes, 355, 356–358
Indicator organisms
bacteriophages as, 354–363
Bacteroides fragilis-infecting bacteriophages as, 356–358, 378–379
coliphages as, 379–380, 384–385
F specific RNA bacteriophages as, 356
somatic coliphages as, 355–356, 377–378
Indigo fermentation, alkaliphiles and, 219–220
Indolacetic acid, biodegradation and, 2385
Industrial biofilms, 555–556, 582–584, 619–632
Industrial biofouling, 619–632
Industrial environment
bioaerosols in, 416–425
biofiltration in, 588
biosurfactants/bioemulsions and, 765
Infections, nosocomial infections (NI), 2235–2250
Infectious airborne bacteria (See also Bioaerosols), 1689–1697
Burkholderia in, 1695–1696
gram-negative bacteria in, 1694–1695
infectious dose in, 1690–1691
Legionella, 1788–1806
Mycobacterium in, 1691–1693
Nocardia in, 1693–1694
prevention and control measures for, 1696
reservoirs and sources for, 1690
Rhodococcus in, 1694
transmission of, 1690
Infectious dose, 1690–1691
Infiltration percolation vs. protozoa, 2333
Influenza, 2743
Information Collection Rule (ICR) protocol, bacteriophages and, 376
Infrared spectrometry, conditioning films and, 934–935
Inipol EAP22, 699
Inline filtration and, 2708
Inoculation/infection
mycorrhizae and, 2129–2130
for nitrogen fixation and, 2202–2204, 2206–2207, 2209
Inocybe, 2124–2132
Inonotus, 2646–2647
Inorganic acids, bioweathering and, 3366
Inorganic contaminants, bioremediation and, 707–708
Inositol, microbial protection from, 432
Inoviridae/Inovirus, 366–374
Insecticides
biocontrol vs., 450–465
biodegradation and, 1421
biofilms and, 88
biopesticides, 351
biotechnology and, 1447–1448
composting of, 916–917
microbial, 1709–1717
regulation of, 2693–2707
Insects
bioluminescence in, 1831
endosymbiosis and, 1114–1115
resistance to microbial insecticides and, 1714–1717
viruses vs., 1711
in water treatment systems, 1723
Insertion elements, DNA, 1199
Insulin, 1384
Integrated Microbial Database (IMD), 1333
Integrated pest management (IPM), 462
Integration, genetic, 1199
Integrons and, 1201
Inteins, Archaea and, 271
Intellectual property, biotechnology, 1861
Interaction studies, toxicity testing and, 3225
Interfacial free energies, adhesion in biofilms and, 122–124
Interferon, 1384
International Water Association (IWA) model, activated sludge and, 14–26, 49
Interplanetary transfer of life and, 2994–2995
Interpro, 1450
Intracellular endosymbiont/intracytobiont, 1113
Intracytoplasmic membrane (ICM), activated sludge denitrification and, 9–14
Intrinsic bioremediation, 695
Invertebrates
algal turf scrubbing (ATS) and, 215–216
water treatment systems vs., 1718–1733
Iodamoeba, 1136
Iodine, 3266–3267
Iodophenyl nitrophenyl phenyltetrazolium chloride (INT), 1783
Ion exchange water treatment systems, 1567, 2018
Ionic environment

Ionic environment (*continued*)
enzyme activity and, 2900–2901
soil microorganisms and, 2060
Ionic strength, viral, 2099
Ionization, viruses vs., 3264–3265
Ionotrophy, biomineralization and, 672
Iosborneol, 980
Iron, iron cycle, 1878, 1882–1893, 1902–1913, 2961
algae biotechnology and, 200
bacteriogenic iron oxides (BIOS), 1407
biofilms and, 1085–1086
bioleaching and, 632–643, 646
biomineralization and, 674–79
bioremediation and, 714
cyanobacteria and, 969–970
flooded soils and, 1325–1326
Gallionella and, oxidation by, 1401–1408
hydrothermal vents and, 1618
in marine/ocean environment, 1701–1704
municipal solid waste landfills and, 1763–1764
nitrogen fixation and, 2213–2215
oxygen and, 2277, 2278, 2283–2284
petroleum reservoirs and, 2430
phytosiderophores in, 2717
soil microorganisms and, 2887
subsurface microbial communities and, 1454–1455, 1464–1466
sulfate-reducing bacteria (SRB) and, 3089
in surface waters, 928, 928
in wetlands for wastewater treatment, 3393
Iron bacteria, Gallionella as, 1401–1408
Iron oxidizing/reducing bacteria (IRB)
in groundwater, 1665, 1667–1669
in petroleum reservoirs and, 2430
soil microorganisms and, 2890
Iron salts, activated sludge foaming and, 6–7
Iron sulfide, sulfate-reducing bacteria (SRB) and, 471–475
Iron sulfur centers, aerobic respiration and, 152–153
Irrigated soils, 1316–1333
IS1071 insertion element, 1200
ISO, bacteriophages and sampling, 376–378
Isoalkanes biodegradation and, 2403–2416
Isobutane, 2427
Isobutyric acid, 228
Isochromatium, phototropism in, 2477–2489
Isolates, identification of, 1958–1967
Isomerase, 1177–1189, 3207–3210
Isomorphism, in minerals, 633
Isoparaffin biodegradation and, 2402–2404
Isoprenoids, bioplastics and, 682–692
Isopropyl methylphosphonate (IMPA), chemical warfare and, 850
Isopropylbenzyne bioaugmentation and bioremediation in, 435
Isorenieratene, in paleolimnology, 2307–2317
Isosphaera, 3145–3147
Isospora, 1722–1723, 1734–1737, 2329–2337, 3277–3287
Isothiazolone, 605, 606
Isotope dilution studies
flooded soils and, 1326–1327
in groundwater, 1669–1671
subsurface microbial communities and, 1456–1464
viruses and, 3305
wastewater/sewage treatment and, 3341
Isotope ratio mass spectrometer (IRMS), 90
Isotropic semivariance, soil microorganisms and, 2897
Isovaleric acid, alkaliphiles and, 228
Iturin in biosurfactants/bioemulsions and, 757–759
Ixodes, endosymbiosis and, 1115, 1123

J

Janua, biofilms and, 614
Jet fuel, composting of, 916–917
Juncus, 2541–2548
June Grass, harm/in harmful algal blooms (HABs) and red tides, 2689–2693

K

Karenia, harm/in harmful algal blooms (HABs) and red tides, 2685–2693
Karlodinium, 2431
Karsts (See Caves and mines)
Karyomastigont, 1124
KEGG, 1450
Keratin, 1447
Keto myxol methylpentoside, in paleolimnology, 2307–2317
Ketodeoxycholic acid, alkaliphiles and, 228
Ketone, 929, 3412
Ketoreductase, 1185
Kick-plate boundary, 829
Kinase, 3207–3210
Kinetic limulus assay with resistant/parallel line estimation (KLARE), 1131
Kinetics of growth
activated sludge processing, 17–18
ambient concentration of nutrients and, 1745–1746
Arrhenius equation for, 1752
bacterioplankton and, 2529
basic concepts of, 1738–1741
biological factors affecting, 1750–1752
buffering capacity in, 1749
catalytic properties of abiotic soil components and, 1750
collision frequency and, 1741–1745
community composition vs., 1751–1752
constants, as a measure of S, 1740–1741
diffusion of gases through soil and, 1749
diffusion of solutes through soil, 1748–1749
doubling time in, 2529
environmental factors vs., 1752
extracellular enzymes and, 1750
first order rate constant in, 1738
general rate constant in, 1741–1742
geometric increase in population in, 1738
growth and uptake parameters in, 1751
growth rates, 1745
leakage rates, 1745
limiting factors to, 1751
liquid diffusion coefficient in, 1749
Michealis–Menten plots in, 1740–1741, 1743
microbial processes in soil, 1748–1757
microgravity environment and, 2997–3001
mixed substrate growth, 1874–1875
models of, 1753–1755
Monod plots in, 1740–41, 1743, 1753–1754
nutrient accumulation and, 1743–1744
nutrient acquisition ability and, 1745
oligotrophic bacteria and, 2274
polar phytoplankton and, 2559–2563

population size and, 1750–1751
problems solved by, 1745–46
respiration data for, 1753
soil physical factors vs., 1748
sorption and, 1749–1750
specific affinity and, 1742–1743
specific bacterial growth rates in, 3344–3345
steady state in, 1738–1740
Stokes–Einstein equation in, 1749
substrate induced growth response (SIGR) in, 1750
substrate induced respiration (SIR) in, 1750
temperature and, 1752–1753
theoretical analysis of cytoarchitectural requirements and, 1745
3/2 power kinetics in, 1755
toxicity testing and, in soils, 3161
turnover time in, 2529
volumetric bacterial growth rates in, 3344
wastewater/sewage treatment and, 3337, 3339–3342
wastewater/sewage treatment and, single species, 3347–3350
water content/moisture vs., 1753
Kitchens, bacteria in home/residential environment and, 338–340
Klebsiella, 386, 2547, 2550, 2552, 3089, 3102
bioaerosols and, 3321, 3322, 3326
biofilms and, 580, 582, 621, 1209, 2341–2356
coliform bacteria and, 895–914
genetically engineered microorganisms (GEMs) and, 1282
genetically modified microorganisms (GMMs) and, 1431
granular activated carbon (GAC) filters and, 1489–1496, 1569–1570
heterotrophic bacteria and, 1541–1552
infectious airborne bacteria and, 1689–1697
municipal solid waste landfills and, 1766
nitrogen fixation and, 2191, 2193–2201, 2212–2221
nosocomial infections and, 2236–2250
in source water, 2968
in spas and hot tubs, 2980–2984
in drinking water, 944, 945, 946
water purifiers vs., 1572–1573
Klebsormidium, subaerial communities and, 3056–3065
Klyveromyces, 880
Knockout studies, genomic, 1449
Koch, Robert, 2269
Kochia, biodegradation and, 2396
Korarchaeota, Archaea and, 260, 287, 295
Krebs cycle, 1125
Kyoto Protocol, desulfurization of fossil fuels, 1041–1051

L

La Nina, 2558
Labeling, flow cytometry and, 1953–1955
Labyrinthula, 2823, 2825
Laccaria, 2124–2132, 2914, 2915
Laccase, 1182–1189, 1387, 2647, 2903–2910
Lachrymaria, 2342–56, 2835–2844
Lactamase, 3207–3210
Lactarius, 2124–2132
Lactase, 1187
Lactate, 742–748, 3062
Lactic acid, activated sludge and, 741–748
Lactobacillus
adhesion in biofilms and, 127–128
biofilms and, 82
cold-adapted microorganisms and, 880
cold-shock response and, 886–895
freeze drying and, 1353–1354, 1357
high hydrostatic pressure (HHP) vs., 1555–1563
in marine/ocean environment, 1701
toxic solvents and, 3150
Lactococcus
biotechnology and, 3204
flow cytometric studies of, 1950
fluorescent studies of, 1835
Lactone, 929
Lactoperoxidase, 1185
Lactose death, viable but not culturable (VBNC) phenomenon and, 3251–3252
Laetiporus, 2647
Lagoons, 2333, 2476
Lakes (See Aquatic ecosystems; Surface waters),
Lambdoid phage, bacteriophages and, 370–373
Lamellibrachia, 1606
Laminar flow, adhesion in biofilms and, 117
Lampenflora, 836–843
Lamprobacter, 2477–2489
Lampropedia, 38
Land effluent percolation, 74
Land farming, 695
Landfills (See Municipal solid waste)

Lanthanides, 671, 1902
Large subunit (LSU), 1333
Larix, ectendomycorrhizal fungi and, 2125–2126
Larvae, macrofouling and, invertebrates, 613–615
Laser scanning microscopy (LSM), 1772–1788
Last Universal Ancestor (LUA), oligotrophic bacteria and, 2268
Late blight of potato spores in, 414
Lathyris, bioremediation and, 725
Laxatoxin, 977
Laxus, 1118
Leachate, landfill, 1767–1768
containment sites for, 1768
dissolved organic carbon (DOC) in, 1768
groundwater contamination and, 1768
heavy metals in, 1768
treatment of, 1768–1769
Leaching, microbial, 2890
Lead biodegradation (See also Heavy metals), 197, 199–200, 607, 1763–64, 1879–1893, 1902–1913, 2961
Leaf litter decomposer fungi, 3355–3358
Leakage rates, 1745
Leather processing, enzymes and, 1183
Leccinum, 2124–2132
Lectins, 570, 1782
Legionella, 313, 1345, 1542, 1689–1697, 1788–1806
bioaerosols and, 3328
biofilms and, 563, 566, 579, 621, 1209, 2341–2356
disinfection and, 1065, 1066
endosymbiosis and, 1123
flow cytometric studies of, 1951
granular activated carbon (GAC) filters and, 1492
heterotrophic bacteria and, 1548, 1550
infectious airborne bacteria and, 1696
nosocomial infections and, 2245
in rainwater roof catchment systems, 2680
sampling of, 2813
in source water, 2968, 2969–2978
in spas and hot tubs, 2980–2984

Legionella, (*continued*)
in drinking water, 945, 3199
Legume rhizobial symbiosis, 1119–1120, 2202–2208, 2786–2787
Leishmania, endosymbiosis and, 1126
Lemna, 973
Lepidoptera toxin, biocontrol use of, 2700
Leptolyngbya
photoautotrophic, in low-light habitats, 839–843
in snow and ice environments, 2876
subaerial communities and, 3059
Leptoplina, endosymbiosis and, 1121–1122
Leptosphaeria, 406, 413, 3360
Leptospira, 1806–1817
in rainwater roof catchment systems, 2680
in spas and hot tubs, 2980–2984
Leptospirillum
bioleaching and, 632–642
biomineralization and, 675
metal biodegradation and, 1904
nitrification and, 2149
Leptospirosis, 1806–1817
Leptothrix, 1401, 2283
biofilms and, 572
biomineralization and, 675, 676
filamentous forms of, in activated sludge, 1291–1306
metal biodegradation and, 1884, 1897, 1904
Leptotrombidium, 1122
Leucaena, 2785
Leuconostoc, 1871
biofilms and, 1221
high hydrostatic pressure (HHP) vs., 1556–1563
Leucoprinus, 2914
Leucothrix, filamentous forms of, in activated sludge, 1302–1306
Leucythophora, 2649
Levansucrase, in soil, 2903–2910
Leveillula, biocontrols and, 454
Leviviridae/Levivirus, 364–374, 364
Lewisite (See Chemical warfare)
Lichenomycota, 2913–2914
Lichenothelia, 1107–1112
Lichens, 2891
Antarctic, 1101–1106
biodeterioration of mineral materials and, 522–523, 524
endolithic, 1100–1112
fungi and symbiosis and, 1367
in hot desert regions, 1107–1110
soil microorganisms and, 2914
subaerial communities and, 3056–3065
weathering and, 3364–3389
Lichenysin, biosurfactants/bioemulsions and, 759
Licmophora, sea ice and, 2837–2844
Licopene, in paleolimnology, 2307–2317
Life cycle, of protozoa, 2615
Lifshitz-van der Waals forces, 101–104, 123, 124, 936, 938, 1600–1601
Ligands, weathering, bioweathering and, 3380–3381
Ligase, 271, 3207–3210
Light nonaqueous phase liquids (LNAPLs), 507–516, 699
Lignin, 693, 1183, 1210, 1760, 2646–2647, 3021
biofilms and, 88
bioplastics and, 682–692
cold-adapted microorganisms in, 872–885
fungi vs., 1385–1386, 1385
Ligninase, 1385–1386
Lime softening (See also pH levels), 2017–2018, 2908–2909
enteroviruses and, 1173–1174
Limestone, biodeterioration of mineral materials and, 518–523
Limit of detection (LOD), 2811
Limit of quantitation (LOQ), 2811
Limonene biodegradation and, 2404
Limulus, bottled water and, 800
Limulus amebocyte lysate assay (LAL), 1130–1131
Linweaver–Burk transformation, 2901
Lipase, 226, 1177–1189, 1212–1223, 1852, 2649, 2903–2910, 3021, 3207–3210
Lipid phase transitions, freeze drying and, 1356
Lipids, 1210, 2489, 3021
activated sludge and, 741–748
aerobic respiration and, 149, 151–152
alkaliphiles and, 137–138
Archaea and, 249–259, 271–272, 279–293
bacterioplankton and, 2519
biofilms and, 85–86, 114, 2960
biomarker use of (See Lipids as biomarkers, below), 663, 1817–1824
cold-adapted microorganisms and, 874–876, 887–888
in surface waters, 928, 928
Lipids as biomarkers, 663, 1817–24
applications for, 1820–1822
aquatic environment analysis and, 1821
aquifer analysis and, 1821
biomass and, 1818–1819
bioremediation and pollution analysis using, 1822
community composition and, 1819
composting analysis, 1822
metabolic activity, 1819–1820
nutritional/physiological status and, 1819
procedures for using, 1820
soil analysis and, 1821
Lipoconjugates, 1817–1824
Lipopolysaccarides (LPS), 109, 417, 1210, 1818–1824, 2882
biofilms and, 2960
biomineralization and, 671
cyanobacteria and, 975
Lipoproteins, biosurfactants/bioemulsions and, 757–760
Lipoteichoic acid, 109
Liquid diffusion coefficient in, 1749
Liquid impingement type bioaerosol samplers, 396
Lirceus, 3020
Lissoclinium, 975
Listeria, 338, 340, 1345
adhesion in biofilms and, 123
biofilms and, 577, 579, 582
biotechnology and, 3206
cold-adapted microorganisms in, 872–885
cold-shock response and, 886–895
in food, 3277–3287
high hydrostatic pressure (HHP) vs., 1555–1563
microbial insecticides using, 1714
municipal solid waste landfills and, 1766
Lithified materials, sampling of, 3074
Lithocarpus, 2125–2126
Lithotrophs, 1824–1829
aerobic respiration and, 151, 157
basaltic rock and, 1826–1828
biofilms and, 81–82
chemolithoautotrophy in, 1824–1826
Gallionella as, 1401–1408
groundwater and, 1827
hyperthermophiles and, 1633
igneous rock and, 1826
prevalence of, 1828
significance of, 1828–1829
weathering and, 1827
Litonotus, 2606
Littorella, 2548
Live/Dead kits, 90, 1783

Liver diseases, Aeromonas and, 1091–1099
Lobose amoeba in, 2616, 2617
Lockett, William, 74, 738
Long Duration Exposure Facility (LDEF), 1038–1041
Loriella, 838–843
Lotus, plant growth promoting rhizobacteria (PGPR) inoculation and, 350
Low light environment (See Caves and mines)
Lowest effect concentration (LEC), 3163
Lowest observed effect concentration (LOEC), 3163
Loxodes, microgravity and, 3000
Luciferase/luciferin
  bioluminescence and, 657–663, 1830–1838
  in wastewater/sewage, 3170
Lucinacea, hydrothermal vents and, 1606
Lucinoma, hydrothermal vents and, 1606
Ludzack–Ettiger process, activated sludge and, 78
Lutein, in paleolimnology, 2307–2317
Lux operons, in bioluminescent research, 658
Lyase, 1210, 2903–2910, 3207–3210
Lycopene, 2459
Lycopersicon, plant growth promoting rhizobacteria (PGPR) inoculation and, 350
Lycopodium, 3198
Lyme borreliosis, 1838–1849
Lymnaea, 972
Lyngbya, 210, 963, 972, 980
  aggregates and consortia in, 164, 170–173
  desert environment and, 1579
  nitrogen fixation and, 2193–2201
Lyngbyatoxin, 977
Lysates, rhizosphere and, 2715
Lysine, 2716, 2899
Lysis, activated sludge processing and, 23–26, 745–746
Lysogenic state in bacteriophages and, 371–373
Lytic state
  biocontrols and, 458–459
  bacteriophages and, 371–373

M

Machining, bioaerosols and, as byproduct of, 419–420
Mackinawite, 2961
Macroalgae, 2302–2306, 2464
Macrocyctis, 1921
Macrofouling, 613–616
Macroinvertebrates, in drinking water, 945
Macromolecule labeling, wastewater/sewage treatment and, 3342
Macromonas, 3111–3116
Magnesium, 1879–1893, 1902–1913, 2774, 2961
Magnetite, 671, 1464–1466
Magnetotactic bacteria, 678
Major histocompatiblity class (MHC), in allergies and illness, 1360
Majusculamides, 1852
malaria, 3399
male-killing bacteria, 1122
Maleylpyruvic acid, biodegradation and, 2295–2300
Mallomonas, 210, 2317–2327, 2467
Maltase, 2899
Maltose, 756, 2716
Maltose sensitive hemagluttinin (MSHA), 1448
Maltotriose, biosurfactants/bioemulsions and, 756
Mamestra, biocontrol use of, 2701
Manganese, manganese cycle, 1878, 1902–1913, 2961
  biomineralization and, 675–676
  cyanobacteria and, 969
  hydrothermal vents and, 1618
  metal biodegradation and, 1884
  oxygen and, 2277
  soil microorganisms and, 2887
  subsurface microbial communities and, 1454–1455
  sulfate-reducing bacteria (SRB) and, 3089
  oxygen and, 2283–2284
Mannanase, 1178–1189
Mannitol, 518, 2778–2789
Mannose, biosurfactants/bioemulsions and, 756
Mannosylerythritol lipids, biosurfactants/bioemulsions and, 755–756
Mantoneilla, photosynthetic pigments in, 2468
Mapping, self-organizing maps in, 1007
Marburg virus, bioterrorism and, 777–778
Marichromatium, 2474, 2477–2489
Marine bacterial isolate (MBI), 715
Marine benthic group (MGIII), 1611
Marine biotechnology (See also Marine/ocean environment), 1850–1863
  adhesion in, 1855–1856
  aquaculture and, 1856–1857, 1859
  biocorrosion in, 1855–1856
  biofilms in, 1855–1856
  biofouling, 1856
  biomass protein from, 1851
  biomaterials and, 1853
  biopolymers and, 1853
  bioprocesses and, 1855–1856, 1858–1861
  bioremediation and, 1855
  carbon dioxide sequestration in, 1855
  ecology of, 1858
  energy production from, 1853–1855
  enzymes and, 1853
  genetic engineering and, 1856, 1858
  health and safety in, 1857–1858
  intellectual property and technology transfer, 1861
  legal aspects of, 1861
  natural products of, 1851–1853
  polysaccharides and, 1853
  wastewater/sewage treatment and, 1855
Marine crearchaeotic group I (MGI), 1611
Marine euryarchaeotic group (MGII), 1611
Marine hydrothermal vent groups (MHVGs), 1614
"Marine snow," 89, 2002
Marine/ocean environment
  actinopoda in, 2618
  aggregates and consortia in, 168–172
  ammonium in, 1698–1701
  amoebas in, 2616, 2617
  Antarctica, 2557–2558
  Archaea in, 276–293
  Arctic Ocean and, 2556–2558
  available dissolved organic carbon (ADOC) and, 1086–1087
  bacteriophages as pollution indicators in, 355
  bacterioplankton in, 2519–2539
  biofilms in, 1081–1091
  biofouling in, 623, 610–619
  biomass of, fungi in, 1397
  bioremediation and, 712–722
  blooms in (See Harmful algal blooms and red tides)
  calcium in, 1707
  carbon and, 1697–1709
  carbonic anhydrase and, 1706
  chlorine in, 1707
  ciliates in, 2619–2620
  Clostridium and, 864–871

Marine/ocean environment (*continued*)
cold-adapted microorganisms in, 872–885
colloids and, 2002
copper in, 1706
denitrification in, 1010–1019
diatoms and sedimentation in, 1059–1061
diazotrophy and diazotrophic bacteria and, 2541–2547, 2550–2551
dimethylsulfide (DMS) and, 1701
dimethylsulfoniopropionate (DMSP) and, 1701
dissolved organic carbon (DOC) and, 1086–1087
disturbance of biofilms in, ecological impact of, 1088
emergent plants and, 2539–2549
endosphere microbiota of, 2548–2549, 2552
endosymbiosis and, 1115–1116
Enterococci in, 1264–1278
eutrophication of algae in, 1189–1194
extracellular polymeric substances (EPS) in, 1081, 1083–1084
fecal contamination in, 1256–1264
ferrodoxin in, 1702
flagellates in, 2618–2619
floc formation and, 2002
foraminifera in, 2616–2617
fungi in, 1394–1400, 2539–2540
Giardia in, 1252–1256
glutamate dehydrogenase (GDH) in, 1698–1701
glutamine synthetase (GS) in, 1698–1701
green fluorescent protein (GFP) studies for, 1498
halophiles, 1501–1512
heterotrophic bacteria and, 1541–1552
hydrocarbons and, 715–719
hydrogen and, 1697–1709
hydrothermal vents, 1604–1628
inorganic nutrients in, 1697–1709
iron and, 1085–1086, 1701–1704
lipid biomarkers of, 1821
"marine snow" in, 89, 2002
meroplankton, 1863–1869
methanogenesis in, 1913–1923
molybdenum in, 1704–1705
nickel in, 1706
nitrates in, 1698–1701, 1702
nitrites in, 1698–1701
nitrogen, nitrogen cycle in, 1010–1019, 1085–1086, 1697–1709, 2176–2188
nitrogen fixation, 2211–2221, 2539–2554, 2828–2829
oil spills and, 693–701, 713, 715–719, 916–917, 2402–2416, 2931
oligotrophic bacteria and, 2271, 2272
osmotic balance and, 1707
oxygen and, 1697–1709, 2277–2288
oxygen minimum zones (OMZs) in, 1016, 2162–2163
particulate organic carbon (POC) and, 1086–1087
pH levels and, 1085–1086
phosphorus and, 1085–1086, 1190
phosphorus cycling in, 1697–1709, 2448–2453
photoheterotrophic bacteria in, 1087–1088
phyllosphere of, 2539–2540, 2824–2825
plankton and, 1082–1083, 2502–2518
plant microbe interactions in, 2539–2554
polar phytoplankton in, 2554–2565
potassium in, 1707
pressure at depth, 1626
primary production in, 2566–2575
Prochlorococcus in, 2576–2593
protozoa and, 1252–1256, 2613–2625
purple and green phototrophic bacteria in, 2470–2480
rhizosphere of, 2540–2548
salt bridges and, 1707
sampling of, 2812–2815
sea ice microorganisms, 2833–2844
seagrass communities in, 2550–2554, 2822–2833
Secchi depth in, 1190
sedimentary bacteria in, 2827–2828
sedimentation in, 1193–1194, 2540–2548
sodium in, 1707
solar radiation and, 1192–1193
stratification within, 715
Streptococci in, 1264–1278
submerged aquatic vegetation (SAV) in, 1190
submerged plants in, 2549–2552
subsurface microorganisms and, 1080
sulfate-reducing bacteria (SRB) and, 1697–1709, 2547–2548, 2551
sulfur and, 1085–1086, 1697–1709
temperature and, 1193
thermophiles and, 3140–3147
trace elements in, 1701–1707
tungsten in, 1706–1707
vadose zone microbiology and, 3236–3246
viruses and, 1252–1256, 3300–3310
water turnover vs. algae in, 1193–1194
zinc in, 1705–1706
Zostera and, 2550–2554, 2822–2833
Marinitoga, 1515–1529, 1620–1628
Marinobacter, 1610, 1619, 1741
Marinococcus, 1506–1512
Marinomonas, 2549
Marshes (See also Marine/ocean environment), 1316–1333
fungi and, 3359–3360
in sediments and sedimentation, 2851–2852
Marteilia, 1857
Martian microbiology, space microbiology and, 2985, 2995
Mass balance equations, biofilms and, 2088–2089
Mass spectrography (MS), 820
biomass estimation and, 2656
conditioning films and, 933–934
detection of, 1132
microarray study of vs., 1974
proteomes and proteins, 309–310
Mass transfer, in biofilms, 2087
Massarina, 3359, 3360
Mastadenovirus, 93
Mastigella, 1125
Mastigocladus, 961, 962, 3142–3147
Mastogloia, salt production and, 2805–2809
Mathanoignis, 1524–1529
Matrix assisted laser desorption ionization mass spectrometry (MALDI MS), 309, 1132
Matrix assisted laser desorption/ionization TOF mass spectrometry (MALDI TOFMS), 933–934
Matrix, biofilm, 547–548
Mattesia, 1710
Mayorella, 2594–2604, 2605
Mechanical filtration, 1566
Mecoprop biodegradation and, 2394
Medicago, 1434

Medical biofilms, 554–555
Medical biosurfactants/bioemulsions and, 765–766
Megaplasmids, captured, 1446
Melanin, 1879
Meloidogyne, 455, 456, 459
Melosira, 206, 210, 2837–2844, 2837
Membrane filters (See also Heterotrophic bacteria), 1863
  bacteriophages and, 375–376
  biodegradable dissolved organic carbon (BDOC) and, 497–498
Membrane inlet mass spectrometry (MIMS), denitrification and, 1015, 1017
Membrane transport, alkaliphiles and, 138
Meningitis, enteroviruses and, 1151
Meningoencephalitis, amoebic, 1343–1350
Mentylobacter, flooded soils and, 1322
Mercury (See also Heavy metals), 605, 1878–1883, 1890, 1894, 1902–1913
  algae biotechnology and, 197
  biodegradation and, 694, 709, 1424–1429, 1446–1447, 1878–1883, 3402
  microbial methylation of, 1886, 1909–1910
  resistance of bacteria to, 608
  sulfate-reducing bacteria (SRB) and, 3089–3090
Mercury drop electrode analysis, conditioning films and, 932
Merismopedia, 1107–1112
Meroplankton, 1863–1869
Mesocyclops, 1718
Mesodinium, 2620, 2626–2632
Mesophiles
  composting and, 915–916
  hydrothermal vents and, 1618
Mesorhizobium
  endosymbiosis and, 1120
  nitrogen fixation and, 2201–2211
  soil salinity and, 2775
Metabolism
  anaerobic granulation and, 238
  anoxic, 9–11
  bacterioplankton and, 2521–2523, 2526–2528
  biodegradation and metabolic pathway evolution in, 1194–1207
  cometabolic reductive dechlorination, 508–509
  hyperthermophiles and, 1633–1637
  identification of isolates in, 1961–1962
  lipid biomarkers of, 1819–1820
  marine biotechnology and, 1850
  microgravity and, 3002–3003
  mixed organic pollutant, 1869–1877
  oligotrophic bacteria and, 2273
  periphyton and, 2359
  permafrost and, 2379–2380
  petroleum reservoirs and, 2427
  in sediments and sedimentation, 2848–2849
  soil microorganisms and, 2951–2956
  subsurface microorganisms and, 1079–1080, 2033
  wastewater/sewage treatment and, 3338–2239
  weathering, bioweathering and, 3375–2289
Metabolites, alkaliphiles and, 228
Metagenome analysis, soil microorganism and diversity in, 539
Metal biodegradation, metal cycling, 708–709, 1875–1901, 1902–1913, 3045, 3216
  adenosine triphosphate (ATP) and, 1878
  arsenic methylation and, 1885–1886
  bioacidification and, 1881
  bioaugmentation and, 1886
  biofilms and, 2960–2963
  bioleaching of, 641–650, 1881
  biomass as bioadsorbents of, 1879–1880
  carbon and, 1878
  catalyzed mineral formation, byproducts of, 1897
  cation classification in, 1902
  chelation of, by organic acids and siderophores, 1881–1882, 2717
  chemolithotrophy and, 1880
  chromium as example of, 1883–1884
  cold-adapted microorganisms and, 3216
  complexation of heavy metals and, 1894, 1902–1913
  death of microbes and, metal overstress, 1898
  enzyme activity and, 2909
  heavy metals and, 1878–1893
  ion composition of, 1878
  iron cycling in, 1903–1907
  manganese as, 1884, 1907–1909
  mercury cycling and methylation in, 1886, 1909–1911
  methylation and volatilization of, 1884, 1894
  microbial processes affecting, 1878–1880
  municipal solid waste landfills and, 1763–1764
  nitrogen fixation and, 2213–2215
  passive mineralization and, 1896
  pH levels and, 1878, 1879, 1880–1882
  phytometallophores, 2717
  phytosiderophores in, 2717
  precipitation of minerals and, 1894–1897, 1898–1899
  proton release and, 1880, 1896–1897
  quinones in, 1883
  redox transformations of, 1882–1886, 1896–1897, 1902–1913
  selenium methylation and, 1884–1885
  solubilization of, by microbes, 1880–1882
  sorption to cell walls, 1879, 1895–1896
  sulfate-reducing bacteria (SRB) and, 1898–1899, 3092–3093
  survival of bacteria in, 1897–1898
  uptake and accumulation of, by living cells, 1878–1879
  uranium cycling in, 1902–1903
Metal chelants, microbial protection from, 432
Metal ion extraction, 259–276, 632–642
Metal ions, viruses vs., 3267
Metal oxidation/reduction, 1446–1447
Metal reducing bacteria, subsurface microbial communities and, 3070
Metal removal, extracellular polymeric substances (EPS) and, 1229
Metal stressed environment (See also Metal biodegradation), 1893–1901
Metal sulfide dissolution, microbiological, 635–638
Metal sulfide oxidizing bacteria, bioleaching and, 634–635
Metallogenium, 632–642, 676, 1904
Metalloids, bioremediation and, 708–709
Metalloprotease, 3207–3210
Metallosphaera, 298, 645–650, 1235, 3144–3147
Metallothionein, algae biotechnology and, 198

Metallurgy, biohydrometallurgy, cold-adapted microorganisms and, 881–882
Metalworking fluids (MWFs), bioaersols and, 419–420
Metanosarcina, 1233
Metaphyton, 2357
Metarhizium, 881, 1710
Metazoa
activated sludge and, 72
enteroviruses vs., 1171–1172
in snow and ice environments, 2874
Meteorites, space microbiology and, 2985, 2994–2995
Methane and methanogenesis (See also Methanogens), 1075, 1913–1923, 2426, 3185–3187
activated sludge and, 738, 740–748
anaerobic oxidation of methane (AOM) and, 288–289
Archaea and, 259–276, 296–297
biodegradation and, 507–516, 694, 2292–2300, 2931
biofilms and, 83, 87
cold-adapted microorganisms in, 872–885
endosymbiosis and, in ocean waters, 1117–1118
energy recovery from landfill gases, 1767
floc formation and, anaerobic methanogenic granules in, 2002
flooded soils and, production of, 1319–1321
halophiles and, 1525
hydrothermal vents and, 1618
marine/ocean environment and, 1913–1923
methanotrophic bacteria, 1923–1936
methylotrophs and, 1923–1925
municipal solid waste landfills and, 1761–1771
nitrification and, 2163–2164
in sediments and sedimentation, 2846
soil biosphere and, 294, 296–297
soil microorganisms and, 2057
Methane monooxygenase (MMO), 1924–1936, 1937–1944, 3186
Methanobacillus, 745
Methanobacteriales, 1630–1646, 1915–1923
Methanobacterium, 1233, 1672
activated sludge and, 742–748
anaerobic granulation and, 232–245
flooded soils and, 1321
genomic studies and, 1448
metal biodegradation and, 1885, 1895
petroleum reservoirs and, 2419, 2429–2431
Methanobrevibacter
activated sludge and, 742–748
anaerobic granulation and, 233–245
flooded soils and, 1321
Methanocalculus, 1524–1529, 1917–1923, 2429–2431
Methanocaldococcus, 1917–1923
Methanochondroitin, Archaea and, 248–249, 248
Methanococcales, 1233, 1523–1529, 1630–1646, 1915–1923
Methanococcoides, 1917–1923
Methanococcus, 1233, 1235, 1524–29, 1622–1628, 1630–1646, 1917–1923, 2292, 3129, 3144–3147
Archaea and, 278–293
hydrothermal vents and, 1611
nitrogen fixation and, 2193–2201, 2214–2221
petroleum reservoirs and, 2429–2431
Methanoculleus, 1321, 1917–1923, 2429–2431
Methanogenesis (See Methane and methanogenesis)
Methanogenium, 1917–1923
anaerobic granulation and, 233–245
biotechnology and, 3205
flooded soils and, 1321
psychrophilic, 2640–2646
Methanogens, 1233–1235, 3185–3187
activated sludge and, 741–748
alkalithermophiles and, 3138
anaerobic granulation and, 238
Archaea and, 246–259, 262, 263, 277–293
halophiles and, 1523–1529
petroleum reservoirs and, 2429
soil borne, 296–297
subaerial communities and, 3057–3065
soil microorganisms and, 2892
Methanohalobium, 1515–1529, 1917–1923
Methanohalophilus, 1513–1529, 1917–1923, 2419, 2429–2431, 3130, 3137–3138
Methanol, 699, 3147–3155
Methanol dehydrogenase (MDH), methanotrophic bacteria and, 1927–1936
Methanolacinia, 1917–1923
Methanolobus, 1524–1529, 1917–1923
Methanomicrobiales, 233–245, 1321, 1523–1529, 1917–1923
Methanoplanus, 1915–1923, 2429–2431
Methanoplasma, 1895
Methanopyrales, 1523–1529, 1630–1646, 1917–1923
Methanopyrus, 1233, 1235, 1524–1529, 1611, 1622–1628, 1630–1646, 1917–1923, 3144–3147
Methanosaeta
activated sludge and, 742–748
anaerobic granulation and, 232–245
Archaea and, 297
biodegradation and, 509
flooded soils and, 1321
metal biodegradation and, 1896
Methanosalum, 1524–1529
Methanosarcina, 1525, 1895, 1917–1923, 3146
activated sludge and, 61, 742–748
anaerobic granulation and, 233–245
Archaea and, 248–249, 295, 297
biodegradation and, 509
biofilms and, 1221
nitrogen fixation and, 2193–2201
petroleum reservoirs and, 2429–2431
stress response and, 3032–3033
Methanosarcinaecea, 1917–1923
Methanosarcinales, 1321, 1523–1529
Methanospirillum
activated sludge and, 742–748
anaerobic granulation and, 232–245
metal biodegradation and, 1896
Methanothermobacter, 1917–1923, 3128–3140
Methanothermus, 295, 1234, 1235, 1630–1646, 3144–3147
Methanothrix, Archaea and, 297
Methanotrophic bacteria, 1923–1944
bioaugmentation and bioremediation in, 435
biofilms and, 82–83
hydrothermal vents and, 1606–1609
Methlybacterium, 1936–44, 3057–3065
Methyl alcohol (MeOH), biodegradation of, 1994–2000
Methyl chlorophenoxyacetic acid (MCPA), biodegradation and, 2385–2393
Methyl ester, in surface waters, 928, 928

Methyl parathion, bioremediation and, 705–712, 705
Methyl t buytylether (MTBE), biodegradation of, 439, 699, 1994–2000, 2410
Methylactobacterium, 1120
Methylation
fungi and, 1388
metal biodegradation and, 1884, 1894
biofilms and, 2963
in sediments and sedimentation, 2846
Methylene bisthiocyanate (MBT), 605–607
Methylene chloride, biodegradation and, 511–514, 1763
Methylisothiazolinone (MIT), 605
Methylobacter, 1323, 1924–1936, 3314–3319
activated sludge and, 35–38
biodegradation and, 1996
biofilms and, 2342–2356
psychrophilic, 2640–46
Methylocaldum, 1322, 1924–1936
Methylocella, 1924–1936
Methylococcus, 1322, 1323, 1924–1944
Methylocystis, 1322, 1924–1944
Methylomicrobium, 1322, 1924–44
Methylomonas, 1322, 1323, 1672, 1924–1944
Methylophaga, nitrogen fixation and, 2214–2221
Methylophilus, in groundwater, 1671
Methylosinus, 1924–1944, 2292
bioaugmentation and bioremediation in, 435–436, 439
flooded soils and, 1322
nitrogen fixation and, 2193–2201
Methylospaera, 1322, 1924–1944, 2640–2646
Methylotrophs, 1923–1925
Methyltrimethylene isothiazolinone (MTI), 605
Methylvaleric acid, alkaliphiles and, 228
Metopus, 1125, 3398–3399
Metsulfuron, composting of, 921–922
Michaelis–Menten equation, 1008, 1740–1741, 1743, 2901
Michaelsarsia, 2508
Micractinium, in wastewater stabilization ponds (WSBs), 3332
Microalgae, cold-adapted microorganisms in, 872–885
Microanalytical assay systems, 819
Microarrays (See also Biochips), 1968–1979
Microautoradiographic studies
activated sludge and, 69
biofilms and, 565
floc microbiology and, 56–57
Microthrix parvicella and, 3
Microbial adhesion to hydrocarbons (MATH), 1599–1604, 2007–2008
Microbial adhesion to solvents (MATS), 1600–1604
Microbial consortium, 3412
Microbial genome sequencing and annotation in, 1442–1443
Microbial insecticides, 1709–1717
Bacillus thuringiensis and, 1710–1717
bacteria in, 1711–1712
Cry toxins and, 1712–1717
efficacy of, 1710–1711
entomopathogens in, 1710
fungi in, 1710, 1711
insect resistance to, 1714–1717
production technology for, 1710
protozoa in, 1711
safety and specificity of, 1710
sustainable agriculture and, 1717
viruses in, 1711
Microbial leaching, 2890
Microbial loop, protozoa and, 2630
Microbial mats, 568–569
aggregates and consortia in, 161, 165–166, 170–173
Archaea and, 286–287
cyanobacteria and, 966–967
cyanobacteria in, 568–569
Gallionella in, 1406
hydrothermal vents and, 1618
hypersaline lakes, 173
in ice, 174–175
nitrogen fixation and, 2218
in septic tank systems, 2858
Microbial tracers, in groundwater, 3194–3202
Microbial volatile organic compounds (MVOCs), 1372–1383
Microbially enhanced oil recovery (MEOR), 2421, 2424–2425
Microbially influenced corrosion (MIC), 464–475, 555–556, 608, 2423–2424
biofouling and, 602–609
genetically engineered microorganisms (GEMs) and, 1228
nuclear waste storage and, 2257–2259
sulfate-reducing bacteria (SRB) and, 3092–3093
Microbiocides, biofouling vs., 602–609
Microchip-based PCR, 1134
Micrococcus, 137, 339, 1102–1106, 1501–1512, 3314–3319
activated sludge and, 64
alkaliphiles and, 139, 225
biofilms and, 580, 1215, 2342–2356
biomineralization and, 674
cold-adapted microorganisms in, 872–885
desert environment and, 1578
granular activated carbon (GAC) filters and, 1490
heterotrophic bacteria and, 1544, 1545
in permafrost, 2369
psychrophilic, 2641–2646
rhizosphere and soil microbes in, 346
subaerial communities and, 3057–3065
subsurface microbial communities and, 2035, 3065–3071
viable but not culturable (VBNC) phenomenon and, 3251
in drinking water, 944, 945
Microcoleus, 963, 965, 970, 971, 1109, 1507–1512, 2286
aggregates and consortia in, 170–173
in desert soils and biological soil crust (BSC), 1020–1023, 1579
salt production and, 2805–2809
subaerial communities and, 3060
Microcolonies
anaerobic granulation and, 237–238
biofouling and, 601–609
Microcyclus, 1490
Microcystin, 977, 987–995, 2340
Microcystis, 206, 207, 210, 972, 979, 980, 984–995, 1191, 1193
Microdomains, 1215
Microelectrodes, biofilm measurement, 90
Microfiltration (See also Filtration; Ultrafiltration), 2334
Microfungi, 1367
desert environment and, 1579
municipal solid waste landfills and, 1766
Microgravity, space microbiology and, 2985, 2994, 2996–3004
Microhabitats, soil microorganisms and, 2058–2059
Microlayer in neuston microbiology and, 2134–2135
Microlunatus, 38, 64
Micromonospora, 1102–1106, 1578
Micromycetes, in permafrost, 2369
Microneustons, 2140

Micropruina, 64
Microscopic particulate analysis (MPA) of in source water, 2972
Microscopy, 1674
bioaerosol samples and, 401
conditioning films and, 935
confocal laser scanning (See Confocal laser scanning microscopy), 1675
dark field–bright field, 1675
differential interference contrast (DIC), 1675
epifluorescence in, 1336–1338, 1675
floc formation and analysis, 2008
Hoffman modulation contrast, 1675
laser scanning microscopy, 1772–1788
phase contrast microscopy, 1674–1675
rotaviruses and, 2765, 2767
soil microorganisms and, 666
Microsensors, rhizosphere and soil microbes in, 349
Microsphaera, 64
Microspheres
adhesion in biofilms and, 128
as microbial tracer in groundwater, 3197–3198
Microsporidia, 1719, 2065–2083, 3277–3287, 3353–3364
Microsporum, 1368, 1373–1383, 2365
Microstrainers, 2013
Microthrix, 2–7, 1288–1306, 1311, 1312
Micrototal analysis, biochip testing, 446–447
Microtox assay, in wastewater/sewage, 3171
Microviridae/Microvirus, 365–374
Mildews, 1647
Military chemicals (See also Chemical warfare; Explosives), 706–707, 916–917, 922–924
Milk products, 1187
Millerite, 2961
Mineral fouling, 619
Mineral water, 796
Mineralization
biodegradation and, 2386, 2931
biofilms and, 82, 2961–2962
protozoa and, 2622–2623
rhizosphere and, 2719–2720
in sediments and sedimentation, 2844
in septic tank systems, 2859
soil microorganisms and, 2887
sulfur cycle and, 3107, 3109–3110
toxicity testing and, in soils, 3159
Minerals, 928
Antarctic soils and, 1026
biomineralization, bacterial, 670–681
in caves and mines, 823
hydrothermal vents and, 1618
municipal solid waste landfills and, 1763–1764
soil microorganisms and, 663–664, 2060
subsurface microbial communities and, interactions with, 1464–1466
Mines (See Acid mine drainage; Caves and mines)
Mining, biomineralization and, 677
Minimum data sets (MDS), 3165
Miscellaneous euryarchaeotic group (MEG), 1611
Mitochondrial origin, endosymbiosis and, 1125
Mixed liquid suspended solid (MLSS) ratio, 54
Mixed organic pollutants, bioremediation and metabolism of, 1869–1877
Mixed substrate growth, 1870
Mixotrophy, protozoa and, 2621–2622, 2629–2630
Mixtricha, 1124
Model viruses, 2101
Modeling, 355, 1002–1010
bioaerosol, 2107–2112
biofilm, 2083–2094, 2340
filtration, 2709–2712
genomic studies and, 1448
kinetics of growth and, 1753
pesticide degradation in soil, 2397–2398
protozoa, in food web, 2623, 2624, 2623
radioactive waste disposal system, 2670–2671
virus transport and removal in subsurface, 2094–2107
weathering, bioweathering and, 3372–3374
Modified Robbins Device (MRD), biofilms and, 557–558
Modified UCT process (MUCT) process, 79–80
Moist air spora, 412–414
Moisture and water content
in allergies and illness and, 1367–1368
Antarctica, 1104
biofilms and, 2960
biofiltration and, 592–593
kinetics of growth and, 1753
municipal solid waste landfills and, 1762
nitrogen fixation and, 2198
permafrost and, 2367–2385
protozoa and, 2595
rhizosphere and, 2724–2725
soil microorganisms and, 1753, 2057, 2060–2061, 2925, 3268–3269
subaerial communities and, 3057–3058, 3059
subsurface microorganisms and, 1075
viruses and, 3268–3269
Mold
airborne toxigenic, 182–189
airborne, 1647–1661
blue mold spores in, 414–415
high hydrostatic pressure (HHP) vs., 1561
slime molds and, 2912–2913
soil microorganisms and, 2912
water molds and, 2912
Molecular biofouling and, 611
Molecular beacons, detection of, 1134
Molecular biology
cold-adapted microorganisms and, 883
enzymes and, 3210
Molecular chaperone machine, 3028, 3048, 3050, 3052
Molecular probes, activated sludge foam monitoring and, 4–7
Molluscs, hydrothermal vents and, 1619
Molybdenite, bioleaching and, 633
Molybdenum, 1882–1893
cyanobacteria and, 969
in marine/ocean environment, 1704–1705
nitrogen fixation and, 2213–2215
soil microorganisms and, 2887
sulfate-reducing bacteria (SRB) and, 3089
Monochloramine, 1069
Moniliella, 122, 454
Monitored natural attenuation (MNA) in, 1941–1942
Monitoring of water purity, aerobic endospores for, 141–149
Monitors, activated sludge foam monitoring and, 4–7
Monochloramine in, 1063–1066, 2172
Monoclonal antibodies, rhizosphere and soil microbes in, 351
Monod equation, 18, 314, 1740–1741, 1743, 1753–1754, 3343
Monoethanolamine bioremediation and, 707
Monohalogens and biofiltration and, 589
Monomedia filtration, 2707

Mononitrotoluenes biodegradation and, 1423–1429
Monooxygenases, 1046, 1996, 2289–2300, 2903–2910, 2941, 3412
Monoraphidium, toxicity testing and, 3221–3230
Monoterpenes, nitrification vs., 2158
Monotropoid mycorrhizae and, 2126
Monte Carlo analysis, in risk assessment, 2749
Montmorillinite, activated sludge foaming and, 6–7
Moraxella, 499, 1853
  biofilms and, 572, 2343–2356
  biotechnology and, 3204
  filamentous forms of, in activated sludge, 1302–1306
  granular activated carbon (GAC) filters and, 1490
  heterotrophic bacteria and, 1541–1552
  subsurface microbial communities and, 3067–3071
  in drinking water, 944
Morganella, explosives biodegradation and, 1985, 1987
Morita, 2269
Moritella, 2269, 2271, 2640–2646
Mortality and morbidity rates, in risk assessment, 2743–2744
Mortar, weathering, bioweathering and, 3370–3371
Mortierella, cold-adapted microorganisms and, 880–881
Most probable number (MPN) technique, 1959, 2030, 2150–2152
Motility
  diatoms and, in biofilms, 1052–1053
  microgravity environment and, 2997–3001
Mougeotia, paleolimnology of, 2304–2306
Mount Saint Helens, quality of soils and, 2951
Mounting specimens, fluorescent probes and, 1335, 1336
Mousses of oil, for biodegradation, 2413
mRNA detection, 2499
MS2 bacteriophages and, 368–370, 387, 389–390, 2101
Mucigel, rhizosphere and, 2715
Muconic acid, biodegradation and, 2295–2300
Mucor, 1187
  biofilms and, 580
  desert environment and, 1579
  explosives biodegradation and, 1983
  subaerial communities and, 3057–3065
Multilocus enzyme electrophoresis (MLEE), 309, 1096
Multiple antibiotic resistance (MAR), 1258–1259
Multiple exposure and immunity, viral, 2747
Multiple regression analysis, 1007–1008
Municipal solid waste (MSW) landfills, 1759–1771
  aerobic processes in, 1759–1762
  anaerobic processes in, 1759–1762
  bacterial populations in, 1764–1765
  bioaerosols released from, 3324–3325
  biochemical methane potential (BMP) in, 1760
  biodegradation and, 1759–1763
  BTEX compounds in, 1763
  carbohydrates in, 1760
  carbon dioxide and, 1760
  containment sites for leachate and, 1768
  decomposition and stabilization of, 1759–1762
  energy recovery from gases of, 1767
  environmental impact of landfills of, 1765–1769
  enzyme activity in, 1760
  epidemiological studies of, 1765
  fermentation in, 1760
  flushing reactors for, 1769–1770
  gas emissions from, 1766–1767
  hazardous wastes and, 1765
  health concerns and, 1765–1766
  hydrogen and, 1760
  inhibition in, 1763–1764
  leachate emissions from, 1767–1768
  leachate treatment and, 1768–1769
  methane production and, 1761–1771
  mineral/metal supplements added to, 1763–1764
  moisture and, 1762
  oxygen and, 1759–1762
  pathogenic microbes and, 1765–1766
  pH levels and, 1760, 1762
  protozoa in, 1765
  sulfate-reducing bacteria (SRBs) in, 1760
  sulfates and sulfides in, 1760
  sustainable waste management and, 1769–1770
  temperature of, 1762
  temperatures within, 1760
  toxic chemicals and, 1765
  viruses and, 1766
  volatile organic compounds (VOCs) and, 1765
  xenobiotic constituents in, 1762
Murein, 2881
Mushroom culture, 1384–1385
Mustard gas (See Chemical warfare)
Mutations, radiation induced, 2993
Mutualism in, 1113
Mycelia, in desert soils and biological soil crust (BSC), 1020–1023
Mycena, 916
Mycetozoa, soil microorganisms and, 2912
Mycobacteria, spores and spore dispersion in, 416–417
Mycobacteria, 313, 1201, 3314–3319
  activated sludge foaming and, 3–7
  bioaerosols and, 3321
  biochips, biochip testing, 447, 448–449
  biodegradation and, 2293–2300
  biofilms and, 563, 621, 2341–2356
  bioluminescence in, 657–663
  biosurfactants/bioemulsions and, 753
  detection of, 1133
  granular activated carbon (GAC) filters and, 1492
  heterotrophic bacteria and, 1548
  infectious airborne bacteria and, 1689–1697
  methanotrophic bacteria and, 1924
  microarray study of, 1974
  Mycobacterium avium complex (MAC), 1689, 1690, 1691–1693, 2112–2120
  nosocomial infections and, 2242
  rhizosphere and soil microbes in, 346
  soil microorganisms and, 2881
  in source water, 2968, 2969–2978
  in spas and hot tubs, 2980–2984
  spores and spore dispersion in, 419, 421
  in drinking water, 945
Mycobacterium avium complex (MAC), 1689, 1690, 1691–1693, 2112–2120
mycolic acid, 3–7, 109, 2881
Mycoplasma, 1449, 1895
Mycopolyspora, 1130
Mycorrhizae, 1099, 1385, 1579, 2120–2132, 2911–2912, 3121

Mycorrhizosphere, 2714
Mycosphaerella, 406, 1395–1400
Mycosporine, 2512
Mycotoxicosis, 1369, 1378–1379
Mycotoxins, 182–189, 779, 1366–1383
Myocarditis, enteroviruses and, 1152
Myonecrosis, Aeromonas and, 1091–1099
Myoviridae/Myovirus, 365–374
Myrica, 2209, 2912
Myrothecium, 779, 2701
Myxococcus, 1215, 1320
Myxolmethyl methylpentoside, in paleolimnology, 2307–2317
Myxomycete, 3000
Myxomycota, 2912
Myxophytes
  cyanobacteria (See also Blue-green algae), 952–982
  photoautotrophic, in low-light habitats, 836–843
Myxoxanthophyll, in paleolimnology, 2307–2317

N
N-Acetlyglytaminylglutamine amide (NAGGN), soil salinity, 2778–2789
Naegleria, 2605
  Antarctic soils and, 1026
  endosymbiosis and, 1123, 1126
  meningoencephalitis and, 1343–1350
  in source water, 2968, 2969–2978
  in spas and hot tubs, 2980–2984
  in wastewater/sewage, 2329–2337
  in water treatment systems, 1718
Nais, 1722
Naked DNA, 1203, 1280
Nalidixic acid, activated sludge foam monitoring, 4–7
Nanoclimates, 3057
Nanoflagellates, bacterioplankton vs., 2531
Nanofossils, 2021
Nanolayer, neuston microbiology, 2134–2135
Nanotechnology, Archaea, 273
Naphthalene biodegradation, 694, 696–712, 1763, 2409, 2298–2300, 2403–2416
Naphthene biodegradation, 2402–2404
Naphthenic acid, bioremediation, 696–712, 2403–2416
Naphthol, composting, 921–922
Nasonia, 1115, 1122
Nassula, 972

Nitrate, 34, 2153–58
activated sludge denitrification and, 20
bioremediation and, 694, 707–708, 709
cyanobacteria and, 969
in marine/ocean environment, 1010–1019, 1698–1701, 1702
nitrogen cycle and, 2176–2188, 2936–2944
nitrogen fixation and, 2188–2221
oxygen and, 2277
primary production and use of, 2566–2575
water treatment systems and, 2167
Nitrate ester, biodegradation, 1421
Nitric acid, 3062
biogenic, in biodeterioration of mineral materials, 524
weathering and, 3364–3389, 3364
Nitric oxide, 3183, 3189–3192
activated sludge denitrification and, 8–14
nitrification and, 2161–2163
soil biosphere and, 294
Nitrification (See also Denitrification), 2144–2167, 2940–2941
activated sludge and, 8–14, 19–20, 49, 74, 76
ammonia monooxygenase (AMO) and, 2145–2167
ammonia oxidizing bacteria (AOB) in, 2144, 2167–2176
anaerobic, 2146–2147
anammox and, 2146
aquatic systems and, 2144–2167
autotrophic, 2144–2145
biochips, biochip testing for bacteria typing in, 448
denitrification and, 2150
desert soils and, 1022
disinfection vs., in water treatment systems, 2172–2175
distribution and abundance of nitrifers for, in aquatic environment, 2150–2152
distribution of, in water and sediments, 2153–2158
euphotic zone, 2159
factors affecting, 2158–2160, 2171–2174
heterotrophic, 2145–2146
identification and enumeration of nitrifiers for, 2169
indicators of, in drinking water, 2170–2171
inhibitory compounds vs., 2158
measurement of, 2152–2153
methane oxidation and, 2163–2164
monitoring of, 2174
monoterpenes vs., 2158
most probable number (MPN) of nitrifiers for, 2150–2152
New Production Paradigm and, 2153
nitrate and, 2153–2158
nitric oxide production during, 2161–2163
nitrifying bacteria in, 2144
nitrite oxidizing bacteria (NOB) in, 2144, 2167–2176
nitrogen cycle and, 2149–2150
nitrogen fixation and, 2188–2221
nitrous oxide production during, 2161–2163
oxygen and, 2160–2161, 2282–2283
oxygen minimum zones and, 2162–2163
pH levels and, 2168–2169
phylogeny of bacteria involved in, 2147–2149
prevention and control of, in drinking water, 2174–2175
rates of, in lakes, 2156–2158
rates of, in marine systems, 2154–2156
in septic tank systems, 2859
soil microorganisms and, 2949
solar radiation or light vs., 2158–2159
substrate concentration vs., 2160
temperature vs., 2158, 2168–2169, 2171–2172
toxicity testing and, in soils, 3159–3161
water treatment systems and, 2167–2176
wetlands and, 3404
Nitrifiers, nitrifying bacteria
activated sludge and, 18–26, 34–35
aerobic respiration and, 151
soil microorganisms and, 2889–2890
subaerial communities and, 3057–3065
in wastewater/sewage, 3172
Nitrilotriacetate (NTA), 1871, 1875–1876
Nitrite, 34
activated sludge and, 8–14, 20, 24–26, 38
bioremediation and, 707–708
in marine/ocean environment, 1010–1019, 1698–1701
nitrogen cycle and, 2176–2188, 2936–2944
nitrogen fixation and, 2188–2221
water treatment systems and, 2167
Nitrite oxidizing bacteria (NOB), 2144, 2167–2176
Nitrobacter, 2145–2167, 2168–2176, 2941
activated sludge and, 13–14, 20, 35, 739
aerobic respiration and, 157
biodeterioration of mineral materials and, 524
biofilms and, 2342–2356
flooded soils and, 1325
granular activated carbon (GAC) filters and, 1490
heterotrophic bacteria and, 1542
soil microorganisms and, 2890
in wastewater/sewage, 3172
Nitrobacteraceae, 2167, 3159
Nitrobenzoate, biodegradation, 1423–1429
Nitrocellulose (NC), biodegradation, 1979–1993
Nitrococcus, 13–14, 1325
Nitrogen and nitrogen cycle (See also Nitrogen fixation), 2149–2150, 2176–2188, 2936–2944, 3183, 3189–3192
activate sludge, removal of, 8–14, 15–26
algal blooms and, 206–207
algal turf scrubbing (ATS) and, 217–218
bacterioplankton and, 2533–2534
biodegradation and, 694, 707–708, 714, 724, 707–708, 2930, 2931, 2932–2933
biofilms and, 1085–1086, 2005
biofiltration and, 589
cold-adapted microorganisms in, 872–885
cyanobacteria and, 967–968
desert environment and, 1577
floc formation and, 2005
flooded soils and, 1324–1325
in marine/ocean environment and, 1697–1709
marine nitrogen cycle in, 1010–1019
mycorrhizae and, 2128
nitric oxide and, 3189–3192
nitrogen fixation in soil, 344
nitrous oxide and, 3189–3192
oxygen and, 2277, 2282–2283
petroleum reservoirs and, 2427–2428

Nitrogen and nitrogen cycle (See also Nitrogen fixation), (*continued*)
primary production and use of, 2566–2575
rhizosphere and, 2722
soil microorganisms and, 663, 667–670
subsurface microbial communities and, 1454–1455, 1461–1463
sulfate-reducing bacteria (SRB) and, 3089
in surface waters, 928, 928
in wetlands for wastewater treatment, 3391–3393
wetlands and, 3404
Nitrogen fixation (See also Rhizobium), 344, 454, 2188–2221
actinorhizal Frankia symbiosis in, 2208–2209
aggregates and consortia in, 167–181
algae and, 1191
alternative nitrogenases in, 2190–2191
associative symbioses in, 2199–2200
bacterioplankton and, 2525
carbon and energy sources for, 2196–2198
chemistry of, 2205
coastal waters and, 2218
cold-adapted microorganisms in, 872–885
combined nitrogen and, 2198
cyanobacterial mats and, 2218
dinitrogenase and, 2205
effective vs. ineffective nodules in, 2204–2205
endosymbiosis and, 1118–1120
energy costs of, 2194–2195
factors affecting, 2207–2208
gene expression and, 2205
genetically modified microorganisms (GMMs) and, 1431, 1434–1437
genetics of nitrogenase and, 2191
grass bacteria association in, 2199–2200
host species and, 2207
importance of, 2201–2202
inoculation/infection for, 2202–2204, 2206–2207, 2209
iron and, 2213–2215
legume rhizobial symbiosis in, 2202–2208
limiting factors for, 2196
marine/ocean environment and, 2211–2221, 2539–2554, 2828–2829
metals and, 2213–2215
methanotrophic bacteria and and, 1929–1930
microbial mats and, 2218
mineral nutrients and, 2208
moisture and, 2198
molybdenum and, 2213–1115
mycorrhizae and, 2120–2132
nitrogen cycle and, 2176–2188, 2936–2944
nitrogen limitation and, 2216
nitrogenase enzyme complex for, 2189–2195, 2211–2221
nodule development on roots and, 2204–2205
nonsymbiotic bacteria and, 2195–2200
nutrients and, 2199, 2208, 2213–2215
oxygen and, 2198, 2213–2215, 2282–2283
pH levels and, 2198–2199, 2207–2208
physiological prerequisites for, 2191–2194
phytoplankton and, 2216
prenodule formation in, 2208
rates of, measuring, 2215–2219
rhizosphere and, 2720
rotation of crops and, 2907
seagrass communities and, 2828–2829
sediments and, 2218–2219
soil biosphere and, 294
soil microorganisms and, 2057–2958, 2887
soil salinity vs., 2786–2787
subaerial communities and, 3057–3065
substrates for nitrogenase and, 2191
sustainable agriculture and, 3120
temperature vs., 2199
toxicity testing and, in soils, 3160
Nitrogen limitation, 2216
Nitrogen oxides, biotrickling filters, 782–795
Nitrogenase, 2189–2195, 2211–2221
Nitroguanidine (NQ), biodegradation, 1979–1993
Nitrophenol, biodegradation, 2931, 3413
Nitrosguanidine (NTG), alkaliphiles, 228
Nitrosobacter, 3057–3065
Nitrosococcus, 9–14, 57, 2147–2176
Nitrosocystis, 2147–2167, 2147
Nitrosolobus, 35
Nitrosomonas, 2145–2167, 2941
activated sludge and, 9–14, 20, 35, 57, 739
biodegradation and, 1447
biodeterioration of mineral materials and, 524
biofilms and, 2342–2356
genetically altered, in biotechnology, 1447
granular activated carbon (GAC) filters and, 1490
streams and, 3019
subaerial communities and, 3057–3065
in wastewater/sewage, 3172
Nitrosospira
activated sludge denitrification and, 9–14, 20, 35, 57
flooded soils and, 1325
subaerial communities and, 3057–3065
Nitrosovibrio
activated sludge and, 35
biodeterioration of mineral materials and, 524
subaerial communities and, 3057–3065
Nitrospira, 2147–2167, 2941
activated sludge denitrification and, 13–14, 20, 35
flooded soils and, 1325
soil microorganism and diversity in, 533
Nitrotoluene biodegradation, 706–712, 1423–1429
Nitrous oxide, 3183, 3184, 3189–3192
activated sludge denitrification and, 8–14, 20, 24–26
biofiltration and, 589
nitrification and, 2161–2163
soil biosphere and, 294
Nitzschia, 1055, 1058, 1061
algal turf scrubbing (ATS) and, 215
photoautotrophic, in low-light habitats, 838–843
salt production and, 2805–2809
sea ice and, 2835–2844
No effect concentration (NEC), 3163
No observed effect concentration (NOEC), 3163
Nocardia, 757
activated sludge foaming and, 1–7
biodegradation and, 2292–2300, 2409
biosurfactants/bioemulsions and, 753, 756
gene transfer and, 1409

infectious airborne bacteria and, 1690, 1693–1694
soil microorganisms and, 2881
subaerial communities and, 3057–3065
Nocardia amarae-like organisms (NALO), 3–7
Nocardiodes, 1027, 1855, 2035, 3067–3071, 3314–3319
Nocardiopsis, 227–228, 881, 1506–1512
N-Octodecane, activated sludge foam monitoring, 4–7
Nodularia, 164, 167–169, 961, 963, 984–995
Nodularin, 977, 987–995
Nomuraea, microbial insecticides using, 1710
Nonaqueous phase liquids (NAPLs), 44, 699
Nonculturable microorganisms, genomic studies, 1450–1451
Nonfilamentous microbes, activated sludge foaming, 1–7
Noninclusion viruses (NPV), 1711
Nonoxidizing biocides, biofouling vs., 604–609
Nonstarch polysaccharides (NSP), 1188
Nontuberculous mycobacteria (NTM), 1690, 1691–93
Norwalk-like viruses, 1586, 2221–2235, 2744–2745
bioaerosols and, 3327
biodegradation and, 3288–3300
in source water, 2969–2978
in spas and hot tubs, 2980–2984
streams and, 3017
Nosema, 1710, 2065–2083, 2701
Nosocomial infections (NI), 2235–50
Nostoc, 207, 966, 972, 975, 980, 984–995, 1107–1112
Antarctic soils and, 1025
desert environment and, 1579
in desert soils and biological soil crust (BSC), 1021–1023
mycorrhizae and, 2120–2124
nitrogen fixation and, 2193–2201
photoautotrophic, in low-light habitats, 840–843
in snow and ice environments, 2876
Nostochopsis, 964, 1109
Nostocoida, 4–7, 64, 1288–1306
Notholca, 1725
Nowakowskiella, 2552
Noxious compounds, weathering, bioweathering, 3367–3368
Nuclear magnetic resonance (NMR), 90, 1449
Nuclear wastes (See Radioactive and nuclear wastes)
Nucleases, oligotrophic bacteria, 2273
Nucleic acid (See also DNA/RNA analysis), 2489, 2716, 2731
activated sludge and, 741–748
biomass estimation using, 2656–2657
databases of, for fluorescent probes, 1333–1334
probes using, in soil contamination, 728–729
soil genetic ecology, 2919–2923
Nucleocapsid of bacteriophages, 364
Nucleoids, 2519, 2884
Nucleomorphs, 1127
Nucleopolyhderosis viruses (NPV), 1711
Nucleotides, biomass estimation, 2654
Nursery inoculation, using mycorrhizae, 2129–2130
Nutraceuticals, 1852–1853
Nutrient accumulation, kinetics of growth, 1743–1744
Nutrient cycling
bacterioplankton and, 2532–2534
protozoa and, 2629
rhizosphere and, 2719
soil microorganisms and, 663, 2946–2947
sustainable agriculture and, 3120
Nutrients and energy sources
acquisition ability, 1745
activated sludge and, 1311
algae and, 1190, 1191–1194
ambient concentration of, 1745–46
bacterioplankton and, 2520, 2521–23, 2530–2531, 2532–2534
coliform bacteria and, 900–901
composting and, 915
desert environment and, 1576, 1582–1583
fungi and, 1648
hydrothermal vents and, 1618
hyperthermophiles and, 1633
marine/ocean environment, 1697–1709
mycorrhizae and cycling, 2127
nitrogen fixation and, 2196–2198, 2199, 2208, 2213–2215
oligotrophic bacteria and, 2267–2277
periphyton and, 2362–2363
plankton and phytoplankton, 2503, 2512–2514
polar phytoplankton and, 2559–2560, 2562–2563
primary production and use of, 2566–2575
protozoa and, 2595, 2596, 2613–2615, 2622–2623
sea ice microorganisms and, 2837–2838
soil microorganisms and, 2057, 2059–2060, 2887, 2927
in source water, 2970
streams and, 3015
stress response and, 3034
vadose zone microbiology and, 3236–3246
wastewater/sewage treatment and, 3337
Nutritional/physiological status, lipid biomarkers, 1819
Nyquist sampling frequency, 1785

O

O serogrouping, fecal contamination, 1259–1260
Obligate intracytobionts, 1113
Obligate symbiosis, 1123
Oceanospirillum, 675, 1228, 1908, 2549
Ochratoxins, 182–189, 1375
Ochromonas, 2317–2327, 2508, 2805–2809, 2837–2844
Octadecabacter, 2640–2646
Octahydro tetranitro tetrazocine (HMX) biodegradation, 1979–1993
Octahydrotetranitrotetrazocine bioremediation, 706–712
Octane biodegradation, 3405, 3412
Oculina, endosymbiosis, 1117
Odentella, 2506
Odor control, biofiltration, 593–601
Odor in water
algal blooms and, 204–213
biotrickling filters vs., 782–795
Oedogonium, algal turf scrubbing (ATS), 215
Off-stream water storage, as pretreatment, 2013–2014
Oidium, 412, 454
Oil industry (See also Hydrocarbons; Petroleum)
biofouling and, 623
biomineralization and, 677
genetically altered microorganisms and, to increase productivity, 1448
microbially enhanced oil recovery (MEOR), 2421, 2424–2425
petroleum reservoirs and microbial activity in, 2416–2426
Oil spills, 693–701, 713, 715–719, 916–917, 2402–2416, 2931

Chromatiaceae in, 2477–2482
ecology of, 2472–2476
Ectothiorhodospiraceae in, 2480, 2482
favorable conditions for, 2473
habitats for, 2474–2476
hydrogen sulfide and, 2473
isolates of, 2476–2481
light and, 2473–2474
oxygen and, 2474
phylogeny of, 2481–2483

purple nonsulfur bacteria in, 2480–2483
salt marshes and, 2475
salt requirements and osmotic adaptations of, 2483–2486
Phototrophs and photoautotrophy, 2471
biofilms and, 83
in permafrost, 2369
soil microorganisms and, 2887
weathering, bioweathering and, 3365
Phragmites, in wastewater treatment reedbeds, 3389–3401
Phragmonema, 838–843
Phthalate, 1822
biofilms and, 86–87
bioremediation and, 707
cold-adapted microorganisms and, 882–883
composting of, 916–917
soil slurry batch reactor for, 51–52
Phycobilins, 2453–2470
Phycobiliproteins, 193–194, 2453–2470
Phycobilisomes, 2461–2462
Phycocyanin, 1852
Phycocyanobilin, 2460
Phycoerythrine (PE), 1676, 2576–2593
Phycoerythrobilin, 2460
Phycopeltis, 3056–3065
Phycosphere, 1056–1057
Phycotoxins, 1857
PHYLIP, 812
Phyllosphere
emergent plants (See also Spartina), 2539–2549
marine/ocean environment and, 2539–2554
seagrass communities in, 2824–2825
submerged plants and, 2549–2552
Phylogenetic oligonucleotide arrays (POAs), 1976–1977
Phylogenetics (See also DNA/RNA analysis), 1446, 2489–2501
Archaea and, 259–260
capillary electrophoresis in, 811–821
cloning and, 2492–2494
denaturing gradient gel electrophoresis in (DGGE) in, 2494–2496
DNA-based, 2492–2496
mRNA detection in, 2499
oligonucleotide probe hybridization in, 2497–2499
polymerase chain reaction (PCR) in, 2492–2494
reverse transcription polymerase chain reaction (RT PCR) in, 2500
ribosomal RNA-based, 2491–2492
RNA-based methods of, 2496–2499
sequencing in, 2491
terminal restriction fragment length polymorphism (T RLFP) in, 2496
transcription in, 2489–2491
translation in, 2489–2491
Phylotypes, 2524
Phyma, 945
Phymatotrichopsis, 2913
Physarum, microgravity, 3000
Physical gaps, in genomic studies, 1443
Physical potential (hydraulic head, water tension, suction), biofiltration, 592
Phytane, 928, 928
Phytanyl ether lipids, 1818–1824
Phytate, 1188
Phytometallophores, 2717
Phytoneuston, 2133
Phytophthora, 407, 1395–1400
biocontrols and, 451, 458
biosurfactants/bioemulsions and, 766
soil microorganisms and, 2912
spores and spore dispersal in, 414
Phytoplankton (See Plankton and phytoplankton)
Phytoremediation, 709, 731–734, 1989–1990
Phytoreovirus, 2753–2773
Phytostimulators, bacterial, 343–354
PICCOLO software, 502
Picea, ectendomycorrhizal fungi, 2125–2126
Piceance Basin, 2045–2047, 2048–2057
Picocyanobacteria, 2526
Piconeustons, 2135–2136
Picornaviridae, 327, 363–364, 1530–1540, 3327
Picrophilus, 1233, 1235, 1625, 3129, 3146
Pigmented bacteria, photosynthetic pigments, 2489
algae biotechnology and, 193
biomass estimation and, 2657
Chemtax analysis of, 2468
concentration and extraction of, 2462
cyanobacteria and, 964–965
distribution of, 2463–2465
fluorometric analysis of, 2462–2463
heterotrophic bacteria and, 1541–1552
high performance liquid chromatography (HPLC) analysis of, 2463
marine algae and bacteria, 2453–2470
marine biotechnology and, 1852–1853
paleolimnology and, 2306–2317
photochemistry of, 2454
photosynthetic, in marine algae and bacteria, 2453–2470
psychrophilic, 2640–2646
purple and green phototrophic bacteria in, 2470–2480
spectrophotometric analysis of, 2462
taxonomy of, 2465–2468
in drinking water, 945
Pili, 2885
Piloderma, 2124–2132
Pimephales, biomonitoring, 3169
Pink snow, 2873
Pink water, 706–712
Pinnularia, 2839, 3057–3065
Pinus, ectendomycorrhizal fungi, 2125–2126, 2128
Pipecolate betaine, soil salinity, 2778–2789
Piptoporus, 2647
Pisolithus, 2124–2132, 2915
Pitch (wood sap) degradation, fungi, 2648–2650
Pithomyces, 408, 412
Plagioplya, 3398–3399
Plague, bioterrorism, 776–777
Planctomycetales
activated sludge denitrification and, 10–14, 38, 71
bacterial counts using, 31
nitrification and, 2146
in snow and ice environments, 2877
soil microorganism and diversity in, 533
Planetary catastrophe, subsurface microorganisms, 1080
Plankton and phytoplankton (See also Bacterioplankton; Harmful algal blooms and red tides; Prochlorococcus), 2502–2518
adaptations of, 2510–2514
Archaea and, 279–285, 288
bacterioplankton in, 2519–2539
biofilms and, 81, 82, 88, 114, 611–612, 1082–1083
biogeochemistry and, 2515–2516

Plankton and phytoplankton (See also Bacterioplankton; Harmful algal blooms and red tides; Prochlorococcus), (*continued*)
biomass of, 2516, 2559–2560, 2653
biotechnology and, 2516
blooms, 970–972, 975–981, 989–990, 2002, 2565
carbon dioxide and, 2515
cell shape in, 2508
cell size of, 2505–2508
cell wall in, 2509, 2555
characteristics of, 2555
chloroplasts in, 2509–2510
cholera and, 856–861
climate changes and, 2515–2516, 2564–2565
colonies of, 2509
culturing, 2516
cyanobacteria and, 970–972, 975–980, 980–981, 989–990, 2555
cyclic climatic events and, 2558–2559
distribution of, 2514–2515
endosymbiosis and, 1115
eutrophication and, 2516
evolutionary history and fossil record of, 2504–2505
eyespot in, 2509
flagella of, 2509
food web and, 2563–2564
grazing and, 2514
growth rates of, 2559–2563
invasions by, 2515
light or solar radiation and, 2502, 2512, 2555–2556, 2560–2562
meroplankton, 1863–1869
microbial attack on, 2514
morphology of, 2505–2510
nitrogen cycle and, 2181
nitrogen fixation and, 1191, 2216
nucleus of, 2510
nutrients and, 2503, 2512–2514, 2559–2560, 2562–2563
osmosregulation and, 2511
ozone hole and, 2564–2565
periphyton vs., 2357–2367
phosphorus cycling and, 2450
photoautotrophs as, 2555
photosynthesis and, 2512
phycosphere of, 1056–1057
phylogenetic relationships in, 2503–2504
polar marine, 2554–2565
primary production of, 2516, 2559–2563, 2566–2575
Prochlorococcus, 2576–2593
products from, 2516
pycnocline and, 2515
reproduction in, 2510
salinity of water and, 2502, 2511, 2563
seasonal succession in, 2515
sinking control, 2510–2511
soil biosphere and as, 205
storage products of, 2510
swimming in, 2511
systematics of, 2504
taxonomy of, 2556
temperature and, 2502, 2511, 2555–2556, 2563, 2564
toxins in, 2514
ultraviolet light and, 2560–2562
viruses vs., 3307–3308
Planktothrix, 972, 984–995
Planococcus, 1501–1512
Plant-assisted microbial bioremediation, 1424–1425
Plant growth (See also Mycorrhizae; Nitrogen fixation; Rhizosphere), 2713–2728
biocontrol and, 450–465
biotechnology and, 351–352
cold-adapted microorganisms and, 881
crop productivity and, 2722–2723
deleterious rhizobacteria (DRB), 2717, 2722
disease resistance and, 2722–2723
flooded soils and, 1328
genetically modified microorganisms (GMMs) and, 1434–1437
inoculation with PGPR and, 346, 350
mycorrhizae and (See Mycorrhizae)
nitrogen fixation and (See Nitrogen fixation)
phytostimulators for, 343–354
plant growth promoting rhizobacteria (PGPB), 2717, 2722
plant growth promoting rhizobacteria (PGPR), 343, 345–346, 349, 454–455, 2722
plant growth regulators (PGRs) in, 344–345
plant–microbe interactions in marine environment, 2539–2554
rhizosphere, 2713–2728
root adsorption and colonization of phytostimulators in, 348
soil microorganisms and, 663
submerged plants and, 2549–2552
sustainable agriculture and, 3121
wetlands and, 3405
Plant growth promoting rhizobacteria (PGPB), 2717, 2722
Plant growth promoting rhizobacteria (PGPR), 343, 345–346, 349, 454–455, 2722
commercial products for, 351–352
inoculation of soil with, 346, 350
Plant growth regulators (PGRs), 344–345
Plant Helper, 881
Plant–microbe interactions, marine/ocean environment, 2539–2554
Plant mucilage in rhizosphere, 2715
Plantae, 2465
Plasmid borne degradation genes, biodegradation, 2387
Plasmid incidence testing, subsurface microorganisms, 2036–2037
Plasmidophora, 2913
Plasmids in soil microorganisms, 1201–1202, 2884
Plasmodiophoromycota, 2912
Plasmodium, 1126, 3399
Plasmopara, 766
Plasticity of microorganism metabolism, 1002
Plastics, bioplastics, 682–692
Platyamoeba, 2595–2604
Platyhelminthes, in water treatment systems, 1718–1719
Plectonema, 972, 1107–1112, 2193–2201, 2282
Plectrovirus, 366–374
Pleistophora, 2066–2083
Pleuorotus, 1384
Pleuorsigma, 2839
Pleurastrum, 3056–3065
Pleurocapsa, 522, 672
Pleurochloris, 838–843
Pleurochrysis, 2508
Pleurococcetum, 3056–3065
Pleurodynia, enteroviruses, 1152
Pleurotus, 454, 2915
Pleustons, 2133
Plexura, 1851
Plug flow reactor (PFR), 44, 75–76
Plug flow reactor with dispersion (PFDR), 44, 75–76
Plugging, in petroleum reservoirs, 2422
Plume height vs. dispersion, in bioaerosols, 2110
Podophyra, 2606
Podosphaera, 454, 2606
Podovirus, 365–374

Pognophora, 1117, 1606
Poindexter, Jeanne, 2269
Point of entry (POE) water treatment devices, 1563–1575
Point of use water treatment devices, 1550–1551, 1563–1575
Polar interactions, conditioning films, 937
Polar lipids, 1817–1824
Polaribacter, 2640–2646
Polaromonas, 2640–2646
Poliovirus, 331, 363, 387, 388, 389, 1146–1156, 1170–1175, 2743, 2745
  bioaerosols and, 3327
  biodegradation and, 3289–3300
  in soil, 3271–3276
  in source water, 2969–2978
  in spas and hot tubs, 2979, 2980–2984
  subsurface microorganisms and, 2025
  water purifiers vs., 1573
  in wetlands for wastewater treatment, 3397–3398
Pollen, bioaerosols, 404–416
Polyacrylamide gel electrophoresis (PAGE), 308, 2765, 2769
Polyangium, desert environment, 1578
Polychaetes, hydrothermal vents, 1619–1620
Polychlorinated aromatic compound biodegradation, 1421
Polychlorinated biphenyls (PCBs), 507–516, 703–713, 726–735, 916–917, 925, 1238–52, 1421, 1447, 1763, 2289–2300, 2933, 3402, 3405
Polychlorinated dibenzodioxin (PCDD), 919–920, 1238–1252
Polychlorinated dibenzofurans (BCDF), 919–920, 919
Polyclonal antibodies, rhizosphere and soil microbes, 351
Polycyclic aromatic hydrocarbons (PAHs), 694, 713–735, 916–919, 2404–2416, 2404, 3211, 3402, 3405, 3412
Polyhexamethylen biguanide (PHMB) (See also Chlorhexidine), 604–605
Polyhydroxy, microbial protection from, 432
Polyhydroxyalkanoates (PHA), 21–26, 38, 78–80, 346–347, 682–692, 3005
Polyhydroxybutyrate (PHB), 21–26, 38, 64–67, 346–347, 436–437, 683–692, 1818–1824, 2270
Polykrikos, 2507
Polymerase chain reaction (PCR), 1853, 2492–2494, 2730, 2733–2739
  adenoviruses and, 97, 98
  Aeromonas assay using, 1096
  astroviruses and, 334
  bacterioplankton and, 2523
  bioaerosol samples and, 402
  biochips, biochip testing and, 443
  biofilms and, 558–559
  detection of, 1132–1134
  FISH vs., 1338–1339
  fungi and, 1370, 1389
  genetically engineered microorganisms (GEMs) and monitoring, 1284–1285
  genetically modified microorganisms (GMMs) and, 1433–1434
  genomic studies and, 1443
  granular activated carbon (GAC) filters and, 1492–1493
  methanotrophic bacteria and, 1931–1932
  microarray study of vs., 1974
  Norwalk-like viruses (NLVs) and, 2221–2235
  soil genetic ecology, 2919–2920
  soil microbe quantification using, 727
  viruses and, 3291–3299
Polymerase, 270–271, 1852, 3207–3210
Polymeric biosurfactants, 760–762
Polymers
  activated sludge foaming and, 6–7
  anaerobic granulation and, 241
  bioplastics and, 682–692
  immobilization of and, 109–110
Polymorphism
  bacterial counts using, 28–29
  capillary electrophoresis in, 811–821
in minerals, 633
Polyols, 518
Polyphenols, 195, 682–692
Polyphosphate accumulating bacteria (PAB), 64–67, 78–80
Polyphosphate accumulating organisms (PAO), 38
Polyphosphates, 3005
  activated sludge and, 73
  bioplastics and, 682–692
Polysaccharides (See also Extracellular polymeric/polysaccharide substances), 109, 458, 1210, 1852
  activated sludge and, 58, 741–743
  algae biotechnology and, 195
  Archaea and, 249
  biofilms and, 85–87, 114
  biomineralization and, 671
  bioplastics and, 682–692
  conditioning films and, 937–938
  floc formation and, 57
  hyperthermophiles and, 1641–1642
  marine biotechnology and, 1853
  mycorrhizae and, 2129
  in surface waters, 928, 928
Polysulfates, bioplastics, 682–692
Polysulfide, bioleaching, 637
Polytypism, in minerals, 633
Polyunsaturated fatty acids (PUFA), 1852–1853
  cold-adapted and psychrophilic microorganisms and, 880–881, 2639, 2644–2645, 3215
Polyvinylchloride (PVC), biofilms, 88
Polyvinylidene dichloride (PVDF), 621
Ponds (See Aquatic ecosystems; Surface waters)
Pontederia, 2548
Popillia, 1712
Populus, mycorrhizae, 2124–2132, 2911
Pore proteins, freeze drying and trehalose introduction, 1357
Pore size, in filtration, 2708, 2712
Pore water sampling, 3073
Poria, 2649
Porifera, 1117
Porins, 2883
Porphyra, 1857
Porphyridium, 189–204, 1853
Porphyrins in aerobic respiration, 153
Porphyromonas, 1213
Porthetria, 1710
Posidonia, 2823–2833
Posttreatment of water, algal blooms vs., 209
Potamogeton, 2550
Potassium (See also Nutrients and energy sources), 1707, 1879–1893, 1902–1913
Potato, late blight, 414
POTWs, biofiltration vs., 598
Powdered activated carbon (PAC), 44
Prasinococcus, 1107–1112
Prasinophyta, 2468, 2504–2518
Prasiola, 1025
PRD1 virus model, 2101
Precipitation, in biofilms, 2962
Precipitation (rain), neuston microbiology, 2139
Precipitation, of minerals/metals, 1894–1899
Predators

Predators (*continued*)
biocontrols and for, 459
fungi as, 2914–2915
protozoa as, 2620–2621
Predicted environment concentration (PEC)
Predicted no effect concentration (PNEC), 3163
Prefoldin, stress response, 3030
Presegmentation image processing, 1677–1681
Pressure (See also High hydrostatic pressure)
deep sea, 1626
petroleum reservoirs and, 2427
soil microorganisms and, 2061
stress response and, 3034
Pressure containers for deep sea sampling, 2814–2815
Pressure-tolerant enzymes, 269
Pretreatment of water, 2012–2015
Primary biodegradation, 2394–2395
Primary production, 2565, 2566–2575
Primary vs. secondary symbionts, 1114–1115
Primulin, 2596
PRINTS, 1450
Printzia, 3056–3065
Pristane, 928, 2403–2416
Pristionchus, 1721
Proacellus, 1722, 1724
Procatechuic acid, biodegradation, 2295–2300
Prochlorococcus (See also Cyanobacteria; Plankton and phytoplankton), 960, 2461, 2576–2593
bacterioplankton and, 2526
endosymbiosis and, 1126
in marine/ocean environment, 1701, 1704
photosynthetic pigments in, 2466
phototropism in, 2471
Prochloron (See also Cyanobacteria), 960, 964, 974, 975, 2471
Prochlorophytes, 952–982, 2471
Prochlorothrix (See also Cyanobacteria), 960, 2471
Productivity, benthic associated, 2573
Productivity, primary production in marine/ocean environment, 2566–2575
Prokaryotes
bioluminescence in, 1831
hydrothermal vents and, 1617–1628
oligotrophic bacteria and, 2267–2277
Proline, 518, 2778–2789
Propane, 435, 2427, 2930
Propidium iodide (PI), 1068
Propionate, 21–26, 236, 742–748
Propionibacter, 40, 2193–2201
Propionic acid, activated sludge, 741–748
Propionic acid phenothiazine (PPT), 1182
Propionigenium, 742–748
Propylene glycol biodegradation, 2930
Prorocecentrum, 2507, 2686–2693
PROSITE, 1450
Prosopis, 2785
Prosthecate bacterium, 2269, 2271
Prosthecochloris, 2474, 2479–2489
Prostheocbacter, 90
Protaspis, 2841
Proteaosome, stress response, 3031–3032, 3052
Proteases, 220–223, 269–270, 1177–1189, 1211–1223, 3021, 3170, 3207–3210
Protein engineering, 3208–3209
Proteinase, 2273, 2903–2910
Proteinchip array for proteomes and proteins, 310
Proteins, 109, 1210, 2489
activated sludge and, 741–748
algae biotechnology and, 193
Archaea and, 248, 263
biofilms and, 85–86, 114
biomass estimation and, 2654
biomineralization and, 671
cold-adapted microorganisms and, 874, 883, 872–885, 888–893
conditioning films and, 937–938
extremeophiles and, 1232–1237
floc formation and, 57, 58
heat-shock proteins and, 3049
microbial protection from, 432
oligotrophic bacteria and, 2270
oxygen sensing, in aerobic respiration regulation, 158
protein engineering and, 3208–3209
proteomes and proteins and, assessing presence of, 305–312
stress proteins and, 3028, 3030–3031, 3036–3039
in surface waters, 928, 928
viable but not culturable (VBNC) phenomenon and, 3253
Proteobacteria, 1204, 2036, 2545, 2549, 2552, 3143–3147
activated sludge and, 9–14, 34, 35, 38, 40, 61, 63, 70
anaerobic granulation and, 233–245
bacterial counts using, 31
bacterioplankton and, 2524–2526
biodegradation and, 510, 511, 512
biofilms and, 570, 571, 1218
endosymbiosis and, 1125
filamentous forms of, in activated sludge, 1299–1306
flooded soils and, 1319, 1320, 1322, 1325, 1326, 1328
fluorescent probes and, 1340
genomic studies and, 1442
halophiles and, 1506–1512, 1515–1529
hydrothermal vents and, 1606, 1609–1611, 1619, 1620
neuston microbiology and, 2139
nitrification and, 2167
nitrogen fixation and, 2214–2221
photosynthetic pigments in, 2470–2471
psychrophilic bacteria and, 2641
soil microorganism and diversity in, 533, 538
subsurface microbial communities and, 2035, 3065–3071
Proteolysis, stress response, 3031–3032, 3052
Proteomes, 305–312
aquatic environment and, 306–307
assessing presence of, 305–312
capillary electrophoresis for, 308
cluster analysis for, 310–311
electrospray ionization mass spectrometry (ESI MS) for, 309
enzyme electrophoresis for, 309
enzyme linked immunosorbent assay (ELISA) for, 309
gel electrophoresis for, 308
GeneChip system for, 310
immunofluorescence for, 309
Internet resources for assessment technology in, 311
mass spectrometry for, 309–310
matrix assisted laser desorption ionization mass spectrometry (MALDI MS) for, 309
multilocus enzyme electrophoresis (MLEE) for, 309
neural networks analysis of, 310–311
polyacrylamide gel electrophoresis (PAGE) for, 308
Proteinchip array for, 310
radioisotope analysis for, 308
Proteorhodopsin, 2471

Proteus
biodeterioration of mineral materials and, 518
cold-adapted microorganisms in, 872–885
desert environment and, 1578
microgravity and, 3000
nosocomial infections and, 2236–2250
in drinking water, 946
Protists, 2874, 3305–3306
Protochatechuate biodegradation, 1423–1429
Protococcus, 3056–65
Proton motive force (PMF) in aerobic respiration, 150
Protoperidinium, 2507
Prototheca, 842–843, 3327
Protozoa, 1857, 2594–2604
abundance of, 2615–2620
acantharian, 2617
actinopoda in, 2618
activated sludge and, 24–26, 72,75, 2332, 2605–2612
amoebas and, 2594, 2605, 2616, 2617
anoxic environments and, 2596
aquatic sediments and, 1252–1256
aquifers containing, 2595–2596, 2599–2602
artificial wetlands and, 2333
bacteriovorous ciliates, 2611
biodegradation and, 2594
bioindicator role of, 2630–2631
biomass of, 2628–2629
bodonids in, 2619
carbon and, 2622–2623
chlorine vs., 2333–2334
choanoflagellates in, 2617–2619
chrysomonads in, 2619
ciliates in, 2594, 2605–2607, 2610–2611, 2617, 2619–2620, 2626–2632
Ciliophora in, 2594
climatic change and, 2630–2631
control of, 2629
counts of, 2596–2597
culturing of, 2594
desert environment and, 1579
diamidinophenylindole (DAPI) counts and, 2596
dinoflagellate in, 2617, 2618
disinfection and, 1066–73, 2333–2334
dissolved organic carbon (DOC) and, 2596
distribution of, 2615–2620
ecological role of, 2620–2623
enteroviruses vs., 1171–1172
filter backwash water containing, 2262–2267
filtering vs., 2332, 2333
flagellates in, 2594, 2605, 2611, 2613, 2617–2619
food processing and, 3276–3287
food web and, 2620–2622, 2630
foraminifera in, 2616–2617
form and function of, 2613–2615
free-living, 2605–2606, 2613
grazing and, 2599–2601
growth rates of, 2615
heliozoan, 2617
high hydrostatic pressure (HHP) vs., 1561
high-rate algae ponds vs., 2333
indicators of sludge treatment performance in, 2608–2609
infiltration percolation vs., 2333
lagoons vs., 2333
Legionella, as host for, 1788–1806
life cycle of, 2615
lobose amoeba in, 2616, 2617
marine/ocean environment and, 2613–2625
measurement of, using aerobic endospores, 141–149
as microbial tracers in groundwater, 3194–3202
microbial insecticides using, 1711
microbial loop and, 2630
mineralization and, 2622–2623
mixotrophy and, 2621–2622, 2629–2630
models of, in food web, 2623, 2624, 2623
moisture and, 2595
municipal solid waste landfills and, 1765
neuston microbiology and, 2140
nutrients and, 2595, 2596, 2613–2615, 2622–2623, 2629
Opercularia in, 2611
oxygen and, 2595
ozonation vs., 2334
parasitic, 2327–2337, 2607
pathogenic, 2607
pH levels and, 2595, 2596
predatory role of, 2620–2621
prey role as, 2622
in rainwater roof catchment systems, 2681–2682
reproduction of, 2615
rhizosphere and soil microbes in, 348
role of, in subsurface, 2599–2601
salt production and, 2805–2809
sampling and enumeration of, 2596–2598, 2626–2627, 2813
Sarcomastigophora in, 2594
scutiocociliate, 2617
seasonal variations in, 2627–2628
sedimentation to remove, 2331–2332
sludge biotic index (SBI) and, 2609–2611
soil dwelling, 2594
soil salinity and, 2775
in spas and hot tubs, 2979
stabilization ponds for removal of, 2333
streams and, 3017, 3019, 3020–3021
subsurface dwelling, 2594
symbiosis and, 2621–2622
taxonomy of, 2594–2598, 2615–2620
tertiary wastewater treatment vs., 2333–2335
testate amoeba and, 2610
tintinnid ciliate, 2617
transport of, in subsurface, 2598–2599
trophic state vs. biomass in, 2628–2629
ultraviolet light vs., 2334
in wastewater stabilization ponds (WSBs), 3334
in wastewater/sewage, 3173
water purifiers vs., 1572–1573, 1572
water treatment systems vs., 1718–1733, 2601–2602
in wetlands for wastewater treatment, 3398–3399
Provannidae, 1606
Providencia, 1890, 1985
Prstachydrine, soil salinity, 2778–2789
Prymenesium, 2508
Prymnesiophyceae, 2467, 2685–2693
Prymnesiophytes, 2504–2518
Pseudoalteromonas, 1057
biofilms and, 615
fluorescent studies of, 1835
hydrothermal vents and, 1610
Pseudoanabaena, 210
Pseudocercosporella, 405
Pseudococcomyxa, 1107–1112
Pseudohalonectria, 3359
Pseudokirchneriella, 3221–30
Pseudomembranous colitis, Clostridium, 862–871
Pseudomonas, 313, 314, 339, 386, 499, 1061, 1132, 1196, 1200, 1201, 1203, 1501–1512, 1672,

Pseudomonas, (*continued*)
2549, 2632–2639, 2694–2695, 2722, 2723, 2725, 2942, 3111–3116, 3160, 3314–3319
activated sludge and, 35–38, 3009
adhesion in biofilms and, 118, 121, 123
aggregates and consortia in, 166
alkaliphiles and, 226
assimilable organic carbon (AOC) and, 316
bioaerosols and, 3325
bioaugmentation and bioremediation using, 436, 438–439
biocontrol use of, 2703, 2705
biocontrols and, 452–455, 457, 458, 460, 462, 2703, 2705
biodegradation and, 511–512, 693, 714–715, 1042–1047, 1421–1429, 1447, 1871, 1872, 1937–1938, 2289–2300, 2386–2393, 2394, 2396, 2408–2410, 2650, 2933
biofilms and, 82, 85, 89, 90, 561, 562, 566, 570, 572, 577, 579, 580, 581, 582, 614, 621, 1209, 1213, 1215, 1219–1220, 2341–2356, 2963
bioleaching and, 635
bioluminescence in, 658–662, 1831
biomineralization and, 674, 675
bioplastics and, 683–692
biosurfactants/bioemulsions and, 752, 763, 766
biotechnology and, 3204
bottled water and, 796, 797, 799–801, 1549–1550
cold-adapted microorganisms in, 872–885, 3215
cold-shock response and, 886–895, 892
desert environment and, 1578, 1580, 1583
desulfurization and, 1048–1049
explosives biodegradation and, 1989
extracellular polymeric substances (EPS) and, 1224
fecal contamination and, 1269, 1271, 1273
floc formation and, 2006
fluorescent studies of, 1835
gene transfer and, 1413–1415
genetically altered, in biotechnology, 1447
genetically engineered microorganisms (GEMs) and, 1279, 1421–1429
genetically modified microorganisms (GMMs) and, 1430–1440
granular activated carbon (GAC) filters and, 1489–1496, 1569–1572
green fluorescent protein (GFP) studies for, 1498–1499
heterotrophic bacteria and, 1541–52, 1544, 1545, 1548, 1549–151550
high hydrostatic pressure (HHP) vs., 1555–1563
hydrothermal vents and, 1610
identification of isolates in, 1964
immobilization of, 110
infectious airborne bacteria and, 1689–1697
metal biodegradation and, 1882, 1884, 1885, 1886, 1889, 1890, 1894
microarray study of, 1977
as microbial tracer in groundwater, 3196–3197, 3200
microbial insecticides using, 1710
microgravity and, 3002
municipal solid waste landfills and, 1766
nitrification and, 2149
nitrogen fixation and, 2193–2201
nosocomial infections and, 2236–2250
in pulp and paper industry, 2649, 2650
radioactive waste degradation and, 2667–2674
resistance in, 607–608, 625, 799
resistant bacterial strains in, stress response, 349
rhizosphere and, 345–354, 2717
soil microorganisms and, 2898, 2926
soil salinity and, 2775, 2779–2789
in source water, 2968, 2969–2978
in spas and hot tubs, 2980–84
spores and spore dispersion in, 421
stress response and, 3042
subaerial communities and, 3057–65
subsurface microbial communities and, 2023, 2035, 3065–3071
toxic solvents and, 3149, 3150, 3151, 3152, 3153
transfer of rDNA from, to other microorganisms, 1426–1427
in wastewater stabilization ponds (WSBs), 3334
in wastewater/sewage, 3172
in drinking water, 944, 945, 946
in wetlands for wastewater treatment, 3393–3397
Pseudomurein, 248, 2886
Pseudonitzchia, 2686–2693
Pseudopleurochloris, 2467
Pseudotrebouxia, 1025
Pseudotsuga, 2125–2126, 2127
Psittacosis, infectious airborne bacteria, 1689–1697
Psychrobacter, 2640–2646
biofilms and, 561
biotechnology and, 3204
cold-adapted microorganisms in, 872–885
fluorescent studies of, 1835
in permafrost, 2369
Psychroflexus, 2640–2646
Psychromonas, 2640–2646
Psychrophiles and psychrotrophs (See also Cold-adapted microorganisms), 871–885, 2639–2646, 3203–3219
Antarctic soils and, 1027
Archaea and, 246–259, 262
biotechnology and, 3203–3219
culturing of, 2641–2642
dimethyldisulfide (DMDS) and, 2645
dimethyloxazoline (DMOX) and, 2645
fatty acid methyl esters (FAME) and, 2644–2645
fatty acids and, 2644–2645
hydrothermal vents and, 1617–1628
polyunsaturated fatty acids (PUFA) and, 2644–2645
sampling of, 2641–2642
sea ice microorganisms, 2833–2844
snow and ice environments, 2872–2880
soil microorganisms and, 2889
temperature and, 2639, 2641, 2642–2645
Psychroserpens, 2640–2646
Pterosperma, 2508
Public health studies, using microbial tracer in groundwater, 3199–3200
Puccinia, 411–412, 454
Pullulanases, alkaliphiles, 225–226
Pullularia, 422
Pulmonary alveolar proteinosis, Mycobacterium avium complex (MAC), 2113–2120
Pulp and paper industry, 2646–2651

biodegradation and, 2646–2651, 2646
biofilms and, 580, 2650
biological bleaching in, 2647–2648
biological pulping process in, 2647
coliform bacteria and, 901–902
enzymes and, 1183–1185
fungal wood degradation in, 2646–2647
lipase and, 2649
pitch degradation in, 2648–2650
staining of wood in, 2648–2650
toxic effluent from, 2650
Pulsed bioremediation, 695
Pulsed field capillary electrophoresis, 815–816
Pulsed field gel electrophoresis (PFGE), 812, 1258, 1260–1261
Purifiers, water, 1567, 1572–1573
Purines in activated sludge, 741–748
Purple nonsulfur bacteria, 2470–2480
phototropism in, 2471–2472, 2480–2483
soil microorganisms and, 2992–2993
Purple sulfur bacteria, 2455, 2458, 2459, 2463, 2465, 3097–3104
Pycnocline, 162, 2515
Pycnoporus, 1387–1391
Pyochelin, 1882
Pyoluteorin (Plt), 457
Pyoverdin, 1882
Pyramimonas, 2508, 2835–2844
Pyrene bioremediation, 696–712
Pyrenophora, 410
Pyrite, 633, 638, 1049
Pyrmidines in activated sludge, 741–748
Pyrobaculum, 298, 1233, 1234, 1512–1529, 1629–1646, 1886, 3146
Pyrobotrys, 3331
Pyrococcus, 1233, 1235, 1512–1529, 1623–1628, 1630–1646, 1706, 1853, 3146
genomic studies and, 1446
halophiles and, 1525
hydrothermal vents and, 1611
Pyrodictium, 533, 1233, 1234, 1235, 1625–1628, 1630–1646, 3144–3147
Archaea and, 298
halophiles and, 1525
hydrothermal vents and, 1611
stress response and, 3026
Pyrodinium, 2507, 2686–2693
Pyrolobus, 287, 1233, 1611, 1625–1628, 1630–1646, 3128–3140, 3141–3147
Pyroloid mycorrhizae, 2126
Pyrophaeophorbide, 2456
Pyrophaeophytin, 2456
Pyrophosphatase, in soil, 2903–2910
Pyrrhophyta, 205, 2466, 2556
Pyrroles, 153, 1852
Pyrrolnitrin (Prn), 457
Pyrrolo quinolone qunione (PQQ), 1927–1936
Pyrsonympha, 1124
Pyruvate, 2172
Pythium, 1395–1400, 3358
biocontrols and, 451, 453, 457, 458, 460
biosurfactants/bioemulsions and, 766
soil microorganisms and, 2912
Pyxidicula, 2605

Q

Q fever, infectious airborne bacteria, 1689–1697
Q loop in aerobic respiration, 153
qCO2, quality of soils, 2954–2956
Quality control of drinking water, 2652
heterotrophic bacteria and, as indicators of, 1546
in rainwater roof catchment systems, 2683
in source water, 2972–2974
Quality of soil, 2944–2957
adenosine triphosphate (ATP) and, 2948
aggrading systems and, 2951
bioindicator interpretation of, 2950–2951, 2953–2954
biomass and, 2948, 3158–3159
chloroform fumigation incubation method (CFIM) and, 2948
conservation reserve programs and, 2951–2952
degrading systems and, 2952–2954
denitrification and, 3160
disturbance of soils and, 3122
enzyme activity and, 2949, 3161
long-term changes in and, monitoring, 3165
measurement of, 2947–2948
metabolism and, 2951–2956
microbial growth rates and, 3161
microbial processes and, 2949
minimum data sets (MDS) for, 3165
Mount Saint Helens and, 2951
mycorrhizae and, 3121
near infrared reflectance (NIR) in, 3165
nitrification and, 2949, 3159–3161
nitrogen fixation and, 3120, 3160
nitrogen mineralization and, 3159
nutrient cycling in, 2946–2947, 3120
organic matter and, 3120
pesticide biodegradation in, 3121–3122
phosphatase activity and, 3160–3161
plant growth and, 3121
qCO2 and, 2954–2956
respiration and, 2948–2949, 3159
rotation of crops and, 3122
sampling of, 2949–2950
soil organic matter (SOM) and, 2945–2957
soil structure and, 3122
sustainable agriculture, 3116–3126
toxicity testing, 3155–3168
Quantification of microbial biomass, 2652–2660
Quantitative structure activity relationships (QSARs), 1249–1250
Quaternary ammonium compounds, soil salinity, 2778–2789
Quiescent cells, viable but not culturable (VBNC) phenomenon, 3252
Quinones and Q pool, 929, 1818–1824, 2489
aerobic respiration and, 151–153, 156, 157
Archaea and, 256
metal biodegradation and, 1883
Quorum sensing, 549, 1220, 3251

R

Radiation and effect on cells, 360–361, 2985–2994
Radioactive and nuclear wastes, 250–260, 2250, 1879–1893, 1902–1903, 2661–2674
algae biotechnology and, 199–200
biodegradation and, 250–260, 1446, 3045
vadose zone microbiology and, 3243–3244
Yucca Mountain repository for, 250–260
Radioallergosorbent (RAST) assay, 1361
Radioisotope analysis for proteomes and proteins, 308
Radiolaria, 2613
Radon, 1377
Raffinose, microbial protection from, 432

Rags (cleaning material), bacteria in home/residential environment, 340
Rainwater roof catchment systems, 2674–2685
Ralstonia, 1200
  activated sludge and, 3006
  biodegradation and, 1875, 2295–2300, 2388
  biofilms and, 567
  bioplastics and, 684–692
  gene transfer and, 1416
  metal biodegradation and, 1882, 1888, 1890
  subsurface microorganisms and, 2035
Raman confocal microspectroscopy, floc formation, 2008
Raman spectroscopic analysis, conditioning films, 935
Random amplified polymorphic DNA (RAPD), 812, 816
Raphidophtya, 2467
Raphidophytes, 2504–2518
Rayleigh vs. open system isotope behavior, subsurface microbial communities, 1457–1461
Readily biodegradable substrate (RB COD), 19–20
Rearrangement, genetic, 1200
Reclamation, desert environment, plant-microbe symbiosis, 1583
Recombinant DNA (See also Biotechnology; enzymes), 1176, 2693–2694
Recombinant DNA Advisory Committee (RAC), 2694–2707
Recreational waters, coliform bacteria, 900
Recycling, enzymes, paper, 1184–1185
Red algae (See also Rhodophyta), 837–843, 2468, 2505–2518
Red Blood Cell Lysis assay, 725
Red fluorescent protein (RFP), 1835–1836
Red snow, 2873
Red tide (See Harmful algal blooms and red tides)
Redfield ratios, primary production (marine), 2566–2575
Redox
  biofilms and, 2960–2963
  biomineralization and, 673–675
  metals, microbial, 1882–1886, 1896–1897, 1902–1913
  soil microorganisms and, 2062
Redoxin, 2293
Reductase, 2297–2300, 3414
Reduction, in biofilms, 2962
Reductive dechlorination, 513–514
Reductive dechlorination and dehalorespiration, 509–510
Reedbeds, wastewater treatment, 2693, 3389–3401
Refractory dissolved organic carbon (RDOC), 487
Regression analysis, 1007–1008
Regression decay, 2108
Regrowth processes, bacterial, 499–504
  assimilable organic carbon (AOC) and, 312–327
  biodegradable dissolved organic carbon (BDOC) and, 499–504
  growth measurement and calibration curves in, 318–319
  Monod equation for, 314
  potential for, 314–315
Regulation of stress response, 3049–3051
Regulation of commercial uses of microorganisms, 2693–2707
Regulation of water systems, in source water, 2974–2975
Regulator functions, in evolution, 1197
Relative humidity, spores and spore dispersion vs., 428–430
Remediation (See Bioremediation)
Remobilization, biofilms, 2965
Remote assay systems, 819
Renibacterium, 1857
Renilla, 1830–1831
Rennet, 1187
Reovirus, 2980–2984, 3398
Replication and repair of genes, 1195–1196
Replication and sampling intensity, in image analysis, 1685
Replicative transposons, 1201
Reporter genes, 727–729
  cold-adapted microorganisms and, 3215
  fluorescent probes and for, 1783–1784
  genetically modified microorganisms (GMMs) and, 1430–1431
  rhizosphere and soil microbes in, 349–351
Reproduction
  bacterioplankton and, 2519
  plankton and phytoplankton, 2510
  protozoa and, 2615
Reproductive parasites, 1120–1123
Residential environment, bacterial contaminants, 338–343, 577–587
Residential environment, fungi, 1372–1383
Resiliency of ecosystems, mycorrhizae, 2127–2128
Resistant bacteria, antibiotic, 607–608, 625
  biochips, biochip testing testing, 448–449
  bottled water and, 799
  Pseudomonads, 799
  bioaerosols and, 432
  fecal contamination and, 1258–1259
  heterotrophic bacteria and, 1545
  multiple antibiotic resistance (MAR), 1258–1259
  nosocomial infections (NI) and, 2235–2250
  in drinking water, 944
Resistance of hosts to viruses, 3308
Resolution, image analysis, 1785
Respiration
  aerobic, 149–160
  biofilms and, 82–83
  kinetics of growth and, 1753
  rates of, in soil, toxicity testing and, 3159
  soil microorganisms and, 2948–2949
  in wastewater/sewage, 3173
  wastewater/sewage treatment and, 3345–3346
Respiratory diseases, 338
  airborne toxigenic molds and, 185–186
  bioaerosols released from wastewater and, 3320–3330
  bioaerosols and, 404–416, 422
  enteroviruses and, 1151
  fungal allergens and, 1359–1366
  Legionella, 1788–1806
  Mycobacterium avium complex (MAC), 2112–2120
Respiratory syncytial virus (RSV), 2743
Restoration of image, 1785
Restriction endonuclease analysis (REA), 1096
Restriction fragment length polymorphism (RFLP), 443, 812, 815, 1003
  biofilms and, 563
  fecal contamination and, 1258
  hydrothermal vents and, 1609
  rotaviruses and, 2765, 2771
Retention of microbes, biofilms, 111
Retinal, 2470–2480
Retrotransconjuant, 1413
Retrotransfer, 1201–1202, 1413, 1427
Return activated sludge (RAS), 75, 79

Reverse osmosis (RO), home water treatment systems using, 1566–1567
Reverse transcriptase polymerase chain reaction (RT-PCR), 1162–1164, 2500
  astroviruses and, 333–335
  methanotrophic bacteria and, 1931–1932
  rotaviruses and, 2765, 2770–2771
  viruses and, 3291–2199
Reynolds number, 114, 1416–1417
Rhabdochromatium, phototropism, 2477–2489
Rhabdosphaera, 2508
Rhamnogalacturonase, 1187
Rhamnolipids, 714–715, 752–753, 764–765
Rhapidophyceae, 2685–2693
Rhizobacterium, 1831
Rhizobiaceae, 2549
Rhizobium, 345–354, 1705, 2282, 2720, 2786–2787, 3120
  biocontrol use of, 2703, 2704, 2705
  bioremediation and, 733
  cold-shock response and, 886–895
  desert environment and, 1583
  endosymbiosis and, 1119–1120
  genetically engineered microorganisms (GEMs) and, 1279
  green fluorescent protein (GFP) studies for, 1499
  legume symbiosis with, 2786–2787
  metal biodegradation and, 1894
  nitrogen fixation and, 2188–2211, 2196, 2201–2211, 2212–2221
  resistant bacterial strains in, stress response, 349
  rhizosphere and soil microbes in, 351
  soil microorganisms and, 2929
  soil salinity and, 2775, 2779–2789
  subsurface microbial communities and, 3067–3071
Rhizoclonium, 215
Rhizoctonia, 451, 462, 766, 1983, 2914
Rhizofiltration, 709
Rhizoplane, 2714
Rhizopoda, 2605
Rhizopogon, 2124–2132
Rhizopus, 1648, 1650, 1659–1660, 3057–3065
Rhizoremediation, 1424–1425
Rhizosolenia, 975, 2506
Rhizosphere (See also Nitrogen fixation; Soil microorganisms), 731, 2713–2728
  actinorhizosphere in, 2714
  antibiotics in, 347–348, 351
  Archaea and, 300–301
  bacteria in, 2717–2719, 2880–2894
  bacterial phytostimulators in, 343–354
  biocontrol and, 450–465
  biodegradation and, 695, 1424–1429
  biodiversity of soil within, 528–544
  biotic and abiotic factors in, vs. PGPR, 349–350
  carbon dioxide use in, 2721–2722
  chelation in, 2717
  chemotaxis of bacteria in, 348–349
  commercial PGPR products for, 351–352
  crop productivity and, 2722–2723
  deleterious rhizobacteria (DRB), 2717
  diazotrophy and diazotrophic bacteria and, 2541–2547, 2550–2551
  disease resistance and, 2722–2723
  effect of, 2714–2716
  endo-, 2714
  endosymbiosis and, 1118–1120
  enzymes in, 2899–2910
  exudates in, 2714, 2716–2717
  flooded soils and, 1322–1323, 1324
  fungi in, 2910–2918
  genetically engineered microorganisms (GEMs) and, 1424–1429
  global warming and, 2721–2722
  immobilization in, 2719–2720
  inoculation with PGPR and, 346, 350
  lysates in, 2715
  marine/ocean environment and, 2540–2548
  microsensors and, 349
  mineralization in, 2719–2720
  motility of bacteria in, 348–349
  mucigel in, 2715
  mycorrhizae and, 1385, 2120–2132, 2714
  nitrogen fixation and, 344, 2188–2221, 2720, 2722
  nutrient cycling in, 2719
  oxygen in, 2724–2725
  pH levels and, 2723
  phosphorous solubilizers in, 346
  phytometallophores in, 2717
  phytoremediation and, 731–734
  phytosiderophores in, 2717
  plant assisted microbial bioremediation, 1424–1425
  plant growth promoting rhizobacteria (PGPB), 2717, 2722
  plant growth promoting rhizobacteria (PGPR), 343–346, 349, 454–455, 2722
  plant growth regulators (PGRs) in, 344–345
  plant mucilage in, 2715
  polyhydroxyalknoate (PHA) in, 346–347
  polyhydroxybutyrate (PHB) in, 346–347
  protozoa and, 348
  reporter genes and, 349–351
  research in, 2725–2726
  resistant bacterial strains in, stress response, 349
  rhizoplane in, 2714
  rhizoremediation, 1424–1425
  root adsorption and colonization of phytostimulators in, 348, 2718–2719
  root structures and, 2715–2716, 2718–2719
  rotation of crops and, 2907
  rRNA probes for rhizobacteria in, 351
  secretions in, 2715, 2716–2717
  siderophores in, 347
  soil microorganisms in, 2880–2894
  soil salinity and, 2775
  submerged plants and, 2550, 2822–2833
  sulfate-reducing bacteria (SRB) and, 2547–2548, 2551, 3091–3092
  temperature and, 2724
  tracking introduced phytostimulators, 350–351
  vadose zone microbiology and, 3236–3246
  water and moisture in, 2724–2725
  wetlands and, 3404–3405
Rhodamine stains, 1676
Rhodanese, in soil, 2903–2910
Rhodobacter, 3314–3319
  aerobic respiration and, 155, 157
  biomineralization and, 675
  metal biodegradation and, 1905
  nitrogen fixation and, 2212–2221
  phototropism in, 2478–2489
Rhodobium, 2478–2489

Rhodococcus, 1201, 1204, 2294–2300
activated sludge foaming and, 3–7
biodegradation and, 1045, 1996, 2392–2393, 2414
biosurfactants/bioemulsions and, 753, 756
desert environment and, 1583, 1584
desulfurization and, 1048–1049
explosives biodegradation and, 1987
filamentous forms of, in activated sludge, 1288–1306, 1312
infectious airborne bacteria and, 1694
molecular probes using, in activated sludge foam monitoring, 4–7
subsurface microbial communities and, 3067–3071
toxic solvents and, 3150, 3153
Rhodocyclus, 32, 40
Rhodoferax, 1300–1306, 2035, 2877
Rhodomicrobium, 675, 3247, 3251
Rhodomonas, 2508
Rhodopene, 2459
Rhodophyta, 837–843, 2357, 2453–2470, 2505–2518
Rhodopinal. in paleolimnology, 2307–2317
Rhodopseudomonas, 173, 2193–2201, 3111–3116
Rhodopsins, 2453–2480
Rhodospillum, 83
Rhodospira, 2473–2474, 2478–2489
Rhodospirillum (See also Rhodothalassium), 1517, 2455–2458, 2465
bioplastics and, 683–692
halophiles and, 1506–1512
nitrogen fixation and, 2193–2201
Rhodosporidium, 127–128
Rhodothalassium, 1517–1529, 2478–2489
Rhodothermus, 1853
Rhodotorula, 872–885, 1368
Rhodovibrio, 1517–1529, 2478–2489
Rhodovulum, 1517–1529, 1854, 2477–2489
Ribose, 2716
Ribosomal Database Project (RDP), 532
Ribosomal intergenic spacer analysis (RISA), 2738–2739
Ribosomal RNA (rRNA), 246–259, 443–450
Ribosomal RNA targeted oligonucleotide probes, 1339–1340
Ribosomes, 2270, 2884
Ribotyping (See also DNA/RNA analysis), 2728–2741
amplified rDNA restriction analysis (ARDRA) in, 2737–2738, 2920
biochips for, 443–450
capillary electrophoresis in, 811–821
clone library screening in, 2734
cloning in, 2732–2733
denaturing gradient gel electrophoresis (DGGE), 2732, 2735–2737, 2921
fecal contamination and, 1261–1263
fingerprinting techniques in, 2734–2735, 2739
forward sample array hybridization, 2731–2732
paramagnetic beads and, 818
polymerase chain reaction (PCR), 2730, 2733–2739
ribosomal intergenic spacer analysis (RISA), 2738–2739
shotgun cloning in, 2732–2733
single-strand conformational polymorphism (SSCP) in, 2737
temperature gradient gel electrophoresis (TGGE), 2735–2737
temporal temperature gradient electrophoresis (TTGE), 2735–2737
terminal restriction fragment length polymorphism (T-RFLP) in, 2737–2738, 2921
Ribulose monophosphate (RuMP) pathway, methanotrophic bacteria, 1927–1936
Rice fields (See also Flooded soils), 1316–1333, 2196, 2741
Richelia, 975, 2214–2221
Ricin, bioterrorism, 778
Rickettsia, 1122, 1123, 1125
Ridgea, 1619
Rifampin resistance, biochip testing, 448–449
Riftia, 1118, 1606–1617, 1619
Rimicaris, 1118, 1609–1610, 1619
Ripening period following backwashing, in filters, 2707
Risk assessment, 2741–2753
applications for, 2749–2750
characterization of risk in, 2748–2749
dose response assessment in, 2745–2747
exposure assessment in, 2747–2748
hazard identification in, 2742
human health outcomes in, 2742–2744
Monte Carlo analysis in, 2749
mortality and morbidity rates in, 2743–2744
multiple exposure and immunity in, 2747
outbreaks of disease and, 2744–2745
transmission methods in, 2744
virus exposure, 2741–2753
River snow, 570–571
Riverine biofilms, 569–572
Rivers (See Aquatic ecosystems; Surface waters)
Rivers Pollution Prevention Act of 1876, 74
RNA (See DNA/RNA analysis)
Robbins device, adhesion in biofilms, 118
Rock salts, 1510–1511
Rock sampling, 829–830
Rocks (See also Caves and mines; Subsurface microbial communities; Weathering and biodeterioration)
endolithic microorganisms in, 1100–1112
igneous, microbial communities in, 1661–1673
oil bearing, subsurface microbes and, 2418–2420
sampling of, 829–830, 3074
subsurface microbial communities and, 1076, 1453–1468, 1824, 3065–3071
weathering and, 3364–3389
Rods, 2882
Root colonization, by rhizobia, 2715–2719
Root zones (See Rhizosphere)
Rosculus, 2594–2604
Roseobacter, 2214–2221, 2522, 2524–2526, 2549
nitrogen fixation and, 2214–2221, 2214
Roseococcus, 2877
Roseospira, 1517–1529
Roseospirillum, 2475, 2478–2489
Rotating annular bioreactors (RAB), 570
Rotating biological contactor, 695
Rotation of crops, 2907, 3122
Rotavirus, 93, 95, 331, 360, 2743, 2745, 2753–2773
bioaerosols and, 3327
in food, 3277–3287
in soil, 3273–3276
in source water, 2969–2978

in spas and hot tubs, 2979, 2980–2984
streams and, 3017
in wastewater stabilization ponds (WSBs), 3334
Rotylenchulus, 456
Roughing filters, 2012–2013
Royal Demolition Explosive (RDX) bioremediation, 706–712, 916–917, 923–924
rRNA targeted probes, bacterial counts using, 29–34
Rubber, and bioplastics, 682–692
Rubisco, biofilms, 85–86
Rubrivivax, 1299–1306, 1996, 1997
Rubrobacter, 1578
Ruegeria, 2549
Ruminococcus, 742–748
Run-of-mine bioleaching, 649
Ruppia, 2550
Rural water supplies, heterotrophic bacteria, 1548
Russula, 2124–2132
Rusts, 411–412

S

S bacteriocytes, 1114
Saccharolytic enzymes, biofouling vs., 606
Saccharomyces
adhesion in biofilms and, 120–121
biosurfactants/bioemulsions and, 762
cold-adapted microorganisms in, 872–885
desiccation and, 1031–1032
enzyme activity and, 2902
freeze drying and, 1354–1355
genomic studies and, 1440
metal biodegradation and, 1886
microarray study of, 1973
as microbial tracer in groundwater, 3197
radiation and, 2987
soil microorganisms and, 2913
toxic solvents and, 3151
Safe Drinking Water Act (SDWA), 2974–2975
Salicylic acid biodegradation, 2295–2300
Salinicoccus, 1506–1512
Salinity (See also Halophiles; Hypersaline environments), 2565, 2774–2789
accumulation vs. nonaccumulation in, 2781
ATP Binding Cassette (ABC) transporters and, 2781
bacteria tolerant to, 2779
bacteriophages and, 389
bacterioplankton and, 2520
compatible solutes and osmoprotectants in, 2776–2781
efflux of compatible solutes in, 2783
enteroviruses and, 1170
gram-negative bacteria in, 2783–2786
gram-positive bacteria and, 2781–2783
nitrogen fixation vs., 2786–2787
osmolarity and, 2775–2776
osmoprotection in, 2783–2786
phases of osmotic adjustment to, 2780–2781
plankton and phytoplankton, 2502, 2511
polar phytoplankton and, 2563
Rhizobium–legume symbiosis in, 2786–2787
salt stress reactions in, 2777–2781
sea ice microorganisms and, 2839–2840
soil microorganisms and, 2774–2789, 3270
stress response and, 3034
symports and, 2781
uptake systems and, 2782–2783
viruses and, 3270
Salinivibrio, 1501–1512

Sodium diethylithiocarbamate, 605–606
Sodium dodecyl sulfate (SDS), 626
Sodium, 1707, 1902–1913
Sodium/hydrogen antiporters, alkaliphiles in, 138
Soft rot fungi, 1389
Soil adaptation, 2386
Soil contamination and bioremediation (See also Quality of soil; Soil microorganisms), 700–707, 722–737, 921–922, 2927–2929
bioavailability of contaminants vs., 725
biosurfactants/bioemulsions and, 764–765
concentration of contaminants in, 725
encapsulation of microbial cells for, 730
genetic engineering and, 729–730, 729

genetically engineered microorganisms (GEMs) in, 726, 729–730
halogenated compounds and, 702–705
hydrocarbon, 700–735
metabolism of contaminants in, 726
military chemicals in, 707
monitoring of, 727–729
most probable number (MPN) quantification in, 727
nucleic acid probes in, 728–729
oil spills and bioremediation of (See also Oil spills), 698–701
pesticides and herbicide, 706, 2395–2397
phytoremediation and, 731–734
polychlorinated biphenyl (PCBs) in, 726–735
polymerase chain reaction (PCR) quantification in, 727
quantification of degrading microorganisms in, 726–727
rate monitoring in, 730–731
reporter systems, reporter genes in, 727–729
rhamnolipids in, 764–765
solubility of contaminants vs., 725
sorption characteristics of contaminants vs., 725
toxicity in, 724–725
Soil genetic ecology, 2918–2923
Soil microorganisms, 2057–2065, 2713–2728, 2880–2894, 2944–2957
accelerated degradation and, 2386
acclimation in, 2386
accumulation of storage materials in, 346–347
acetogens in, 2892
acidophiles and, 2889
actinomycetes in, 2882, 2889, 2912
adaptation of, 2057
adenosine triphosphate (ATP) and, 2883–2884, 2889
adhesion in, 2926
aerobic processes and, 2888, 2930–2932
aggregate formation in, 2924–2925
Amplified ribosomal DNA restriction analysis (ARDRA), 536–537
anaerobic processes and, 2888, 2891–2893, 2932–2933
analysis of distribution of, 2896–2898
Antarctic, 1023–1029
antibiotics in, 347–348, 351
appendages to, 2885–2886
Archaea and, 293–305, 2880–2886
Ascomycota in, 2913–2914
assessment of, 665–667
atmospheric composition ad, 2061
Bacillus thuringiensis and (See Bacillus thuringiensis), 2058
Bacteria and, 664–665, 2880–2894, 2912
bacterial artificial chromosome (BAC) and, 539
bacterial phytostimulators in, 343–354
bacteriophages and, 381, 389–390
Basidiomycota in, 2914
bioaugmentation and bioremediation in, 434–442
biocontrol and, 450–465
biodegradation and bioremediation by, 349–350, 2923–2936
biodiversity in, 294–295, 528–544, 2925–2926
biological factors affecting, 1750–1752
biological soil crusts (BSCs) and, 1019–1023
biomass of, 294–295, 663–670, 2895, 2948
biosphere and, 294
biotic and abiotic factors vs. PGPR in, 349–350
capsules and, 2884
carbon and, 663, 666–670, 2059–2060, 2887
carbon dioxide and, 2057, 2061
carbon monoxide and, 294
carbonyl sulfide and, 294
catalytic properties of abiotic soil components and, 1750
cell envelope in, 2881–2884
cell retention on surfaces, 2926
cell structure and function in, 2880–2886
cell wall in, 2882
characteristics of, 2063
chemoautotrophs in, 2889, 2891–2892
chemotaxis of bacteria in, 348–349
chemotrophs in, 2887
chloroform fumigation incubation method (CFIM) and, 666–667, 2948
chytrids in, 2913
clays and, 2058–2059
cold desert environment and, 1023–1029
cold-adapted microorganisms in, 872–885, 2889
colonization in, 2926–2927
commercial PGPR products for, 351–352
community composition of, 294, 528, 664, 665, 1751–1752
contaminants vs., 2927–2929
culturing of, 666–667
cyanobacteria in, 2890–2891
cytoplasm in, 2884–2885
cytoplasmic membrane in, 2883–2884
decomposition in, 2911–2912
denitrifying bacteria in, 2891
density and distribution of, 2925–2926
desert environment and, 1019–1029, 1576–1586
differential display (DD) technique for, 538
diffusion of gases through soil and, 1749
diffusion of solutes through soil, 1748–1749
distribution of, 665, 2894–2899
disturbance of soils and, 3122
DNA analysis of, 528–544
electromagnetic radiation and, 2061
electron transport and, 2884
endolithic microorganisms in, 1100–1112
endospores in, 2886
environmental factors vs., 1752
enzymes of, 2899–2910, 2949
Eucarya and, 2880–2886, 2912
extracellular enzymes and, 1750
factors affecting activity of, 2057–2065
fauna in, 664–665
FFSB cluster in, 533–534
"fingerprinting" of microbial community in, 536–537
flooded soils, 1316–1333
fluorescence in situ hybridization (FISH) studies of, 529, 538
functional gene analysis in, 535–536
fungi in, 664–665, 2910–2918
gas–liquid interface and, 3274–3275
genetically engineered microorganisms (GEMs) in, 726, 729–730
genetically modified microorganisms (GMMs) in, 1429–1440
gram-negative bacteria in, 2881–2886
gram-positive bacteria in, 2881–2886
green bacteria in, 2992–2993

Soil microorganisms, (*continued*)
green fluorescent protein (GFP) studies for, 1498
growth and uptake parameters in, 1751
growth factors for, 2060
habitat of, minerals and organic matter in, 663–664, 2888–2889
halophiles, 297–298, 2889
heterotrophs in, 2889, 2891
hot desert environment and, 1576–1586
humic substances and, 1750
hydraulic conditions and, 3273
hydrogen oxidizing bacteria in, 2890
immobilization and, 2887
inclusions in, 2884–2885
inoculation with PGPR and, 346, 350
interactions among, 2063
ionic composition and, 2060
iron and, 2887
iron oxidizing bacteria in, 2890

kinetics of growth in, 1748–1757
land use and, 2895
leaching in, microbial, 2890
lichens in, 2914
limiting factors to, 1751
lipid biomarkers of, 1821
lipopolysaccarides (LPS) in, 2882
metabolism of, 346, 2951–2956
metagenome analysis of, 539
methane and methanogens in, 294, 296–297, 2057, 2892
microbial activity analysis, at functional level, 537–539
microhabitats for, 2058–2059
microscopic study of, 666
mineralization and, 2887
minerals and, 2060
modeling, 1753–1755
molecular characterization of, 528–544
motility of bacteria in, 348–349, 2926
mycolic acid and, 2881
mycorrhizae and, 2120–2132, 2911–2912
nicotinamide adenine dinucleotide (NAD) in, 2887
nicotinamide adenine dinucleotide phosphate (NADP) in, 2887
nitric oxide and, 294
nitrification and, 2949
nitrifying bacteria in, 2889–2890
nitrogen and nitrogen cycle of, 663, 667–670, 2936–2944
nitrogen fixation (BNF) in, 294, 344, 2057–2058, 2188–2211, 2887, 2936–2944
nitrous oxide and, 294
nucleoids in, 2884
nutrients and energy sources for, 663, 2057, 2059–2060, 2887, 2927, 2946–2947
oil spills vs., 700–701
organic matter and, 663–664, 669–670, 3271–3272
osmosis and, 2775–2776
oxidation reduction potential, 2062
oxygen and, 2057, 2061, 2887–2888
pathogenic bacteria in, 2058
periplasm in, 2884
permafrost and, 2367–2385
pesticide degradation and, 2385–2402
pH levels and, 2061–2062, 2889, 3269–3270
phospholipid ester linked fatty acids (PLFA) studies in, 538–539
phosphorous solubilizers in, 346
photoautotrophs in, 2890–2892
phototrophs in, 2887
phylotype richness in, 528
plant growth and, 663
plant growth promoting rhizobacteria (PGPR), 343–345, 349, 454–455, 2722
plant growth regulators (PGRs) in, 344–345
plasmids in, 2884
polyhydroxyalknoate (PHA) in, 346–347
polyhydroxybutyrate (PHB) in, 346–347
population size and, 1750–1751
pressure and, 2061
protozoa and, 348, 2594
psychrophiles and, 2889
purple bacteria in, 2992–2993
qCO2 and, 2954–2956
quality of soil vs., 2944–2957
resistant bacterial strains in, stress response, 349
respiration and, 2948–2949
rhizosphere for, 2713–2728
ribosomes in, 2884
RNA analysis of, 528–544
root adsorption and colonization of phytostimulators in, 348
rRNA probes for rhizobacteria in, 351
salinity and, 700–701, 2774–2789, 3270
salt stress reactions in, 2777–2781
sampling of, 665–666, 2815–2818, 2896
in sediments, marine, 2540–48
separation distance in distribution of, 2897
Shannon's index and, 528
siderophores in, 347, 2887
single-strand conformational polymorphism (SSCP), 536–537
slime molds and, 2912–2913
small subunit ribosomal RNA (SSU rRNA) analysis of, 531–535
soil adaptation and, 2386
soil genetic ecology and, 2918–2923
soil organic matter (SOM) and, 2945–2957
soil structure and, 2924–2925, 3122, 3271
solar radiation and, 2061
sorption and, 1749–1750
spatial distribution of, 2063
staphylococci in, 2882
streptobacilli in, 2882
streptococci in, 2882
substrate induced growth response (SIGR) in, 1750
substrate induced respiration (SIR) in, 1750
subsurface microbial communities and, 1074–1081, 1453–1468, 3065–3071
sulfate-reducing bacteria (SRB) in, 2891
sulfolobales and, 298–299
sulfur and sulfur cycle in, 2887, 3104–3116
sulfur oxidizing bacteria in, 2890
surfaces of attachment for, 2062–2063
sustainable agriculture, 3116–3126
temperature and, 1752–1753, 2061, 3268
temperature gradient gel electrophoresis (TGGE), 536–537
terminal fragment length polymorphism (T-RFLP), 536–537
terrestrial cluster in, 533–534
thermophiles in, 2888–2889
thermoplasmales and, 297
thermoproteales in, 298

3/2 power kinetics, to model growth, 1755
toxic chemicals vs., 2927–2929
toxicity testing for, 3155–3168
trace gases and, 3183–3194
tracking introduced phytostimulators in, 350–351
vadose zone and, 3236–3246
viruses in, 3268–3276
water and moisture for, 1753, 2057, 2060–2061, 2925, 3268–3269
water molds and, 2912
xerophiles and, 2889
yeasts in, 2913–2914
Zygomycota in, 2913
Soil organic matter (SOM), 2945–2957
Soil sampling, 2815–2818
Soil slurry sequencing batch reactor (SS-SBR), 51–52
Soil vapor extraction, 695
Solar cosmic radiation (SCR), space microbiology, 2989–292991
Solar lakes, sabkhas, pools and lagoons of Sinai, 1509
Solar particle events (SPEs), 2989–2991
Solar powered disinfection system, for RRCS, 2682–2683
Solar radiation (See also Ultraviolet radiation)
algae and, 1192–1193
Antarctica, 1025, 1103
bacterioplankton and, 2520
desert environment and, 1021–1022
enteroviruses and, 1170
fungi and growth and, 1368
heterotrophic bacteria and, 1540
neuston microbiology and, 2136–2137
nitrification vs., 2158–2159
periphyton vs., 2362
phototropism in, 2473–2474
plankton and phytoplankton, 2502, 2512
polar phytoplankton and, 2555–2556, 2560–2562
sea ice microorganisms and, 2840–2841
soil microorganisms and, 2061
in source water, 2970
space microbiology and, 2985
subaerial communities and, 3059, 3060–3061
ultraviolet and (See Ultraviolet radiation)
in wastewater stabilization ponds (WSBs), 3336
Solar salt works, 2804–2809
Solar salterns, 1508–1509, 1511
Solemya, 1606
Solentia, 172–173
Solid waste management
bioaerosols released from, 3320–3330
Solid waste treatment (See Municipal solid waste landfills)
Solids retention time (SRT), 2006
Solubility, bioremediation, of contaminants, 725
Soluble methane monooxygenase (sMMO), 435–436
Soluble microbial products (SMP), activated sludge processing, 24–26
Soluble nonreactive phosphorus (SNP), 2448–2453
Soluble reactive phosphorus (SRP), 217–218, 2448–2453
Solvents biodegradation, 507–516, 693, 713, 714, 1447–1448, 3147–3155, 3368
Soman (See Chemical warfare)
Somatic coliphages (See also Bacteriophages), 355–356, 377–379, 2709
Sophorolipids, biosurfactants/bioemulsions, 753–755
Sorghum, nitrogen fixation, 2199
Sorption characteristics, 1749–1750
biofilm, 2958–2967
bioremediation and, of contaminants, 725
extracellular polymeric substances (EPS) and, 1228–1229
Sorting cells, flow cytometry, 1944–1958
SOS response, viable but not culturable (VBNC) phenomenon, 3252
Source water protection, 2967–2978
assimilable organic carbon (AOC) in, 2972
biochemical oxygen demand (BOD) in, 2972
chemical oxygen demand (COD) in, 2972
Clean Water Act (CWA) and, 2975
Clostridium in, 2974
coliform bacteria in, 2973
coliphages in, 2974
competition among microbes in, 2970
dissolved oxygen (DO) in, 2972
enterococci in, 2974
Escherichia coli in, 2973
fecal contamination in, 2973, 2974
fecal pathogen transport to, 2968–2970
groundwater and, 2971–2972
indicators of quality in, 2972–2974
microscopic particulate analysis (MPA) of, 2972
nonmicrobial indicators of fecal contamination in, 2974
nutrients and, 2970
pathogen sources in, 2968
protective strategies of microbes in, 2970–2971
regulation of, 2974–2975
Safe Drinking Water Act (SDWA), 2974–2975
solar radiation and, 2970
stormwater in, 2969–2970
stream microbiology and, 3015–3024
streptococci in, 2974
surface waters and, 2971
temperature of water and, 2970
total organic carbon (TOC) in, 2972
total oxygen demand (TOD) in, 2972
ultraviolet and, 2970
vadose zone microbiology and, 3236–3246
Souring, petroleum reservoirs, 2422
Soxhlet extraction, 924
Soygro, 351
Spa and hot tub microbiology, 2978–2984
Space microbiology, 2985–2996
antibiotic effectiveness in, 3001
clinorotation and simulated microgravity in, 3000
crew health and life support systems, 3001–3002
desiccation and, 1035–1039
early experiments in, 2998
eukaryotes and, 3000–3001
genetics and, 3001
interplanetary transfer of life and, 2994–2995
Martian life and, 2985, 2995
meteorites and, 2985, 2994
microgravity and, 2985, 2994, 2996–3004
mutations, radiation induced, 2993
photolyase and, 2987
radiation and effect on cells, 2985–2994
sporulation and secondary metabolites in, 3002–3003
subsurface microorganisms and, 1080
Spaherosporella, 2125–2126

Spaherotilus, 3101
Spalling, 517
Sparganium, 2548
Sparging, 695
Spartina, 1397, 2539–2554
Specific affinity, 1742–1743
Specific bacterial growth rates, 3344–3345
Specific UV absorbance (SUVA), biodegradable dissolved organic carbon (BDOC), 485
Specificity, microbial insecticides using, 1710
Spectrophotometric analysis, pigments, 2462
Spelaeopogon, 838–843
Spelunking (See Caves and mines)
Spent filter backwash water (SFBW), 2262–2267
Sphacelotheca, 411
Sphaerobacter, 3129
Sphaerotheca, 454
Sphaerotilis, 3009
  activated sludge foaming and, 4–7
  bacterial counts using, 27–29
  biomineralization and, 675
  filamentous forms of, in activated sludge, 1291–1306, 1310, 1312
  metal biodegradation and, 1897
Sphagnum, endosymbiosis, 1118
Sphalerite, 633, 637–638
Spheroidene, in paleolimnology, 2307–2317
Spheroidenone, in paleolimnology, 2307–2317
Sphingomonas, 1204, 3314–3319
  activated sludge and, 71
  biodegradation and, 2409
  granular activated carbon (GAC) filters and, 1490, 1569–1570
  subsurface microbial communities and, 2035, 3065–3071
Spiniferomonas, 2317–2327
Spirilla, 2882
Spirilloxanthin, 2459
Spirillum, 57, 166, 316
Spirobis, 614
Spirochaeta, 57, 1124, 1123, 1515–1529, 1515, 2885
Spirogyra, 205
Spiromicrovirus, 364–374
Spiroplasma, 1114–1115, 1122
Spirulina, 980, 1507–1512, 1853
  algae biotechnology and, 189–204
  alkaliphiles and, 134
  nitrogen fixation and, 2193–2201
  salt production and, 2805–2809
Spodoptera, biocontrol use, 2701
Sponges (cleaning material), bacteria in home/residential environment, 340
Spongospora, 2913
Sporangiospores, 1647, 2889
Sporcybe, 945
Spore prints, 1652
Spores and spore dispersal (See also Allergies; Fungi)
  active dispersal mechanisms in, 405–407
  aerobic endospores and, 140–149
  airborne toxigenic molds and, 183–184
  airborne, of fungi, 183–184
  apple scab spores in, 413
  ascospores in, 412–414
  Aspergillus, 418
  atmospheric transport of, 407
  basidiospores in, 412–414
  bioaerosols and, 404–416
  bioterrorism and, 779–789
  blue mold, 414–415
  Buller's drop and, 406
  deposition of, 407, 428
  desiccation and, 1029, 1031, 1037–1041
  diffusion rates for, 427
  dispersal mechanisms in, 405–407
  dry air spora in, 405, 408–414
  fungal, 404–415, 1359–1383, 1647–1653, 3354–3355
  Fusarium, 413–414
  high hydrostatic pressure (HHP) vs., 1559–1563
  late blight of potato, 414
  macrofouling, from algal, 615–616
  as microbial tracer in groundwater, 3197–3198
  microgravity and, 3002–3003
  moist air spora in, 412–414
  mycobacteria and, 416–417
  open air factor (OAF) and, 430–431
  oxygen inactivation in, 430
  ozone vs., 430–431
  passive dispersal mechanisms in, 405
  pollutants vs., 430
  relative humidity vs., 428–430
  rusts, 411–412
  sampling of, 1650–1651
  saphrophytes and, 416
  smuts, 410–411
  temperature vs., 431
  ultraviolet radiation vs., 431
  uredospores in, 411–412
Sporidesmium, 454
Sporobolomyces, 1367–1372, 2369, 3057–3065
Sporomusa, 1320
Sporotrichum, 2666–2674
Sprinkler type wastewater systems, bioaerosol release from, 3323–3324
Spriophyllum (See also Gallionella), 1401
Sprirogyra, 215, 2304–2306
Spumella, 2595–2604, 3197
Stabilization of activated sludge, 738
Stabilization and maturation period in composting, 915
Stabilization ponds, wastewater (WSBs), 3330–3337
  algae in, 3331–3332
  ammonia and sulfide toxicity in, 3332
  bacteria in, 3330–3331, 3334–3336
  biological oxygen demand (BOD) and, 3336
  helminth eggs in, 3333–3334
  light intensity and, 3336
  pathogen removal from, 3333–3336
  pH levels and, 3331–3332, 3336
  photosynthetic bacteria in, 3332–3333
  protozoa in, 2333, 3334
  temperature and, 3335–3336
  time of retention and, 3335–3336
  viruses in, 3334
Stachybotrys, 182–189, 1648, 1660
  in allergies and illness, 1367–1372, 1374–1383
  biofilms and, 555
  bioterrorism and, 779
  detection of, 1133, 1134
Stalk forming bacteria, Gallionella as, 1401–1408
Staphylococcus, 339, 340, 341, 499, 1629–1646
  adhesion in biofilms and, 123
  bacteriophages and, 355
  bioaerosols and, 3327
  biofilms and, 556, 562, 577, 580, 1215, 1218, 2342–2356
  bioluminescence in, 658–662
  bottled water and, 798
  fecal contamination and, 1269, 1273
  gene transfer and, 1409, 1413–1415
  heterotrophic bacteria and, 1545, 1548
  high hydrostatic pressure (HHP) vs., 1555–1563
  municipal solid waste landfills and, 1766

nosocomial infections and, 2236–2250
resistance in, 607
soil microorganisms and, 2882
in spas and hot tubs, 2980–2984
spores and spore dispersion in, 421
subsurface microbial communities and, 3067–3071
in drinking water, 944, 945
Staphylococcus aureus enterotoxin (B/SEB), bioterrorism, 778
Staphylothermus, 1234, 1235, 1611, 1625–1628
Starch degrading enzymes, 223–226, 1180–1183, 1210
Starches, bioplastics, 682–692
Starvation survival, 2019–2028, 3036–3037
oligotrophic bacteria, 2267–2277
stress response and, 3041–3045
subsurface microorganisms and, 1080
Staurastrum, 2304–2306
Stauroneis, 1054, 1058
Steady state, 1738–1740
Stemphylium, 412, 1579
Stenotrophomonas, 420, 454, 1987, 2236–2250
Steric forces, 2004
Sterols
biofilms and, 85–86
fecal contamination and, 1257
Stetteria, 1525, 1629–1646
Stichococcus, 1102–1106
biodeterioration of mineral materials and, 519
photoautotrophic, in low-light habitats, 840–843
subaerial communities and, 3056–3065
Stigeoclonium, 196, 215, 2362
Stigmatella, 1578
Stigonema, 519, 2835–2844, 3056–3065
Stoichiometry, in activated sludge processing, 17–18
Stoichiometric matrix, in biofilms, 2086–2087
Stokes–Einstein equation, 1749
Stone, bioweathering, 3364–3374
Storage of samples, 2811–2812
Storage polymers, 3004–3014
activated sludge studies in, 3010–3011
anaerobic/aerobic storage in EBPR process and, 3011–3013
anoxic storage in nitrogen removal processes and, 3011
balanced growth conditions in, 3007
bulking and foaming control with, 3008–3011
enhanced biological phosphorus removal (EBPR) and, 3005, 3011–3013
glycogen as, 3005
kinetic (internal) induction and, 3007–3008
metabolic (external) induction and, 3006–3007
mixed culture studies in, 3010
polyhydroxyalkanoates (PHA) as, 3005
polyphosphates as, 3005
pure culture studies in, 3009–3010
unbalanced growth conditions and, 3006–3008
Storage-related phenomenon, subsurface microbial communities, 3315–3316
Stored water supplies
heterotrophic bacteria and, 1541–1552
off-stream storage in, as pretreatment, 2013–2014
Stormwater, 2969–2970
Stramenopila, 1394–1400, 2912
Stream microbiology (See also Surface water), 3015–3024
Streptobacilli soil microorganisms, 2882
Streptococcus
adhesion in biofilms and, 127–128
bioaerosols and, 3321, 3327
biofilms and, 82, 555
bioluminescence in, 658–662, 1831
biosurfactants/bioemulsions and, 765
fecal contamination and, 1256, 1264–1278
filamentous forms of, in activated sludge, 1302–1306
fluorescent studies of, 1835
gene transfer and, 1409, 1413–1415
granular activated carbon (GAC) filters and, 1489–1496
high hydrostatic pressure (HHP) vs., 1556–1563
in marine/ocean environment, 1702
metal biodegradation and, 1889
microarray study of, 1973
municipal solid waste landfills and, 1766
soil microorganisms and, 2882
in source water, 2974
in spas and hot tubs, 2980–2984
viable but not culturable (VBNC) phenomenon and, 3253
water treatment systems and, 2013
Streptomyces, 423, 458, 1102–1106, 2062, 2282, 2723, 2889
alkaliphiles and, 223, 226
biocontrols and, 452, 455, 458
desert environment and, 1578, 1583
gene transfer and, 1409
genetically altered, in biotechnology, 1448
green fluorescent protein (GFP) studies for, 1498
metal biodegradation and, 1890
microbial insecticides using, 1710
microgravity and, 3002
nitrogen fixation and, 2191
soil microorganisms and, 2912
stress response and, 3048
subsurface microbial communities and, 3067–3071
Streptoverticillium, 880, 2912
Stress and strain forces, in biofilms, failure, 547–548
Stress proteins, 3028, 3030–3031, 3036–3039
Stress response, 3024–3034
antioxidants and, 3031
antistress mechanisms and, 3030–3031
Bacteria and, 3025, 3034–3046
bioremediation/biodegradation and, 3043–3045
built in protein stability and, 3031
cell membranes and, 3031
cell robustness and, 3038–3039
chaperones and, 3028, 3048, 3050, 3052
chaperonins and, 3028–3029, 3048, 3052
cloning and, 3026
cochaperones in, 3030
DNA repair in, 3039
early studies of, 3025–3026
envelope reinforcement in, 3039
Eo70 and, 3039–3040
Eucarya and, 3025
general stress resistance (GSR) and, 3038–3043
heat-shock protein (hsp70) and, 3026–3028, 3050
heat-shock proteins and, 3031, 3049
heat-shock, 3046–3055
holoenzymes and, 3039
manipulating robustness and, 3045

Stress response, (*continued*)
molecular chaperone machine and, 3028, 3048, 3050, 3052
molecular regulation of, 3039
multicellular structures and, 3032–3033
new perspectives on, 3052–3053
nutrients and, 3034
optimum temperature for growth (OTG), 3025
osmolarity and, 3031, 3034
oxidative stress and, 3037
oxygen and, 3034
pH levels and, 3034
posttranslational regulation of gene expression for, 3040–3043
prefoldin in, 3030
pressure and, 3034
proteaosome and, 3031–3032, 3052
protein repair in, 3039
proteolysis and, 3031–3032, 3052
regulation in, 3049–3051
salinity and, 3034
sensing stress and, 3041
sigma factors and, 3040
starvation survival and, 3036–3037, 3041–3042, 3043–3045
stress genes and, 3039
stress proteins and, 3028, 3030–3031, 3036–3039
temperature and, 3034, 3046–3055
thermotolerance and, 3053
toxic solvents and, 3153
two-component systems and, 3041–3042
viable but not culturable (VBNC) phenomenon and, 3252
Strobilidium, 2626–2632
Stromatolites, 983
aggregates and consortia in, 172–173
biomineralization and, 678
Strombidium, 2626–2632
Strontium, in algae biotechnology, 199
Structural units of bacteriophages, 364
Structure activity relationships (SARs), 1249–1250
Stygiolobus, 298, 1235, 1629–1646
Stylaria, 1722
Stylosanthes, 2202
Styrene bioremediation, 707, 3147–3155
Subaerial communities, 3055–3065
Subfossil algae, 2301–2306
Subgrouping, rotaviruses, 2769
Submerged aquatic vegetation (SAV), 1190
Submerged plants
marine/ocean environment and, 2549–2552
seagrass and Zostera, 2550–2554, 2822–2833
Substrata, periphyton, 2363–2364
Substrate
enzyme activity and, 2901
nitrification and, 2160
Substrate activated death (SAD), 3251
Substrate induced growth response (SIGR), 1750
Substrate induced respiration (SIR), 1750
Subsurface irrigation systems, septic tank, 2855
Subsurface microbial communities (See also Caves and mines; Soil microorganisms), 1074–1081, 1453–1468, 3065–3071
abundance of, 2034–2035
activity of, case study evidence of, 1455–1456
adenosine diphosphate (ADP) in, 2022
adenosine triphosphate (ATP) and, 2022
adenylate energy charge (AEC) and, 2022
Atlantic Coastal Plain aquifers and, 2028–2042
bacterial counts, 2031
basaltic rock and, 1826–1828
biodegradation in, 2033
biodiversity of, 2034–2036, 3314–3315
biomass of, 1076, 1077–1078, 1080
carbon and, 1075
carbon dioxide and, 1074–1075, 1461–1463
catalyzed oxidation reduction reactions in, 1454–1455
in caves and mines, 1076, 1078–1079
chemolithoautotrophs in, 1075, 1455, 1824–1826
chemolithotrophs in, 1075, 1455
cold-adapted microorganisms and, 2025
community analysis of, 2030–2040
cryptobiosis in, 2021
culturing of, 1079
diagenesis and, 1074
diglyceride fatty acid (DGFA) and, 2030
dissolved organic carbon (DOC) and, 1074
dissolved organic matter (DOM) in, 1455
distribution of, 1076
DNA analysis of, 2035
dolomite, 1464–1466
energy sources for, 1074–1075
factors affecting, 2033–2034
gene probes for, 2036
geochemical effects of, 1453–1468
green rust, 1464–1466
groundwater and, 1076, 1079, 1454–1468, 1827, 2025
halophiles in, 2024–2025
high temperature environment, 2047–2057
hydrogen and, 1464–1466
igneous rock aquifers, 1661–1673, 1826
iron and, 1464–1466
isotopes and, 1456–1464
isotopic fractionation and, 1461
lithotrophs in, 1824–1829
magnetite and, 1464–1466
in marine/ocean environment, 1080
measuring metabolic activity of, 1079–1080, 2033
methane production and, 1075
microbial fluid interactions in, 1454–1464
microbial mineral interactions in, 1464–1466
microbial reduction of oxygen, nitrogen, carbon dioxide by, 1461–1463
most probable number (MPN) in, 2030
nitrogen and, 1461–1463
nutrients and energy sources for, 2020–21, 2033–2034, 2045–2046
oil bearing rock formations and, 2418–2420
organic matter and, 1074, 1075 and, 1455
oxidation and oxygen in, 174–75, 1461–1463
permafrost and, 2367–2385
petroleum reservoirs and, 2416–2426
phosphates and, 1464–1466
phospholipid fatty acids (PFLA) in, 2030, 3315
phylogeny of, 3065–3068
planetary catastrophe and evolution in, 1080
plasmid incidence testing in, 2036–2037
pore size in media of, 1075–1076

protozoa and, 2594
Rayleigh vs. open system isotope behavior and, 1457–1461
rock and, 1076
sampling of enumeration of, 1076–1079, 2030, 3071–3087
in San Juan Basin, 2045
sedimentary organic matter (SOM) and, 1455
sedimentary rocks and, 2418–2420
siderite and, 1464–1466
spatial distribution of, 2037–2039
starvation survival in, 1080, 2019–2028
storage related phenomenon in, 3315–3316
sulfate-reducing bacteria (SRB) in, 1075, 1454, 1457, 2419–2420, 2422–2424, 3091
survival of, long term, 3316–3317
temperature and, 1075
transport in, 2039–2040
viable but not culturable (VBNC) phenomenon in, 3316–3317
virus transport and removal in subsurface, 2094–2107
vivianite and, 1464–1466
volcanic tuffs and, 3110–3119
water and, 1075
Subtilisin, 3207–3210
Subtractive hybridization, 1451–1452
Subtropical waters
aggregates and consortia in, 168–170
nitrogen cycle and, 2182–2183
Prochlorococcus, 2576–2593
Succinate, 21–26, 153, 154
Sucrose, 518, 2716
anaerobic granulation and, 235–237
biosurfactants/bioemulsions and, 756
soil salinity and, 2778–2789
Suctoria, 2606
Sudden infant death syndrome (SIDS), 186
Sugar glasses and stabilization, in freeze drying, 1351–1354
Sugar processing, heterotrophic bacteria, 1544–1545
Sugars, 2716
in activated sludge, 741–743
microbial protection from, 432
soil salinity and, 2778–2789
in surface waters, 928, 928
Suillus, 2124–2132, 2915
Sulfatase, 3021
Sulfate-reducing bacteria (SRB), 1898–1899, 2419–2424, 3087–3996, 3146, 3193
activity of, 3091–3092
adenosine triphosphate (ATP) and, 3087
aggregates and consortia in, 165–166
applications for, 3092
assimilatory sulfate reduction in, 3087
biocorrosion and, 464–475, 3092–3093
biodeterioration of mineral materials and, 524
biofilms and, 2962, 3091–3092
biofouling and, 3091
biomineralization and, 672
bioremediation and, 708
carbon and, 3087–3088
chromium and, 3089
detection of, 3093–3094
dissimilatory sulfate reduction in, 3087
distribution of, 3090–3091, 3102
flooded soils and, 3114
in groundwater, 1665, 1667–1669
halophiles and, 1519
heavy metals and, 3089–3090
hydrogen sulfide production and, 3092
iron and, 3089
manganese and, 3089
in marine/ocean environment and, 1697–1709, 2547–2548, 2551
mercury and, 3089–3090
metals and, 3092–3093
microbially influenced corrosion (MIC) and, 3092–3093
molybdenum and, 3089
municipal solid waste landfills and, 1760
nitrogen and, 3089
oxygen and, 2277, 2285–2286
petroleum reservoirs and, 2428–2429
in sediments and sedimentation, 2844–2853
selenium and, 3089
soil microorganisms and, 2891
subsurface microbial communities and, 1075, 2055, 1454, 1457, 3091
sulfur and, 3088–3089, 3113–3115
sulfur bacteria and, 3098–3100
uranium and, 3089
Sulfates and sulfides, 2042–2043, 2042, 2277, 3184
biogenesis and oxidation of, 3113
biomineralization of, bacterial, 670–681
municipal solid waste landfills and, 1760
oxygen and, 2277
soil salinity and, 2774
in wastewater stabilization ponds (WSBs), 3332
Sulfhydryls, biomineralization, 671
Sulfobacillus, 3129
bioleaching and, 644–650
biomineralization and, 675
metal biodegradation and, 1904
Sulfoindocyanine dyes, 1334
Sulfolane bioremediation, 707
Sulfolobales, 298–299, 1629–1646, 3146
Sulfolobus, 1233, 1235, 1629–1646, 3113, 3144–3147
Archaea and, 298
biodegradation and, 1045
bioleaching and, 632–642
metal biodegradation and, 1904
stress response and, 3026
Sulfonic acid, biodegradation, 2297–2300
Sulfonium compounds, soil salinity, 2778–2789
Sulfophobococcus, 1629–1646
Sulfuorococcus, 298
Sulfuorspirillum, 1609–1610
Sulfur and sulfur cycling, 3096–3100, 3104–3116, 3184, 3192–3193
biofilms and, 82, 1085–1086
biofiltration and, 589
biogenesis and oxidation of sulfides in, 3113
bioleaching and, 632–642
cyanobacteria and, 969
desulfurization of fossil fuels, 1041–1051
endosymbiosis and, in ocean waters, 1117–1118
flooded soils and, 1326
hyperthermophiles and, 1633
in marine/ocean environment and, 1697–1709
oxygen and, 2277, 2278, 2284–2285
in sediments and sedimentation, 2844–2853
soil microorganisms and, 2887
subsurface microbial communities and, 1454–1455
sulfate-reducing bacteria (SRB) (See Sulfate-reducing bacteria)
thiosulfate shunt in, 3112
in wetlands for wastewater treatment, 3393

Sulfur bacteria in drinking water, 3096–3104
Sulfur dependent anaerobic methane oxidation, 288–289
Sulfur dioxide, 589, 3183, 3192–3193
Sulfur mustard (See Chemical warfare)
Sulfur oxidizing bacteria, 1610, 2890, 3097–3098
Sulfuric acid
biogenic, in biodeterioration of mineral materials, 524
weathering and, 3364–3389
Sulfuricoccus, 3129
Sulfurisphaera, 1629–1646, 3146
Sulofolobus, 295, 675, 1233
Sunlight (See Solar radiation; Ultraviolet radiation)
Supercritical fluid chromatography (SFC), 255–256
Superoxide dismutase (SOD), 2278
Surface complexation precipitation theory (SCPT), 1406–1407
Surface embedded biocides, 606
Surface enhanced Raman spectroscopy (SERS) analysis, 935
Surface film, neuston microbiology, 2134–2135
Surface microlayer, neuston microbiology, 2134–2135
Surface nanolayer, neuston microbiology, 2134–2135
Surface waters
artificial wetlands and reedbeds in wastewater treatment, 3389–3401
bacterioplankton in, 2519–2539
biofilms in, 569–572
biomineralization and, 677–678
bioremediation and, 708, 712–722
carbon in, 928
caves and mines, 821–835
ciliates in, 2626–2632
Clostridium and, 864–871
cold-adapted microorganisms in, 872–885
coliform bacteria and, 900, 902–903
conditioning films and, 928–941
dissolved organic carbon (DOC) in, 928
Enterococci in, 1264–1278
fecal contamination in, 1256–64
floc formation and, 2000–2002
flooded soils and, 1316–1333
fungi in, 3353–3364
green fluorescent protein (GFP) studies for, 1498
halogenated compound pollution of, 705
heterotrophic bacteria and, 1540, 1541–1552
humic substances in, 928
hydrocarbons and, 715–719
lipid biomarkers of, 1821
meroplankton and, 1863–1869
microorganisms in, 1724
nitrification and, 2156–2148
oil spills and, 715–719
organic inorganic matter in, 928
in paleolimnology, chrysophyte structures and, 2317–2327
particulate organic carbon (POC) and, 928
pathogens in, 2971
periphyton, 2357–2367
permafrost and, 2367–2385
Prochlorococcus in, 2576–2593
river snow in, 570–571
sampling of, 2812–2815
snow and ice environments, 2872–2880
source water using, 2971
stratification within, 715
stream microbiology, 3015–3024
Streptococci in, 1264–1278
vadose zone microbiology and, 3236–3246
Surfactants (See also Biosurfactants), 1–7, 714–715, 750–770, 2411
Surfactin, 757–759
Sustainable agriculture, 3116–3126
disturbance of soils and, 3122
microbial insecticides using, 1717
mycorrhizae and, 3121
nitrogen fixation and, 3120
nutrient cycling in, 3120
organic matter and, 3120
pesticide biodegradation in, 3121–3122
plant growth and, 3121
rotation of crops and, 3122
soil structure and, 3122
strategies for, 3122–3124
Sustainable waste management (See also Municipal solid waste landfills), 1769–1770
Swimming, plankton and phytoplankton, 2511
SwissProt, 1450
Symbiont, 1113
Symbiosis (See also Mycorrhizae; Nitrogen fixation; Rhizobium)
actinorhizal Frankia symbiosis in, 2208–2209
associative symbioses in, 2199–2200
cyanobacteria and, 973–975
desert environment and reclamation and, 1583
endosymbiosis, 1112–1130
fungi and, 1367
grass bacteria association in, 2199–2200
hydrothermal vents and, 1619
legume–rhizobial symbiosis in, 2202–2208, 2786–2787
mycorrhizae and, 2120–2132
nitrogen fixation and, 344, 2188–2221
plant–microbe interactions in marine environment, 2539–2554
protozoa and, 2621–2622
soil salinity and, 2775
Symbiosome, 1113
Symbitotrophic systems, 1113–1120
Symhyonema, 838–843
Symploca, 210, 980
Symports, soil salinity, 2781
Synchytrium, 2913
Synechococcus, 210, 972, 973, 2461, 2576, 3141–3147, 3307
aggregates and consortia in, 170–172, 173, 174
alkaliphiles and, 134
bacterioplankton and, 2526, 2532
biodeterioration of mineral materials and, 521
biofilms and, 83
biomineralization and, 672
cold-shock response and, 888–895, 888
in marine/ocean environment, 1701, 1704, 1706
phosphorus cycling and, 2451
photoautotrophic, in low-light habitats, 838–843
photosynthetic pigments in, 2464
salt production and, 2805–2809
Synechocystis, 969
aggregates and consortia in, 170–173
biodeterioration of mineral materials and, 519
phosphorus cycling and, 2451
radiation and, 2987
salt production and, 2805–2809
Synedra, 206, 210
Synthase, 3207–3210
Syntrophic degradation, in activated sludge, 744–745
Syntrophobacter, 234–235, 745, 1340
Syntrophomonas, 745
Syntrophospora, 745
Syntrophus, 509
syntrophy, 83–84, 240–241, 1113–1120, 1320
Synura, 206, 210, 2317–2327, 2317, 2467
Syracosphaera, 2508

Syringodium, 2549
SYTO statins, 1777, 1949
Sytox stains, 1783
Syurophyceae, 2467

T
T-helper cells, 1359–1366, 1378
Tabellaria, 210
Tabun (See Chemical warfare)
Taenia, 3277–3287, 3399
Talaromyces, 451, 453, 916, 3144–3147
Talc, activated sludge foaming, 6–7
Tamyl methyl ether (TAME) biodegradation, 1994–2000
Tartigrades, in snow and ice environments, 2874
Taste of water, vs. algal blooms, 204–213
Taxonomy
  bacterioplankton and, 2526–2528
  protozoa and, 2615–2620
Taylorsville Basin, 2053–2057
t-butyl alcohol (TBA) biodegradation, 1994–2000
Technetium, 671–681, 1879–1893
Technology transfer issues, 1861
Tectiviridae/Tectivirus, 365–374
Teichoic acid, 109
Teichuronic acid, 109
Teichuronopeptide (TUP), 221
Telluria, 455, 3067–3071
Tellurite, resistance of bacteria to, 608
Temperate marine ecosystems
  aggregates and consortia in, 170–172
  nitrogen cycle and, 2181–2182
Temperature
  activated sludge and, 1311
  algae and, 1193
  alkalithermophiles, 3127–3140
  Antarctic soils and, 1023–1025, 1103
  Arrhenius equation for, 1752
  bacteriophages vs., 387
  bacterioplankton and, 2520–2521, 2531
  biodegradable dissolved organic carbon (BDOC) and, 495
  biofiltration vs., 593
  bioremediation and, 713, 723
  composting vs., 915–916
  denitrification vs., in marine environment, 1016–1017
  desert environment and, 1576, 1583
  enteroviruses and, 1169
  enzyme activity and, 2900
  extremeophiles and, 1232–1237
  harmful algal blooms (HABs) and red tides, 2689–2690
  heat-shock response, 3046–3055
  heterotrophic bacteria and, 1541–1552
  high temperature subsurface environment, 2047–2057
  hydrothermal vents, 1604–1628
  hyperthermophiles and, 1642
  kinetics of growth and, 1752–1753
  municipal solid waste landfills and, 1760, 1762
  neuston microbiology and, 2139
  nitrification vs., 2158, 2168–2169, 2171–2172
  nitrogen fixation vs., 2199
  oil recovery from petroleum reservoirs and, 2421
  periphyton and, 2361–2362
  permafrost and, 2367–2385
  pesticide degradation vs., 2394
  petroleum reservoirs and, 2427
  plankton and phytoplankton, 2502, 2511
  polar phytoplankton and, 2555–2556, 2563, 2564
  psychrophilic bacteria and, 2639, 2641, 2642–2645
  rhizosphere and, 2724
  sea ice microorganisms and, 2839
  in septic tank systems, 2857
  snow and ice environments, 2872–2880
  soil microorganisms and, 1752–1753, 2061, 3268
  of source water, 2970
  spores and spore dispersion vs., 431
  stress response and, 3024–3034, 3046–3055
  subaerial communities and, 3058, 3061
  subsurface microorganisms and, 1075
  temperature gradient gel electrophoresis (TGGE), 299, 536–537, 818–819, 2735–2737, 2735
  temporal temperature gradient electrophoresis (TTGE), 2735–2737
  thermophiles and, 3127–3147
  viruses vs., 2099–2100, 3268
  of in wastewater stabilization ponds (WSBs), 3335–3336
  weathering, bioweathering and, 3381–3382
Temperature gradient gel electrophoresis (TGGE), 299, 536–537, 818–819, 2735–2737
Temporal temperature gradient electrophoresis (TTGE), 2735–2737
Tephrocybe, 2914
Teratogens, biodegradation, 507–516
Terbutryn composting, 921–922
Termamyl, 1181
Terminal electron accepting processes (TEAP), 2932, 3404
Terminal fragment length polymorphism (T-RFLP), 28–29, 71, 177–178, 278, 299, 536–537, 563, 829, 1974, 2496, 2737–2738, 2921
  Archaea and and, 278, 299
  biofilms and, 563
  soil microorganism and diversity in, 536–537
  bacterial counts using, 28–29
  microarray study of vs., 1974
  activated sludge and, 71
  aggregates and consortia in, 177–178, 177
Termites, endosymbiosis, 1118
Terpenoids, algae biotechnology, 195
Terrabacter, 40, 3065–3071, 3314–3319

desert environment and, 1577
granular activated carbon (GAC) filters and, 1491
in source water, 2972
in wetlands for wastewater treatment, 3391
Total oxygen demand (TOD), in source water, 2972
Total petroleum hydrocarbons (TPH), 916–919
Toxic chemicals, 2340, 3147–3155
activated sludge and, 72, 75
algae biotechnology and, 196–200
algal/in algal blooms, 204–213
biodegradation and, 724–725, 1421
biofiltration and, 591
composting of, 916–917, 916
enzyme activity and, 2909
municipal solid waste landfills and, 1765
neuston microbiology and, 2137–2139
nitrogen cycle and, 2942
in pulp and paper industry, 2650
resistance of bacteria to, 608
soil microorganisms vs., 2927–2929
Toxic flow, 3226
Toxic load, 3226
Toxic Pfiesteria complex (TPC) (See Pfiesteria)
Toxic pneumonitis, 1369
Toxic print, 3226
Toxic Substances Control Act (TSCA), 1280, 2695–2707
Toxicity characteristic leachate protocol (TCLP) analysis, 846
Toxicity identification evaluation (TIE), 3168
Toxicity reduction evaluation (TRE), 3168
Toxicity testing, algal, 3219–3230
algal solid phase assay (ASPA) in, 3227–3228
eutrophication and, 3220
exposures testing, 3220–3225
hazardous wastes, hazardous effluents and, 3225–3227
interaction studies using, 3225
species used in, 3221–3222
toxic flow in, 3226
toxic load in, 3226
toxic print in, 3226
toxicity testing, bioterrorism and, 773–775
Toxicity testing, in soils
biomass and, 3158–3159
bound effect concentration (BEC), 3163
denitrification and, 3160
dose response testing in, 3162–3164
effective concentration (ECx), 3163
enzyme activity and, 3161
heavy metals and, 3162
international guidelines for, 3164
long term changes in soil quality and, monitoring, 3165
lowest effect concentration (LEC), 3163
lowest observed effect concentration (LOEC), 3163
microbial growth rates and, 3161
minimum data sets (MDS) for, 3165
near infrared reflectance (NIR) in, 3165
nitrification and, 3159–3161
nitrogen fixation and, 3160
nitrogen mineralization and, 3159
no effect concentration (NEC), 3163
no observed effect concentration (NOEC), 3163
phosphatase activity and, 3160–3161
predicted environment concentration (PEC), 3163
predicted no effect concentration (PNEC), 3163
respiration rates and, 3159
sampling for, 3166
screening and testing of chemicals and metals in, 3161–3164
Toxicity testing, in wastewater, 3168–3175

Toxicity testing, in wastewater, (*continued*)
algal toxicity assays for, 3172–3173
ATP-based assays for, 3171
bacterial biosensors for, 3172
biochemical oxygen demand (BOD) in, 3168
biomonitoring in, 3168
de novo enzyme biosynthesis tests in, 3172
enzyme assays in, 3169–3171
growth inhibition assays in, 3171–3172
microbial assays and, 3171
Microtox assay in, 3171
nitrifying bacteria in, 3172
protozoa in, 3173
respirometry in, 3173
toxicity identification evaluation (TIE) in, 3168
toxicity reduction evaluation (TRE) in, 3168
urease toxicity assay (UTA) and, 3170
whole effluent toxicity (WET) in, 3168
Toxicology, algae biotechnology, 196–199
Toxins
bioterrorism and 778–779
cyanobacteria and, 975–980, 982–995
plankton and phytoplankton, 2514
Toxocara, 3399
Toxoplasma, 3176–3183
disinfection and, 1067–1073
in food, 3277–3287
in source water, 2969–2978
in water treatment systems, 1719
Toxothrix, 3101
Trace elements, in marine/ocean environment, 1701–1707
Trace gases, soil, 3183–3194
Trace metals, cyanobacteria, 969–970
Tracehophtyes, 2504–2518
Tracers
geochemical, 3081–3082
groundwater, microbial, 3194–3202
microbiological, 3079–3081
viral, 3305

Antarctic soils and, 1027
bacteriophages and, 355
biofilms and, 562, 567, 1209, 1219
bioluminescence in, 658–662
biomass estimation and, 2656
biomineralization and, 675
bioterrorism and (See Cholera)
bottled water and, 799
cold-adapted microorganisms in, 872–885
cold-shock response and, 886–895
endosymbiosis and, 1117
fecal contamination and, 1273
genetically altered, in biotechnology, 1446, 1447
genomic studies and, 1442, 1443, 1445, 1448, 1451
heterotrophic bacteria and, 1541–1552
high hydrostatic pressure (HHP) vs., 1555–1563
hydrothermal vents and, 1610
identification of isolates in, 1960
metal biodegradation and, 1884
nitrogen fixation and, 2214–2221
phosphorus cycling and, 2451
in source water, 2969–2978
in spas and hot tubs, 2980–2984
subsurface microorganisms and, 2021, 2025
toxic solvents and, 3152
in wastewater stabilization ponds (WSBs), 3330, 3334–3336
in wastewater/sewage, 3171
in drinking water, 945, 949, 3199
Vibrionacea, 803
Video cameras, 1676
Vinyl acetate bioremediation, 707
Vinyl chloride (VC) bioremediation, 434–442, 510–514, 701–712, 919–920, 919
Vinyl chloride polychlorinated biphenyls (See Polychlorinated biphenyls, PCBs)
Violooxanthin, 2512
Virion of bacteriophages, 364
Viruses (See also specific viruses, e.g., astrovirus, poliovirus, etc.), 338, 363, 417
activated sludge and, 70
adsorption to soil of, 2097–2098, 3270, 3273–3274
advection and dispersion of, 2101
aerosol type, 3255–3260
aggregation of, bacteriophages and, 389, 3271
algae biotechnology vs., 195–196
aquatic sediments and, 1252–1256
bacteria in home/residential environment and, 342
bacterial infection by, 3304–3305
bacteriophage theta X174, 2101–2102
bacteriophages and as index of, 374–384, 357, 2101
bacterioplankton vs.., 2531–2532
bioaerosols and, 3221–3222, 3327
biofilms and, 2342, 2353
bioterrorism and, 777–778
bromine and iodine vs., 3266–3267
cations and, 2099
cell culture assay of, 3291
chlorine vs., 3265–3267
coliphages, 2974
decay of, 3305
disinfection of, 3260–3268
dispersion of, 2101
DNA synthesis in, 3305
dose response assessment in, 2745–2747
exposure assessment in, 2747–2748
F specific RNA bacteriophages and, 2102
filtration vs., 2097
fluorescent tracers for, 3305
food processing and, 3276–3287
food web and, 3306–3307
gas liquid interface and, 3274–3275
gene transfer using, 3205, 3308
groundwater and, 3288–3300
hazard identification in, 2742
heat/thermal disinfection vs., 3264
high hydrostatic pressure (HHP) vs., 1561
human health outcomes in, 2742–2744
hydraulic conditions vs., in soil, 3273
hydrophobicity of soils and, 2098
ionic strength in, 2099
ionization vs., 3264–3265
isotope dilution studies of, 3305
marine/ocean environment and, 3300–3310
metal ions vs., 3267
as microbial tracers in groundwater, 3194–3202
microbial activity vs., 2100, 3268
microbial insecticides using, 1711
model, 2101
modeling of transport and removal in subsurface, 2094–2107
mortality and morbidity rates from, 2743–2744
MS2 model, 2101
multiple exposure and immunity in, 2747
municipal solid waste landfills and, 1766
neuston microbiology and, 2140–2141
organic matter and, 2099, 3271–3272
outbreaks of disease from, 2744–2745
ozonation vs., 3262
particulate matter and soil vs., 2100
pH levels and, 3269–3270
plankton vs., 3307–3308
polymerase chain reaction (PCR) and, 3291–3299
PRD1 model, 2101
protists and, 3305–3306
in rainwater roof catchment systems, 2681–2682
removal of, through soil transport, 2102–2105
resistance of hosts to, 3308
respiratory syncytial virus (RSV), 2743
reverse transcription PCR (RT PCR), 3291–3299
risk assessment of environmental exposure to, 2741–2753
salinity and, 3270
seasonal trends in, 3296–3299
soil pH vs., 2098
soil survival of, 3268–3276
in source water, 2969–2978
in spas and hot tubs, 2979
streams and, 3016–3017
subsurface microorganisms and, 2025
taxonomy of, 364–366
temperature vs., 2099–2100, 3268
transmission methods in, 2744
unsaturated conditions and, 2100–2101
in wastewater stabilization ponds (WSBs), 3330, 3334
water and moisture for, 3268–3269
water purifiers vs., 1572–1573, 1572
water treatment systems and, 1160–1164, 3288–3300
waterborne diseases and, 2743
in wetlands for wastewater treatment, 3397–3398
Vitamins, 2716

Vitrification, freeze drying, 1351–1354
Vittaforma, 2066–2083, 2329–2337
Vivianite, for subsurface microbial communities, 1464–1466
Volatile fatty acids (VFA), 235, 242–243, 1760
Volatile organic compounds (VOCs)
biofiltration vs., 598
biotrickling filters, 782–795
composting and, 919–920
fungi and, 1366–1383
municipal solid waste landfills and, 1765
Volatilization, metal biodegradation, 1884, 1894
Volcanic rocks, subsurface microbial communities, 3065, 3110–3119
Volumetric bacterial growth rates, 3344
Volvox, 206, 1863–1869
Vorticella, 2342–2356, 2608, 2611, 2620
VX agents (See Chemical warfare)
VX ICB, chemical warfare, 850–851

W

Wall and gate, 695
Wall-less spirochete, psychrophilic, 2640–2646
Wallemia, 1130
Wards method, 1006
Washing, fluorescent probes, 1335, 1336
Waste activated sludge (WAS), 738
Waste management (See also Municipal solid waste landfills), 1769–1770
Waste treatment, odor control and biofiltration, 593–601
Wastewater/sewage treatment (See also Activated sludge), 26–31, 1850
activated sludge and, 26–31, 739, 2332, 3342–3345
adenosine triphosphate (ATP) in, 3338–3339
algae biotechnology and, 199–200
algal toxicity assays for, 3172–3173
algal turf scrubbing (ATS) and, 213–219
anaerobic granulation and, 232–245
anaerobic migrating bed reactor (AMBR), 232
anaerobic sequencing bed reactor (ASBR), 232
artificial wetlands and, 2333
ATP-based assays for, 3171
bacteria in, 3337, 3338
bacterial biosensors for, 3172
bacteriophages as indicators in, 354–363
bioaerosols released from, 420–421, 3320–3330
biochemical oxygen demand (BOD) in, 3168
biodiversity in, 3337
biofilms and, 86–87, 3346–3347
biofiltration in, 588
biological nutrient removal (BNR) processes and, 3337–3339
biomonitoring in, 3168
bioremediation and, 693
blue-green algae, 206
chemical transformations in, 3337
cold-adapted microorganisms and, 882
coliform bacteria, 895–905
Cryptosporidium in, 1252–1256
de novo enzyme biosynthesis tests in, 3172
dehydrogenase in, 3338
deoxythymidine diphosphate (dTDP) and, 3340–3341
deoxythymidine triphosphate (dTTP) and, 3339–3342
deoxyuridine monophosphate (dUMP) and, 3340–3341
dinoflagellates in, 205
disinfection in, 2333–2334
DNA/RNA analysis in, 3339–3342
enteric viruses in sediment from, 1252–1256
Enterococci in, 1264–1278
enteroviruses and, 1171–1172
enzyme assays in, 3169–3171
expanded granular sludge blanket (EGSB), 232
filamentous bacteria in, 1287–1306
filtration in, 2332, 2333
Giardia in, 1252–1256
green, 205
growth inhibition assays in, 3171–3172
hepatitis viruses and, 1530–1540
heterotrophic bacteria and, 1541–1552
high-rate algae ponds in, 2333
infiltration percolation in, 2333
isotope dilution in, 3341
kinetics of growth and, single species, 3339–3342, 3347–3350
lagoons in, 2333
macromolecule labeling in, 3342
marine biotechnology and, 1855
metabolism vs. growth in, 3338–3339
microbial assays and, 3171
microfiltration in, 2334
Microtox assay in, 3171
NADH and, 3338–3339
nitrifying bacteria in, 3172
nutrients and, 3337
odor control and biofiltration in, 593–601
oxygen uptake rate (OUR) in, 3345–3346
parasites in, 2327–37
principles and biochemical pathways in, 3340–3341
protozoa in, 1252–56, 2327–2337
Pseudomonas, 2632–2639
reedbeds for, 3389–3401
respiration in, 3173, 3345–3346
Salmonella and, 2789–2802
sampling of, 2813
sand filters in, 2333
sedimentation in, 2331–2332
septic tank systems and, 2853–2864
specific bacterial growth rates in, 3344–3345
sprinkler type systems, bioaerosol release from, 3323–3324
stabilization ponds (WSPs) in, 2333, 3330–3337
Streptococci in, 1264–78
tertiary treatments in, 2333–2335
thymidine rates in, 3339–3342
toxicity identification evaluation (TIE) in, 3168
toxicity reduction evaluation (TRE) in, 3168
toxicity testing in, 3168–3175
upflow anaerobic sludge blanket (UASB), 232
upflow sludge bed filters (USBF), 232
urease toxicity assay (UTA) and, 3170
vadose zone microbiology and, 3242
viruses in, 1252–1256
volumetric bacterial growth rates in, 3344
wetlands for, 3389–3401
whole effluent toxicity (WET) in, 3168
yellow green or golden brown algae in, 206
Water absorbing polymers (WAP), 239
Water (See Moisture and water content)
Water molds, 2912

Water pollution (See Aquatic ecosystems; Groundwater pollution; Marine/ocean environment; Surface waters)
Water purifiers, 1567, 1572–1573
Water treatment systems (See also Distribution system for water), 941, 2012–2019
adhesion of, 1052–1053
aeration in, 2017, 2266
aerobic endospores used to measure efficacy of, 141–149
Aeromonas and, 1091–1099
algal blooms and, 204–213
algal turf scrubbing (ATS) and, 213–219
ammonium in, 2167
annelida in, 1722
anolytes in, 604
antibiotic resistant bacteria in, 944
asellidae in, 1722–1723, 1722
assessing presence of microorganisms in, 1726–1727
assimilable organic carbon (AOC) and, 312–327, 1729
astroviruses and detection, 334
bacteriophages as indicators in, 354–363, 375–377
Bacteroides fragilis-infecting bacteriophages in, 356–358, 378–379
bank infiltration and, 2014–2015
benchmark values for, 1729–1730
biodegradable dissolved organic carbon (BDOC) and, 484–507, 1729
biofilm formation rate (BFR) in, 1729
biofilms and, 560–575, 620–622, 945–947
biofouling and, 601–609, 620–622
biologically active carbon (BAC), 1489, 1491
bottled water and, 795–802
bromine compounds and, 603
cell cell interactions in, 1056–1058
chemical composition of water in, 3100–3101
chemistry of water in, 606–607
chloramines in, 1069
chlorine compounds and, 603, 625–626, 1063–1067, 1069, 1172
chlorine dioxide in, 1063–1066, 1067, 1069–1070
chrionomidae in, 1723
clarification in, high-rate, 2017
Clean Water Act (CWA) and, 2975
Clostridium and, 866–871
coagulation process in, 2015–18
coliform bacteria in, 895–914, 944, 946–951
coliphages in, 379–380, 384–385
controlling microbial quality in, 941–952, 1727–1730
crustacea in, 1722–1723
Cryptosporidium in, 1719, 1727
CT disinfection concept for, 1065–1065
cyanobacteria and, 980, 982–995
cyanotoxins in, 982–995
deterioration of, microbiological, 1720
diamidinopheylindole (DAPI) in, 1068
diptera in, 1723
disinfection by products (DBPs) in, 1066
disinfection in, 359–361, 1063–1073, 1729, 2172–2175, 2266, 3260–3268
dissolved air floation (DAF) in, 2017, 2266
distribution systems for, 941–952, 1725
efficacy of treatment, factors affecting, 606–608
electrochemically activated water in, 603–604
electronegative filters in, 1156–1159
electropositive filters in, 1159–1160
Enterococci in, 1264–1278
enteroviruses and, 1156–1165
equalization in, 2265–2266
extracellular matrix (ECM) and, 1054, 1058
F specific RNA bacteriophages in, 356
fecal contamination in, 1256–1264
feeding, growth, and reproduction of microorganisms in, 1725–1726
filtration, 2012–2013
floc formation in, 2015–2018
fluorescein diacetate (FDA) in, 1068
Giardia in, 1719, 1727
granular activated carbon (GAC) filters in, 315, 1489–1496
groundwater immigration of microorganisms to, 1723–1724
growth of microorganisms in, 1724–1725
hepatitis viruses and, 1530–1540
heterotrophic bacteria and, as quality indicators, 1540–1552
home or point of use treatment devices for, 1550–1551, 1563–1575
in-line coagulation in, 2018
insects in, 1723
invertebrates in, 1718–1733
ion exchange in, 2018
isopoda in, 1722–1723
lime softening in, 2017–2018
macroinvertebrates in, 945
microorganisms in, 943–945
microsporidia in, 2079–2080
microstrainers in, 2013
monitoring microbial activity in, 947–948
monochloramine in, 1063–1066, 1069
Monod equation, regrowth of bacteria in, 314
nematodes in, 1718–1722
nitrate in, 2167
nitrification and, 2167–2176
nitrifying bacteria in, 2167–2176
nitrite in, 2167
nutrient levels in water of, 489
odor control and biofiltration in, 593–601
off-stream storage in, 2013–2014
oliogchaeta in, 1722
opportunistic pathogens in, 944–945
ozonation and, 603, 1067, 1070–1071, 1172–1173
parasitic invertebrates in, 1718–1719
pathogen hosts in, 1719–1720
pathogenic bacteria in, case studies in, 948–951
pH levels and, 2017–2018
phycosphere of, 1056–1057
pigmented bacteria in, 945
platyhelminthes in, 1718–1719
point of entry (POE) water treatment devices, 1563–1575
potential for bacterial regrowth in, 314–315
pretreatment in, 2012–2015
propidium iodide (PI) in, 1068
protozoa and, 1718, 33, 2262–2267, 2601–2602
protozoan parasites in, disinfection of, 1066–1073
Pseudomonas, 2632–2639
rainwater roof catchment systems, 2674–2685

raw and SFBW quality parameters for, 2265
regrowth of bacteria in, 313–319, 499–504
resistance of bacteria in, 607–608, 625
reverse transcription polymerase chain reaction (RT-PCR) for, 1162–1164
roughing filters and, 2012–2013
Safe Drinking Water Act (SDWA), 2974–2975
Salmonella and, 2789–2802
sampling of, 2813
sedimentation in, 2015–2018, 2266
settling of microorganisms in, 1725
somatic coliphages in, 355–356, 377–378
source water protection and, 2967–2978
spent filter backwash water (SFBW), 2262–2267
stability of water in, 947
Streptococci in, 1264–1278
substratum and, 1055–1056
sulfate-reducing bacteria (SRB) and, 3098–3100
sulfur bacteria in, 3096–3104
surface energy of substratum and, 1055–1056
surface water immigration of microorganisms to, 1724
survival of microorganisms in, 1725
Total Coliform Rule (TCR) and, 905–907
ultrafiltration and, 2266
ultramicrobacteria in, 945
ultraviolet disinfection and, 1071, 1173, 3230–3235
vertebrates in, 1723
viruses in, 1160–1164, 3260–3268, 3288–3300
Water turnover, algae vs., 1193–1194
Waterborne diseases, 2340
aerobic endospores and, as measurement of, 140–149
Aeromonas and, 1091–1099
bioterrorism and, 779
Campylobacter and, 803–811
cholera and, 853–861
Cryptosporidium and, 650–657
Cyclospora and, 995–1001
disinfection and, 1067
Entamoeba and, 1136–1146
Enterococci in, 1264–1278
enteroviruses and, 1146–1156
Giardia and, 1469–1489
hepatitis, 1530–1540
high hydrostatic pressure (HHP) vs., 1561
human caliciviruses and, 1586–1598
Isospora and coccidiosis in, 1734–1737
Legionella and, 1788–1806
leptospirosis, 1806–1817
microsporidia and, 2065–2083
Norwalk-like viruses (NLVs) and, 2221–2235
pathogenic Escherichia coli and, 2337–2339
Pfiesteria and toxic Pfiesteria complex (TPC), 2431–2447
Pseudomonas and, 2632–2639
in rainwater roof catchment systems, 2681–2682
risk assessment and, 2749
rotavirus and, 2753–2773
Salmonella and, 2789–2802
Shigella and, 2865–2871
source water protection and, 2967–2978
in spas and hot tubs, 2979–2981
streams and, 3017
Streptococci in, 1264–1278
virus transport and removal in subsurface, 2094–2107
viruses and, 92–100, 2743, 3288–3300
Waterborne viruses, adenoviruses as, 92–100
Watersheds, stream microbiology, 3015–3024
Weathering and biodeterioration, 516–528, 3364–3389
acid degradation in, 517
algae and, 519–522, 524–525
alkaline degradation in, 517–518
alkoxysiloxanes and, 518
autotrophic bacteria and, 523
bacteria and, 523
biofilms and, 516
biological weathering and, 517
biopitting in, 518
cement/in cement and concrete, 523–525
chelation in, 517
chemical weathering and, 516–517
chemoorganotrophic bacteria and, 525
chemotrophic bacteria and, 523
cyanobacteria and, 519–522, 524–525
depolymerization in, 518
endolithic organism and, 517–528, 1105
epilithic organisms and, 517–528
extracellular polymeric substances (EPS) and, 518, 1227–1228
fungi and, 518–519, 524
lichens and, 522–523
in limestone, shale and sandstone, 518–523
lithotrophs and, 1827
nitric acid and, biogenic, 524
organic acid and, biogenic, 524–525
osmotic protectants and, 518
oxalic acid and, 524
patina in, 518
in silicon and silicates, 517–518
spalling in, 517
sulfate-reducing bacteria (SRB) and, 524
sulfuric acid and, biogenic, 524
Wells, sulfur bacteria, control, 3103
Wetlands (See also Marine/ocean environment; Marshes; Surface waters), 1316–1333, 3389–3401, 3401–3417
aerobic processes in, 3403–3405
anaerobic processes in, 3403–3405
biodegradation in, 3401–3417
biogeochemistry of, 3402–3405
carbonaceous biochemical oxygen demand (CBOD) in, 3391
catabolic activity in, 3411–3415
chemical oxygen demand (COD) in, 3391
dioxygenases in, 3412
enzyme activity in, 3410–3415
flooded soils and, 3403–3404

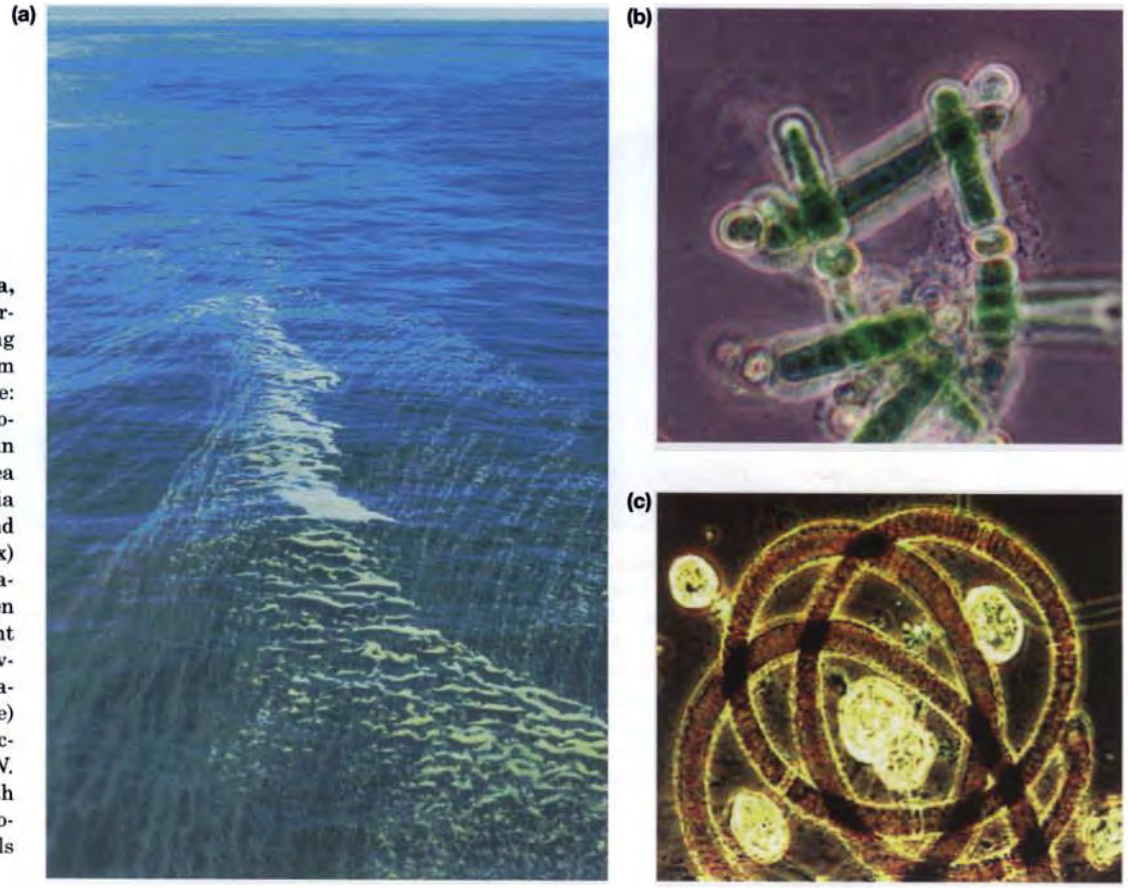
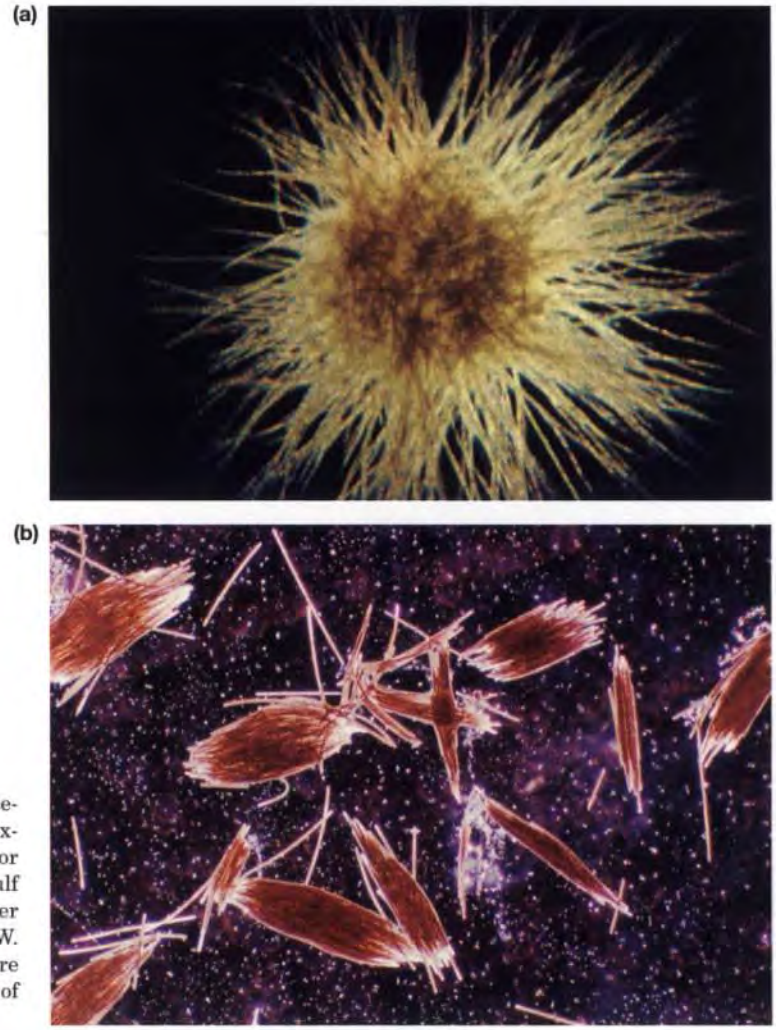
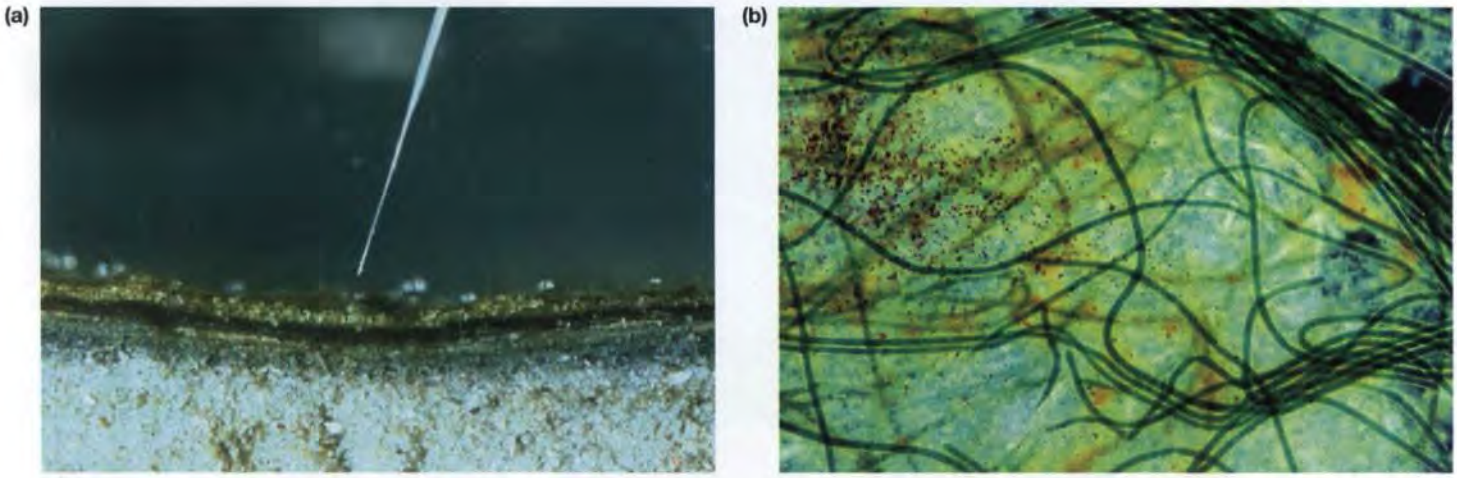
Aggregates and Consortia, Microbial, Figure 3. Microbial associations with bloom-forming cyanobacteria: (**a**) bacteria inside *Anabaeana spiroides* coils; (**b**) bacteria around *Gomphosphaeria* colonies; (c) bacteria on heterocyst of *Anabaeana oscillarioides*.



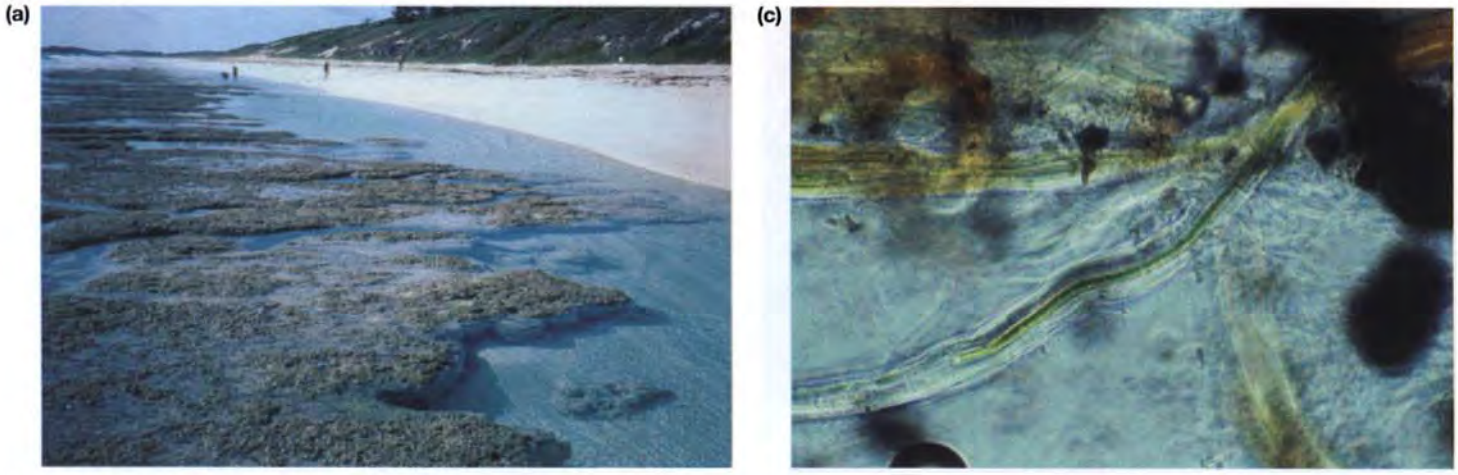
Aggregates and Consortia, Microbial, Figure 5. Observations of the N_2 fixing cyanobacterial bloom from *Nodularia* spp. Left-hand side: a *Nodularia*-dominated cyanobacterial bloom observed in the Gulf of Finland, Baltic Sea (photo courtesy of Pia Moisander). Upper right-hand side: photomicrograph (400x) of several *Nodularia* sp. filaments, showing the nitrogen fixing heterocysts (round, light green cells), neighboring heavily (green) pigmented vegetative (photosynthetically active) cells, as well as associated bacteria. Lower right: coiled *N. spumigena* aggregates with associated bacteria and protozoans present inside the coils (400x).



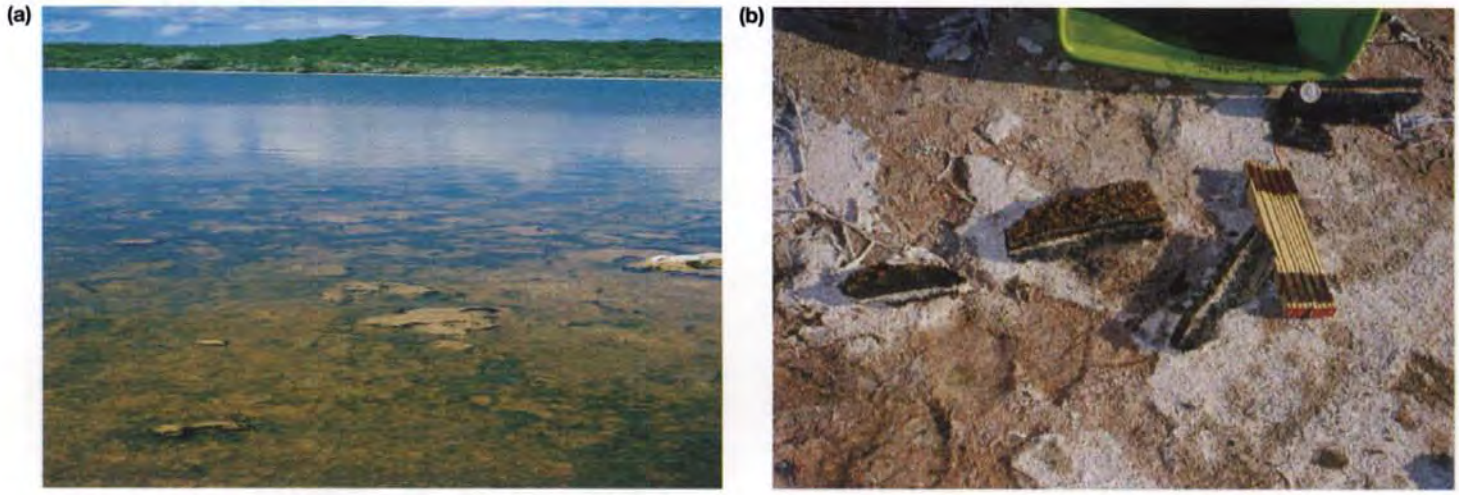
Aggregates and Consortia, Microbial, Figure 6. Surface-dwelling aggregates of the filamentous marine planktonic N_2 fixing cyanobacteria *Trichodesmium* spp. Upper frame: radial, or "puff"-shaped aggregates, sampled during a bloom in the Gulf Stream, W. Atlantic Ocean, off the coast of North Carolina. Lower frame: fusiform "tuft"-shaped aggregates sampled in the W. Atlantic Ocean near San Salvador Island, Bahamas. For more details on the N_2 fixing characteristics, and microbial ecology of these aggregates see Paerl (149).



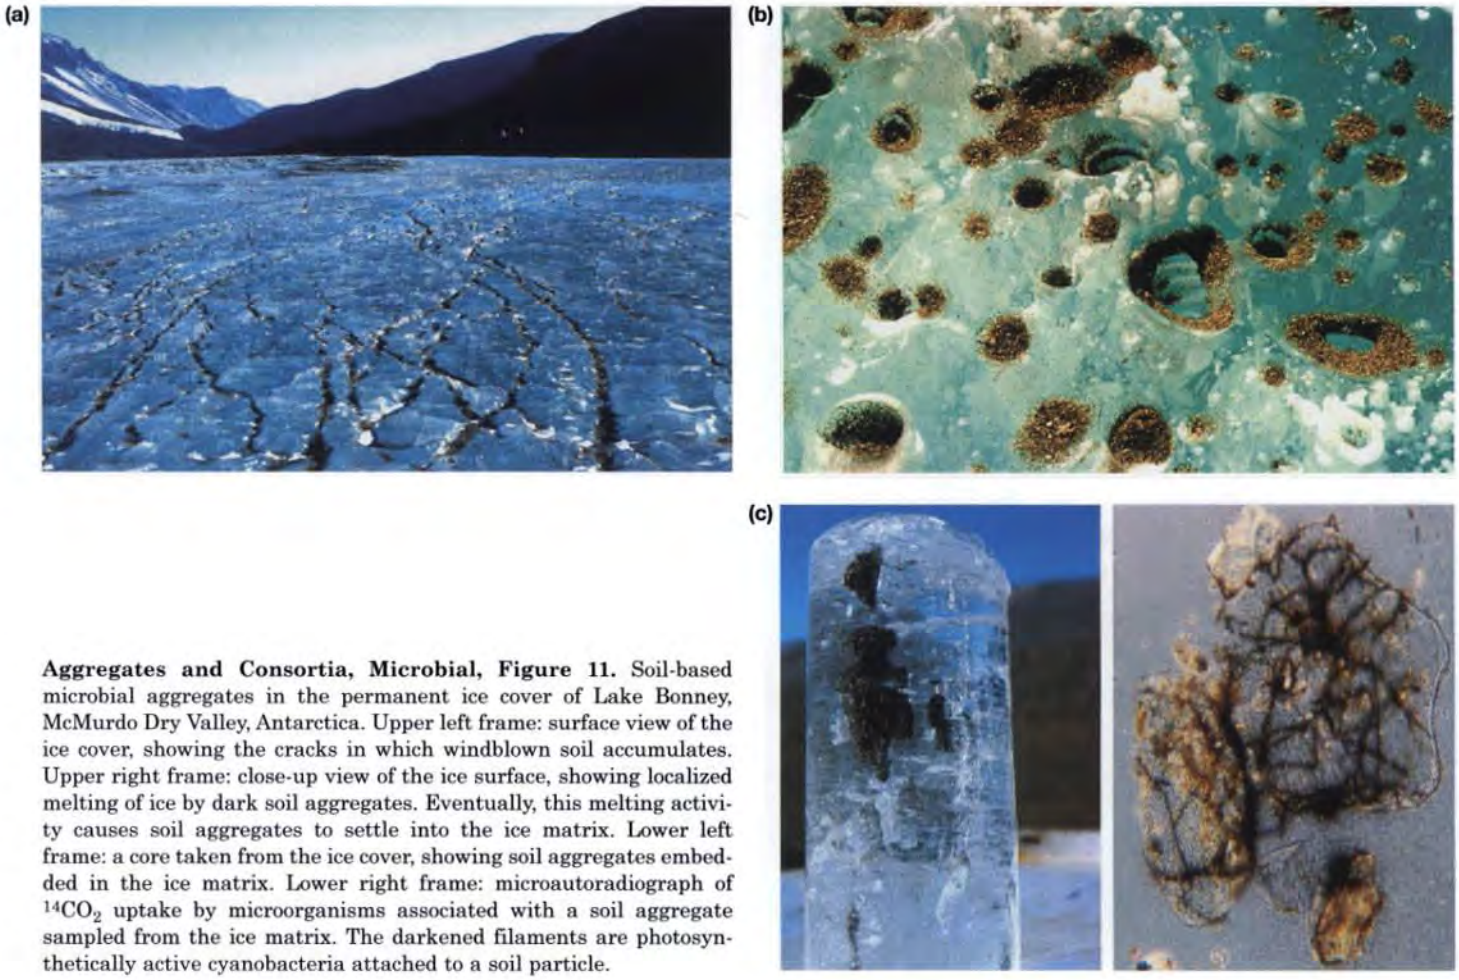
Aggregates and Consortia, Microbial, Figure 7. Laminated microbial mat obtained from the Bird Shoal, coastal North Carolina. As is the case with most marine intertidal mats, microalgal biomass and production is dominated by cyanobacteria. The cyanobacteria are concentrated in the upper, illuminated segment of the mat. The mat thickness is approximately 0.5 cm. Left frame: cross-section of the mat, showing distinct microbial laminations. Phototrophic cyanobacteria dominate the upper, euphotic zone of the mat. Below that is a layer composed of photosynthetic bacteria, cyanobacteria, and heterotrophic bacteria. The lowest layer contains obligate anaerobic heterotrophs, including sulfate-reducing bacteria. Methanogenic bacteria can also be found in this layer. The mat is situated on highly porous sands, which allow for rapid exchange of sweater and oxygen. Hence, the lighter oxygenated appearance of the lower sand layer. The tip (~100 μm diameter) of an oxygen microelectrode is shown for size reference. Right frame: photomicrograph of the mat matrix. Shown are nonheterocystous filamentous cyanobacteria (*Microcoleus chthonoplastes*) and a variety of bacteria, including microcolonies of purple photosynthetic bacteria (*Chromatium* sp.).



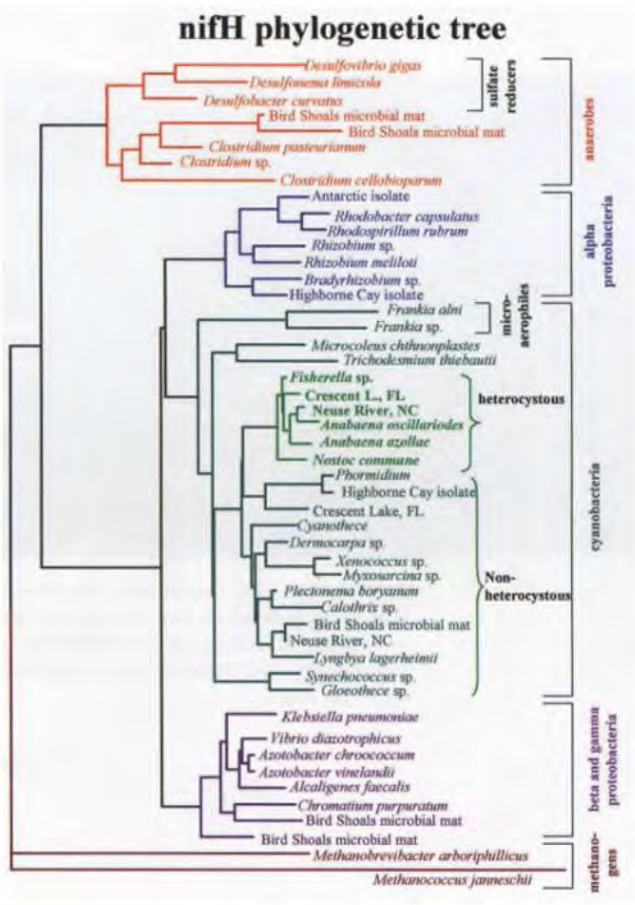
Aggregates and Consortia, Microbial, Figure 9. Stromatolitic mat communities on the Exuma Islands, Bahamas. Upper frame: view of the subtidal stromatolites situated off a beach at Highborne Cay, Exumas. Lower frame: cross-sectional view of a laminated ($CaCO_3$) stromatolite, showing the cyanobacteria-dominated mat residing on the surface of the stromatolite. Right frame: photomicrograph, showing the aggregated filamentous cyanobacteria (*Schizothrix* sp.) comprising a bulk of the surface mat.



Aggregates and Consortia, Microbial, Figure 10. Left frame: hypersaline (100 to 160 psu) Salt Pond, located on San Salvador Island, Bahamas. The entire bottom of this lake is dominated by laminated mats dominated by filamentous, nonheterocystous cyanobacteria (*Microcoleus* sp., *Lyngbya* sp., and *Oscillatoria* sp.). Right frame: close-up side view pieces of laminated mat excised from the Pond.



Aggregates and Consortia, Microbial, Figure 11. Soil-based microbial aggregates in the permanent ice cover of Lake Bonney, McMurdo Dry Valley, Antarctica. Upper left frame: surface view of the ice cover, showing the cracks in which windblown soil accumulates. Upper right frame: close-up view of the ice surface, showing localized melting of ice by dark soil aggregates. Eventually, this melting activity causes soil aggregates to settle into the ice matrix. Lower left frame: a core taken from the ice cover, showing soil aggregates embedded in the ice matrix. Lower right frame: microautoradiograph of $^{14}CO_2$ uptake by microorganisms associated with a soil aggregate sampled from the ice matrix. The darkened filaments are photosynthetically active cyanobacteria attached to a soil particle.



Aggregates and Consortia, Microbial, Figure 13. Phylogentic tree of nitrogen fixing microbial groups, many of which participate in consortial associations. The tree was based on analysis of a 326 base pair nucleotide fragment of the *nifH* gene, which encodes for the highly conserved dinitrogenase reductase subunit of nitrogenase, the N_2 fixing enzyme complex. The tree was constructed by the neighbor-joining method and bootstrap values greater than 50% are given above or beside the corresponding nodes.

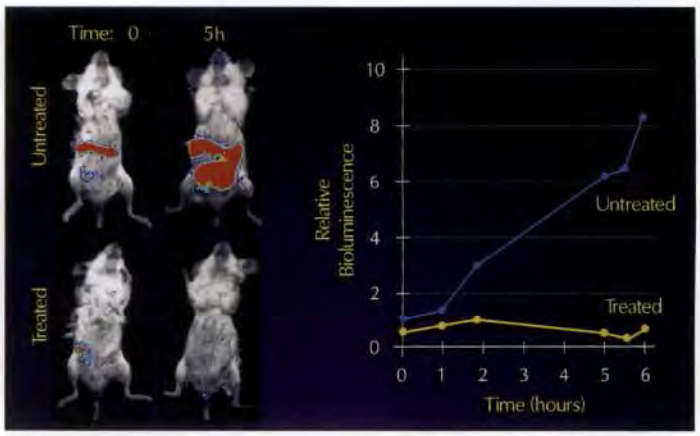
Biodeterioration of Mineral Materials, Figure 8. Intense black discoloration caused by growth of mainly mitosporic fungi and cyanobacteria on the east-facing painted wall of a church in Ouro Preto, Brazil.

Bioleaching of Metals, Figure 1. The Rio Tinto, Spain, passing through the historic mining area. Note the ochre-colored water, which is reported to have dissolved ferric iron concentrations more than 2 g/L (1).

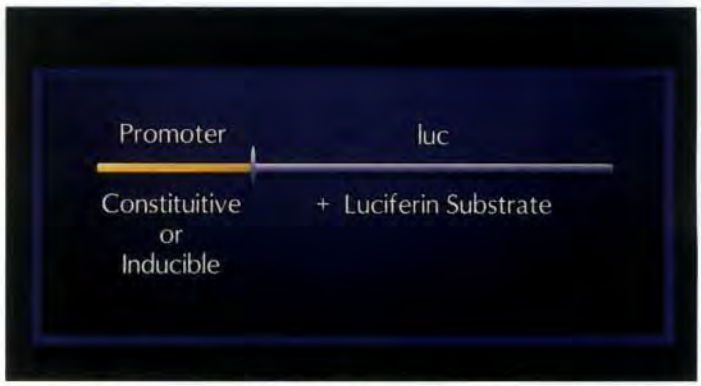
Bioleaching of Metals, Figure 2. A view of the Roman-era iron mines at Parys Mountain, Anglesey, Wales.

Bioleaching of Metals, Figure 6. One of the three biooxidation pretreatment heaps measuring approximately 1,000 by 500 feet, with ore stacked to 30 feet, containing 709,000 tons of low-grade refractory ore. Courtesy of Dr. J. Brierley, Newmont Mining Corporation.

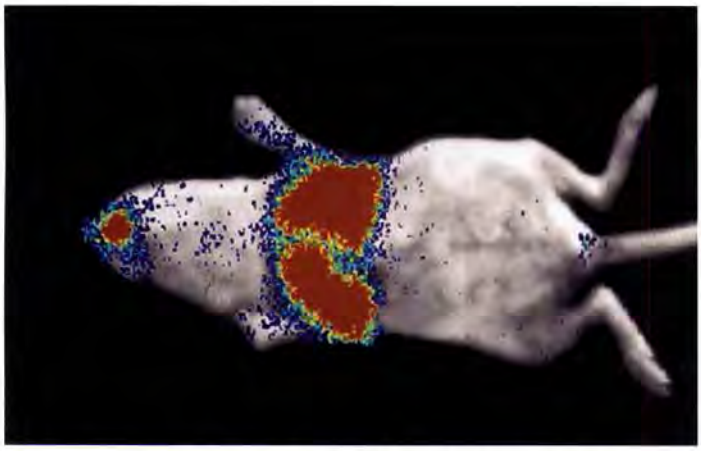


Bioluminescence Methodology, Figure 1. GI infection/Salmonella. The pseudocolor image is a color depiction of the intensity and quantity of photons with red being most intense and violet least intense. Untreated and treated mice are depicted at time zero (eight days after oral inoculation) with SL1344 lux *S. typhimurium,* but before treatment with ciprofloxacin. The same mice were imaged five and a half hours after treatment with ciprofloxacin (untreated control-received injection of phosphate-buffered saline). The graph shows relative bioluminescence intensity measured from the abdominal area at the time after treatment for both treated and untreated animals.

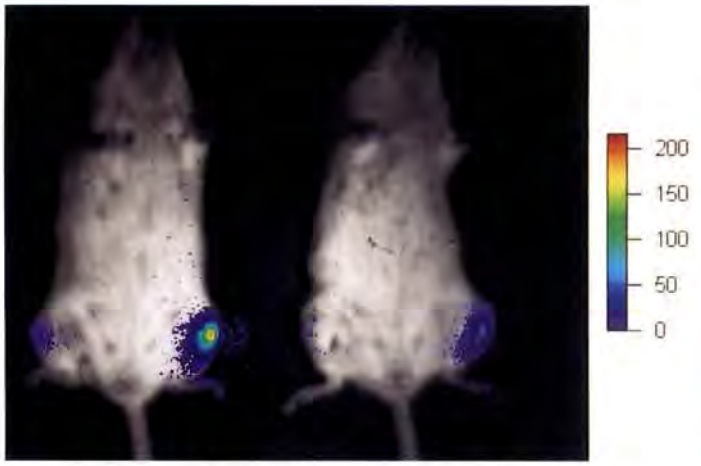
Bioluminescence Methodology, Figure 2. Prokaryotic Expression. For expression of light from prokaryotic cells, a construct is used that includes the *lux* operon from *P. luminescens* is an appropriate gram-negative or gram-positive plasmid vehicle. More recent constructs include transposons for chromosomal integration. Expression of the *luc* gene from the North American firefly may also be used in prokaryotes as long as the luciferin substrate is administered.



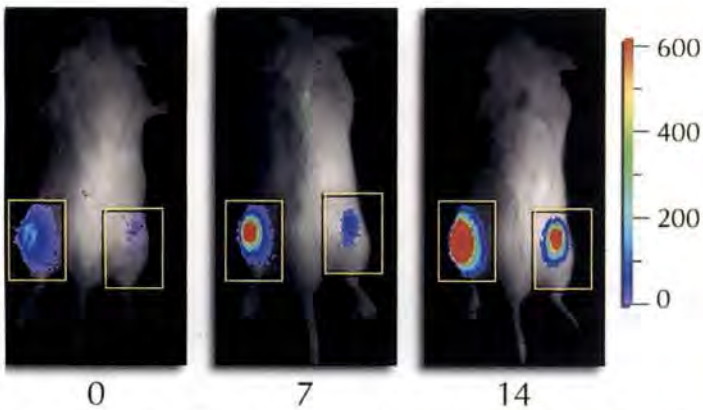
Bioluminescence Methodology, Figure 3. Eukaryrotic Expression. Expression of light from Eukaryrotic cells is accomplished with the pGL3 vector (Promega) containing the *luc* gene of the North American firefly regulated by an SV40 viral promoter. Luciferin is administered introperitoneally as the substrate for the enzymatic reaction.



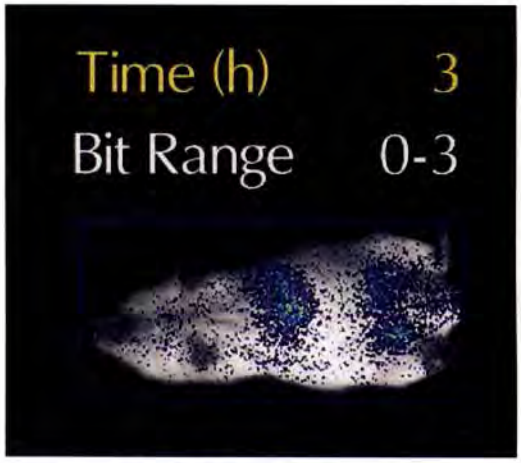
Bioluminescence Methodology, Figure 4. Lung Model. Neonatal mice (under two weeks of age) are susceptible to lung infection following oral inoculation with *S. typhimurium* SL1344 lux. A nasopharangeal infection is common in both adults and neonates from this mode of inoculation.



Bioluminescence Methodology, Figure 5. Soft tissue thigh model *Lux* tagged *E. coli* are injected at 10^4 bacteria/mL (right thigh) and 10^5 bacteria/mL (left thigh). Bacteria can then be quantified noninvasively with and without antibiotic treatment.



Bioluminescence Methodology, Figure 6. Labeled tumor cells. Labeled NIH 3T3 cells were injected with matrigel at zero time [10^4 cells (right thigh) and 10^5 cells (left thigh)] and mice were imaged between 7 and 14 days to monitor the increase in cell number, as demonstrated by the increase in red pixels of the pseudocolor image.



Bioluminescence Methodology, Figure 7. Transgenic animal exposed to heavy cadmium. A mouse line transgenic for a cadmium-regulated element, the hemooxygenase promoter, demonstrates in vivo monitoring of cadmium induction of *luc* in front of the *luc* gene. 10 mM cadmium was delivered IP and the mouse was imaged at zero and three hours. The three-hour time point with a camera sensitivity set at a bit range of zero to three is shown here.

Desert Environments — Soil Communities in Cold Deserts, Figure 2. View in Wright Valley from the helicopter — a landscape typical of the Dry Valleys. Photograph by Wolf Vladimir Vishniac.

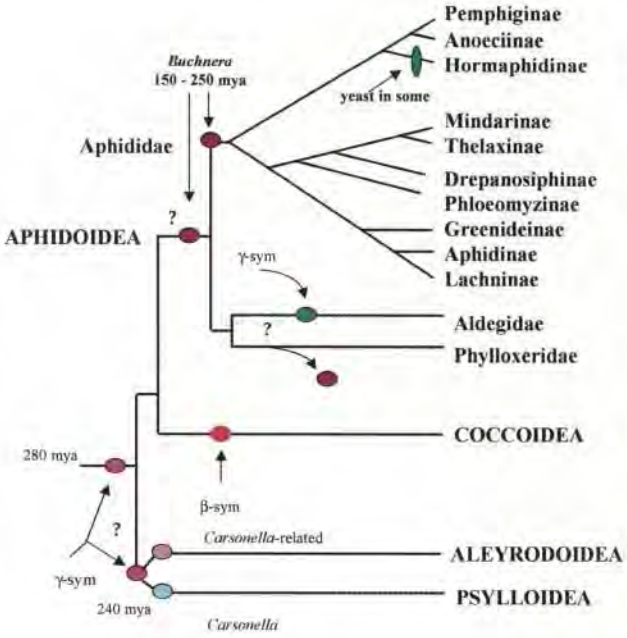
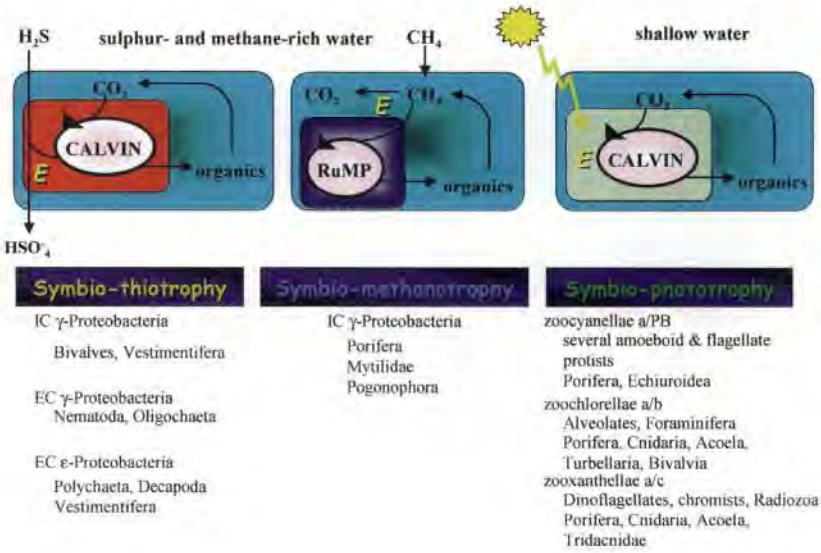
Endosymbiosis in Ecology and Evolution, Figure 1. Terminology. Schematic drawing of a cross-section of a multicellular host to illustrate the relative position of symbionts. Ectosymbionts (at right) are positioned on the external surfaces of the host body, on the ectoderm, or on the intestinal cavity. Endosymbionts (at left) may be extracellular, or in other words, located between cells of tissues or within the host body fluids (e.g., the blood), or the endosymbionts may be harbored within the host cells, free into the cytoplasm, or enclosed in a membrane (symbiosome).

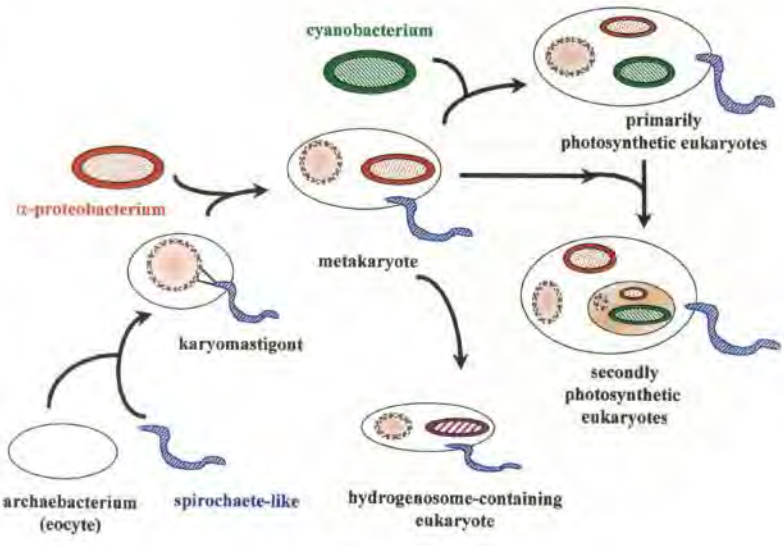


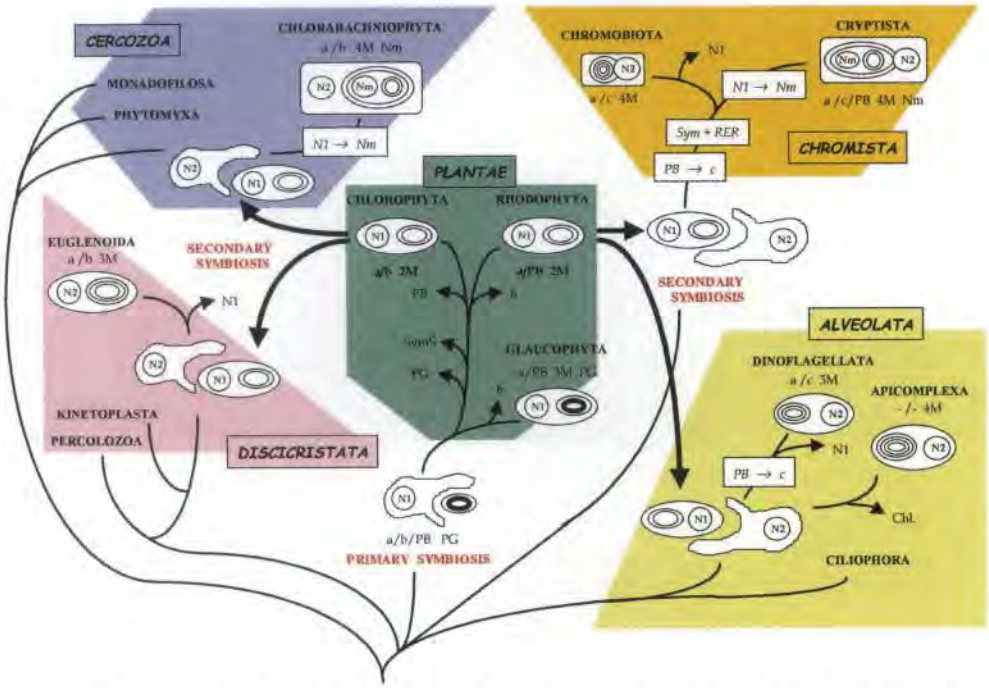
Endosymbiosis in Ecology and Evolution, Figure 2. Phylogeny of Sternorrhyncha and origin of P-symbionts. Dendrogramm showing the evolutionary history of the four superfamilies (in capitals) of the suborder Sternorrhyncha (order Homoptera). For the superfamily Aphidoidea the three families are indicated, and for the family Aphididae the subfamilies are also indicated. Circles indicate the origin of the infection by the primary symbionts, with the estimated time in million of years ago (mya). Extracellular yeasts have replaced *Buchnera* in the tribe Cerataphidini within the subfamily Hormaphidinae. Members of the family Aldegidae possess a γ-symbiont, but it is not known whether it belongs to *Buchnera*, whereas the family Phylloxeridae is lacking of symbiont, perhaps lost. Coccoidea harbor both γ- and β-symbionts, but the β-symbionts seem to be the P-symbionts. They form a monophyletic clade in molecular phylogenies based on 16S rDNA analyses, whereas the γ-symbionts appear polyphyletic. Members of the superfamilies Aleyrodoidea and Psylloidea harbor closely related γ -symbionts, perhaps evolving from a unique γ -symbiont infecting a common ancestor.



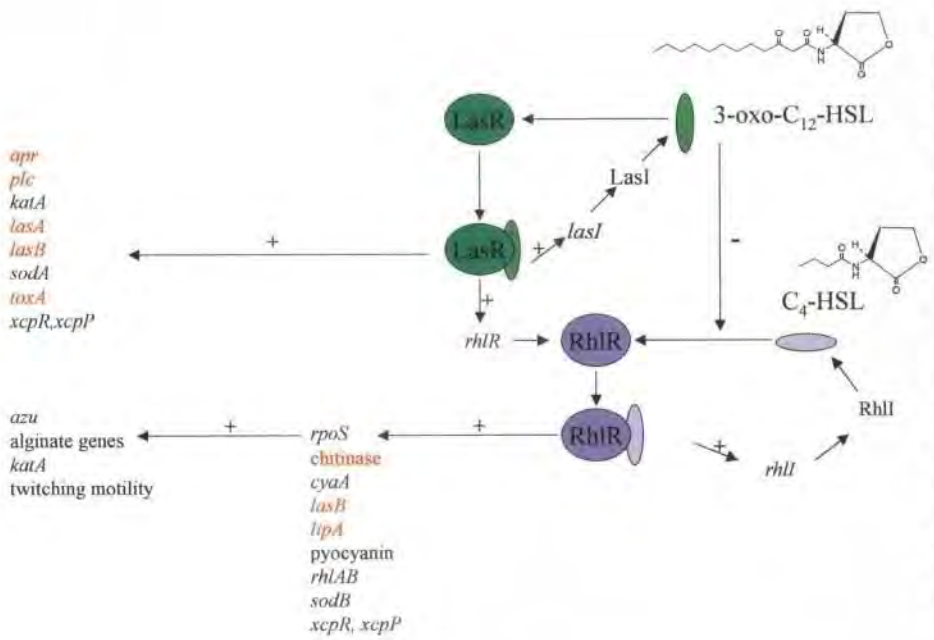
Endosymbiosis in Ecology and Evolution, Figure 3. Symbiotrophic animals.

Endosymbiosis in Ecology and Evolution, Figure 5. Serial endosymbiotic theory. The ancestral eukaryote cell is supposed to have originated from an archabacterium (eocyte), perhaps as a result of a merger with an eubacterium (spirochaete), as a motility symbiosis, or as a failed predation. A system of internal membranes has been developed to include all the genetic materials, giving rise to the nucleus, whereas the motility symbiosis reached a high integration, giving rise to the eukaryotic flagellum. The cell at this step is called a *kariomastigont*. At one moment a novel episode of endosymbiosis with an α-proteobacterium appears, giving rise to the mitochondrion. The cell at this step is called a *metakaryote*. Some metakaryotes adapt several times and independently to anaerobic habitats changing the mitochondrion into a hydrogenosome. Endosymbiosis with a cyanobacterium has allowed the emergence of photosynthetic eukaryotes, that form at the present the kingdom of Plantae. Successive episodes of secondary symbioses between a plant and a phagotrophic metakaryote originate the secondarily photosynthetic eukaryotes (euglenoids, chlorarachniophytes, chromist algae and some alveolates). Whereas the first steps of the evolution of the eukaryotic cell are still disputed, several theories have been proposed, the origin and evolution of mitochondria and plastids are now widely accepted.

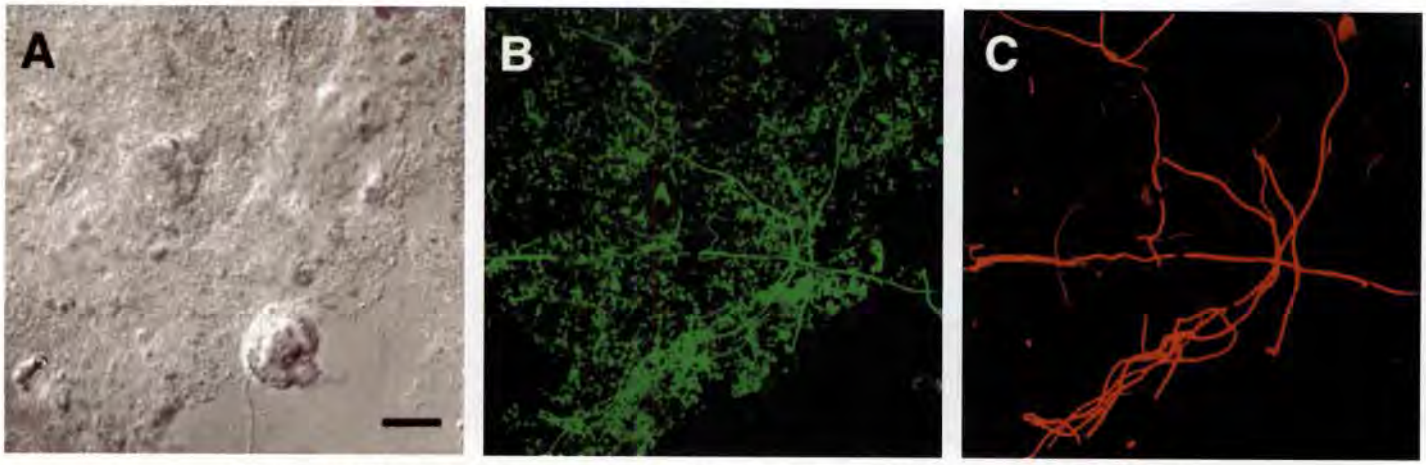




Endosymbiosis in Ecology and Evolution, Figure 6. Origin and evolution of the eukaryotic algae. The five lineages of eukaryotes containing photosynthetic members are indicated: Alveolata, Cercozoa, Chromista, Discicristata, and Plantae (according to Cavalier-Smith 1998 (111)), with the pigment composition (a, b, c and PB, for chlorophylls *a, b, c,* and phycobilins, respectively). The number of plastid membranes is also indicated (2 M, 3 M, 4 M, for two, three, or four membranes), as well as the eventual presence of peptidoglycan (PG), and the retention of the nucleus of the primary alga as nucleomorph (Nm). N1 = nucleus of the primary alga; N2 = nucleus of the secondary alga. In squares are indicated the major transitions: substitution of phycobilins with chlorophyll *c* (PB → c), degeneration of the primary alga nucleus N1 into a nucelomorph (N1 → Nm), fusion of the symbiosome membrane with the rough endoplasmic reticulum (Sym + RER). A single event of primary symbiosis between a phagotrophic eukaryote and a cyanobacterium has led to the establishment of the kingdom of Plantae, the only primarily photosynthetic eukaryotes. Lineages within the kingdom Plantae then diverged by differential losses of plastid pigments. Episodes of secondary symbioses (large arrows in bold) between a green alga or a red alga and some phagotrophic protists, have led to the euglenophytes and chlorarachniophytes, and to the dinoflagellates and chromist algae, respectively. The non-photosynthetic apicoplast of Apicomplexa seems to have originated from a green alga. In the Chromista, both Cryptista and Chromobiota harbor members without plastids, probably because of secondary loss. Cryptista and some Chromobiota (e.g., Eustigmatophycea) also possess phycobilins.



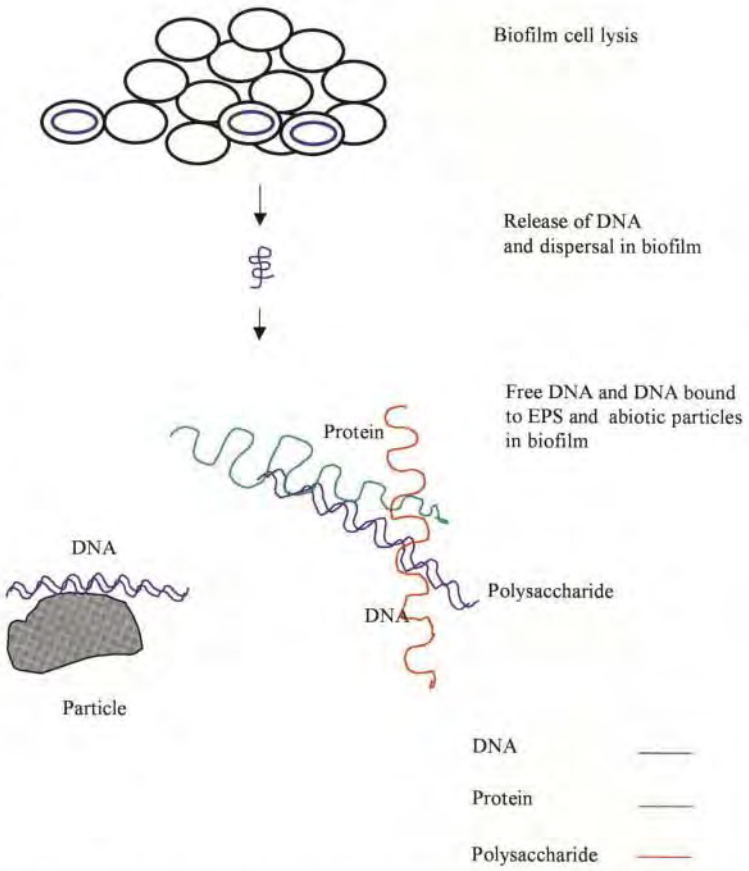
Extracellular Enzymes in Biofilms, Figure 2. Quorum-sensing regulation of gene expression in *P. aeruginosa*. A plus (+) sign indicates positive regulation, a minus (–) sign indicates negative regulation. The genes encoding extracellular enzymes are printed in red. The main regulatory system consists of the regulator LasR and the autoinducer synthetase LasI, which directs the synthesis of 3-oxo-C_{12}-HSL. The LasR-3-oxo-C_{12}-HSL complex positively regulates the expression of genes *aprA* (encoding alkaline protease), *plcN* (phospholipase C), *katA* (catalase), *lasA* (staphylolytic elastase), *lasB* (elastase), *sodA* (superoxide dismutase), *toxA* (exotoxin A), *xcpR* and *xcpP* (proteins of the type II secretion system), and *rhlR* (the regulator RhlR). The RhlR-C_4-HSL complex positively regulates the expression of genes *rpoS* (stationary-phase sigma factor), a chitinase gene, *lasB* (elastase), *lipA* (lipase), *rhlAB* (rhamnosyltransferase), *sodB* (superoxide dismutase), and *xcpR* and *xcpP* (proteins of the type II secretion system). The sigma factor RpoS itself positively controls the expression of genes *azu* (azurin), *katA* (catalase), and the genes involved in the biosynthesis of alginate and type IV pili required for twitching motility.



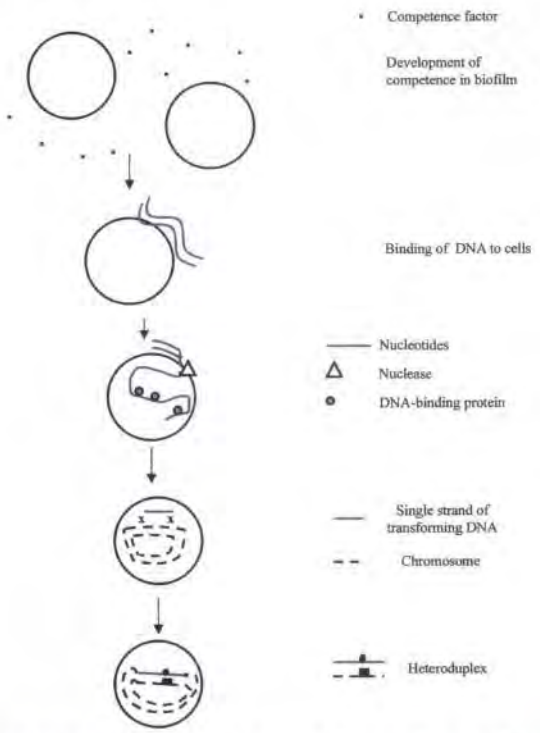
Filamentous Bacteria in Activated Sludge: Current Taxonomic Status and Ecology, Figure 4. In situ identification of Thiothrix/Eikelboom Type 021N in activated-sludge flocs using confocal laser scanning microscopy. (**a**) Transmission micrograph. (**b**) FISH using probe GAM42a specific for the γ-subclass of Proteobacteria. (**c**) FISH with probe G123T specific for Thiothrix/Eikelboom Type 021N (8). Bar represents 20 μm. Micrographs were recorded by Matthias Horn.

Fungi in Marine/Estuarine Waters, Figure 1. Typical deposit of ejected ascospores of two species of loculoascomycetes from naturally decaying smooth cordgrass leaf blades of Georgia saltmarshes (9). The smaller (about 7 μm wide), hyaline, 2-celled spores are of *Mycosphaerella* sp. 2 [Kohlmeyer and Kohlmeyer (31)] (Dothideales), and the larger (about 11 μm wide), dark, 4-celled spores are of *Phaeosphaeria spartinicola* (Pleosporales). The spores were explosively expelled at a rate of hundred per square centimeters per hour, onto a capture glass placed in front of a wetted decaying leaf, and many have germinated to hyphae. These two species are nearly always intimately mixed in the leaf-decay system, and may be mutualists (9,30,32).

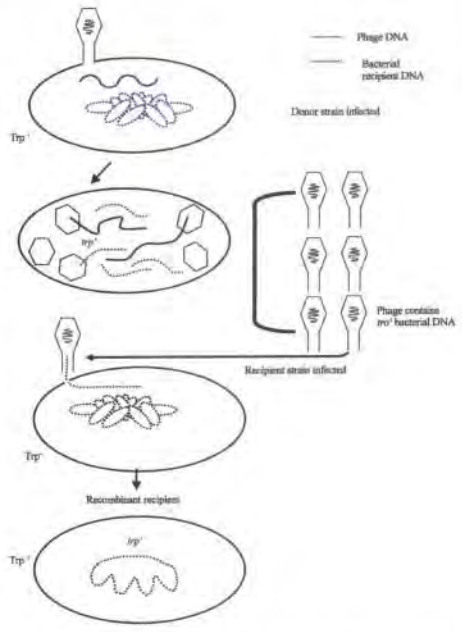
Fungi in Marine/Estuarine Waters, Figure 2. Zoosporangium of the cosmopolitan marine oomycote *H. vesicula* (about 40 μm wide at the widest point) (4,36). This is the "delicate" variety; see References 11 and 37 for photos of the "robust" variety. Species of *Halophytophthora* are common and rapid pervaders of fallen mangrove leaves (34,36,38,39). At full maturity, the inverted cone visible at the tip of the sporangium (left end) everts into a delicate, ephemeral release vesicle, and the biflagellate zoospores seen crammed against one another in the sporangium swim away through the vesicle.



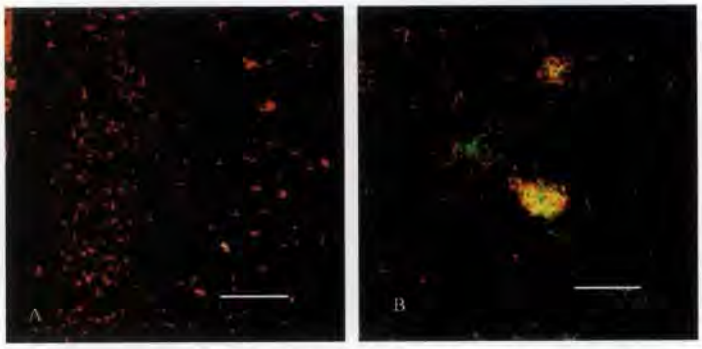
Gene Exchange in Biofilms, Figure 5. Conceptual view of the fate of DNA after cell lysis in a biofilm, depicting the first three steps in natural transformation (see text for details). The released DNA is either bound to biofilm constituents such as EPSs, cells, and abiotic particles or present as free DNA. See Figures 6 and 7 for uptake of DNA and internal processing by cells.



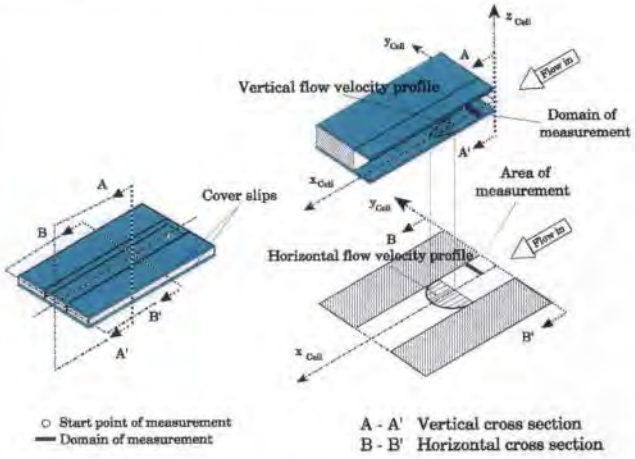
Gene Exchange in Biofilms, Figure 6. Uptake by and integration of transforming DNA into the chromosome of *Streptococcus pneumoniae*. Competence factors accumulate as the cells reach a high density. Double-stranded DNA binds to the cell and one strand is degraded. The remaining single strand replaces the strand of the same sequence in the chromosome, creating a "heteroduplex," in which one strand comes from the donor and one comes from the recipient. *Source:* Redrawn after Ref. 11 with permission from the American Society for Microbiology, © 1997.



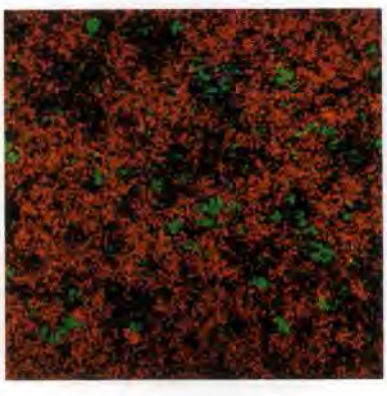
Gene Exchange in Biofilms, Figure 8. An example of generalized transduction. A phage infects a Trp^+ bacterium, and in the course of packaging DNA heads, the phage mistakenly packages some bacterial DNA containing the trp region instead of its own DNA into a head. In the next infection, this transducing phage infects the Trp^+ bacterial DNA instead of phage DNA into the Trp^- bacterium. If the incoming DNA recombines with the chromosome, a Trp^+ recombinant transductant may arise. Only one strand of the DNA is shown. *Source:* Redrawn after Ref. 11 with permission from the American Society for Microbiology, © 1997.



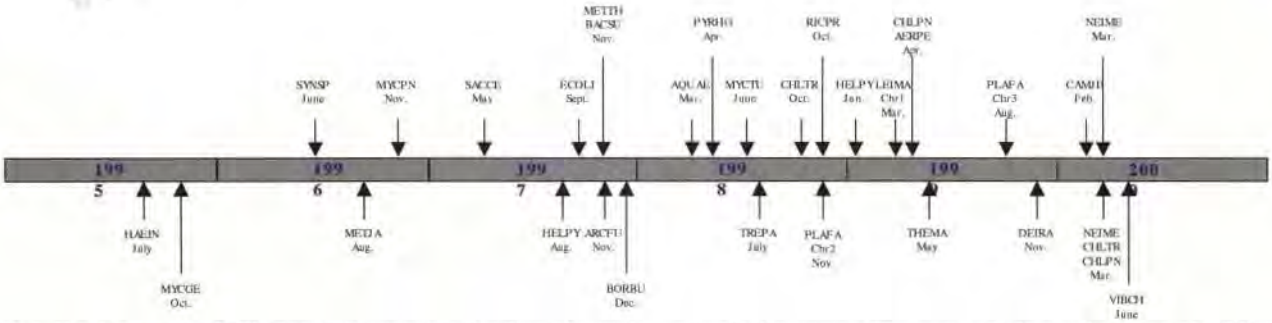
Gene Exchange in Biofilms, Figure 9. Transconjugant cells in a biofilm of *R. metallidurans* AE104 cultivated under nutrient-rich (**a**) and nutrient-poor (**b**) conditions. Recipient cells were grown as a confluent biofilm on microscope slides and exposed to high densities of donor and helper cells to allow transfer of the mob^+ plasmid, which carried the gene for the GFP. CLSM signals were collected consecutively and stored as gray scale images. AE104 cells were detected by FISH with a TRITC-labeled rRNA-directed oligonucleotide probe specific to the β-proteobacteria subgroup. With computer-assisted coloring, recipient AE104 cells were assigned the color red. Donor *E. coli* strain GM16 cells were detected based on the fluorescence emitted by GFP and are depicted in green. Transconjugants emitted both green light owing to GFP and red light owing to hybridization with the TRITC-labeled rRNA-directed oligonucleotide probe and are shown in yellow. Bar, 25 µm. *Source:* after Ref. 70; reprinted with permission from the American Society for Microbiology, © 1998.



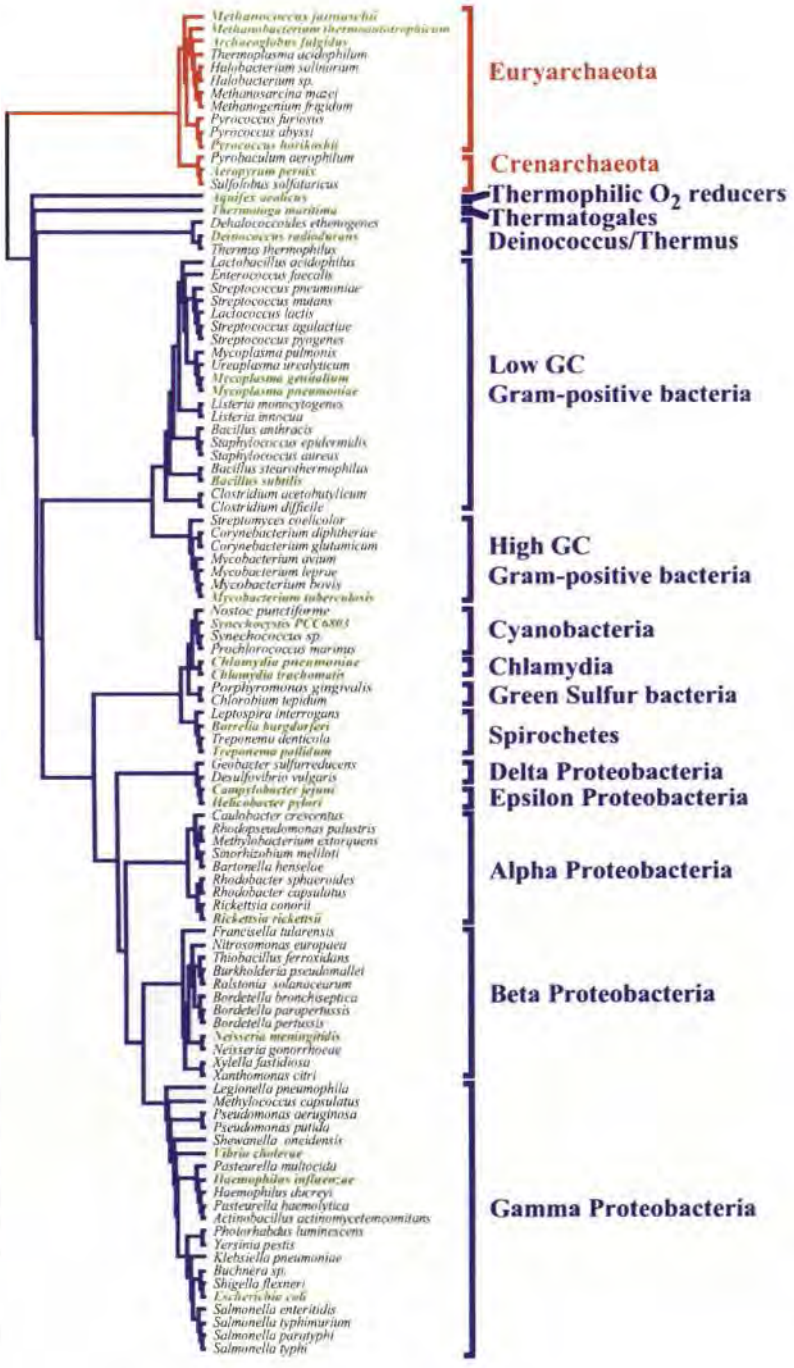
Gene Exchange in Biofilms, Figure 10. Schematic view of the flow cell indicating fluid velocity profiles and domain of measurement typically used to investigate gene tranfer events. *Source:* after Ref. 68; reprinted with permission from the American Society for Microbiology, © 1998.



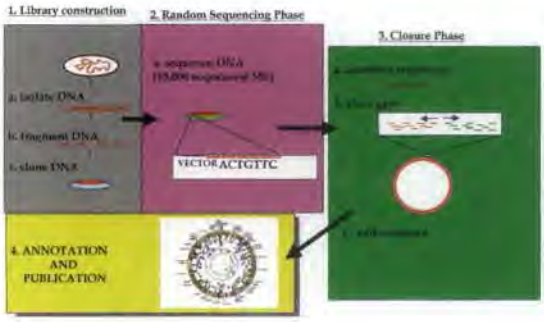
Gene Exchange in Biofilms, Figure 11. Transformant cells in an 18-hour biofilm of *Acinetobacter* sp. BD413 grown in a flow cell and exposed to 1 µg plasmid DNA/mL for 20 minutes. Cells were visualized with the general nucleic acid stain Syto 60 (Molecular Probes, Eugene, Oregon) and were detected with an LSM410 confocal laser scanning microscope (Zeiss, Jena, Germany). Transformants were detected by the emission of light owing to the GFP encoded by the plasmid, pGAR1.



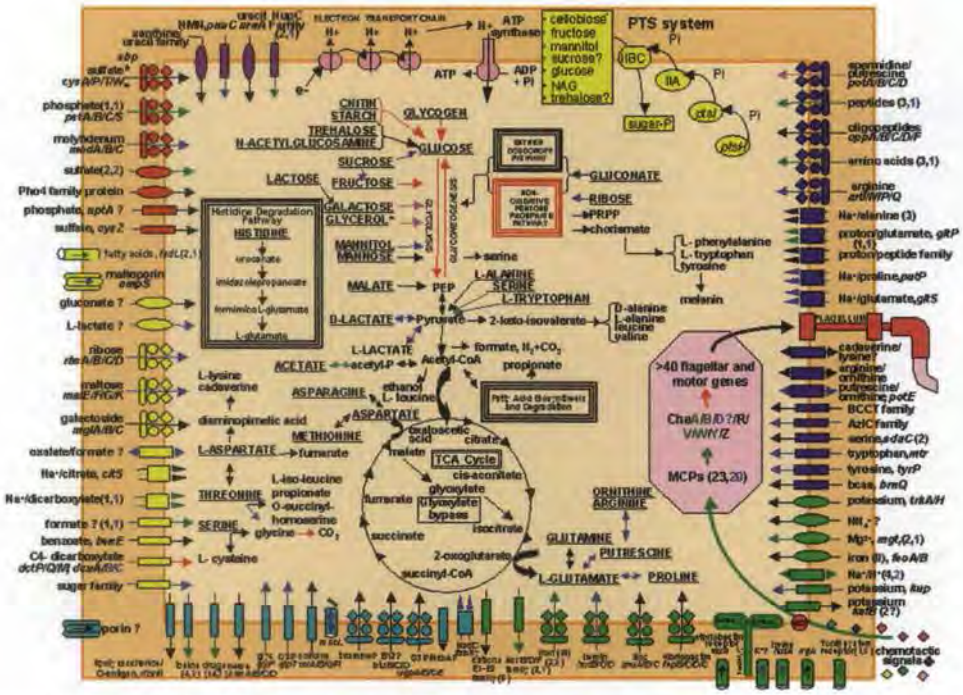
Genomics, Environmental, Figure 1. Sequencing timeline of complete microbial genomes. The arrows indicate the dates of publication for each of the completed genomes. The organism abbreviations are as follows: HAEIN, *Haemophilus influenzae*; MYCGE, *Mycoplasma genitalium;* SYNSP, *Synechocystis* PCC6803; METJA, *Methanococcus jannaschii;* MYCPN, *Mycoplasma pneumoniae;* SACCE, *Saccharomyces cerevisiae;* HELPY, *Helicobacter pylori;* ECOLI, *Escherichia coli;* METTH, *Methanobacterium thermoautotrophicum*; BACSU, *Bacillus subtilis;* ARCFU, *Archaeglobus fulgidus;* BORBU, *Borrelia burgdorferii;* AQUAE, *Aquifex aeolicus;* PYRHO, *Pyrcoccus horikoshii;* MYCTU, *Mycobacterium tuberculosis;* TREPA, *Treponema pallidum;* CHLTR, *Chlamydia trachomatis;* RICPR, *Rickettsia prowazekii;* PLAFA, *Plasmodium falciparum;* LEIMA, *Leishmania major;* CHLPN, *Chlamydia pneumoniae;* AERPE, *Aeropyrum pernix;* THEMA, *Thermotoga maritima;* DEIRA, *Deinococcus radiodurans;* CAMJE, *Campylobacter jejuni;* NEIMA, *Neisseria menigiditis;* VICHO, *Vibrio cholerae.*



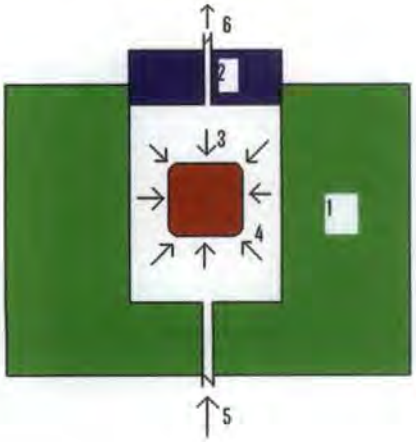
Genomics, Environmental, Figure 2. Phylogenetic tree based on 16S-rRNA sequences for each of the prokaryotic organisms whose complete genome sequence has been published (highlighted in green) and other organisms for which genome sequencing projects are underway. (*http://www.tigr.org/tdb/mdb/mdb.html*). The major prokaryotic phylogenetic groupings are indicated to the right of the tree. The *archaea* are indicated in red and the *eubacteria* are indicated in blue. The phylogenetic tree was derived from sequences from the Ribosomal Database project (RDP) (*http://www.cme.msu.edu/RDP/html/index.html*) using Phylip (52) for tree construction. In some instances where the rRNA sequence of the particular strain was not available, the rRNA of a close relative was substituted.



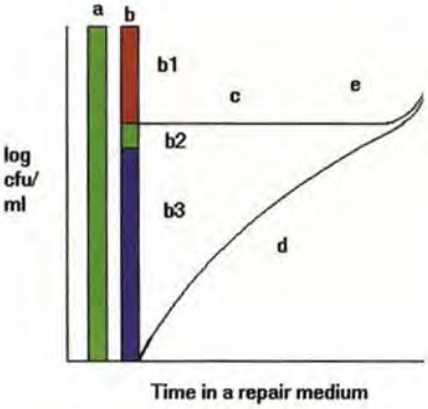
Genomics, Environmental, Figure 3. Strategy for random shotgun sequencing of microbial genomes. The first phase involves construction of small and large insert libraries with DNA from the organism of interest. The second phase involves the sequencing of random clones from the libraries to a predetermined level of coverage. The third phase involves assembling the random sequences into contiguous segments and subsequent gap closure. Finally, the completed sequence is annotated and published.



Genomics, Environmental, Figure 4. Reconstruction of transport and metabolism of *V. cholerae* on the basis of the annotated genome sequence. Pathways for energy production and the metabolism of organic compounds, acids and aldehydes are shown. Transporters are grouped by substrate specificity: cations (green), anions (red), carbohydrates (yellow), nucleosides, purines, and pyrimidines (purple), amino acids/peptides/amines (dark blue, and other (light blue). Question marks associated with transporters indicate a putative gene, uncertainty in substrate specificity, or direction of transport. Permeases are represented as ovals, ABC transporters are shown as composite figures of ovals, diamonds, and circles, porins are represented as three ovals, the large-conductance mechanosensitive channel is shown as a gated cylinder, other cylinders represent outer membrane transporters or receptors; all other transporters are drawn as rectangles. Export or import of solutes is designated by the direction of the arrow through the transporter. If a precise substrate could not be determined for a transporter, no gene name was assigned and a more general common name reflecting the type of substrate being transported was used. Gene location on the two chromosomes, for both transporters and metabolic steps, is indicated by arrow color: all genes located on the large chromosome (black), all genes located on the small chromosome (blue), all genes needed for the complete pathway on one chromosome, but a duplicate copy of one or more genes on the other chromosome** (purple), required genes on both chromosomes (red), complete pathway on both chromosomes (green). Gene numbers on the two chromosomes are in parenthesis and follow the color scheme for gene location. Substrates underlined and capitalized can be used as energy sources. Abbreviations: PRPP, phosphoribosyl-pyrophosphate; PEP, phosphoenolpyruvate; PTS, phosphoenolpyruvate-dependent phosphotransferase system; ATP, adeosine triphosphate; ADP, adenosine diphosphate; MCP, methyl-accepting chemotaxis protein; NAG, N-acetylglucosamine; G3P, glycerol-3-phosphate; GLYC, glycerol; NMN, nicotinamide mononucleutide. *Because *V. cholerae* does not use cellobiose, we expect this PTS system to be involved in chitobiose transport. **Complete pathways, except for glycerol, are found on the large chromosome.

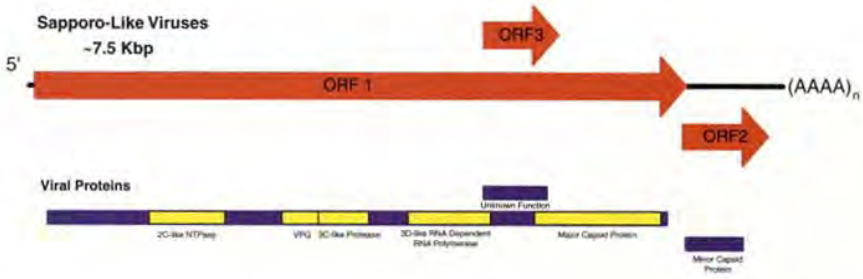


High Hydrostatic Pressure: Microbial Inactivation and Food Preservation, Figure 1. Schematic diagram of a high hydrostatic pressure vessel (7). The food package (4) is put in liquid (3) inside the chamber (1), which is closed at the top with a movable cylinder (2) with an opening and a valve (6) to remove air and excess liquid prior to pressurization. Once the chamber is closed, excess liquid is pumped through the inlet tube (5) that has a valve which closes when the desired pressure level is reached. The pressure is maintained constant during pressurization time, at the end of which the inlet valve (5) opens and the excess liquid is removed from the chamber by gravity. The liquid in the chamber can be heated by installing a heating coil around the vessel (7). The process is clean, energy efficient, and requires relatively less space compared with other food-processing methods.

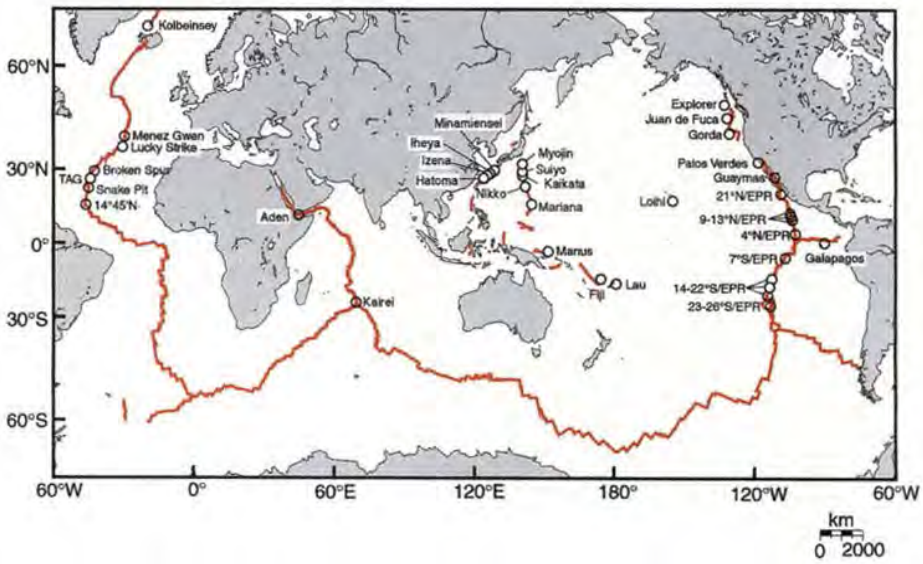


High Hydrostatic Pressure: Microbial Inactivation and Food Preservation, Figure 2. Schematic presentation of the effect of pressurization of a normal bacterial cell suspension (**a**) leading to production of three subpopulations (**b**), namely, dead cells (**b1**), normal cells (**b2**) and sublethally injured cells (**b3**). During subsequent incubation of the cells in a favorable environment for a period, the total survivor counts (b1+ = *hboxb2* = c) in a nonselective agar medium remain unchanged, suggesting no cell multiplication. However, the counts on selective agar medium increases rapidly (**d**) due to repair of injury and regain in resistance to selective environment; the rate of repair differs due to differences in the extent of injury among different cells. Cell multiplication starts following repair of injury as indicated by simultaneous increase in counts in both media (**e**).

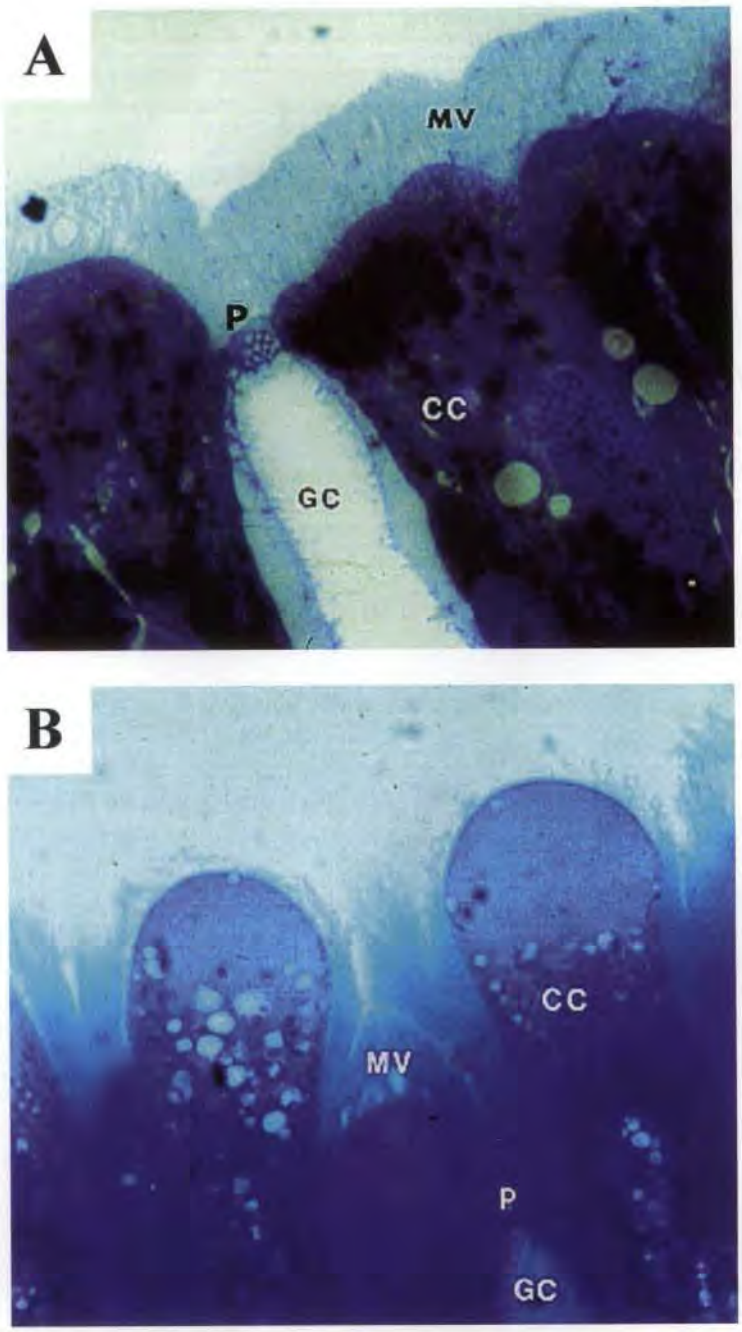
High Hydrostatic Pressure: Microbial Inactivation and Food Preservation, Figure 3. Scanning electron micrographs of *Leuconostoc mesenteroides* Ly cells (25,000 X). X (**a**) Unpressurized control. The cells are lenticular, about 1 × 1.5 mμ in size diplococcal stage with distinct constriction between the two cells. (**b**) Immediately after pressurization at 345 MPa for 5 minutes at 25°C. Pressurization caused more than 99% cell death, but the cells did not show a major visible change on the surface or on gross morphology. (**c**) Pressurized cells after 30 minutes incubation at 25°C after pressurization. Many cells were lysed (with the separation of cell wall between the two cells).



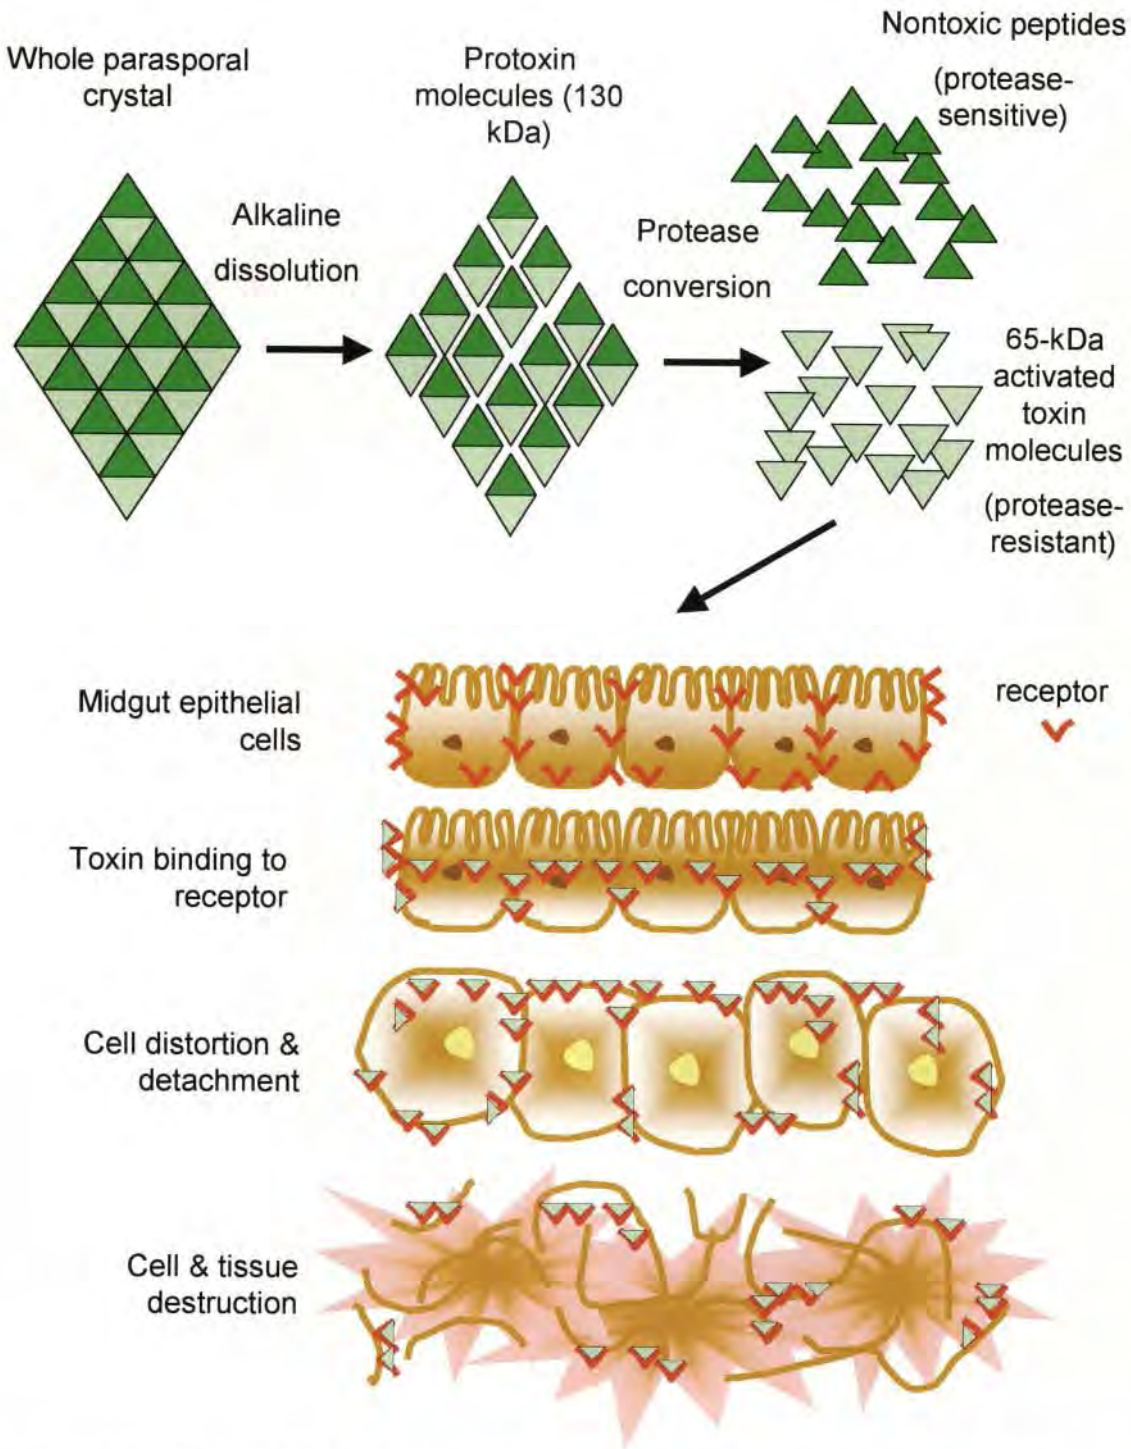
Human Caliciviruses: Basic Virology and Epidemiology, Figure 2. Comparision of the genomic organization of NLVs and SLVs. Open reading frames are indicated by red arrows, corresponding viral proteins are indicated in blue. Yellow highlighted regions represent individual proteins, presumably posttranslationally cleaved from the ORF1 polyprotein.



Hydrothermal Vents: Biodiversity in Deep-Sea Hydrothermal Vents, Figure 1. Location of map of deep-sea hydrothermal vent sites found so far.

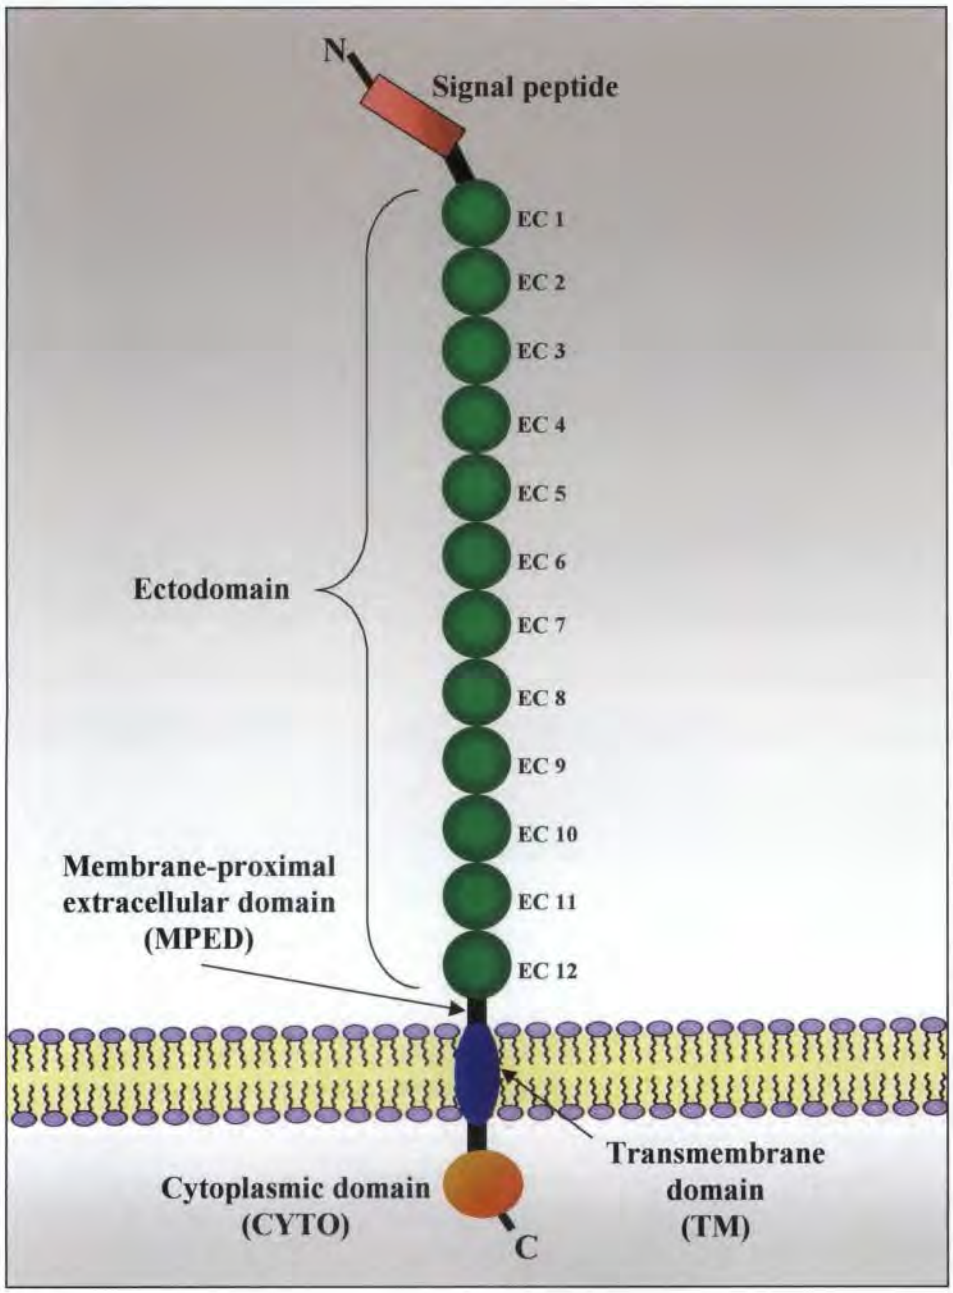


Insecticides Microbial, Figure 2. Effects of Cry1Ab toxin on *Manduca sexta* midgut epithelium. The midgut of insect larvae is a tube lined with columnar epithelial cells (CC). The apical ends of the midgut epithelial cells contain microvilli (MV) and this surface appearance is referred to as a *brush border.* Another type of cell that is present in the midgut is the goblet cell (GC). Goblet cells are intercalated with the columnar epithelial cells. Goblet cells contain a pore (P) at their apical ends through which enzymes and ions are secreted into the midgut. All cells that are facing the inner cavity of the midgut are attached to a basal membrane, which surrounds the tissue. The normal morphological features of the midgut epithelium change dramatically in about 1,530 minutes when a susceptible insect ingests Cry toxin. Micrographs of longitudinal sections of healthy (Panel A) and intoxicated (Panel B) midgut tissue from fourth instar *M. sexta* larvae show the morphological changes in the epithelial cells. On exposure to Cry1Ab toxin, the columnar cells swell and lose their microvillar structure, whereas the goblet cells do not appear to be affected, suggesting that toxin receptors are specifically expressed on the epithelial cells. Apical cell membrane distortion and total cell disruption occurs within one hour of intoxication, leading to devastation of the midgut tissue and death of the insect.

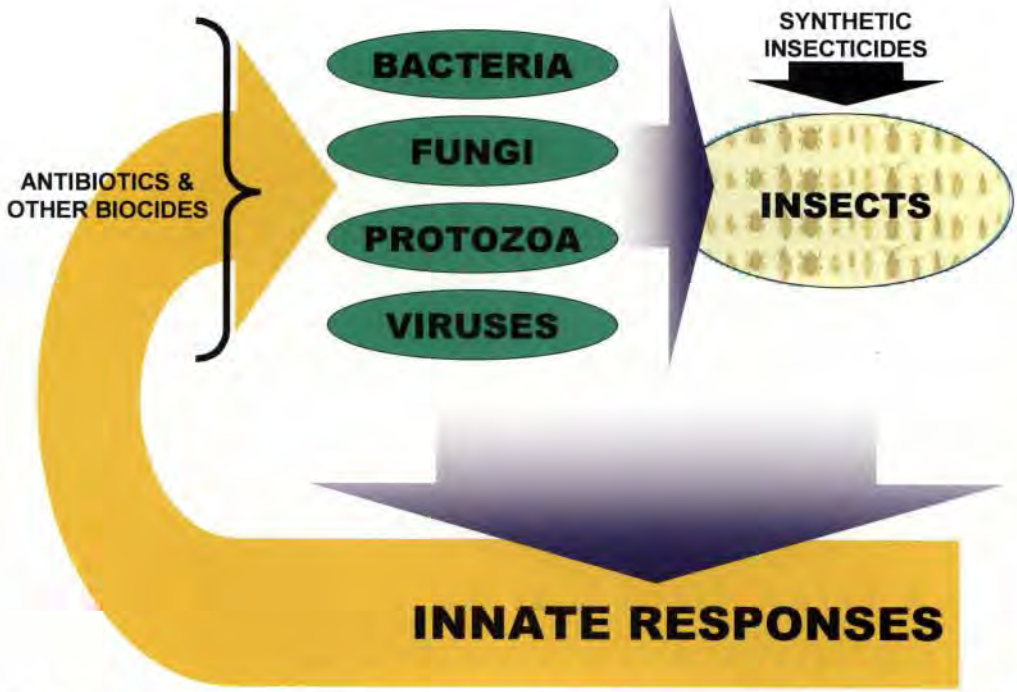


Insecticides Microbial, Figure 3. Activation of parasporal crystals and receptor mediated toxicity of Cry proteins. The entomopathogenic activity of *B. thuringiensis* mainly resides in the parasporal crystals that are composed of protoxin protein molecules. Following ingestion by a target insect, the protoxin is solubilized and converted to active toxin that binds to specific receptors on the surface of midgut epithelial cells. Both the specific physiological environment and the activity of proteolytic enzymes in the midgut of susceptible insects are involved in protoxin activation. Protoxin activation generates two polypeptide fragments, one that is hydrolyzed by midgut proteases and one (activated toxin) that is quite resistant to proteolytic attack in the target insect. Toxin binding to specific receptors on the epithelial cells brings about distortion, enlargement, and detachment of the cells, leading to devastation of the midgut tissue and death of the insect. On ingestion by a susceptible insect, the parasporal crystals are solubilized and the protein toxin is activated by alkaline conditions and the acitivity of proteolytic enzymes in the insect's gut. The toxicity of the activated toxin is dependent on the presence of specific receptor sites on the insect's midgut surface. Specific receptor-toxin interactions also determine the range of insect species killed by individual subspecies of *B. thuringiensis*. If the activated toxin attaches to receptor sites, it leads to destruction of the gut wall, causing the gut contents to leak into the body cavity and bloodstream.

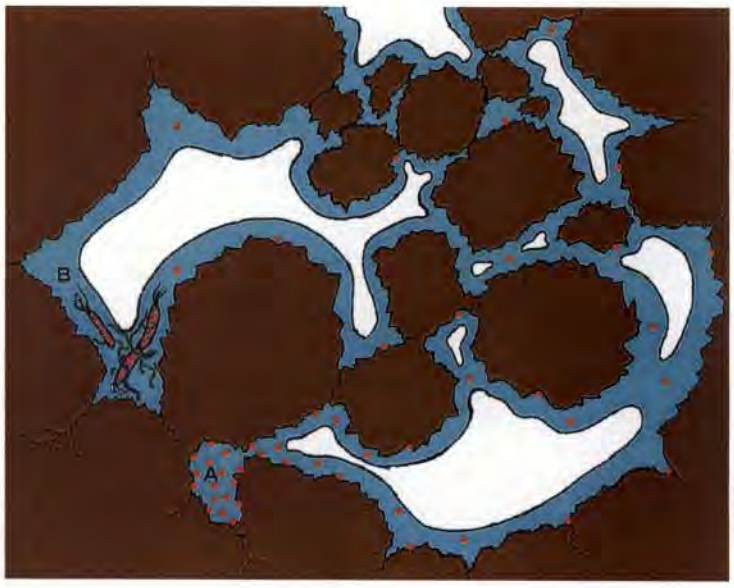
Insecticides Microbial, Figure 4. Effect of Cry1Ab toxin of *B. thuringiensis* on *M. sexta* larva. *Bacillus thuringiensis*-based insecticides are applied much like synthetic insecticides. Such insecticides are inactivated within a few days in most outdoor situations compared with the long-lasting presence of many chemical insecticides. Soon after ingesting whole cells of *B. thuringiensis* or activated toxin, susceptible insect larvae are poisoned and they stop feeding. If the appropriate amount of material is applied at the right time, the immediate and highly selective effect of *B. thuringiensis* is realized. *Manduca sexta* larvae feeding on a normal diet are large green in color. Larvae that have consumed Cry1Ab toxin turn black and usually die immediately or within a couple of days after sepsis. Vegetative cells of *B. thuringiensis* may multiply in the infected host, however, without producing abundant spores or parasporal crystals. The end result is that no infective units are released into the environment when a poisoned insect dies. Until the early 1980s, commercial *B. thuringiensis* products were effective only against caterpillars. However, strains that kill not only caterpillars but also several other types of pests have been identified and developed for commercial use. New isolates of *B. thuringiensis* with new Cry toxin variants will increase the spectrum of pests that can be controlled.



Insecticides Microbial, Figure 5. BT-R_1, the cadherin receptor of *M. sexta* for Cry1A toxins. On the basis of the predicted amino acid sequence, the BT-R_1 receptor (210 kDa) is composed of four domains: (*1*) ectodomain (EC), (*2*) membrane-proximal extracellular domain (MPED), (*3*) transmembrane domain (TM), and (*4*) cytoplasmic domain (CYTO). Downstream of a membrane signal sequence, the ectodomain consists of 12 cadherin repeats composed of β-sheets that are structured as ectodomain modules (EC1 through EC12). The ectodomain harbors putative molecular adhesion sequences. The structural features along with the protein-domain architecture indicate that BT-R_1 is a new type of heterophilic cadherin with a close relationship to protocadherins in the cadherin superfamily. The Cry1A toxins of *B. thuringiensis* bind to BT-R_1 with high affinity and specificity. Most probably, toxin binding adversely affects the structure and function of BT-R_1, consequently, compromising the integrity of the midgut epithelial cells that express the receptor molecule.



Insecticides Microbial, Figure 6. The relationship between innate responses and resistance to microbial insecticides. Innate cellular defense involves nonspecific responses found in organisms ranging from plants to humans. Invertebrates, including insects, do not produce antibodies and T cells to combat microbial challenges, as do vertebrate animals and humans. Instead, they rely primarily on innate responses to defend themselves against biological challenges. Constant contact of epithelial cells in the mucosal linings of animals harboring various microbes, and a large number of diverse antigens, has brought about the evolution of innate defense mechanisms. Innate responses are first-line cellular defenses and are pivotal to protecting an organism from potential invasion by various pathogens, while tolerating an indigenous microbial flora and a plethora of antigens commonly present in different food sources. Furthermore, information relays between innate defense reactions and adaptive protective devices now are appreciated as ancient evolutionary conserved immune responses. In fact, since the discovery of antimicrobial activities in the cabbage looper *Hyalophora cecropia,* studies of the fruit fly *Drosophila melanogaster* and mosquitoes have revealed notable conservation of innate defense mechanisms in both insects and mammals, especially in mucosal epithelia. Some innate defense mechanisms that guard against unwelcome microbes and antigens respond rapidly and promote adaptive functional changes, including the expression of those molecules that modulate various cell surface activities. The responses are triggered on the surface of epithelial cells on recognition of particular molecular motifs by certain surface receptors. Communication with signaling pathways promotes special physiological adaptations to the cell surface that somehow protect the cell against foreign invaders. Most often, these reactions sustain cellular adaptation on prolonged exposure to microbial activity or other stress conditions and eventually lead to resistance. however, the quick evolution of microbial pathogens is a potential for overcoming such resistance, generating natural competition involving continual challenges and responses that lead to resistance development among species. For instance, widespread commercial use of *B. thuringiensis* Cry toxins to control pest insects has produced insects that are resistant to this entomopathogen. Moreover, chemical insecticides stress insect population forcing many individuals to acquire an enhanced detoxification capacity and increased state of resistance, raising the potential for insects to become refractory to multiple insect-control agents. Therefore, it is crucual to implicate integrated pest management strategies with microbial insecticides and chemical-based pesticids to gain the greatest possible benefits.



Kinetics of Microbial Processes and Population Growth in Soil, Figure 1. Diagram showing substrate molecules (red dots) diffusing down a concentration gradient from microspore A to bacterial colony B. The solid phase is shown in brown, the liquid phase in blue, and the gas phase in white. Note the relatively long distance that molecules must travel despite the short linear distance between A and B, because of the tortuosity of the water films. The substrate molecules are also shown adsorbing to soil surfaces, further slowing their movement.

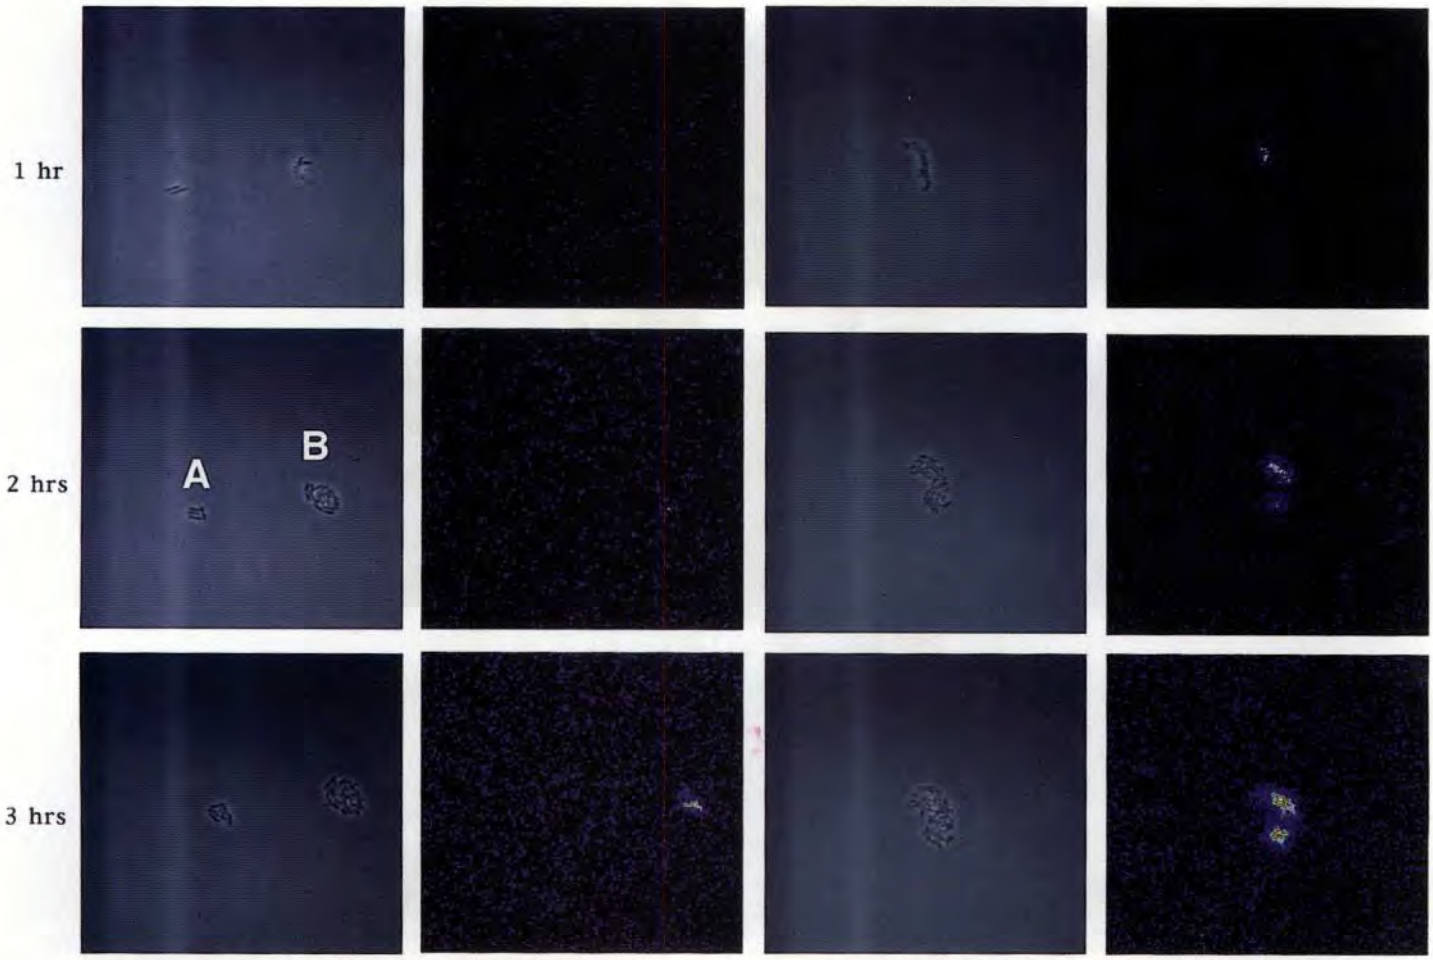
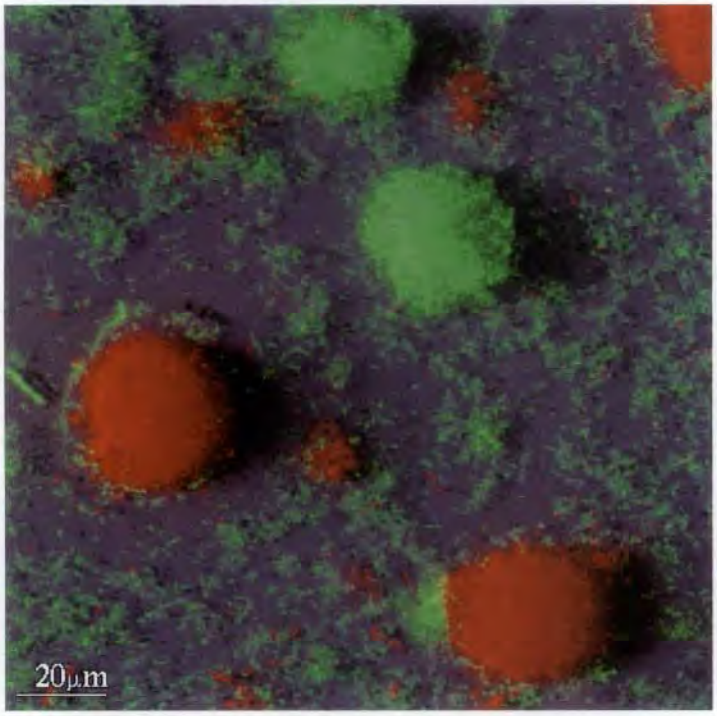
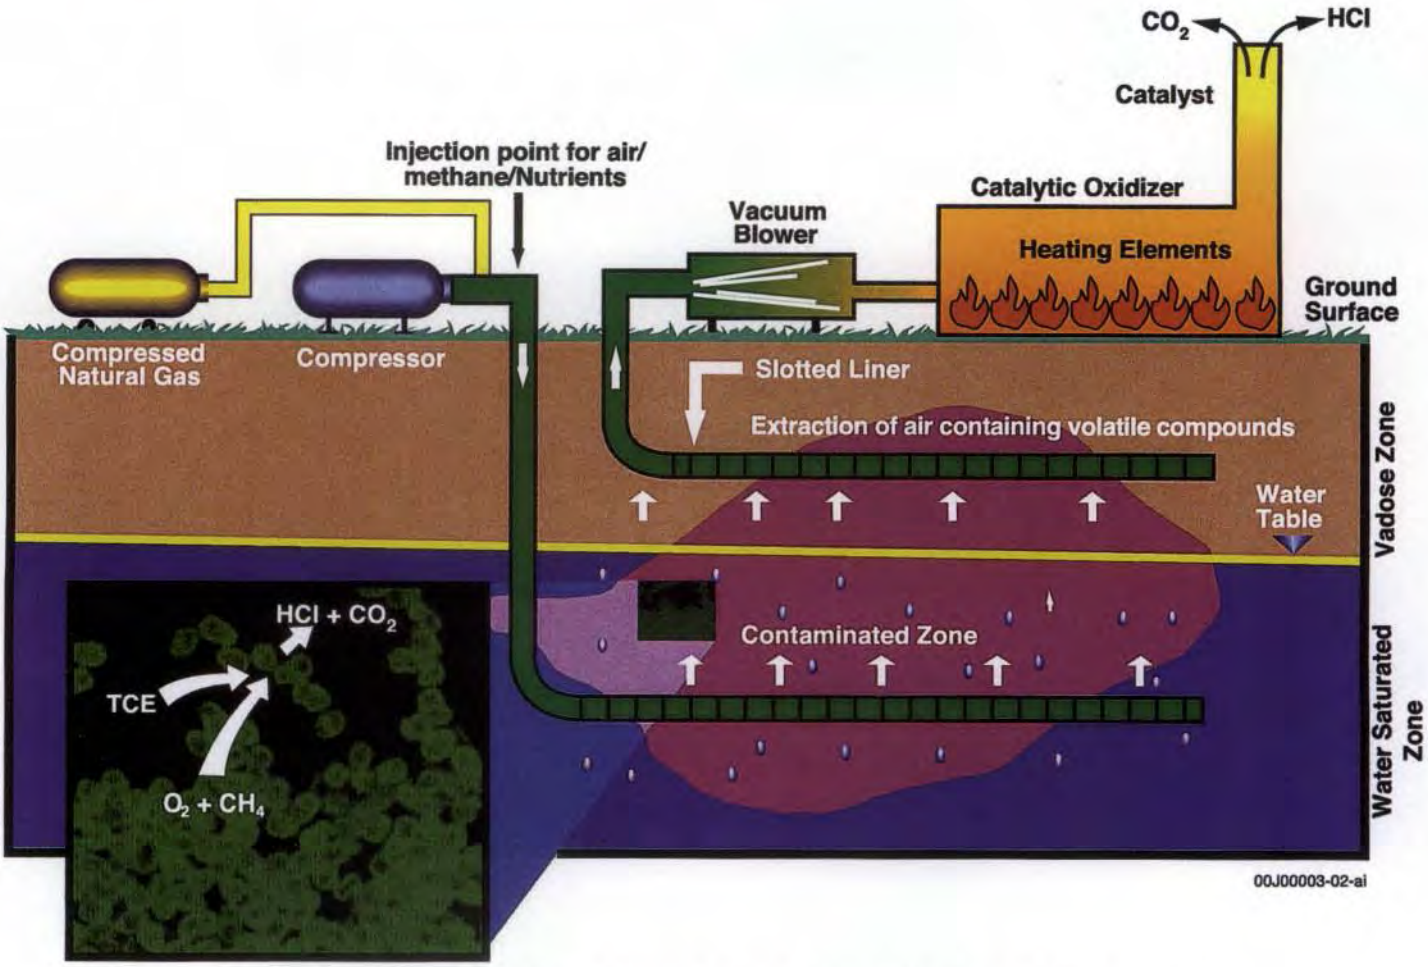
Laser Scanning Microscopy in Combination with Fluorescence Techniques for Biofilm Study, Figure 6. Bacteria and lectins 3/4 channels (plate with four images).



Luciferase and Green Fluorescent Protein as Bioreporters in Microbial Systems, Figure 1. Spatiotemporally resolved monitoring of toluene metabolism in genetically engineered *Psuedomonas putida* cells growing in a biofilm. Transmitted light images and photon-counting images (light production) of colonies in which a chromosomally integrated fusion between the toluene-degradation gene and luciferase (*tod-lux*) responds to the presence of toluene introduced at time zero. Three colonies were monitored over the course of three hours. The columns at the left show limited growth in two colonies (transmitted light images) and no induction (light production) from colony A, whereas colony B shows increased light emission over the three-hour monitoring period. The two right columns show marked growth and high light production from a third colony in the same experiment. This colony shows two distinct centers of light production (photon-counting image at three hours). The pseudocolor scale in the photon-counting images shows low light production in black and blue, with high light production in green through red/yellow.



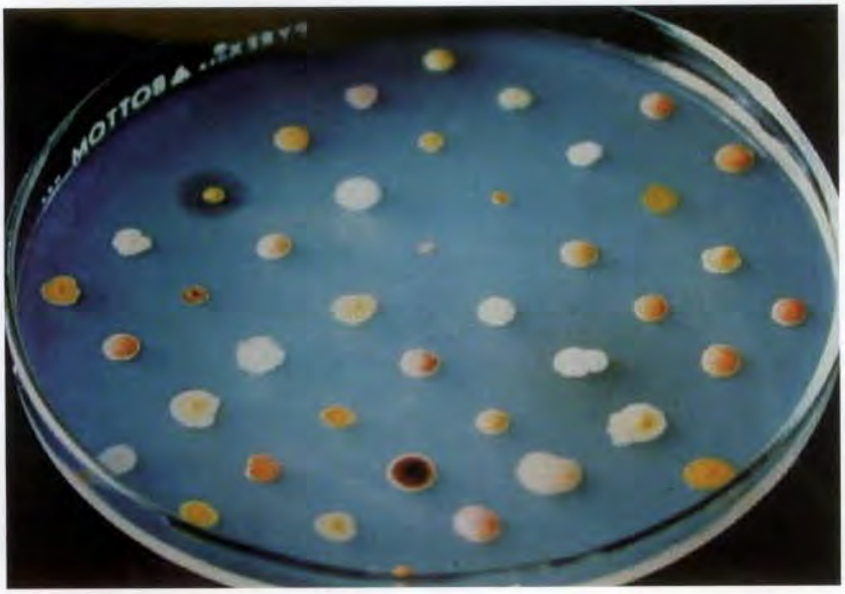
Luciferase and Green Fluorescent Protein as Bioreporters in Microbial Systems, Figure 3. *Psuedomonas* sp. B13 was transformed with either GFP or RFP (chromosomal integration of the fluorescent protein gene under control of a strong promoter), and the fluorescently labeled cells were inoculated simultaneously into an in vitro biofilm growth system. This confocal micrograph shows the biofilm five days of development. Note that the two bacterial types present in the inoculum, although isogenic except for the respective fluorescent protein gene, tend not to mix within the colonies.



Methanotrophic Bacteria: Use in Bioremediation, Figure 2. A side view of the horizontal wells in relation to the surface nutrient injection and extraction systems Modified from WSRC, Test Plan for In Situ Bioremediation Demonstration of the Savannah River Integrated Demonstration Project DOE/OTD TTP No.: SR 0566-01 (U), WSRC-RD-91-23, Westinghouse Savannah River Company, Aiken, SC, 1992.

Methanotrophic Bacteria: Use in Bioremediation, Figure 3. Concentrated groundwater methanotrophic bacteria on 0.2-μm filter labeled with fluorescent monoclonal-antibodies.

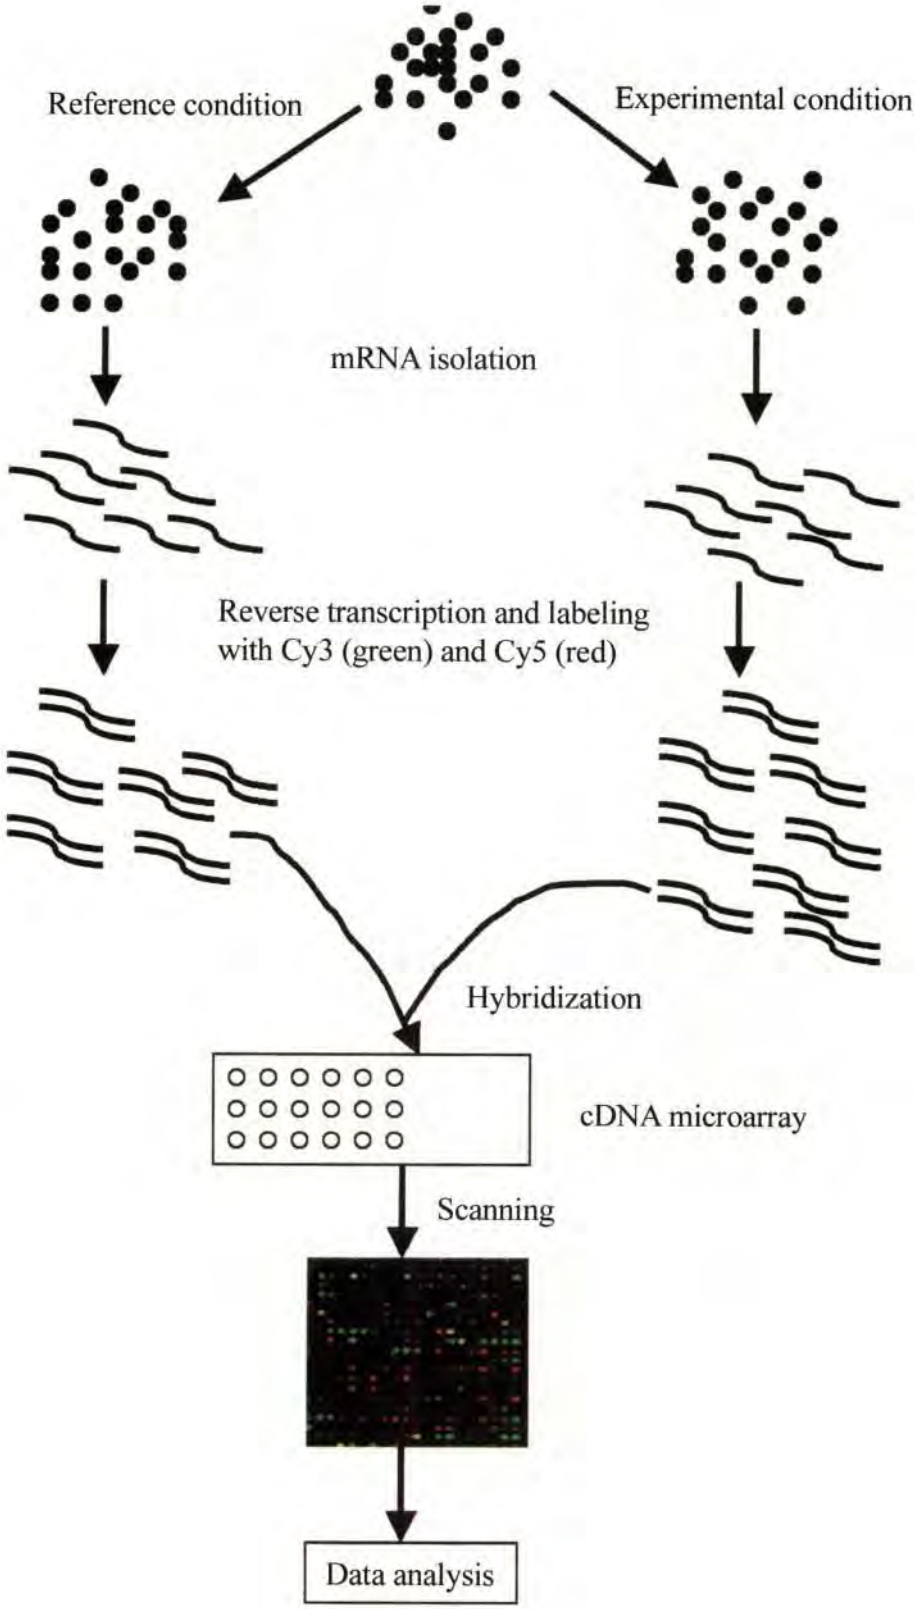
Methanotrophic Bacteria: Use in Bioremediation, Figure 4. In situ gaseous nutrient injection system at the Savannah River Site 70-acre nonradioactive waste disposal facility depicting the 400 ft and 600 ft horizontal wells. Insert is gas-nutrient pumping station.



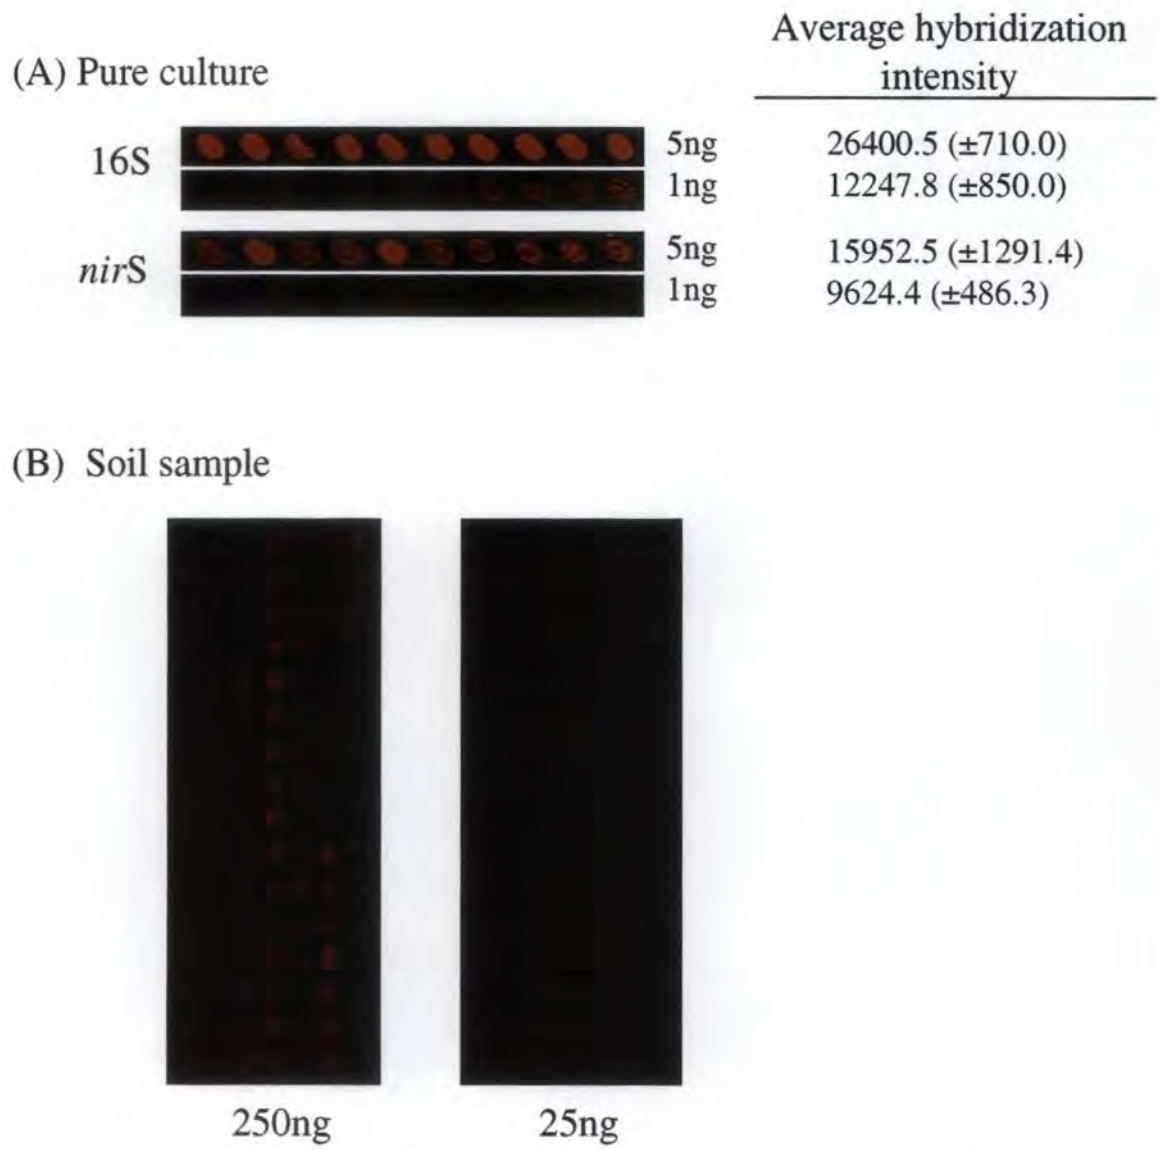
Methods for the Identification of Microbial Isolates, Figure 1. A bacterial garden of subsurface isolates applied to a grid after initial isolation from spread plates. Various colony morphologies and pigment production (e.g., dark colony surrounded by a light ring) can be useful during the identification process. Note: the colony surrounded by a dark ring demonstrates a physiological characteristic, such as agar degradation, that is potentially useful in identification.

Methods for the Identification of Microbial Isolates, Figure 3. Anaerobic chambers can be used to grow bacteria under defined atmospheric conditions. The gaseous composition can be manipulated to mimic natural environmental conditions.

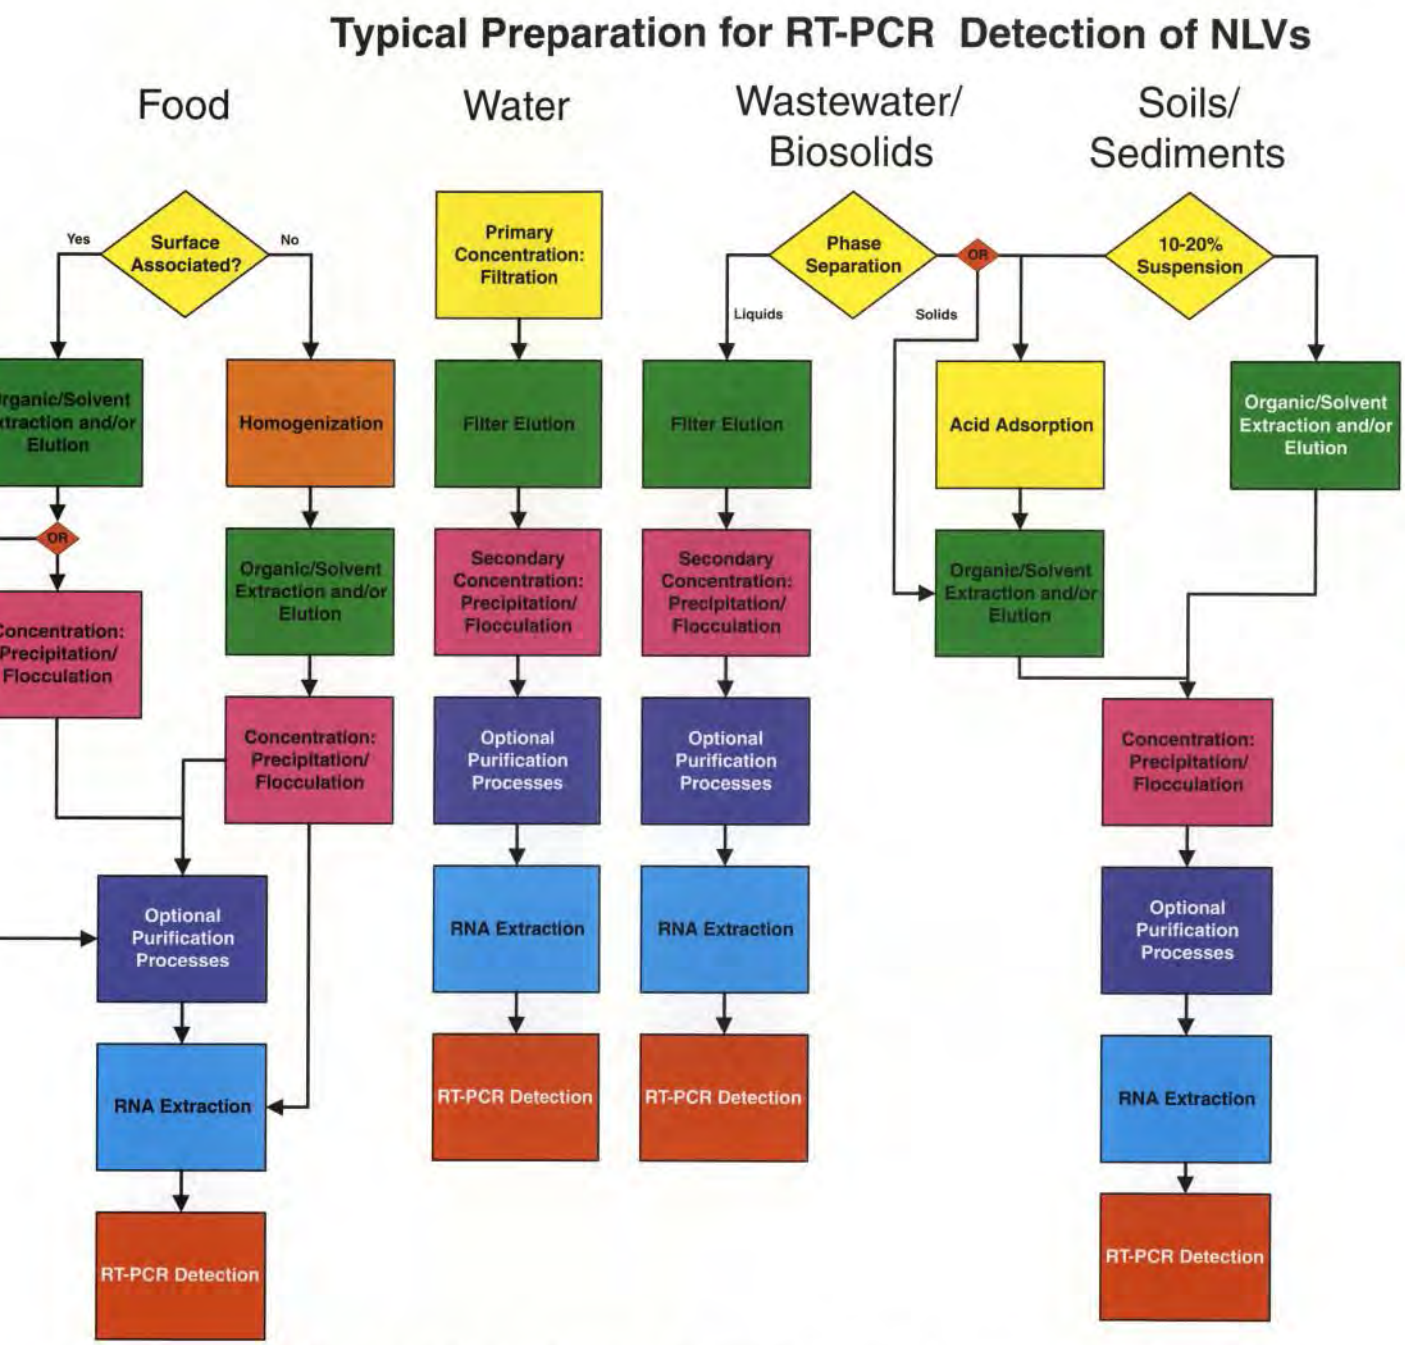
Methods for the Identification of Microbial Isolates, Figure 6. BIOLOG microtiter plates are used to create a metabolic fingerprint useful in the identification of bacterial isolates. Dark-colored wells indicate oxidation of individual carbon substrates.



Microarrays: Applications in Environmental Microbiology, Figure 2. General scheme of microarray experiments for monitoring gene expression.

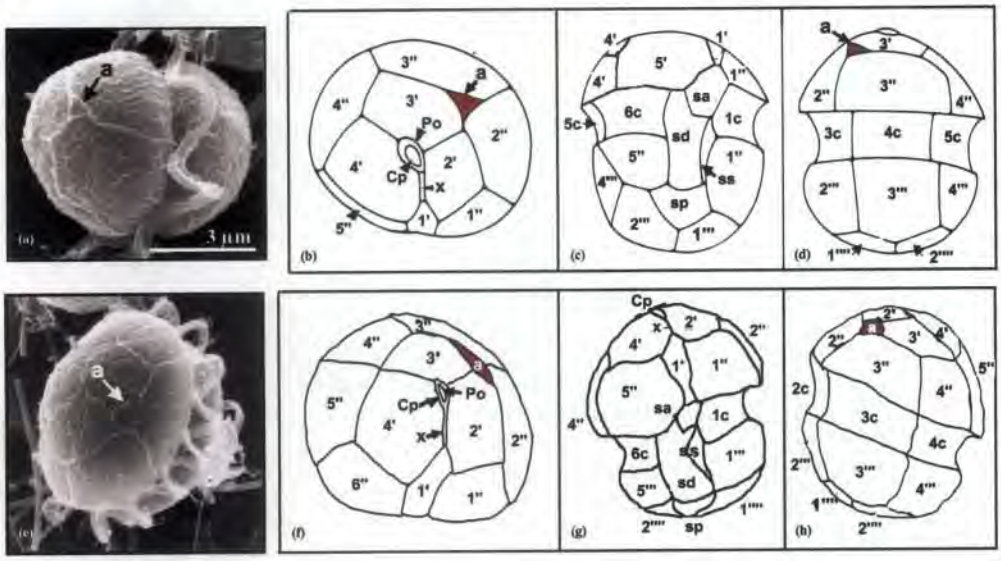


Microarrays: Applications in Environmental Microbiology, Figure 4. Array hybridization images showing the detection sensitivity with labeled pure genomic DNA and bulk community DNA from soil. (**a**) Genomic DNA from a pure culture of *nir*S-containing *Pseudomonas stutzeri* was labeled with Cy5 using a random primer labeling method. The target DNA was hybridized to nitrogen cycle microarrays at total concentrations of 1 and 5 ng. The average hybridization intensity at each target DNA concentration is presented. (**b**) Genomic DNA from surface soil was labeled with Cy5 as described in (**a**) and hybridized at total concentrations of 25 and 250 ng with the nitrogen cycle microarrays.

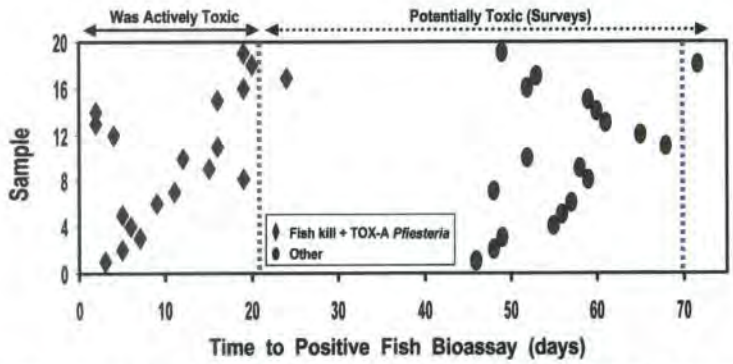


Norwalk-like Viruses: Detection Methodologies and Environmental Fate, Figure 1. Typical preparation of various samples for RT-PCR detection of NLVs. Corresponding steps between samples types are indicated by the same colored polygon.

Pfiesteria, Figure 1. Light micrograph of a *Pfiesteria shumwayae* toxic zoospore (TOX-A functional type) with its peduncle (extended appendage used for attachment and feeding, arrow) attached to a larval sheepshead minnow (*Cyprinodon variegatus*), engaged in suctioning the contents from the tissue in active feeding (process called myzocytosis) (scale bar = 10μm). (From 1. J.M. Burkholder, H.B. Glasgow, and N.J. Deamer-Melia, Phycologia 40, (2001).



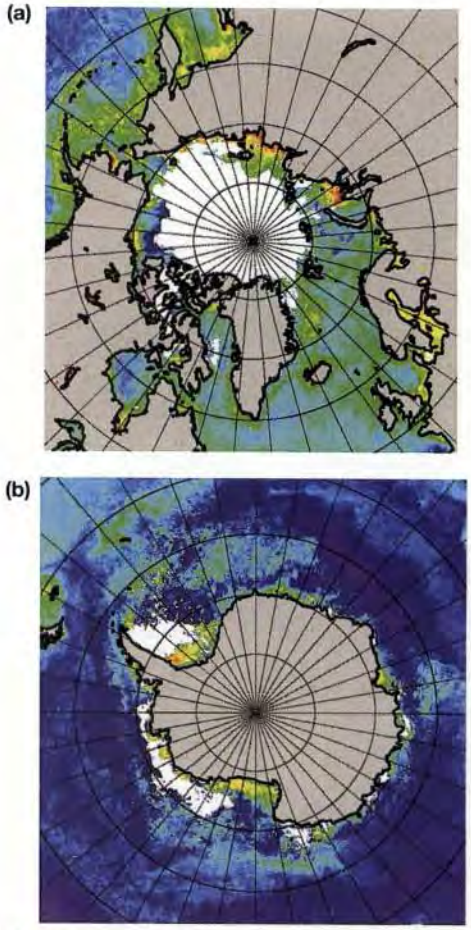
Pfiesteria, Figure 3. (**a**) Scanning electron micrograph of a suture-swollen zoospore of *Pfiesteria piscicida*, showing the three-sided anterior intercalary plate (**a**) (scale bar = 3μm); and (**b–d**) drawings of the plate structure of P. *piscicida* in (**b**) apical, (**c**) ventral, and (**d**) dorsal view (modified from 4. K.A. Steidinger et al., J. Phycol, 32, 157–164 (1996).); (**e**) scanning electron micrograph of a suture-swollen zoospore of *Pfiesteria shumwayae*, showing the four-sided anterior intercalary plate (**a**) (scale bar = 1μm; photograph by H. Glasgow, North Carolina State University); and (F-H) drawing of the plate structure traced from actual zoospores, including apical (**f**), ventral (**g**), and dorsal (**h**) views. (From 1. J. M. Burkholder, H. B. Glasgow, and N. J. Deamer-Melia, Phycologia 40, (2001).



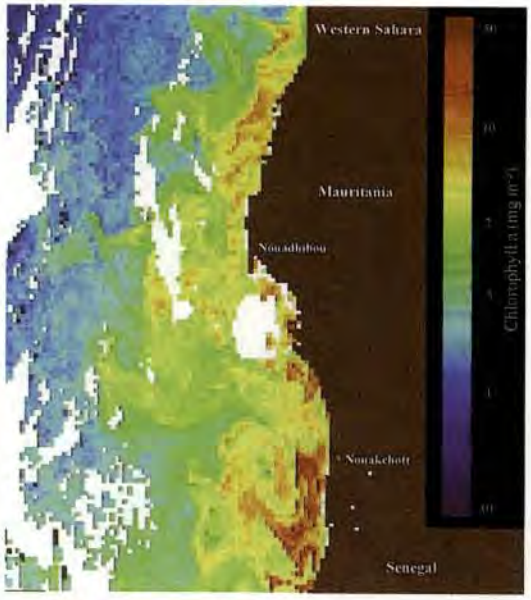
Pfiesteria, Figure 7. Comparison of the time interval required for positive fish bioassays (with fish-killing activity) for samples collected from estuarine fish kills in which actively toxic *Pfiesteria* spp.(TOX-A functional type) were implicated as primary causative agents (black diamonds; n = 20), versus samples that yielded toxic *Pfiesteria* in fish bioassays wherein the samples were taken during survey efforts in estuarine waters without diseased or dying fish (open ovals; n = 20)(8). The latter estuarine areas were interpreted to contain potentially toxic populations of TPC species (TOX-B functional type). In all cases, sample transport and other delays extended for 1 to 2 days; such handling is regarded as especially important for recently toxic populations, for example in efforts to implicate versus rule out involvement of actively toxic *Pfiesteria* from in-progress estuarine fish kills. Note that 19 of the 20 samples from events that we diagnosed as having involved actively toxic *Pfiesteria* were positive for fish-killing activity within 20 days (longest lag period, 1 sample within 24 days). To err conservatively, we consider that samples appropriately handled (with <3 days' lapse, including transport, following collection during an in-progress fish kill) should produce fish-killing activity within ≤21 days for actively toxic *Pfiesteria* to be implicated as a causative agent involved in the kill. Also note that samples that contained potentially toxic *Pfiesteria* populations that had not been recently in actively toxic mode toward fish did not show fish-killing activity until incubated with live fish for more than 6 weeks; 19 of the 20 samples from that set were ichthyotoxic by 10 weeks, with 1 sample requiring slightly longer. On the basis of well over 1,000 fish bioassays with estuarine samples, thus far we have not obtained toxic isolates of TPC species that have required more than 10.5 weeks to exhibit fish-killing activity, with two exceptions that required more than 12 weeks (8).

Pfiesteria, Figure 9. Actively toxic zoospores of *Pfiesteria piscicida* in the process of devouring an oyster pediveliger larva (scale bar = 10 μm), Note that many zoospores are swarming around the larva, and that some had used their peduncles to pry open the larva's shells to gain access to the soft tissue of the still-live organism, which were being rapidly consumed. The tissues of this larva were completely consumed by the zoospores within less than 30 minutes, except for the tough adductor muscle which was not attacked. (Photo from 36. J. Springer, Interactions Between Two Commercially Important Species of Bivalve Molluscs and the Toxic Estuarine Dinoflagellate, Pfiesteria piscicida, MS Thesis, North Carolina State University, Raleigh, N.C., 2000.)

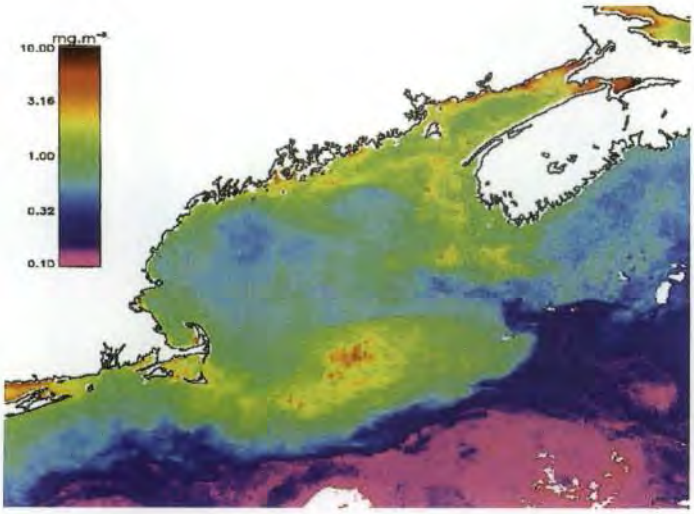
Pfiesteria, Figure 10. Focal lesion development resulting from exposure of tilapia (*Oreochromis mossambicus*, total length 5–7 cm) to actively toxic, clonal *Pfiesteria piscicida* in controlled laboratory trials, including (upper panel) Tilapia after 8–12 hr of exposure to 2.3 – 5.4 x 10^3 toxic zoospores/ mL (scale bar = 5 cm); and (lower panel) Oblique lateral view showing a deep, bleeding, ulcerated focal lesion posterior to the pectoral fin (scale bar = 1 cm).



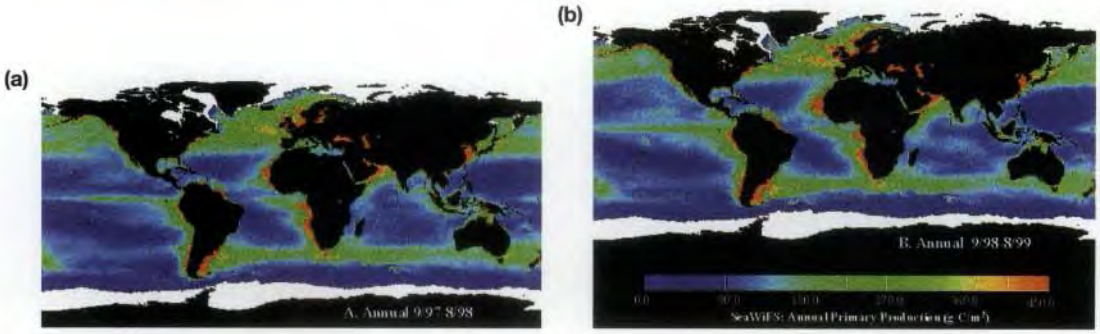
Polar Marine Phytoplankton, Figure 3. Satellite data showing polar projection maps of mean chlorophyll-a concentrations during summer in both polar regions. Highest chlorophyll-a concentrations are indicted by red, with decreasing concentrations as per the spectrum, with violet representing the lowest concentrations. The solid brown indicates areas where no data were obtained because of either ice or cloud cover.



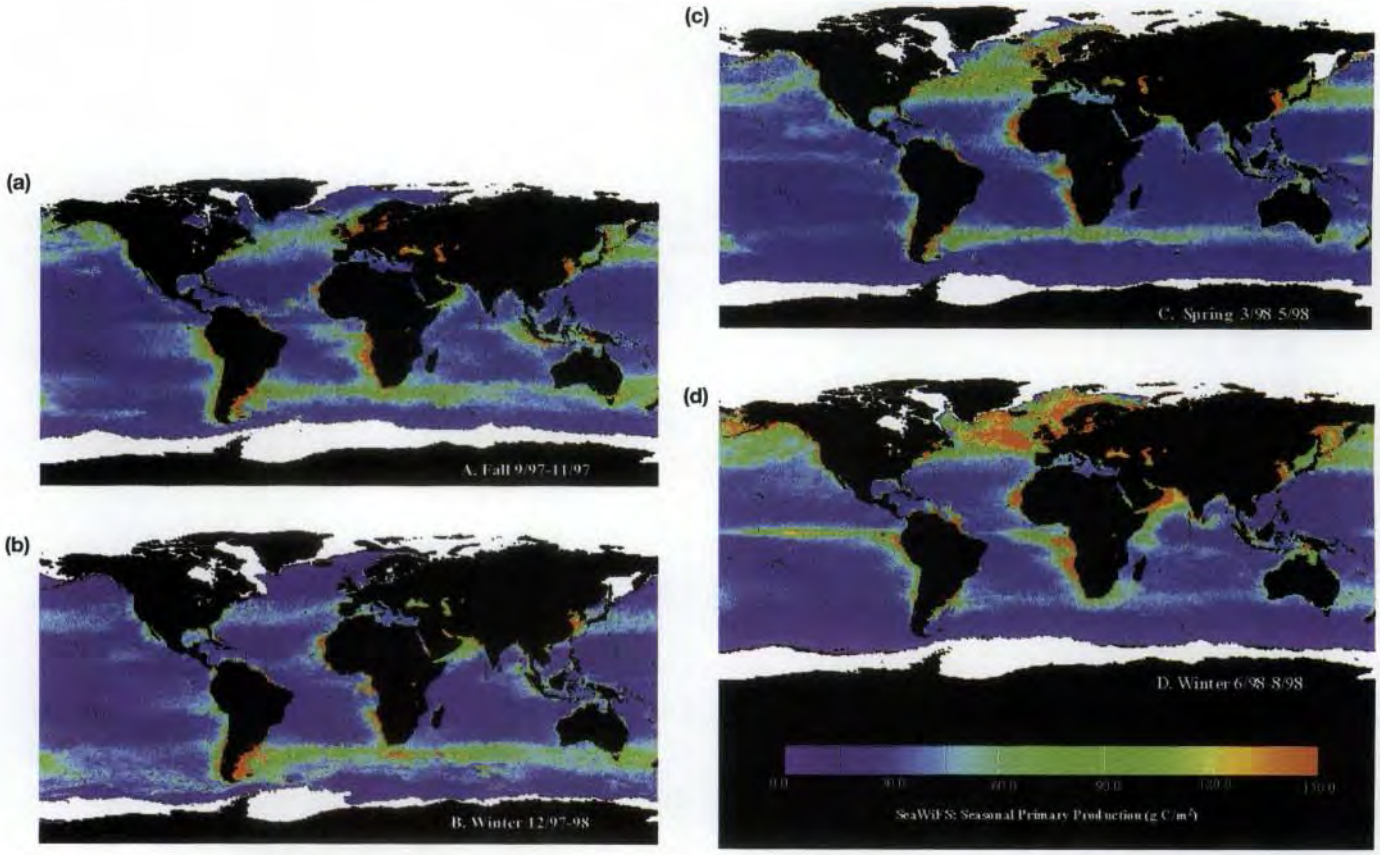
Primary Productivity in the Marine Environment, Figure 3. A SeaWiFS image of pigment concentrations off the coast of northwest Africa (March 22, 2001). Note the strong variations both offshore and along shore.



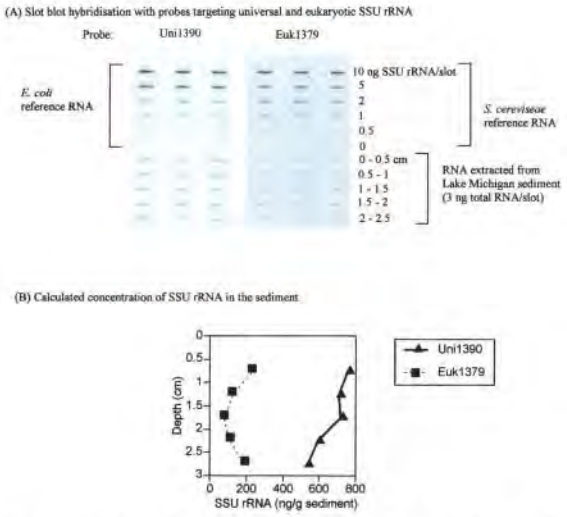
Primary Productivity in the Marine Environment, Figure 4. A SeaWiFS composite of pigment concentrations off the northeast coast of the United States (June 18–26, 1999). Note the presence of a large warm-core ring that substantially influences pigment concentrations and productivity.



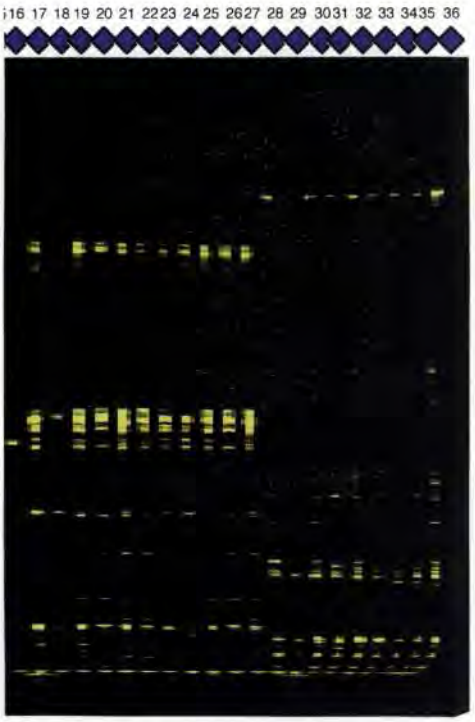
Primary Productivity in the Marine Environment, Figure 5. SeaWiFS annual composites of pigment concentrations throughout the ocean. (**a**) 1997–1998 and (**b**) 1998–1999. Strong spatial variations between years are observed, particularly in the equatorial pacific.



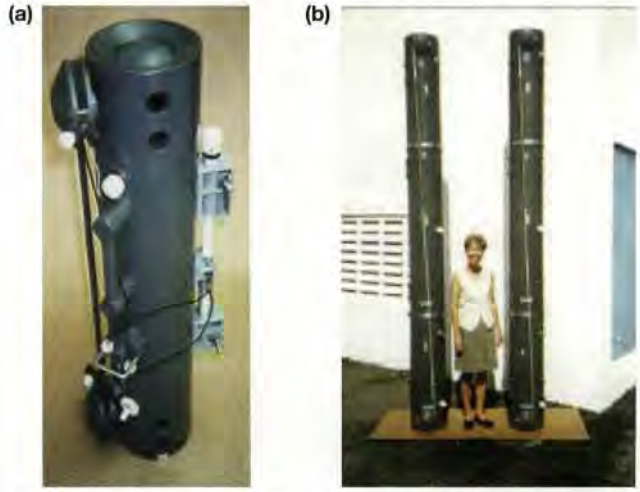
Primary Productivity in the Marine Environment, Figure 6. Estimates of primary productivity in (**a**) autumn, (**b**) winter, (**c**) spring, and (**d**) summer derived from satellite pigment estimates, incident irradiance, and the model of [M. Behrenfeld and P.G. Falkowski, *Limnol, Oceanogr.* **42**, 1–20 (1997)].



Ribotyping Methods For Assessment of In Situ Microbial Community Structure, Figure 2. Quantitative membrane forward-array hybridization. This experiment quantified the numbers of all microorganisms (Bacterial, Archaeal, and Eukaryotic) using a universal probe, and the numbers of eukaryotic microorganisms with depth in a freshwater lake sediment. The amount of probe bound was compared to the level of probe bound to standard quantities of Eukaryotic (*Saccharomyces cerevisiae*) and prokaryotic (*Escherichia coli*) SSU RNA. The quality of both the RNA and hybridization membrane are of crucial importance in such studies (17,23). Courtesy of Barbara J. MacGregor, Max Planck Institute for Marine Microbiology, Germany.



Ribotyping Methods For Assessment of In Situ Microbial Community Structure, Figure 6. T-RFLP analysis of bacterial communities. This digital image was generated by an ABI337 automatic sequencing apparatus and shows lanes 16–36 of a T-RFLP gel. Lane 16, the single band was produced from a pure culture of *Alcaligenes eutrophus*. Lanes 17–27 are profiles from DNA extractions from subsamples of a control soil, and lanes 28–36 are from a contaminated plot. The profiles of the control and contaminated soils are clearly different, demonstrating that the bacterial community has responded to the presence of the contaminant. Courtesy of Terrence L. Marsh, Department of Microbiology, Michigan State University, U.S.A.



Sampling Techniques for Environmental Microbiology, Figure 2. Go-Flo sample bottle with closed top valve. Ball valves at each end are opened when the bottle reaches 1 atm pressure (about 30 ft) and are closed by a messenger (or electronically) when the bottle reaches the desired depth. Bottles typically range from 2.5 to 30L (**a**) but can be made as large as 200 L (**b**). Images and information generously provided by General Oceanics, Inc. (*http://www.General Oceanics.com*).
